The *DSM-IV-TR* includes a diagnosis of caffeine-induced anxiety disorder (60). Caffeine-induced anxiety disorder is characterized by prominent anxiety, panic attacks, obsessions, or compulsions etiologically related to caffeine use. It is not necessary to meet full criteria for a *DSM-IV-TR* anxiety disorder to qualify for a diagnosis of caffeine-induced anxiety disorder. The prevalence and incidence of caffeine-induced anxiety disorder is not known.

CAFFEINE DEPENDENCE

Substance dependence is defined by a cluster of cognitive, behavioral, and physiological symptoms indicating that an individual continues to use a substance despite experiencing significant substance-related problems (60). The *DSM-IV-TR* does not presently include caffeine in its diagnostic schema for substance dependence. In contrast, the World Health Organization's *ICD-10* includes a diagnosis of substance dependence on caffeine, using very similar diagnostic criteria as

the *DSM-IV-TR*. The rationale for excluding substance dependence on caffeine during the last major revision of the *DSM* in 1994 was that although it had been established that caffeine produces physical dependence, there was a lack of information pertaining to other features of substance dependence such as the inability to stop caffeine use and continued caffeine use despite knowledge of negative health consequences (81).

Since that time a number of published studies have described adults and adolescents who report problematic caffeine consumption and fulfill *DSM-IV-TR* substance dependence criteria on caffeine (Table 22.4) (74,77,79,87,88). For example, one investigation found that 16 of 99 individuals who self-identified as having psychological or physical dependence on caffeine met *DSM-IV* criteria for substance dependence on caffeine, when only a restrictive set of four of the seven *DSM-IV* criteria that seemed most appropriate to problematic caffeine use were assessed (use despite harm, desire, or unsuccessful efforts to stop, withdrawal, and tolerance) (74). Using the same four criteria, another study identified adolescents who fulfilled diagnostic criteria for caffeine dependence (79). A study of pregnant women found that 57% of caffeine users fulfilled *DSM-IV* criteria for lifetime substance dependence on caffeine by endorsing three or more of the seven criteria (87).

The one population-based survey to date suggests that when individuals in the general population are surveyed about their caffeine use, a surprisingly large proportion endorse substance dependence criteria. In a random digit dialing telephone survey in which all seven *DSM-IV* criteria for substance dependence were assessed, 30% of caffeine users fulfilled diagnostic criteria by endorsing three or more

TABLE 22.4

Prevalence of endorsement of *DSM-IV* criteria for substance dependence among caffeine users (in %)

	General population		<i>DSM-IV</i> defined caffeine dependent individuals		
	Adults ^a (Ref. 77)	Pregnant women ^a (Ref. 87)	Adults ^b (Ref. 74)	Adolescents ^b (Ref. 79)	College students ^a (Ref. 88)
Used despite harm	14	43	94	58	57
Desire or unsuccessful efforts to stop	56	45	81	83	60
Withdrawal	18	77	94	100	73
Tolerance	8	50	75	92	70
Used more than intended	28	45	—	—	83
Give up activities to use	<1	0	—	—	20
Great deal of time with the drug	50	25	—	—	77
Endorsed three or more criteria	30	57	100	100	100

^a Assessed all seven *DSM-IV* criteria for substance dependence.

^b Assessed four *DSM-IV* criteria thought to be most pertinent to a meaningful assessment of problematic caffeine use.

dependence criteria. When the more restrictive set of four criteria were used, as in the studies described above, 9% met criteria for substance dependence. The most commonly reported symptom (56%) was persistent desire or unsuccessful efforts to cut down or control caffeine use (77).

As shown in Table 22.4, the rates of endorsement of the individual criteria vary widely across samples and data collection methodologies. The five *DSM-IV-TR* criteria for substance dependence that appear to be most pertinent to a meaningful assessment of problematic caffeine use are: (a) continued use despite knowledge of a persistent or recurrent physical or psychological problem that is likely to have been caused or exacerbated by the substance; (b) persistent desire or unsuccessful efforts to cut down or control substance use; (c) characteristic withdrawal syndrome or use of the substance to relieve or avoid withdrawal symptoms; (d) tolerance as defined by a need for markedly increased amounts of the substance to achieve desired effect, or markedly diminished effect with continued use of same amount of substance; and (e) substance is often taken in larger amounts or over a longer period than was intended. The remaining two criteria would not seem to be relevant to a widely available, culturally accepted drug like caffeine: (f) important social, occupational, or recreational activities are given up or reduced because of substance use and (g) a great deal of time is spent in activities necessary to obtain the substance, use the substance, or recover from its effects. Furthermore, inclusion of the last criterion could trivialize the diagnosis of caffeine dependence (e.g., sipping soft drinks throughout the day).

Individuals meeting criteria for caffeine dependence have shown a wide range of daily caffeine intake and have been consumers of various types of caffeinated products (e.g., coffee, soft drinks, tea, medications). A diagnosis of caffeine dependence has been shown to prospectively predict a greater incidence of caffeine reinforcement (89) and more severe withdrawal (74). Furthermore, among a sample of pregnant women advised by their physician to eliminate all caffeine throughout pregnancy, a caffeine dependence diagnosis predicted greater use of caffeine during pregnancy and a history of daily cigarette smoking (87). In that study, those with a caffeine dependence diagnosis and a family history of alcoholism used potentially problematic amounts of caffeine during pregnancy (i.e., half used more than 300 mg/day). Caffeine dependence has also been shown to be associated with a past history of alcohol abuse or dependence (74).

Available research and case reports suggest that a clinically meaningful caffeine dependence syndrome does exist. Additional research is needed to determine the prevalence of the disorder, the utility and clinical significance of the diagnosis, its relationship with other drug dependencies, and effective treatment strategies. Therapeutic assistance should be made available for those who feel that their caffeine use is problematic and have been unable to quit on their own. The Composite International Diagnostic Interview–Substance Abuse Module (CIDI-SAM), a well-regarded structured in-

terview focused on substance-use disorders, contains a section for caffeine dependence according to *DSM-IV-TR* and *ICD-10* criteria.

CAFFEINE AND OTHER DRUGS OF DEPENDENCE

Alcohol

Heavy use and clinical dependence on caffeine is associated with heavy use and clinical dependence on alcohol (90). In one study, almost 60% of individuals fulfilling *DSM-IV* diagnostic criteria for substance dependence on caffeine had a history of alcohol abuse or dependence (74). Despite common lore that caffeine reverses the impairing effects of alcohol, controlled research suggests that such effects are generally of small magnitude and highly inconsistent across different types of behavioral and subjective measures. There is suggestive evidence that individuals consuming caffeine with alcohol tend to underestimate their levels of intoxication and impairment and may be more prone to injury (1). The popular practice of combining caffeinated energy drinks and alcohol, presumably to counteract the sedative effects of alcohol, suggests there is a need for research in this area.

Benzodiazepines

Benzodiazepines and benzodiazepine-like drugs (e.g., zolpidem) are widely used in the treatment of anxiety disorders and insomnia. Animal and human studies suggest a mutually antagonistic relationship between caffeine and benzodiazepines. An important clinical implication is that caffeine use should be evaluated when treating anxiety or insomnia with benzodiazepines. One study reported that a greater percentage of heavy caffeine consumers also use benzodiazepine minor tranquilizers; however, in general, rates of caffeine intake are similar among benzodiazepine users and nonusers.

Nicotine and Cigarette Smoking

Epidemiologic studies have shown that cigarette smokers consume more caffeine than nonsmokers (91), a finding that is consistent with the observation that cigarette smoking increases caffeine metabolism. Several studies have shown that cigarette smoking abstinence results in significant increases in caffeine blood levels among heavy caffeine consumers, presumably due to a reversal of smoking-induced increased caffeine metabolism. Although it has been posited that this effect could make smoking cessation attempts more difficult, the clinical significance has not been demonstrated (91). Some human and animal studies have demonstrated that caffeine can increase the reinforcing and discriminative stimulus effects of intravenous nicotine (92). Some studies have failed to show that caffeine administra-

tion reliably increases cigarette smoking or nicotine self-administration (93,94).

Cocaine

There is little epidemiologic data on the co-occurrence of caffeine and cocaine use. One study reported that the prevalence of caffeine use among cocaine abusers is lower than the general population (95). Interestingly, in that same study, cocaine users who consumed caffeine reported using less cocaine than those who do not regularly consume caffeine.

In animal studies caffeine increases the acquisition of cocaine self-administration, reinstates responding previously maintained by cocaine, and potentiates the stimulant and discriminative stimulus effects of cocaine (22). Caffeine was shown to produce cocaine-appropriate responding in a cocaine versus placebo discrimination study (50). The subjective effects of intravenous caffeine have been reported as cocaine-like in one study (96), but not another (97). Intravenous caffeine administration has been shown to produce a significant increase in craving for cocaine in cocaine abusers (96); however, oral administration of caffeine has not produced this effect (98). Although the documented interactions between caffeine and cocaine are interesting, the clinical importance has not been established.

CLINICAL IMPLICATIONS

Given the wide range of symptoms produced by excessive caffeine use and withdrawal, as described throughout this chapter, caffeine use should be routinely assessed during medical and psychiatric evaluations. Caffeine use or intoxication should be assessed in individuals with complaints of anxiety, insomnia, headaches, palpitations, tachycardia, or gastrointestinal disturbance. Caffeine intoxication should be considered in the differential diagnosis of amphetamine or cocaine intoxication, mania, medication-induced side effects, hyperthyroidism, and pheochromocytoma. Likewise, caffeine withdrawal should be considered when patients present with headaches, fatigue, mood disturbances, or difficulty concentrating. Caffeine withdrawal should be considered in the differential diagnosis of migraine or other headache disorders, viral illnesses, and other drug withdrawal states.

Caffeine users who are instructed to refrain from all food and beverages prior to medical procedures may be at risk for experiencing caffeine withdrawal. Caffeine withdrawal has been identified as a cause of postoperative headaches, and caffeine supplements during surgery have been shown to be effective in preventing withdrawal (29).

Caffeine interacts with a number of medications. Caffeine and benzodiazepine-like drugs (e.g., diazepam, alprazolam, triazolam) are mutually antagonistic, and thus caffeine use may interfere with the efficacy of benzodiazepines (4). Caffeine may also interfere with the metabolism of the antipsychotic clozapine as well as the bronchodilator

theophylline to an extent that may be clinically significant (15). Case studies have suggested that caffeine withdrawal may be associated with increased serum lithium concentrations and lithium toxicity (15). Numerous compounds have been shown to decrease the rate of elimination of caffeine including oral contraceptive steroids, cimetidine, and fluvoxamine (15).

TREATMENT

Reduction or elimination of caffeine is advised for individuals who have caffeine-related psychopathology or when it is believed that caffeine is causing or exacerbating medical or psychiatric problems, or interfering with medication efficacy. A surprisingly large percentage of caffeine users in the general population (56%) report a desire or unsuccessful efforts to stop or reduce caffeine use (77). Fourteen percent of adults with a lifetime history of caffeine use report stopping caffeine completely, usually due to health concerns or unpleasant side effects (99).

There are no published reports of treatment interventions designed to assist individuals who would like to completely eliminate caffeine. Several reports suggest the efficacy of a structured caffeine reduction regimen (i.e., caffeine fading) for achieving substantial reductions of caffeine intake (4). A study of patients recruited from a urinary continence clinic found that a 4-week reduction program with a consumption goal of <100 mg/day was effective at reducing caffeine intake as well as urinary frequency and urgency outcomes (36).

Given the limited number of treatment strategies that have been evaluated for reducing or eliminating caffeine consumption, a reasonable approach is to adapt validated behavioral techniques used to treat dependence on other drugs (e.g., tobacco dependence). Effective behavior modification strategies include coping response training, self-monitoring, social support, and reinforcement for abstinence. Substance abuse treatment strategies including motivational interviewing and relapse prevention could also be readily applied to the treatment of caffeine dependence. Providing a list of caffeine-containing products may help to increase awareness of sources of caffeine and should facilitate self-monitoring efforts (Table 22.1). Some individuals may not readily accept the idea that caffeine is contributing to their problems (e.g., insomnia, anxiety). Such individuals should be encouraged to engage in a caffeine-free trial. There is some evidence that withdrawal symptoms may thwart quit attempts. Gradually reducing caffeine consumption may help attenuate withdrawal symptoms, although there has been no systematic research to determine the most efficacious reduction schedule. In general, reduction schedules over the course of 3 to 4 weeks have been shown to be effective. No data about the probability of relapse is currently available, although relapse after caffeine reduction has been reported (4). Table 22.5 lists practical guidelines for reducing or ceasing caffeine use.

TABLE 22.5 Guidelines for reducing or eliminating caffeine

1) <i>Education</i>	Patients should be educated about potential sources of caffeine. It may be useful to provide patients with a list of common caffeinated products (see Table 22.1). Some individuals may not be aware that caffeine is present in noncola beverages such as lemon-lime soft drinks and products made with guarana, maté, or kola nut.
2) <i>Self-monitoring</i>	Caffeine use should be self-monitored using a food diary for 1–2 weeks to determine a baseline level. If a self-monitoring period is not feasible, treatment providers can determine a rough estimate of total caffeine consumption via self-report. Self-monitoring should also be continued during the caffeine reduction phase of treatment.
3) <i>Calculate total daily caffeine consumption (mg)</i>	Calculate daily caffeine exposure in milligrams, taking into account the caffeine content of specific products, the serving sizes, and the number of servings.
4) <i>Determine a caffeine modification goal</i>	Decide on a caffeine modification goal with the patient. Some individuals may be interested in completely eliminating caffeine, whereas others may want to reduce their caffeine consumption. Individuals who would like to continue to consume some amount of caffeine, but who want to avoid experiencing withdrawal symptoms if they omit caffeine for a day, should be advised to consume no more than 50 mg/day.
5) <i>Generate a gradual reduction schedule</i>	A gradual reduction schedule should help to prevent or alleviate caffeine withdrawal symptoms. A reasonable decrease would be 10–25% of the baseline dose every few days until the caffeine moderation or cessation goal is achieved. Patients should identify a noncaffeinated substitute for their usual caffeine-containing beverage. Caffeinated beverages can either be omitted to achieve the desire amount or can be mixed with decaffeinated beverages.
6) <i>Employ behavior modification techniques</i>	Patients may benefit from behavior modification techniques shown to be effective in the treatment of dependence on other substances (e.g., nicotine). Such strategies may include self-monitoring, coping response training, reinforcement for abstinence, identifying barriers to change, social support, and reframing withdrawal as a temporary inconvenience.
7) <i>Follow-up</i>	Schedule a follow-up contact with the patient to check on the patient's progress.

ACKNOWLEDGMENTS

Preparation of this chapter was supported, in part, by the United States Public Health Service grant R01 DA03890 from the National Institute on Drug Abuse.

INTRODUCTION

This chapter reviews the anabolic–androgenic steroids (AAS), the much-maligned molecules which, in addition to their legitimate uses, have engendered a clandestine industry of advisors, purveyors, and drug-test manipulators. All of the AAS are analogs of testosterone, and all promote muscle growth (anabolic) and masculinizing (androgenic) effects to greater or lesser degrees. As opposed to the corticosteroids and female gonadotrophic steroids like estrogen and progesterone, athletes and others may use the AAS illicitly in the supraphysiologic doses necessary for increasing lean body mass, shortening muscle recovery time, and increasing strength, thereby enhancing athletic performance and muscle size.

The historical development of the AAS began with the observation that the testes produced a substance—the hormone testosterone—which controlled masculinization, and proceeded through increasingly sophisticated attempts to understand, control, and eventually replicate the hormone's effect. Those scientific efforts have resulted in the present day's wide availability of various AAS, on both the licit and illicit markets. They are perhaps the most sought-after substances on the Internet, usually by those seeking their muscle-building effects. The political, legal, and cultural contexts for AAS use provide a fascinating example of science used for societally approved uses and for uses that are forbidden—and the sometimes confusing boundary between with two.

There remains little doubt that the AAS do enhance muscle growth, strength, and in some cases athletic performance, although the side effect profile of the drugs limits their non-clinical use to those willing to risk significant harm, in addition to legal jeopardy and disqualification from legitimate sports competitions. The excess levels of testosterone which all of the AAS elicit in the nonhypogonadic user stimulate muscle growth as long as the user exercises those muscles, but also provoke ligament rupture, cardiac lipoprotein abnormalities, virilizing effects in women, feminizing effects in men, and psychiatric abnormalities.

Since illicit use of the AAS is both illegal and banned by sports organizations, a significant amount of science has developed around testing and avoiding detection of AAS use. A large criminal industry has arisen to manufacture and deliver these drugs illicitly, often leading to the same sorts of illegal dangerous behaviors usually associated with more conventional drugs of abuse. The ethical issues surrounding the use of drugs for performance enhancement present a variety of conundrums for the thinking person, best addressed with the

scientific facts in hand and a full understanding of the variety of approaches already in place.

HISTORY OF THE AAS

Although farmers have known for centuries that castration of livestock promoted domestication of their farm animals, and human beings have created eunuchs and castratos for specific reasons, it was not until 1849 that Dr. Arnold Berthold demonstrated the effects of castration on roosters and the reversal of those effects when the testis were surgically returned to the abdominal cavity. This elegant experiment showed that some factor in the testis, later named testosterone, controls male sexual characteristics (1). In 1889 Dr. Charles Brown Sequard trumped Berthold by injecting himself with an extract of dog and guinea pig testicles, and documented an increase in his own physical strength, intellectual functioning, and appetite. This self-injection instigated a boom in the injection of testis derivatives and the transplantation of both animal and human testicles, advertised as an “Elixir of Life” and promoted by “... physicians uneducated in the techniques and inherent risk of animal injection ... putting many patients at risk for infection and inflammation” (2).

As Figure 23.1 shows, testosterone was first synthesized in 1935; despite hints and suppositions, no conclusive evidence exists of performance-enhancing use of steroids by competitive athletes until the 1950s. Although records are understandably sparse, AAS use by the Soviet National Weightlifting teams of the mid-1950s has been deemed quite likely, and the U.S. Olympic team physician at the time, Dr. John Ziegler, acknowledged learning from the Soviets to prescribe testosterone to the U.S. weightlifters. Dr. Ziegler later prescribed the first commercially available AAS, Dianabol (methandrostebolone) to his charges. The obvious masculinized appearance of female track and field athletes from the Eastern European countries in the late 1950s and early 1960s raised suspicions, which were ultimately confirmed, that the women were taking testosterone and/or AAS (3).

An article written by a German scientist collaborating with a former German Democratic Republic (GDR) Olympic Team discus thrower (4) reveals the facts about the GDR's well-coordinated use of performance-enhancing drugs—mostly AAS—during the years 1966 to 1989. That country's elite sports establishment, assisted by physicians and other scientists, encouraged the use of AAS by several generations of athletes, including minors and women who were given

AAS Time line

Figure 23.1. Historical time line.

large dosages of testosterone and other AAS. In their pursuit of Olympic medals, the coaches and scientists foisted high doses of AAS on athletes who were initially unknowing, and many of whom were coerced into consenting to ongoing use of the drugs that were so obviously damaging their bodies while enhancing their athletic achievements.

The GDR athletic/medical establishment kept careful records of the substances athletes took, as well as the improvement in athletic performances attributable to the drugs. Using an “On-Off Protocol,” the scientists were able to prove that a particular athlete’s 2-m improvement in her shot-put score was attributable to the Oral-Turbinol she took, and not to other variables like additional training, nutrition, or coaching. In order to avoid detection, the athletes’ testosterone:epitestosterone (T:E) levels were closely monitored, and they were given the biologically inert epitestosterone with the purpose of passing the increasingly frequent drug tests. The GDR scientists also dutifully recorded the AAS sequelae both acutely and over the years: hirsutism, acne, amenorrhea, ovarian cyst formation, voice changes, libido disturbance, hepatomegaly, and bile duct damage.

In response to the increasing use of performance-enhancing drugs by these and other elite athletes, the International Olympic Committee banned the use of the AAS in 1967, began general drug testing in 1968, and started specifically testing for AAS in 1976. The Olympics were eventually followed by the U.S. National Collegiate Athletic Association (NCAA) and professional sports organizations in banning and testing for the AAS and other performance-enhancing drugs, although a cursory look at the sports pages over the last several years will reveal that testing has hardly rid sports, amateur or professional, of illicit AAS use (5).

American societal viewpoints about drug-related performance enhancement and the AAS specifically have been ambiguous, with organized medicine expressing a certain ambivalence about the use of AAS. As late as 1977 the American College of Sports Medicine, while acknowledging the dangers of AAS use, still formally believed that the AAS were not particularly effective in normals, or in high dosages for athletes: “The administration of anabolic–androgenic steroids to healthy humans below age 50 in medically approved therapeutic doses often does not of itself bring about any significant improvements in strength, aerobic endurance, lean body mass, or body weight. There is no conclusive evidence that extremely large doses of anabolic–androgenic steroids either aid or hinder athletic performance ...” (6).

However, when Canadian sprinter Ben Johnson was disqualified several days after his gold medal race in the 1988 Olympic 100-m dash, a sea change occurred in worldwide public attitudes toward the AAS, and performance-enhancing drugs in general (7). In addition to catalyzing the Olympic drug-testing program, other sports organizations and the U.S. government began taking AAS use seriously.

The Anabolic Steroids Control Act of 1990 (8) added the AAS to schedule III of the Schedule of Federal Controlled Substances. Schedule III drugs, which include the barbiturates and ketamine, are defined as follows:

- A. The drug or other substance has a potential for abuse less than the drugs or other substances in schedules I and II.
- B. The drug or other substance has a currently accepted medical use in treatment in the United States.
- C. Abuse of the drug or other substance may lead to moderate or low physical dependence or high psychological dependence (9).

Interestingly, the American Medical Association (AMA) opposed the scheduling of the AAS on the grounds that the health effects of the AAS were unclear, there was no good evidence of physical or psychological dependence, and the change side-stepped the usual process of drug scheduling change via the U.S. Attorney General's office (10). The rescheduling listed the common AAS used by athletes, provided jail time for any advisor who induced another person to take AAS, and even included human growth hormone (HGH) in the same category of illegal substances.

In contrast to the Anabolic Steroids Control Act of 1990, the Dietary Supplement Health and Education Act of 1994 (DSHEA) (11) weakened—however unintentionally—the prevention and enforcement efforts directed at the AAS. In essence, DSHEA eliminated the Food and Drug Administration's ability to regulate the myriad products considered herbs, nutritional supplements, or dietary supplements: basically anything not a medication for a specific illness. The broad definition of these “nondrug” substances was intended to include substances like “ginseng, garlic, fish oils, psyllium, glandulars, and mixtures of these . . .” (11) and placed the burden of proving safety and efficacy on the manufacturers. In the DSHEA legislation, the manufacturers were forbidden from making any claims of medical effectiveness and admonished to adhere to good manufacturing practices, but were allowed to provide “third party” educational materials, as long as the materials presented a (undefined) balanced view of the science underlying whatever claims were actually made about the supplement. Substances like DHEA and melatonin were specifically protected by DSHEA from FDA oversight.

The result of DSHEA's deregulation of the supplement industry was a concomitant looseness in the production, packaging, and labeling of nonpharmaceutical supplements. In a 2001 study of over-the-counter (OTC) supplements (12), researchers found that of the 12 brands of (then-legal) AAS supplements they bought at health-food stores, 11 did not even meet the DSHEA labeling requirements. One brand contained 10 mg of testosterone, an illegal additive not listed on the label, and the others contained inaccurate amounts of their active ingredient based on the labeling. In light of a more recent apparent mislabeling case—in which a professional athlete claimed to have bought an androstenedione-tainted supplement at a GNC store in Florida (13), the mislabeling and contamination of nutritional supplements continues. Even more worrisome than a sports-related suspension is a recent case series (14) of liver and kidney damage due to contaminated dietary supplements. According to the gastroenterologists who first documented these cases, OTC nutritional supplements containing AAS were inadvertently taken by their patients, two of whom evidenced hepatotoxic reactions, and one who suffered a nephrotoxic reaction.

EPIDEMIOLOGY OF AAS USE

The epidemiology of AAS use in the United States is complicated by several definitional, scientific, and practical variables. The fluidity of boundaries between testosterone, the

synthetic AAS, and nutritional supplements makes for a nightmare in constructing surveys, and often the survey takers are reluctant to disclose their illicit behavior. Individuals coming from various perspectives—users, drug testers, sports officials, and legislators—have vested interests in promoting a high or low estimates of those who are actually taking AAS. The surveys and studies mentioned below reflect the self-acknowledged use of mostly illicit AAS by athletes and young people who, at least when they were using the AAS, must have hidden that use. So, the veracity of their reports is suspect, and the reader must remember that past and present AAS users may answer survey questions inaccurately, refuse to answer at all, or evade even the best surveying techniques.

In his memorable *Sports Illustrated* cover story of 2002 (15), former major league baseball (MLB) player Ken Caminiti estimated that “at least half” of MLB players were actively using steroids, while his similarly retired former competitor Jose Canseco estimated that “85%” of MLB players use AAS, although he himself did not take the illicit substances. Washington Redskins tackle Jon Jansen subsequently said on HBO's *Costas Now* that “maybe 15–20 percent” of NFL players took HGH, but quickly (though not very convincingly) recanted by saying that no one he knew on his team took HGH, “but other guys have talked about what goes on in other places” (16). Caminiti later died from a drug overdose (17) and Canseco published a book chronicling widespread use of AAS in MLB, including his own (18). But elite athletes who speak publicly often have obvious biases: showing that his or her own use is the norm, salving a conscience, or looking for personal publicity or book sales.

In an attempt to more rigorously quantify, among other things, AAS use and attitudes among professional athletes, all 3683 members of the National Football League's retired Player's Association were sent a survey about their AAS use, and 2552 former players responded (19). Of those admittedly self-selected former players, 9.1% admitted using AAS during their careers. The average age of the responders was 53.8 (± 13.4) years, with an average career length of 6.6 (± 3.6) years. Predictably, those who had played positions requiring the most size and strength reported the highest use of AAS, with offensive and defensive linemen admitting rates of 16.3% and 14.8%, respectively. Also predictably, among those players who were active in the 1980s, a total of 20.3% admitted that they had used AAS during their careers. The study authors also note a significant correlation between AAS use and joint/cartilage injuries, disc herniations, meniscus injuries, elbow injuries, spine injuries, and foot/toe/ankle injuries, but no association between self-reported AAS use and muscle/tendon injuries.

Data supplied by government agencies and universities provide more accurate, if less pungent, assessments of drug use. For the last 33 years, the Survey Research Center in the University of Michigan's Institute for Social Research has published a yearly assessment of the drug-related behaviors, attitudes, and values of U.S. high school and college students (20). “Various stimulant drugs show continuing grad-

Trends in Lifetime Prevalence of AAS Use in Grade 12

Figure 23.2. Use among high school students. Data from <http://www.monitoringthefuture.org/data/08data/pr08t1/pdf>.

ual declines among teens in 2008, most illicit drugs hold steady” (21). Since 1991 the surveyors have asked about the AAS, and have therefore been able to track the usage and attitudes behind that usage of a generation of American young people.

As Figures 23.2 and 23.3 show, there was a sharp increase in the use of AAS by high school students in the late 1990s, and then a decrease in use up until the present. The past five years have seen an increase in those 12th graders who say that they see “great risk” in using steroids, which likely caused the concomitant decrease in use.

A smaller but more sophisticated study protocol on the subject of athlete’s attitudes toward the AAS (22) asked two groups of male athletes—one with the average age of 22 years old and one with the average age of 53—why they chose *not* to use AAS. The younger group mentioned power, control,

body image, and narcissism as reasons they avoided the AAS, while the older group focused on the (unfair) enhancement of athletic performance as a reason to avoid the AAS. Both the older and younger men agreed that media representations of the male physique were simply “unattainable without chemical means.”

AAS users choose their particular substances using a variety of criteria, including availability, anabolic:androgenic effect ratio, cost, reputation, and sometimes simply fashion. The Internet provides many sources of advice for which AAS to use, along with convenient links to buy those drugs, and books like “The Steroid Bible” (23)—a 126-page wire-bound manual which retails for \$49.95—provide comprehensive, if illegal, advice on how to use the AAS safely and effectively. Table 23.1 shows some of the more widely available AAS, along with their routes of use, half-lives, and provenance.

Trends in Disapproval of AAS Use in Grade 12

Figure 23.3. Disapproval among high school seniors. Data from <http://www.monitoringthefuture.org/data/08data/pr08t1/pdf>.

TABLE 23.1 Widely available anabolic–androgenic steroids

Generic name	Trade names	Route	Half-life	Provenance
Boldenone undecanoate	Equipoise	i.m.	14 days	Veterinary
Methandrostenolone	Dianabol	p.o.	6 hours	Non-U.S.
Methenolone enanthane	Primobolan	i.m.	10.5 days	Non-U.S.
Methyltestosterone	Metandren, Testomet, Android	p.o.	4 days	U.S.
Nandrolone decanoate	Deca-Durobolin	i.m.	14 days	U.S.
Nandrolone phenpropionate	Durobolin	i.m.	4.5 days	U.S.
Oxandrolone	Oxandrin	p.o.	9 hours	U.S.
Stanozolol	Winstrol	i.m./p.o.	p.o. 9 hours/i.m. 1 day	U.S.
Testosterone	AndroGel	Cutaneous	1.5 hours	U.S.
Testosterone cypionate	Depo-testosterone	i.m.	12 days	U.S.
Trenbolone	Finaplix-H	s.c./i.m.	3 days	Veterinary

INDICATIONS FOR AAS USE

Although the AAS have now become synonymous with cheating in athletic competition, they were initially prescribed for legitimate medical conditions, and continue to have well-defined indications for the treatment of various chronic diseases and medical conditions. Treatment of both hypogonadism and growth hormone deficiency (GHD) in males can include the use of testosterone or the AAS (24).

One review paper (25) looked at the legitimate uses for the AAS documented in the medical literature between 1966 and 2000, and found that the majority of recommendations were for the palliation of the cachexia and muscle wasting associated with chronic disease. The authors found consistent documentation of AAS use for the treatment of muscle loss associated with human immunodeficiency virus (HIV) infection, and severe burns, as well as numerous examples of the AAS recommended for the treatment of anemia related to leukemia or renal failure. Despite their general optimism about the use of AAS for debilitating medical syndromes, the authors are careful to point out the potential risks associated with even appropriately prescribed AAS:

Because of possible side effects associated with AAS therapy, several precautions should be taken before administering AAS. The possibility of altered liver function, especially with 17 α -alkylated anabolic steroids, warrants serial liver function testing. The androgenic nature of all anabolic steroids necessitates the testing of PSA levels in men before therapy is initialized. Additionally, serum lipids should be checked, as AAS therapy may be detrimental to patients at high risk for cardiovascular complications, especially those with low serum HDL levels (25).

Regardless of whether they are used for medically managed and legitimate purposes, or ad hoc and illegitimately, the

anabolic effects of the AAS do not necessarily confer functional strength. Even with necessary weight-bearing exercise as a concomitant, muscle growth derived from the AAS improves size of the muscle more than function: the earliest widespread use of AAS by nonelite athletes was in the bodybuilding community, where the desired end result was muscle size and definition, rather than actual strength. Of course, some AAS use obviously does promote functional strength, as evidenced by the hordes of amateur and professional athletes who use them for performance enhancement purposes, despite the drugs' dangers, cost, legal risks, and risks of disqualification. Although in many sports an overabundance of muscle can degrade necessary agility and range of motion, many athletes have learned to titrate their dosages to promote more modest muscle growth while enhancing muscular injury healing.

Those adolescents and others who use the AAS solely for aesthetic reasons are responding to changing societal norms and ideals, as cleverly demonstrated by a pair of studies by Harrison Pope and his colleagues. Popular action figures over a period of 30 years were measured (26), and seen to have grown in average size in the period from the 1960s to the 1990s, from an equivalent of a 32-in. waist/44-in. chest, and a 12-in. bicep to—in the 1990s—the equivalent of a 55-in. bicep. Even casual inspection of the action dolls over that time period reveals their evolution from a normal-appearing male physique to a grotesquely muscle-bound individual who is regularly placed into the hands of a largely male group of toddlers. In a follow-up study, Pope and his colleagues (27) examined the centerfolds in *Playgirl* magazine from 1973 to 1997, and noticed that the body mass index (BMI) and the fat-free mass index (FFMI) of the models demonstrated an increase in muscular “denseness” and general muscularity over the study period, demonstrating again

our society's increasing fascination with muscularity as a prized aesthetic value, if not necessarily as an avenue for athletic performance.

Pope terms this male obsession with a perfect—and muscular—body “The Adonis Complex” (28), and compares it to “anorexia in reverse” for men. Although he can cite multiple descriptive research studies by his group and others, Pope does not attempt to define one singular cause for this societal body dysmorphic disorder, but rather points to a variety of psychological and cultural phenomena which provoke and then support the unrealistic expectations that both men and women have of their own bodies.

The proliferation of “antiaging” clinics presents a dilemma for the competent clinician and organized medicine in general since these clinics often make promises and deliver therapies far beyond the accepted standard of care, but mimic accepted medical practice. The antiaging clinics merely expand upon the reasonable health habits promoted for aging people, and the cosmetic medications and surgical procedures that mainstream medicine promotes for the baby boomer generation struggling against old age. The aging male who would never consider buying drugs on the street or visiting a shaman is much more amenable to consultation with a clinic which advertised in an airline magazine, yellow pages, or the Internet.

An organization called “The American Academy of Anti-Aging Medicine” (29), founded in 1992, claims 22,000 members worldwide, 85% of whom are physicians. The organizations stated goals are to “... (serve) as an advocate for the new clinical specialty of anti-aging medical science and (act) as a conduit to the physicians, scientist, and the educated public who wish to benefit from the almost daily breakthrough in biotechnology which promise both a greater quality as well as quantity of life.” In addition to facilitating referrals to members of the organization, the Web site features books for sale such as “Grow Young with HGH,” and “Cellular Phones: Medical Menaces of a Modern-Day Convenience.”

One Internet advertisement for an antiaging clinic (30) promotes “hormone replacement therapy” with “testosterone pellet therapy” and promises, among other things, that the treatment for men “increases muscle, improves sexual libido (*sic*) and performance, increases energy, reduces depression, improves memory & concentration, reduces sleep disturbances, protects against heart disease, improves the skin's elasticity, encourages bone growth, improves blood flow....” While some of the above responses might indeed occur for the truly hypogonadal male, many of the clinics do not even test testosterone levels or other relevant indices, or support the treatment of testosterone values which are merely in the lower range of normal.

Although the range of clinics which call themselves “antiaging” is certainly broad and contains some legitimate medical providers, the industry itself has become notorious for providing useless, illicit, and sometimes dangerous preparations. In his report to the Commissioner of Major League Baseball on AAS and other performance-enhancing substances (PES) (31), former Senator George Mitchell wrote

about a criminal justice investigation “... including several so-called ‘rejuvenation centers,’ exposing another source of illegal performance enhancing substances. Some businesses that describe themselves as anti-aging or rejuvenation centers sell steroids or human growth hormone and arrange for buyers to obtain prescriptions for those substance from corrupt or suspended physicians, or even, in some cases, a dentist. The prescriptions are then filled by a compounding pharmacy affiliated with the center and delivered to the buyer whether through the mail or at the ‘clinic.’”

Although the provision of HGH is a standard treatment at many antiaging clinics, HGH is usually combined with testosterone or the AAS in order to achieve appreciable results. Do these interventions have a favorable risk:benefit ratio for the aging, but healthy, individual?

One early study done in 1996 (32) assigned 43 normal men to one of four groups: placebo with no exercise, testosterone with no exercise, placebo and exercise, and testosterone plus exercise. The subjects received 600 mg of testosterone enanthate injection or a placebo weekly for 10 weeks, and the exercise groups did standardized weightlifting exercises three times per week. The outcome variables were fat-free mass, muscle size, and arm strength, as well as endocrine responses and mood/behavior.

Those individuals, given the massive dosages of testosterone, had markedly elevated testosterone levels at 10 weeks, 2828 ng/dl in the no-exercise groups and 3244 ng/dl in the exercise groups, while the placebo groups did not change from their normal baseline testosterone levels. The no-exercise subjects given testosterone had statistically significant increases over baseline in triceps size, quadriceps size, bench-press strength, and squatting strength, and the exercise subjects given testosterone had improvements on all parameters when compared to either no-exercise group. Exercise combined with testosterone, not surprisingly, improved both muscle strength and function. There were no observed negative effects on cardiovascular lipid profiles or mood and behavior, despite the authors' diligent attempts to monitor for any such side effects. The 10-week time frame probably prevented the emergence of any such side effects, and even the supraphysiologic dosage of testosterone given is far below that taken by many illicit users. In their conclusions, the authors opine that while the AAS might be clinically useful for immobilized patients, cancer- or HIV-related cachexia, or other wasting disorders, but point out that “...(our) results in no way justify the use of anabolic–androgenic steroids in sports, because, with extended use, such drugs have potentially serious adverse effects on the cardiovascular system, prostate and lipid metabolism, and insulin sensitivity. Moreover the use of any performance-enhancing agent in sports raises serious ethical issues. ...”

A later (2002) randomized and placebo controlled study (33) of 27 women and 34 men, all older than 68 years, examined the effects of HGH and testosterone in an aging population and found that although HGH with or without testosterone or AAS did in fact increase lean body mass and decreased fat mass, and HGH and testosterone together slightly increased muscle strength and $\dot{V}O_2$ max in men; both

sets of results came at the expense of frequent adverse effects. Although the study lasted only 26 weeks, these statistically significant side effects—tied to both HGH and the testosterone/AAS use—included edema, carpal tunnel syndrome, arthralgias, glucose intolerance, and frank diabetes. The authors note that the improvements in lean body mass and decreased fat after the hormonal treatments were about the same as those reported after three times per week exercise training for six months, but less than the improvements found in subjects exercising once per week.

AAS METABOLISM

Males produce about 95% of their testosterone, the endogenous analog for all the AAS, in testicular Leydig cells, with the rest produced in the adrenal glands. Females produce relatively small amounts of testosterone in the ovaries. Most circulating testosterone is bound to sex hormone binding protein (SHBP); only the free testosterone is biologically active (34). The hormone's *androgenic* effects are mediated by the metabolism of testosterone to the more-potent 5 α -dihydrotestosterone (DHT) by the 5 α -reductase, which resides in specifically male target tissue like the prostate gland, seminal vesicles, and external genitalia. These androgenic, or virilizing, effects occur in the male fetus, adolescent, and adult, to varying degrees according to the level of circulating testosterone. In some other tissues, like adipose and brain, aromatase converts circulating testosterone to estradiol, a fact of great importance to those who ingest exogenous testosterone or AAS (35).

The *anabolic* effects of testosterone and its AAS mimickers are promotion of bone and muscle growth, as the hormone promotes protein synthesis, decreases protein catabolism, and increases erythropoiesis. Although AAS with pure anabolic effects in the absence of any androgenic side effects would be ideal for athletes, no such compound has yet been developed. However, testosterone and the various AAS vary widely in the ratio of anabolic to androgenic effects. Testosterone and methyltestosterone (Android and others) have about a 1:1 ratio of androgenic to anabolic effects, fluoxymesterone (Halotestin and others) has a 1:3 ratio and oxandrolone (Oxandrin) can have a 1:13 ratio (36). The androgenic activity of any compound is most accurately determined by using a variant of the Hershberger assay, in which lab animals are exposed to AAS, sacrificed, and have their androgen-sensitive tissue like bulbocavernosus muscle, ventral prostate, and seminal vesicles weighed (37). Of course, the Hershberger assay suffers from being a laboratory-derived procedure using an animal model, and illicit AAS users, of course, simply look up Internet estimates or listen to word of mouth in the gyms.

As Figure 23.4 demonstrates in simplified form, all endogenous testosterone derives from (noncirculating) cholesterol, the basic steroid molecule that is metabolized to androstenedione and pregenenolone, and then to testosterone. Testosterone is eventually broken down into 5 α -DHT and estradiol in peripheral tissue. Modification of the basic four-ringed steroid structure—three cyclohexane rings and a

cyclopentane ring—confers varying degrees of oral availability, serum half-life, and side effect profile.

For instance, substitution of a methyl or ethyl group for the hydrogen at the 17th position of the cyclopentane ring confers oral availability on the resultant AAS by reducing hepatic first-pass metabolism. Paradoxically, these orally available compounds—like stanozolol (Winstrol)—have turned out to confer more adverse effects than the injectable compounds, because of their hepatotoxicity. Esterification at the 17- β position allows for longer serum half-life of the molecule because of increased lipophilicity and a resultant slower release from the oily injection vehicle into the blood stream. Testosterone cypionate (Depo-testosterone) and nandrolone decanoate (Deca-Durobolin) both have longer half-lives than their nonesterified building-block molecules, with that half-life directly related to the length of the ester chain (35).

Cynthia Kuhn (38) nicely reviewed the four basic ways in which structural and pharmacokinetic properties can be expressed from the basic testosterone structure. First, the standard testosterone molecule can be utilized parenterally, as a skin patch, skin cream, or alternatively in a micronized oral preparation. Secondly, esterification at the 17- β site (as noted above) promotes lipophilicity on the testosterone cypionate, propionate, enanthate, and undecanoate preparations. Thirdly, manipulation at the 17- α site produces methyltestosterone, danazol, and oxandrolone, which resist hepatic first-pass metabolism and become orally available, but therefore have increased liver toxicity. Finally, various modifications at the A, B, or C rings (as with mesterolone, nortestosterone, and nandrolone) provide (variously) slowed metabolism, enhanced androgen receptor affinity, resistance to aromatization to estradiol, and decreased metabolite binding to androgen receptors.

AAS-related “dietary supplements” are simply prohormones that have the same or similar biologic effects as the AAS themselves, but remained available long after the AAS were placed on the Federal Schedule. For instance, the prohormone supplements dehydroepiandrosterone (DHEA) and androstenedione were legal and available OTC when baseball superstar Mark McGuire was famously noticed by a news reporter to display a bottle of “Andro” in his clubhouse locker (39). DHEA, though banned by most major sports organizations, still remains available as a dietary supplement, reportedly because of an intervention by a U.S. senator with many supplement manufacturers in his home state (40). Although these supplements usually are less potent than the AAS, they nonetheless are converted to testosterone and cause measurable androgenic and anabolic effects.

In addition, some substances marketed as dietary supplements actually contain AAS, and on July 28, 2009 the U.S. FDA issued a consumer advisory (41), along with a warning to one of the manufacturers, American Cellular Laboratories, which advised consumers to avoid the most obvious culprits, those substances which are marketed as AAS or with names that sound like AAS. The advisory made the point that these products may contain synthetic AAS or AAS-like active ingredients and are therefore not dietary supplements, and specifically mentioned Tren-Tren-Streme, MASS Xtreme, Estro Xtreme,

Figure 23.4. Biosynthesis and metabolism of testosterone.

and substances marketed as “similar to Stanozolol,” “similar to Boldenone,” or “very similar to 1-testosterone.”

The advisory’s statement on health risks of these products was detailed and quite worrisome:

Adverse event reports received by FDA for body building products that are labeled to contain steroids or steroid alternatives involve men (ages 22 to 55) and include cases of serious liver injury, stroke, kidney failure and pulmonary embolism (blockage of an artery in the lung). Acute liver injury is known to be a possible harmful effect of using anabolic steroid-containing products. In addition, anabolic steroids may cause other serious long-term adverse health consequences in men, women, and children. These include shrinkage of the testes and male infertility, masculinization in women, breast enlargement in males, short stature in children, adverse effects on blood lipid levels, and increased risk of heart attack and stroke.

DESIGNER AAS

A variety of AAS—the “designer steroids”—have been designed specifically to evade drug testing and provide a high anabolic–androgenic profile. Although epitestosterone was used by the GDR to evade drug tests and is still prescribed by some physi-

cians despite its biologic inertness and ineffectuality for any purpose other than evading drug testing, other more sophisticated strategies have been developed for evading those tests. For instance, Norbolethone, which was initially packaged as “The Clear” by notorious AAS purveyor Victor Conte of San Francisco’s BALCO laboratory (42) was developed in the 1960s, never marketed because of concerns about potential toxicity, but came to light as a present day illicit AAS when U.S. cyclist Tammy Thomas was found to have an elevated T:E ratio at the 2000 World Cycling Championships in Belgium. Thomas was eventually found to have been using norbolethone provided by Victor Conte and chemist Patrick Arnold at BALCO labs (43).

After the exposure of norbolethone as “The Clear,” Arnold, newspaper accounts allege (44), changed the active ingredient in “The Clear” to tetrahydrogestrinone (THG), a previously unknown molecule structurally related to two AAS already banned by the World Anti-Doping Association (WADA), gestrinone and trenbolone. In his 2004 report on the discovery of the new substance THG (45), AAS expert Don Catlin described his work identifying the unknown substance provided to him in “a spent syringe that had allegedly contained an anabolic androgenic steroid undetectable by sport drug control urine tests (which had been) provided

anonymously to the United States Anti-Doping Agency.” By using standard laboratory techniques and some educated hypotheses about the new substance, Catlin and his team were able to identify the THG, the reason for its previous undetectability, and develop a lab assay to effectively deny future illicit AAS users THG, at least.

In an interesting legal side note to the discovery of THG, four NFL players were found to have THG in their urine samples—which had been collected before a test for THG was available (46). The NFL tested a total of 4000 samples and found only these four positives. Because retrospective testing found the substance, the league fined the players for AAS use although THG was not technically banned before it had been discovered. The NFL Players Association protested the fines.

AAS users obtain their information about these substances from a large variety of sources: friends, suppliers, easily obtainable manuals, and—probably most importantly—sophisticated Internet sites, blogs, and chatrooms. The information that users get, both on optimum regimens and managing the inevitable side effects of AAS use, ranges from scientifically accurate to frankly criminal. But since all of the advice constitutes the practice of medicine without a license, there is little chance for the second opinions and considered trials that are, ideally at least, the province of legitimate medical practice.

The underground AAS pharmacologists have come up with several protocols of AAS use (47), the first of which is “stacking” in which the user takes several different agents from different classes of AAS in order to reap the particular benefits of each. Pyramiding is the not-unreasonable pattern of tapering up the ingested AAS and then a tapering down at the end of a cycle, to avoid withdrawal. Bodybuilding gyms and the Internet are replete with self-proclaimed experts who offer to guide the novice through a bodybuilding regimen, which often enough reveals substantial results within a few months, leading to increased faith in the “coach.”

COMPLICATIONS OF AAS USE

Use of the AAS has been associated with numerous medical problems, some more serious than others. Since the supraphysiologic dosages used illicitly cannot be prescribed ethically to research study participants, researchers often rely on convenience samples of AAS users who present with medical problems, as well as animal models, to determine and characterize these complications. Given the usually clandestine nature of AAS use, the population of AAS users who experience no side effects or subclinical side effects remains unknown since they neither seek nor receive medical attention. Keeping these caveats in mind, however, there exists a convincing literature of well-documented medical problems attributable to the AAS.

Most dramatic is the occasional cardiac death attributed to the AAS, including a well-documented case report of two AAS-using athletes who died from sudden cardiac arrhythmias (48). Two bodybuilders, one aged 29 and the other aged 30, collapsed and died without any obvious reasons, and were found to have been using stanozolol, nandrolone, and testosterone, but no

drugs of abuse or ethanol. Cardiac pathology revealed that the athletes had normal gross cardiac pathology, so simple cardiomegaly was not the cause of death. The T:E ratio in one case was 28.7, and in the second was 42, far above the 6 commonly considered the upper limit of normal.

Despite the absence of gross cardiomegaly, the pathology report did show focal myocardial fibrosis and contraction band necrosis, which the authors attribute to the use of AAS combined with exercise, rather than simply exercise itself. Since the cardiac vessels and conduction systems appeared free of pathology, the authors were convinced that this “direct injury” to the heart was the likely cause of death. They hypothesized that “...the combined effects of vigorous weight training, anabolic steroid use, and androgen sensitivity may have predisposed these young men to myocardial injury and subsequent sudden cardiac death.”

A small study of 6 AAS-using bodybuilders compared to 9 non-AAS-using bodybuilders and 16 age-matched sedentary controls showed by Doppler echocardiography of the left ventricular (LV) myocardium that there was no increase in LV wall thickness in the AAS users (49). However, the AAS users exhibited a smaller passive component to LV filling, which the authors speculate was related to their AAS use, and conclude that “... the decrease in LV relaxation properties might have been due to an alteration in the active properties of the myocardium, but that has yet to be confirmed.”

In a broader review of the cardiac arrhythmias linked to illicit drug use by athletes, Furlanello and colleagues (50) acknowledge the more significant clinical ramifications of the QTc prolongation associated with the use of ephedra and caffeine products, as well as the myocardial infarction and ventricular tachycardia experienced by athletes using amphetamines. However, they point out that the AAS are often taken with diuretics to avoid detection, and HGH to enhance anabolic effects, both of which potentiate cardiac problems such as myocardial hypertrophy and hypotension.

In a less dramatic, though arguably more common way, AAS users consistently suffer from serum lipoprotein abnormalities caused by their AAS use. Given the cardiac pathology associated with low high-density lipoprotein (HDL) values, it is worth considering the AAS well-documented effects on serum lipoproteins. AAS users consistently experience falling levels of HDL after a few days of AAS use, probably related to stimulation of hepatic triglyceride lipase, which is responsible for modulating HDL-2 and apolipoprotein-A1. Interestingly, the 17-alkylated AAS reduce HDL by about half, while nandrolone and testosterone esters have little effect, probably because testosterone does not induce triglyceride lipase. Total cholesterol often remains stable in AAS users, because LDL is increased by AAS use (51).

Kuipers and his colleagues (52) injected 100 mg of nandrolone decanoate into a cohort of bodybuilders each week for 8 weeks, and compared various physical parameters to a control group of bodybuilders 8 weeks later. They found that the nandrolone-using bodybuilders experienced a 25% to 27% decreases in HDL, which reverted to normal 6 weeks after they stopped using the nandrolone. Like many such

studies, this one is hampered by the ethical imperative to give research subjects the usual dosages prescribed for legitimate medical problems, although AAS users probably use more, as evidenced by one Web-based information source (53) which also contains advertisements for nandrolone decanoate: “Standard dosage of Nandrolone is 2 mg per pound of body weight. For Example, a 90 kg (200 pound) athlete should take 400 mg per week. Maximum dosages can be as high as 1000–1500 mg per week.” Had the Kuipers study injected their subjects with 1500 mg/week of nandrolone decanoate (15 times higher than their study dosage!) they might well have found more or longer-lasting damage to lipid profiles.

One naturalistic study (54) that did not quantify the actual dosage of the AAS used nonetheless found valuable information about the differential effects of the AAS when compared to weightlifting or running. When compared to recreational weightlifters, heavyweight lifters, and runners, the small group of seven AAS users had significantly lower HDL levels and significantly higher LDL levels, but no difference in blood pressure. Not surprisingly, the runners had significantly lower body mass index (5% as compared to 11% for the recreational weightlifters, 10% for the heavyweight lifters, and 11% for the steroid users). The AAS users did have elevated LV mass, not explained by the fact that the steroid users were heavier in general, since this effect had been factored out.

Despite the clear evidence that AAS use causes perturbations in serum lipid profiles, and the uncontested connection between lowered HDL levels and heart disease, there is as yet little convincing evidence that AAS users suffer clinically significant lipid profile abnormalities. One study of the reversibility of AAS-related side effects (55) found that HDL decreases in fact resolved after the 12 to 43 months in which the subjects had not been taking AAS, after their long-term use. Fifteen athletes who were former AAS users were compared to 17 still-using athletes on a variety of parameters including hemoglobin, platelets, ALT, AST, testosterone, LH, and FSH. After more than a year of abstinence by the 15 ex-users, many still had increased ALT levels and depressed testosterone synthesis, and their HDL cholesterol and other parameters had normalized, although of course the clinical ramifications are not necessarily clear, even with this return to normal values.

Musculoskeletal injuries related to AAS use by adults are usually related to tendon and ligament damage caused by AAS-mediated muscle growth, without concomitant connective tissue growth. In addition, the AAS combined with exercise may interact with tendon collagen fibrils, decreasing the tensile strength of the tendon, just when it is needed to handle the newly enlarged musculature (56). One case report (57) of a 32-year-old professional bodybuilder describes his acute pain at attempting to squat-lift 400 lbs: he was found to have ruptured both quadriceps tendons. History revealed a 10-year history of multiple PES, including AAS. His use of testosterone was estimated at six times the recommended daily dose, and he had already suffered from gynecomastia, acne, and loss of his libido. Children and adolescents also experience specific musculoskeletal side effects of AAS use; this will be reviewed below.

Although hepatic pathology is often cited as one of the most worrisome potential side effects of AAS use, the literature reveals several relatively inconsequential hepatic conditions associated with AAS, and only a few serious maladies. Peliosis hepatitis—blood-filled cysts in the liver—has been associated with tuberculosis, the use of oral contraceptives by women, and AAS use by men. Despite the understandable concern about having any sort of liver pathology, peliosis hepatitis is itself usually considered a benign finding, and is usually discovered only incidentally (58).

Similarly, liver function tests (LFTs) are often elevated in those who are presently using AAS or have recently stopped (59), but the LFTs usually normalize after a relatively short period of time, with systemic damage to the liver unclear. In an animal study which sheds light on the mechanism of hepatic changes caused by the AAS, Vieira and colleagues (60) compared, over 5-weeks' time, four groups of Westar rats: a control group, a group receiving low dose of nandrolone decanoate, intermediate doses, and supraphysiologic doses. The nandrolone caused a dose-dependent increase in LFTs (although all remained within the normal range), and an increase in collagen deposition to the liver parenchyma and portal space. They also noted an increase in the Kupffer macrophage cells, presumably deployed to defend liver tissue against collagen deposition. The Kupffer cells are implicated in some models of liver fibrosis and cirrhosis. The 5-week time span of the study, as well as the lack of a comparable human model detract from the study's clinical relevance, but the mechanism does seem quite similar to observations in human AAS users.

The most worrisome hepatic side effect linked with the AAS is hepatocellular carcinoma, a tumor whose prevalence has been increasing over the last two decades (61). This tumor occurs mostly in those over 65 years of age, has about a 3:1 male to female prevalence ratio, a poor prognosis, and few distinct risk factors: previous hepatitis C infection, heavy alcohol consumption, and diabetes/obesity. However, between 15% and 50% of new cases have none of these risk factors, leading to a search for other associations or etiologies. Since the disease is more prevalent in men—who have higher endogenous testosterone levels than women—AAS use should be one possible line of inquiry. But the reports on hepatocellular carcinoma in AAS users are case reports that suggest (62,63) but do not prove a connection between the sometimes massive use of AAS by the subjects and their subsequent cancer diagnoses.

The most common sex-specific side effects of the AAS in men, testicular atrophy and gynecomastia, are caused by downregulation of testicular production of testosterone and aromatization to estrogen, respectively. Although the AAS certainly cause testicular atrophy and subsequent impotence, loss of libido, and decreased sperm count, it is less clear that the AAS actually cause permanent infertility. In men, the AAS apparently directly damage sperm via altered meiotic segregation, but this effect usually resolves after cessation of AAS use (64).

Deca-Durabolin (nandrolone decanoate) is quite popular among AAS users because it has little liver toxicity and a high anabolic:androgenic effect ratio. However, the molecule

Figure 23.5. Sex-specific effects of AAS use.

is a progestin and can incite gynecomastia, suppression of the hypothalamic–pituitary–testicular axis, and complete cessation of endogenous testosterone production. The subsequent impotence—termed “Deca-Dick” by amateur pharmacologists—can be addressed by the use of testosterone production stimulants like HCG both during and after the Deca-Durobin cycle, but there is no guarantee of any salutary effect. Many Deca-Durobin users complain of impotence long after they have stopped using the drug, and even after attempts at stimulation of testosterone production.

Women who ingest AAS experience the effects of an abnormally high testosterone level, and therefore show easily predictable effects: increase in muscle size, deepening of the voice, increased facial hair, clitoral enlargement, and menstrual problems (65). Sex-specific effects of AAS are presented in Figure 23.5.

In one survey of AAS use patterns that suggests the relative prevalence of specific side effects, 21 gyms in Great Britain were surveyed (66), and although only 59% of individuals questioned responded, the responses were clearly segregated by sex. Fifty-five percent of the men reported testicular atrophy, 52% had gynecomastia, 36% had elevated blood pressure,

and 26% reported tendon injuries. Among the women who responded to the questionnaire, 8 out of 13 (61%) reported menstrual problems and fluid retention, 4 had clitoral enlargement, and 3 complained of a decrease in breast size.

The damaging physical effects of the AAS on children and adolescents are even more marked and well described than on adults. Even those who advocate for the legitimization of AAS use would deny the drugs to children. A long list of risks specific to children and adolescents who use AAS is topped by potential abnormalities in pubertal sexual development modulated by testosterone. An animal model predicts (67) that exogenous testosterone (and therefore AAS) will increase aggression, cause permanent damage to neurotransmitter systems, and provoke a reinforcing effect distinct from that caused by the androgen receptors themselves. Even more worrisome are those proven maladies that demonstrably occur in adolescents who use AAS, most prominently psychiatric effects and musculoskeletal problems.

Although adolescents, like adults, face the danger of tendon rupture from accelerated muscle growth, adolescents have the unique added problem of premature epiphyseal plate closure (68). The epiphyseal plate cartilage presents the obvious

place for a break when pressure is applied to the entire system, which results in premature closure of the plate, and resultant short stature.

PSYCHIATRIC COMPLICATIONS OF AAS USE

The AAS also cause behavioral and psychiatric phenomena, the most distinctive of which is known popularly as “roid rage.” As in the case of World Wrestling Entertainment wrestler Chris Benoit, the popular media may exaggerate the effects of steroids on complex human behaviors (69), but the horrific nature of Benoit’s act—strangling his wife and suffocating his 7-year-old son before hanging himself—lends itself to hyperbole and a search for causes. Benoit’s stage moniker as “The Canadian Crippler” and the reported deliveries of AAS, HGH, and testosterone to his home lent decisive, if circumstantial, weight to the notion that “roid rage” caused the Benoit tragedy. However, the peer-reviewed literature contains multiple case series and literature reviews documenting AAS-related hostility, aggression, hallucinations, and delusions (70,71).

AAS-related mood perturbations may be even more prominent in children. In one preliminary report, researchers at the University of Iowa (72) surveyed 86,000 6th, 8th, and 11th graders about their use of drugs and alcohol and their attitudes toward school, family, and their community. Not surprisingly, the percentage of AAS users increased as the students aged, with 0.8% of the 6th grade boys acknowledging ever using steroids, as did 2% and 4.5% of the 8th grade and 11th grade boys. For the girls, the percentages were lower but still substantial: 0.7%, 1.8%, and 2.9%, respectively. Aggressive behavior toward others was admitted by 64.1% of the boys who had ever used AAS, as compared to 22.6% who had never used AAS. And of the boys who used AAS, 36.9% of the 11th grade boys and 53.5% of the 11th grade girls had experienced suicidal ideation, compared to 10.6% and 16.8% of the non-AAS-using boys and girls. Although these data show association, not causation, the clear connection between AAS and emotional abnormalities in high school students deserves closer scrutiny.

For adults also, AAS-related affective symptoms are much more common than psychosis, and the affective symptoms are generally experienced by unsophisticated AAS users who are taking dosages at the high end of the spectrum, far beyond the dosages for performance enhancement. Mood symptoms can include depression, hypomania, and frank mania (73). One manifestation of withdrawal from AAS can be a profound depression (74), which has been implicated in the completed suicide of some users, although another school of thought within psychology makes the point that normal developmental changes, as well as substances *in general* predispose adolescents to impulsive behaviors like suicide (75).

Although the very existence of true physiologic dependence and withdrawal from AAS has been questioned, careful analysis shows that both phenomena occur, especially in the heavy AAS user. An early case study of an AAS user who stopped abruptly revealed typical correlates of withdrawal,

Figure 23.6. Symptoms of AAS withdrawal. Adapted from Brower KJ, Blow FC, Young JP, et al. Symptoms and correlates of anabolic–androgenic steroid dependence. *Br J Addict.* 1991;86:759–768.

including the sudden onset of dysphoria, fatigue, psychomotor retardation, impaired concentration, along with suicidal ideation (76). This symptom picture disappeared after 4 days. The same authors later reported a case series of 49 AAS-using competitive weightlifters (77) and found that 94% endorsed at least one symptom of *DSM-III-R* dependence, with 84% experiencing physiologic withdrawal, 51% using more AAS than intended, and 49% spending more time than they had intended on substance-related activities (77) (Fig. 23.6).

When compared to cocaine and heroin, the AAS are decidedly less likely to cause addiction problems like tolerance, withdrawal, and continued use despite the user’s awareness of adverse consequences. However, researchers have put the “addictiveness” of the AAS on the spectrum closer to mild reinforcers like caffeine, nicotine, and benzodiazepines (78).

Perhaps more important than the peer-reviewed research about the addictive aspects of the AAS are the statements of AAS users and their loved ones. In a Web site (79) developed to commemorating the life of Taylor Hooton, a high school athlete whose suicide at the age of 16 was associated with his abrupt cessation of AAS, his parents and coaches discuss their initial ignorance about the effects of AAS. In addition, they review the apparent psychiatric effects of his use, and the apparent catastrophic and self-destructive effects of his decrease in AAS usage. Although NFL linebacker Lyle Alzado’s belief that his use of AAS caused his ultimately-fatal CNS lymphoma tumor has no scientific support, his description of the AAS’s profound compulsive hold on him is both heartfelt and consistent with what people say about other addictive substances: “... I started taking anabolic steroids in 1969, and I

never stopped. Not when I retired from the NFL in 1985. Not ever. I couldn't According to the guys around the gym, if you go on steroids for six to eight weeks, then you're supposed to stop for the same number of weeks. Me, I'd be on the stuff for 10 or 12 weeks, and then I'd go off for only two, maybe three weeks, and I'd feel that was enough. It was addicting, mentally addicting. I just didn't feel strong unless I was taking something ..." (80).

Despite user reports and the scientific data available, some writers continue to advocate for less demonization of the AAS for performance enhancement, and offer data and alternative philosophical approaches to make their points. One advocate for medical prescription of the AAS, Anthony Millar, followed 169 amateur athletes (81) who were prescribed a 7 to 9 week course of AAS, at dosages which did not exceed the equivalent of 500 mg per week of testosterone, although most received far less. The subjects showed a mean weight gain of 4.6 pounds, with a reportedly "significant" loss of body fat in those who had a prestudy body fat of 16% or more. The report does not quantify physical activity or diet, although the subjects were advised to train more than 4 days per week and ingest a high protein diet. Observed side effects were elevation of LFTs, total cholesterol, and lowering of HDL, as well as instances of decreased libido, all of which resolved after the study period. Three instances of gynecomastia were treated with Tamoxifen at 20 mg/day over a 4-week period, which, the author reports, "settled down" the breast inflammation, though again no data are given. From this mostly observational study, Dr. Millar concludes that small doses of the AAS can be used safely, and that ending the prohibition of AAS use would reduce overall harm from the drugs because of the present situation in which, unfairly (to his mind) "... more side effects and catastrophic events are attributed to the use of anabolic steroids rather than their *abuse*."

In a more-favorable-than-not review article, Hoffman and Ratamess (82) opined that some AAS side effects are exaggerated in attempts to prevent use, and that drug-testing programs do not necessarily decrease use of the AAS. They note the difficulty in studying, under laboratory conditions, AAS dosages and patterns used in the "real world" of gyms and bedrooms, and make the point that contributing factors such as genetic predisposition and diet might account for some effects now attributed to the AAS. Rather than a polemic for or against AAS use, the authors write that they merely advocate for more accurate information about AAS effect and side effects.

In a nonscientific but provocative documentary about AAS use in the United States (83), actor Chris Bell examines use of the AAS by his own brothers, as well American icons like Sylvester Stallone and Hulk Hogan. In true documentary fashion, Bell highlights the profound inconsistency in public discourse about the AAS, and notes the acceptance of other potentially dangerous modes of enhancement, like laser eye surgery, the injection of corticosteroids, and β -blockers for stage fright. The movie is not one-sided, however, skewering the supplement industry and anti-AAS crusader Congressman Henry Waxman, along with those who warn about catastrophic if unproven side effects for the AAS.

SUBSTANCES USED CONCOMITANTLY WITH THE AAS

A variety of other substances are often used along with the AAS, some to augment the effects of AAS, and some to counteract AAS side effects. One of the most commonly used adjuncts to the AAS is HGH and, starting in 1985, recombinant human growth hormone (rHGH). Native HGH is produced by the anterior pituitary, and the most common form of the hormone contains 191 amino acids. It is only available in injectable form, has a short circulating half-life (about 20 minutes) as well as a biologic half-life of 9 to 17 hours. HGH has been available commercially for 40 years, and has well-defined pediatric indications for GHD, idiopathic short stature, Turner syndrome, Prader-Willi syndrome, Noonan syndrome, and chronic renal insufficiency, with investigational use for cystic fibrosis, juvenile idiopathic arthritis, and inflammatory bowel disease (84).

Athletes taking HGH hope for the anabolic and lipolytic effects seen in patients with GHD and others with genuine HGH deficiencies, although the data supporting any sustained good effects in normals who take nothing but HGH is not particularly convincing. And reported side effects of HGH include insulin resistance, increases in very low density lipoproteins (VLDLs), arthralgia, myalgia, hypertension, cardiac failure, and an increased rate of malignancies (85).

Although the illicit use of HGH is banned by all sports organizations, despite some hopeful media reports (86), no widely available test procedure to detect HGH has been found. Although serum HGH tests were conducted at the 2004 Athens, 2006 Turin, and 2008 Beijing Olympic Games, the results were never announced, leaving some skeptical of the test's efficacy.

In addition to the AAS, stimulants are often used by athletes trying to gain a competitive advantage. Doping athletes can use commonly prescribed attention-deficit hyperactivity disorder (ADHD) remedies like amphetamine (Adderall and others); methylphenidate (Ritalin and others); OTCs like caffeine, guarana, or pseudoephedrine; or banned but previously available supplements such as ephedra. On occasion athletes will even try highly toxic drugs of abuse like cocaine for performance enhancement, although this strategy usually leads to disaster very quickly. One commonly abused stimulant is clenbuterol, a β_2 adrenergic agonist prescribed as a decongestant but used by athletes as a partitioning agent.

In attempts to "flush their system" and obtain a false-negative urine toxicology results, athletes sometimes use diuretics such as loop diuretics (e.g., hydrochlorothiazide), various herbal preparations, and simple overingestion of water (87). Consequently, loop diuretics are banned by most sports organizations unless the athlete has a documented therapeutic use exemption (TUE, as described later in this chapter). Since diuretics are perceived as relatively benign, athletes often significantly underestimate the potential risks they face of dehydration, heat stroke, kidney failure, hyponatremia, and hypokalemia with their use.

Human chorionic gonadotropin (HCG) can be used by AAS users to counteract the AAS-stimulated down-regulation of androgen production by the interstitial cells of the testes. HCG stimulates the testes to again produce testosterone, even in the ex-AAS user who may have stopped using AAS, but whose testicular function did not return. In addition, HCG is reputed to raise testosterone levels without affecting the T:E ratio, another reason athletes might use the substance. A 1995 survey of male AAS users found that 32% of the 52 users questioned had used HCG in their attempts to negate the effects of their AAS use (88). A high-profile professional baseball player recently suspended for his use of HCG (89) presumably demonstrates the ongoing use of HCG as an adjunctive treatment for those who use AAS, with the resultant testicular atrophy and shutdown.

ETHICS OF AAS USE

Any consideration of the ethics of PES use in sports necessitates an understanding of the meaning of sport, and some definition of what actually constitutes a PES, seemingly obvious concepts which become murkier when critically examined. For instance, the main focus of most sports—intense competition—lends itself to whatever sort of enhancement an athlete can muster, substances included. A swimmer choosing to wear a speed-enhancing suit, a bicyclist training at high altitude, or a skier using expensive waxes are all normative events in competitive sport, but all are also regulated by authorities within the sport. What if an athlete wants to avoid traveling to the mountains, and simply use a hypoxic chamber? Or take a substance like erythropoietin (EPO), which also raise hemoglobin levels?

And what about prosthetic devices? In one closely watched case, South African sprinter Oscar Pistorius (90) had bilateral below-the-knee amputations requiring the use of prostheses to walk, much less run. In order to compete at the Olympic level using the J-shaped prosthesis called the “Cheetah,” Pistorius had to bring his case before the International Association of Athletics Foundations (IAAF) where his lawyers asserted, based on comparison studies of Pistorius’ running with the endurance, fatigability, and sprinting mechanics of able-bodied athletes, that the prostheses conferred no advantage. The study data showed that Pistorius had a sprinting gait markedly dissimilar from other athletes, that he took 34% less time in the air between steps, and that he exhibited considerably less force on ground in relation to his body weight. So, although the authors concluded that Pistorius’ abilities were generally similar to able-bodied athletes, this was clearly an opinion judgment call rather than an exact comparison. The IAAF accepted the reasoning of the investigators and allowed Pistorius to compete with his prostheses. Certain swimsuits can be banned, rules can be modified, and new technologies can be accepted or rejected, but all of these decisions require thoughtful and ultimately subjective judgments about the meaning of sport itself.

The use of substances to improve performance seems to many a separate case, but the same sorts of ambiguities exist

in this category. Some substances, like protein powders, are allowed by all major sports, while others, like the AAS, are banned by all sports organizations. Some legitimate medications, like the β -agonists used to treat asthma, are banned by some sports organizations and not others, while other medications like the β -blockers used to treat hypertension are banned in some sports (biathlon) but not others (boxing). Just to confuse the picture, all major sports organizations must allow for the possibility that some banned substances—most notably stimulants and diuretics—may be medically necessary for a particular athlete and therefore undeniable for those who meet clinical criteria for taking that particular medication. Separating out those athletes who merely *want* the medication as opposed to those who both *want* and *need* the medications is the difficult task faced in the granting of sports TUEs, as described below.

Antidoping programs and the necessary testing often appear to be unnecessarily paternalistic, with paternalism defined by ethicist Thomas Murray as “... doing something to or for another person for their benefit but without regard for that individual’s preferences” (91). This certainly seems to be an incongruity in athletics: if society allows adults to smash into opposing linebackers and drive race cars at 180 miles/h for the sake of sport, how can society forbid those same individuals from taking another acknowledged risk involving the PES? As Dr. Murray points out, however, there is an important difference between the risks inherent in a sport, and those that the athlete chooses to take on, and the athletes’ choices are hardly unconstrained. If unregulated, the enormous pressures put on athletes—even those who are not professional—results in potentially self-destructive behaviors with the PES that could lead to grotesquely dangerous drug use which would surely spread to other athletes who wish to compete. Each sport has the right and obligation to regulate the boundaries of competition, from the distance between the pitching mound and home plate, to the weight of the hockey puck, all the way to what substances the players may ingest.

As one antidoping expert pointed out, the choices presented to an athlete are excruciatingly simple: “If you compete in a sport where everyone is using performance-enhancing drugs, then you have three choices: compete at a disadvantage, quit the sport, or go against your principles and take the drugs ... all three are poor ethical choices” (92).

Dr. Murray, the ethicist, sets out five elements for an ethically successful and fair antidoping program, the first of which is adequate analytic capacity. That is, the scientific basis of the testing devices, laboratory procedures, and staff certification must all be as close to unquestionable as possible. Second, the sampling strategy must be tailored to the sport at hand, as well as the substances that are usually used in that sport. Testing only during competition when competitors can stop their substance of choice just before competition and come out clean makes no sense, and newer techniques—including access to serum samples and ongoing comparison of sequential lab values—are potential necessities in future drug testing. Third, the program must have an adjudication process

that is “fair, open and reliable.” Fourth, research into doping and drug testing must continue to provide strategies and laboratory techniques to handle the inevitable challenges in antidoping strategies. Finally, Murray recommends that the antidoping community set forth a clear set of principles as to why doping is wrong, and have a uniform and fair process for banning or allowing various substances.

Another ethical conundrum within sports doping is the role of physicians in providing treatment for athletes at all levels. Although some physicians and others provide clearly illegal services and substances to athletes, others function at the boundary between legitimate medicine and banned/illegal protocols. In the words of one sports medicine specialist quoted in the UNESCO Courier:

Sport presents doctors with a paradox. Most of them believe physical activity makes for a balanced life. But they are also well aware that competition upsets the balance, and those chemical-based treatments can be prescribed to supplement deficiencies. If they respond to such demands, they are only reinforcing the alienating emphasis put on performance at all costs, of which sport is just the most striking example . . . Sport medicine is a forerunner of the medicine of the future—a medicine at the behest of institutions in the business of boosting efficiency. It runs the risk of ushering in a common norm dictating people’s appearance (though cosmetic surgery), character (through prenatal diagnosis) and social behavior, namely through the demand for performance in all fields, be it professional, sexual, or sporting (93).

THERAPEUTIC USE EXEMPTIONS (TUES)

All major sports organizations, both professional and amateur, have policies in place that contemplate the use of banned substances by athletes who take the medications for legitimate medical reasons: the TUE. The Olympics (94), the NCAA (95), the National Football League (96), Major League Baseball (97), the Professional Golf Association (98), and the National Hockey League (99), all have appeal processes for evaluating TUE requests.

While the idea is simple—in the words of the ethicist Murray: “Therapy is good, enhancement is suspect” (100), Murray points out that the line between the two often becomes blurred, changeable, and entirely indefinable. The World Anti-Doping Association publishes criteria (101) for TUEs, which attempt to clarify the four salient points:

“... The four criteria that must be fulfilled before a TUE is granted are set forth in the International Standard for TUEs:

1. The *Athlete* would experience a significant impairment to health if the *Prohibited Substance* or *Prohibited Method* were to be withheld in the course of treating an acute or chronic medical condition . . .
2. The *therapeutic Use* of the *Prohibited Substance* or *Prohibited Method* would produce no additional enhancement of performance other than that which might be anticipated by a return to a state of normal health following the treatment of a legitimate medical condition. The *Use* of any

Prohibited Substance or *Prohibited Method* to increase ‘low-normal’ levels of any endogenous hormone is not considered an acceptable *therapeutic* intervention . . . Enhancement of performance should be taken to mean the return by the athlete to his/her level of performance prior to the onset of the medical condition requiring treatment. This means that there may be some enhancement of individual performance as a result of the efficacy of the treatment. Nevertheless, such enhancement must not exceed the level of performance of the athlete prior to the onset of his/her medical condition.

3. There is no reasonable *therapeutic* alternative to the *Use* of the otherwise *Prohibited Substance* or *Prohibited Method* . . .
4. The necessity for the *Use* of the otherwise *Prohibited Substance* or *Prohibited Method* cannot be a consequence, wholly or in part, of prior non-*therapeutic Use* of any substance from the *Prohibited List* . . .”

Most TUEs in sport are for stimulants used to treat ADHD, β -adrenergic agonists to treat COPD, and β -blockers to treat asthma, although the NCAA itself (102) granted appeals in 2007 for players who had taken testosterone and the synthetic AAS Danazol and Madol (desoxymethyltestosterone), presumably on the basis of legitimate therapeutic use.

LEGAL ISSUES IN THE USE OF AAS

Despite the widespread nature of antiaging clinics who advertise and prescribe HGH with the veneer of legitimacy, and the clandestine pharmacies that provide the substance to athletes, those prescriptions are, contrary to most off-label prescriptions, specifically banned by the Food and Drug Administration (FDA) (103). In a warning alert published in January 2007, the FDA noted that HGH is not a dietary supplement, and specifically *banned* its use for “anti-aging, bodybuilding, or athletic enhancement.”

The AAS are on the Federal Schedule III list, putting them in the same category as the following (quite dissimilar) substances: codeine, ketamine, and buprenorphine, all of which have well-accepted medical uses. Schedule III substances are categorized as having the following characteristics (104):

- “1. The drug or other substance has less potential for abuse than the drugs or other substances in schedules I and II.
2. The drug or other substance has a currently accepted medical use in treatment in the United States.
3. Abuse of the drug or other substance may lead to moderate or low physical dependence or high psychological dependence.
4. Anabolic steroids, codeine and hydrocodone with aspirin or Tylenol®, and some barbiturates are examples of Schedule III substances.”

Clearly, then, the AAS were placed on the Schedule III list as an acknowledgment that they have some therapeutic uses and may have to be prescribed to certain individuals. But practically speaking, most AAS are provided illegally, and have high degrees of criminal activity associated with them.

A 2007 DEA operation code-named “Raw Deal” (105) revealed much about the criminal and highly dangerous

provenance of many of the AAS purchased over the Internet by U.S. citizens. In a worldwide sting operation, agents from the FDA's Office of Criminal Investigations, the U.S. Postal Inspection Service, the IRS, and other federal law-enforcement agencies, coordinated by the DEA, executed 143 federal search warrants in entering 56 steroid labs. In addition to the 11.4 million steroid dosage units and 242 kg of raw steroid powder found in China, the agents also seized \$6.5 million, along with 25 vehicles, 3 boats, and 71 weapons. Although the operation was focused on the AAS and HGH, they also found conversion kits for sale to individuals who could then convert raw materials in steroids, as well as ketamine, fentanyl, ephedrine, pseudoephedrine, and GHB.

"Raw Deal" displayed the criminal infrastructure of AAS production, distribution, and sales over the Internet, not unlike drug cartels that supply users with drugs of abuse like cocaine and heroin. In addition, the operation demonstrated the haphazard and unhygienic conditions in which the drugs for sale were produced: "many of the underground labs seized in Operation Raw Deal are extremely unsanitary, further illustrating the danger in buying these products illegally. For example, recent lab seizures uncovered huge amounts of raw materials being mixed in bathtubs and bathroom sinks." This description of the illicit and criminal industry that provides AAS to users certainly correlates with clinical experience. AAS users often complain that the substances they receive do not appear to contain what the Internet advertisements claim.

TESTING FOR AAS

Testing for the use of AAS is fraught with technical, legal, and practical difficulties, not least of which is the inherent difficulty in designing testing programs that provide accurate and timely results while fairly treating those athletes being tested. Although the science of drug testing is growing by leaps and bounds, collection procedures and laboratory protocols remain imperfect both because of scientific realities and sometimes due to efforts by athletes to fake testing results.

In the most common test for AAS, exogenous use of testosterone or AAS can be detected by checking the urinary T:E ratio using high-resolution gas chromatography/mass spectroscopy (GC/MS). Since epitestosterone is unaffected by exogenous testosterone, the usual 1:1 ratio will shift upwards if the user ingests testosterone. Because some individuals have naturally elevated T:E ratios, sports organizations define an upper limit of normal for this ratio, usually 4:1 or 6:1. If an athlete claims to have a naturally elevated T:E ratio, sequential testing over several months can prove or disprove the claim because T:E ratios are stable unless manipulated by exogenous administration of testosterone. Epitestosterone has no physiologic effect, so the only reason to ingest epitestosterone would be to deceive a drug test, as demonstrated by the GDR teams of the 1960s, as described above.

GC/MS testing works by separating the various molecules in a sample by their chromatographic retention time, and breaking each one down to its characteristic ions (106). Iso-

tope ratio mass spectroscopy (IRMS) testing can be used later, if necessary, to differentiate endogenous testosterone and epitestosterone from the exogenous varieties. IRMS identifies the carbon isotope ratio. Endogenous testosterone contains about 98.8% ^{12}C and only 1.1% ^{13}C , while pharmaceutically produced testosterone has a much lower percentage of the ^{13}C isotope.

Although laboratory protocols are vital in obtaining an accurate result, so is the forensic quality of the collection, packaging, transport, and laboratory handling of the samples. The World Anti-Doping Agency (WADA) for instance, published a 22-page protocol for urine collection alone (107), which assigns a "Doping Control Officer" who arranges a chaperone to accompany the athlete from the moment the athlete is notified of the required drug test until he or she arrives to a "Doping Control Station." The document describes the right of the athlete being tested to have a representative accompany him or her, provisions for (very minimal) privacy and confidentiality, and defines target testing for specific athletes or categories of athletes, weighted selections, and random selections. The code goes on to mandate that a witness of the same gender as the athlete observe the athlete "... Remove all clothing between the waists and midthigh, in order that the Witness has an unobstructed view of the sample provision ... The Witness shall directly observe the Athlete provide the sample, adjusting his/her body position so as to have a clear view of the sample leaving the athlete's body ..."

In addition, a valid "Chain of Custody" between the donating athlete, the collector, and the laboratory must be in place. Usually collecting agencies immediately split the donated urine sample into an "A" and "B" sample for later separate testing if one sample is found to contain a banned substance (108). Immediate testing at the collection site for pH, temperature, and specific gravity can increase the likelihood that a sample is valid. These sorts of carefully planned routines and procedures are absolutely necessary, both in order to provide accurate results, and to address the inevitable legal challenges that arise when a positive result causes loss of income and/or public announcement of a player's name.

TREATMENT OF AAS USERS

Treatment of AAS use must begin with a comprehensive evaluation focused on the actual effects of the substances used, any withdrawal if the substance is stopped or decreased, and concomitant substance use or mental illness. Many AAS users who have used small amounts of AAS or used AAS for a short period of time stop without any untoward effects. Often they must stop their use to avoid sanctions or detection, or because of parental disapproval. However, some AAS users find it difficult to stop their use, some experience withdrawal, and an even smaller percentage show classic signs of addiction: continued use despite knowledge of adverse consequences, compulsive use, and sustained withdrawal.

For those AAS users who require treatment, the evaluating clinician should be knowledgeable about AAS, addiction in

general, and the particular ethos of the culture within which the user resides (109).

As with all addiction, the clinician should advise that the user avoid—in Alcoholics Anonymous parlance—the people, places, and things associated with the AAS use. For the athlete using AAS, this often means eschewing the gyms and practice fields where he or she had obtained the substance and isolating himself or herself from teammates, both difficult but necessary tasks in avoiding further use. The necessary paradigm shift, away from intense competition and toward a healthy lifestyle, can be managed with the help of a therapist or counselor knowledgeable about competitive athletics, and in the best situation, knowledgeable about the athlete's particular sport.

The affective syndromes like depression and anxiety that can arise from stopping AAS may have catastrophic consequences, including self-harm and completed suicide. The clinician assisting a person stopping AAS should therefore monitor the user carefully for incipient affective symptoms, and aggressively treat any symptoms that do arise. Antidepressant medications such as fluoxetine and venlafaxine may be used in treating persistent dysphoria, but since their response time is 2 to 6 weeks, the depressed AAS users should remain under closely monitored psychotherapy during (at least) that time.

Similarly, AAS withdrawal can be treated symptomatically with hormonal treatment (110) under the care of an endocrinologist knowledgeable and experienced in working with AAS users, who in order to have engendered their withdrawal symptoms most likely use supraphysiologic dosages far beyond what any physician would recommend for the treatment of any medical condition. Endocrinologists may recommend gradually tapering dosages of testosterone, the AAS that the individual was using, and even attempt stimulation of the hypothalamic–pituitary–testis axis via hormonal manipulation. The treating endocrinologist and psychiatrist should collaborate closely to render optimum care while keeping the patient as free as possible of AAS withdrawal symptomatology, both physical and psychiatric.

CONCLUSIONS

The science around the use of AAS for performance enhancement is relatively meager for easily understandable reasons; most use is illicit and therefore hidden from scientific inquiry, and the large doses of AAS used by many users could not be ethically prescribed to study subjects, because of potential danger associated with such use. This justifiably sparse body of scientific knowledge about AAS effects and side effects does, however, engenders discourse on the subject which is long on opinion and philosophy, but short on fact.

Some argue that the AAS present reasonable risks that should be assessed not by legal authorities or sports organizations, but by the users themselves. They argue that reasonable adults should make their own choices, as with other substances, and point out that allowing legitimate use of the AAS would eliminate the criminal manufacturing and distribution practices now in place, as well as allow legitimate physicians

to give advice to athletes using the AAS. Despite the lack of ultimate clarity on the side effect profiles of the AAS, it is clear that they cause physical as well as psychiatric morbidity far in excess of any benefit. But in fact legitimate avenues are already available for those patients with a legitimate need for the AAS: physicians who treat HIV and other wasting disease may prescribe the AAS without concern about censure.

The Internet remains a vast repository of information combined with misinformation, most obviously when there is something to sell, in this case the AAS. The Internet user can be easily led astray by even well-meaning and apparently legitimate Web sites that purport to educate the reader. For instance, one Web site “About.com” (111) gives information about the AAS, but includes advertisements for buying AAS over the Internet, and lists as the first “Risk” for AAS users the following: “Increased Liver Function.” This sounds like a good thing: who wouldn't want one's internal organs to increase in their functioning? But of course the risk is “Increased Liver Function Tests” and the casual or naïve reader would not see the error, and would hardly be put off by the suggested “Risk.”

The use of AAS for legitimate medical purposes deserves more inquiry into present uses, and investigations of potential beyond the relatively small group of wasting diseases for which those medications are now indicated. And the use of AAS for performance enhancement, anathema though it is to most of the medical world, deserves ongoing research if only to further clarify the dangers of illicit use and develop better strategies for prevention, testing, and treatment.

Eating Disorders and Substance Use Disorders

Harry A. Brandt ■ Steven F. Crawford ■ Katherine A. Halmi

INTRODUCTION

Eating disorders (EDs) and substance use disorders (SUDs) share several common elements. Both groups of illnesses are characterized by high rates of morbidity and mortality. Both pose substantial clinical challenges to the highly experienced clinician. Both have high rates of relapse and recidivism. Additionally, both sets of illnesses commonly co-occur with each other and with a number of other Axis I and Axis II diagnoses, further complicating assessment and treatment. Because of the frequent co-occurrence of SUDs and EDs, investigators have long searched for common etiologic factors in the development and perpetuation of these illnesses. To date, no single link or factor has emerged, yet the high rate of co-occurrence itself holds important implications for appropriate diagnostic assessment and treatment, and will likely guide future directions of investigation. This chapter will provide an update on ED and SUD comorbidity with applicability to those working in the substance abuse disorder and ED fields. Possible etiologic vulnerabilities underlying both sets of illnesses including a conceptual allostatic model for EDs and some general treatment recommendations for patients with co-occurring illness will be presented.

BRIEF DESCRIPTIONS OF MAJOR EATING DISORDER SYNDROMES

The EDs described in the current classification system are anorexia nervosa (AN), bulimia nervosa (BN), eating disorder not otherwise specified (EDNOS), and, in a research category, binge-eating disorder (BED).

Anorexia Nervosa (AN)

The *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision (DSM-IV-TR)* (1) criteria for AN are shown in Table 24.1. The current diagnostic schema also includes a subtyping designation for those who do not regularly engage in purging behaviors (restricting subtype) and those who regularly engage in binge-eating or purging behavior (binge-purge subtype).

Bulimia Nervosa (BN)

The *DSM-IV-TR* criteria for BN are presented in Table 24.2. These criteria include a subtype designation for those who engage in self-induced vomiting or the misuse of laxatives, diuretics, or enemas (purging type) and those who use other compensatory behaviors such as fasting or excessive exercise, but do not engage in self-induced vomiting or laxative, diuretic, or enema use (nonpurging type).

Eating Disorder Not Otherwise Specified (EDNOS)

According to the *DSM-IV-TR*, individuals presenting with “disorders of eating that do not meet the criteria for any specific eating disorder” (p. 550), that is, individuals not meeting criteria for AN or BN, are classified as having an EDNOS. The most commonly noted EDNOS variant is BED, for which research criteria are included in the appendix to *DSM-IV-TR*. The criteria for EDNOS can be found in Table 24.3.

Persons in the EDNOS group fail to meet the criteria for one of the specific EDs but have significant symptoms and problems. Indeed, many in the field have questioned the significance for an individual patient of failing to meet a specific criterion, such as the necessity that amenorrhea be present for a diagnosis of AN to be made in females (2). In addition to the specific BED criteria, investigators have proposed diagnostic criteria for additional forms of EDNOS, including purging disorder (PD) (3), characterized by patients with a consistent pattern of purging as a compensatory behavior, and night-eating syndrome (4).

GENERAL EPIDEMIOLOGY OF EATING DISORDER SYNDROMES

Estimates suggest that 0.5% to 2.0% of girls and women are affected by AN across their lifetime (5–7). While a 1:10 male-to-female ratio in diagnosis has been frequently cited, recent epidemiologic work reflects a less dramatic but still highly significant gender difference (6). A review of incidence studies further suggests that the number of new cases per 100,000

TABLE 24.1 DSM-IV-TR criteria for anorexia nervosa (AN)

- A) Refusal to maintain body weight at or above a minimally normal weight for age and height (e.g., weight loss leading to maintenance of body weight less than 85% of that expected, or failure to make expected weight gain during periods of growth, leading to body weight less than 85% of that expected).
- B) Intense fear of gaining weight or becoming fat, even though underweight.
- C) Disturbance in the way in which one's body weight or shape is experienced; undue influence of body weight or shape.
- D) In postmenarcheal females, amenorrhea, i.e., the absence of at least three consecutive menstrual cycles. (A woman is considered to have amenorrhea if her periods occur only following hormone [e.g., estrogen] administration.)

TABLE 24.2 DSM-IV-TR criteria for bulimia nervosa (BN)

- A) Recurrent episodes of binge eating. An episode of binge eating is characterized by both of the following:
 - 1) Eating, in a discrete period of time (e.g., within any 2-hour period), an amount of food that is definitely larger than most people would eat during a similar period of time and under similar circumstances.
 - 2) A sense of lack of control over eating during the episode (e.g., a feeling that one cannot stop eating or control what or how much one is eating).
- B) Recurrent inappropriate compensatory behavior in order to prevent weight gain, such as self-induced vomiting; misuse of laxatives, diuretics, enemas, or other medications; fasting; or excessive exercise.
- C) The binge eating and inappropriate compensatory behaviors both occur, on average, at least twice a week for 3 months.
- D) Self-evaluation is unduly influenced by body shape and weight.
- E) The disturbance does not occur exclusively during episodes of AN.

Adapted from American Psychiatric Association. *The Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition. Text Revision.* Washington, DC: American Psychiatric Association; 2000.

TABLE 24.3 DSM-IV-TR criteria for eating disorder not otherwise specified (EDNOS)

- A) Recurrent episodes of binge eating. An episode of binge eating is characterized by both of the following:
 - 1) Eating, in a discrete period of time (e.g., within any 2-hour period), an amount of food that is definitely larger than most people would eat during a similar period of time and under similar circumstances.
 - 2) A sense of lack of control over eating during the episode (e.g., a feeling that one cannot stop eating or control what or how much one is eating).
- B) The binge-eating episodes are associated with three or more of the following:
 - 1) Eating much more rapidly than normal.
 - 2) Eating until feeling uncomfortably full.
 - 3) Eating large amounts of food when not feeling physically hungry.
 - 4) Eating alone because of being embarrassed by how much one is eating.
 - 5) Feeling disgusted with oneself, depressed, or very guilty after overeating.
- C) Marked distress regarding binge eating is present.
- D) The binge eating occurs, on average, at least 2 days a week for 6 months.
- E) The binge eating is not associated with the regular use of inappropriate compensatory behaviors (e.g., purging, fasting, and excessive exercise) and does not occur exclusively during the course of anorexia nervosa or bulimia nervosa.

population has increased over the 20th century, although the size of the increase was modest (8).

The prevalence estimates of BN have varied widely since its inclusion as a diagnostic category in the *DSM* in 1979. This variation may relate to changes in definitions, populations examined, and possibly, prevalence over time. A review of epidemiologic studies suggests that approximately 2% to 3% of young women meet *DSM-IV-TR* criteria for BN, with a lifetime prevalence of 1.5% for females and 0.5% for males (6). For both AN and BN, studies of incidence and prevalence have struggled to explain whether variances in prevalence are due to actual change, recall bias, growing awareness of the syndromes, or changes in media attention to the illnesses over time (9).

A number of studies indicate that BED is more common than either AN or BN in the general population. Using data from the National Comorbidity Survey Replication, Hudson and colleagues (6) reported lifetime prevalence estimates for BED of 3.5% in women and 2.0% in men (6). This was nearly double the rates reported for AN and BN combined in that survey. The prevalence of BED is noted to be even higher among the obese and in those seeking bariatric surgery or other weight loss interventions (10).

DEMOGRAPHICS OF EATING DISORDER SYNDROMES

While most commonly developing during the adolescence and young adulthood, EDs can occur at any point in the life cycle. The peak in age of onset for AN occurs between ages 13 and 17, although some patients develop anorexia earlier in childhood and some in later adulthood (5). The peak in age of onset for BN ranges from late adolescence through young adulthood. Although less is known about the onset and natural course of BED, it appears that a majority of individuals develop this illness in young-to-middle adulthood. Unlike AN and BN, severe dieting behaviors and profound concern about weight are not necessarily present prior to the onset of binge-eating behavior. Although AN and BN and, to a lesser extent, BED are all more common in females, it is important not to neglect these EDs in men (11). Few gender differences in the specific features, symptoms, morbidity, and mortality of the disorders have been found by researchers (12).

COMORBIDITY OF EATING DISORDERS AND SUBSTANCE ABUSE

SUDs and EDs commonly co-occur in both clinical populations and research samples. The overall prevalence of drug and alcohol abuse in ED patients is approximately 50%, compared with a prevalence of approximately 9% in the general population (13). Conversely, over 35% of individuals with SUDs report having EDs compared with a rate of 1% to 3% in the general population (13,14). Lifetime prevalence studies have reported rates of SUD of up to 27% in populations with AN, with significantly higher rates in the binge-purge

subtype; up to 55% in those with BN; and 23% of those with BED (15,6). A recent meta-analysis of 16 studies confirmed higher prevalence rates of drug use in eating-disordered individuals than in controls. In particular, the analysis showed elevated levels of opiate abuse, cannabis abuse, and general illicit drug use. Risk was shown to be higher in individuals with BN, somewhat less in those with BED, and negligible in those with restrictive AN (16). The clinical course of development of substance use problems in ED patients is highly variable with onset at various stages of illness, suggesting that clinicians should remain attentive to the potential emergence of substance use problems long after initial presentation (17).

CONCEPTUAL ISSUES AND CONFOUNDING FACTORS IN ASSESSING COMORBIDITY

In addition to many of the usual confounding factors in studies (recruitment methods, population selection, standardized interviews vs. self reports, etc.), there are numerous complexities in evaluating the relationship between SUDs and EDs. This perhaps reflects the underlying heterogeneity in the definition of comorbidity. Various studies of comorbidity have used alternate definitions including co-occurrence of disorders that are random and independent, co-occurrence of disorders that share common etiologic underpinnings, or different disorders that may have a shared causal relationship. Overlapping diagnostic criteria may lead to falsely elevated rates of comorbidity. For example, the impulsivity criterion of borderline personality disorder can be met by binge behavior in AN, BN, and BED, or the substance use in SUD. Another study initially found higher rates of various psychiatric problems in women with BN and alcoholism than in a comparison group with BN without alcoholism; however, it was ultimately revealed through multivariate analysis that borderline personality disorder was the sole distinguishing variable between the two groups (18). Carefully designed trials have suggested that some of the apparent co-occurrence between EDs and SUDs may be, at least in part, related to other psychiatric comorbidities. The relationship between BN and alcohol use disorder reported by the National Women's Study may have been the result of associations with other psychiatric disorders such as major depressive disorder and posttraumatic stress disorder (19).

A number of investigators have pointed out the critical importance of selecting appropriate control groups to allow for correct interpretation of patterns of comorbidity. These control groups might include psychiatric populations without the ED and/or SUD (20). Several studies with relevant control groups have shown that, although EDs and SUDs co-occur, the co-occurrence is less dramatic in the relevant comparison group as opposed to the frequently used "normal" control group. For example, Grilo and colleagues found that although EDs are frequently diagnosed among inpatients with SUDs, they are also commonly seen in other psychiatric inpatients (21,22). In this properly controlled study, the frequency of AN and BN was not greater in patients with SUDs than in those

without SUDs. As mentioned previously, some studies have also elucidated that patients with restrictive or nonpurging AN may be less likely to develop SUDs. This factor needs to be considered when interpreting earlier work that did not take into consideration the importance of the subtyping of AN patients. A further limitation in some studies is the lack of inclusion of rates of individuals with subthreshold EDs. One study reported that EDNOS (but not full AN or BN) was significantly more common in individuals with substance use diagnoses than those without it. Therefore, some studies may underemphasize the actual co-occurrence relationship. Clinically, the finding of an association between subclinical ED and SUD suggests the importance of a thorough assessment to facilitate early treatment (21,22).

RELATIONSHIP OF SUBSTANCE USE TO BINGE EATING

It is of clinical and theoretic importance that among individuals with some form of ED, nicotine, alcohol, and illicit drug use is much more common in those individuals who binge eat, regardless of whether they have AN, binge-purge-type AN, BN, or BED. This was replicated in a 10-year prospective study (23). The risk of onset of an SUD in persons hospitalized for AN was six times greater among those who reported binge eating while underweight compared with those with no history of binge eating as reported during the index hospitalization. Some epidemiologic studies have reported that alcohol use disorders were much more prevalent among women with AN with binge eating compared with those with AN without binge eating (24), although this pattern has not been consistently noted (25–28). A recent sample of ED probands from the Price Foundation Genetic Study revealed that the prevalence of SUD differed across the AN subtypes, with increased prevalence in the group with binge eating. Similarly, individuals who purged were more likely to report substance abuse than those who did not purge (29). The relationship of SUDs to binge-eating and purging behaviors raises interesting conceptual issues in relation to animal models that have generally revealed that food restriction enhances and food satiation reduces the self-administration of nearly every illicit substance with abuse potential (30).

PATTERNS OF SUBSTANCE ABUSE IN EATING DISORDERS

It is important to note that because of their drive for thinness, ED patients may be motivated to utilize appetite-suppressing substances (e.g., cocaine, amphetamines, and thyroid hormone) (24). However, it has also been noted that the use of substances that promote appetitive behavior (e.g., cannabis and opiates) is not uncommon among eating-disordered patients (17). In some cases, patients may be unaware that these agents may trigger binge behavior. Further, patients with EDs frequently misuse or abuse drugs not usually considered as drugs of abuse. These include laxatives, diuretics, thyroid hormone, and insulin.

HYPOTHESES TO EXPLAIN THE EATING DISORDER—SUBSTANCE USE DISORDER COMORBIDITY

Several hypotheses have been proposed to account for the comorbid occurrence of EDs and SUDs. These have generally been separated into those postulating a “shared etiology” versus a “causal etiology” (31). The “shared” etiology hypotheses suggest that both disorders stem from a common underlying predisposition and broadly include personality (i.e., both sets of illnesses result from a so-called addictive personality), family history (i.e., both sets of illnesses share family risk factors), developmental (i.e., both sets of illnesses result from susceptibility to external pressure such as cultural pressures to be thin in EDs and peer pressure to experiment with drugs in adolescence in SUDs), and biogenetic (i.e., both sets of disorders share a common biologic vulnerability toward addiction to substances, or to starvation or bingeing and purging). The “causal” etiology hypotheses focus on the influence one disorder may have on the development of another. These hypotheses include self-medication (i.e., individuals with EDs use drugs to diminish hunger, modify affects, increase energy, etc.) and food deprivation (i.e., individuals with restrictive food intake are prone to excessive substance use as a compensatory behavior).

Possible Shared Causation of Eating Disorders and Substance Use Disorders

Various animal models of eating behavior have been utilized in attempts to understand etiologic factors in the development of EDs. Some animals exhibit binge-like behavior when exposed to certain environmental factors (e.g., food restriction, stress, intermittent exposure to highly palatable food, etc.) thought to play a role in the development of human EDs (14). Notably, not only do these animals overeat palatable food, but they have also been shown to be more prone to develop addictive behavior when exposed to alcohol and cocaine. These studies suggest that under certain conditions, palatable food may produce oversensitivity of reward circuits as has been postulated to occur in SUDs (32,33). Some studies have focused on the endogenous opiate peptides (EOP) as likely candidates for dysregulation in both ED and SUD. The activity of the EOP has been shown in animal models to have an impact on patterns of food and alcohol consumption (34,35). Naltrexone, an opiate antagonist, has been used as a treatment in BN and in alcohol and drug addiction. Other neurochemical systems that have received research attention include the gamma-aminobutyric acid (GABA), serotonin (36), cholecystokinin, peptide YY, and dopamine systems, all of which can have an important impact on food and alcohol consumption (35).

Environmental and Social Factors

A number of studies have suggested that family conflict and parental modeling behavior are also major risk factors for both ED and SUDs. Just as some children may learn about

dieting or an emphasis on weight from parents, they may also learn from parents to use substances as a way of coping with stress (37). Broader sociocultural influences may also contribute to the development of both sets of illnesses. The media, social environment, and peer social interaction all may play a significant role in the initial experimentation with dieting, bulimic behavior, and similarly, the initiation of drug use. Culture may also provide potent reinforcement as a perpetuating factor in both ED and SUDs.

Individual Factors, Personality, and Impulsivity

Some researchers have proposed that an addictive personality might predispose certain individuals to become addicted to one or multiple substances and/or behaviors such as those involved in EDs. Proponents of this theory, from both biobehavioral and dynamic perspectives, view food and substances as addictive substrates. While theoretically appealing, empirical evidence for this connection in personality is not conclusive. Efforts to isolate psychological characteristics common to ED and substance abuse patients have not been successful. Further, Fairburn and others have made cogent arguments that refute the conceptual model of food as an addictive substance (38). However, it has been commonly hypothesized that an association between SUDs and EDs reflects the influence of the underlying personality traits such as impulsivity. Borderline personality disorder and other cluster B personality syndromes are commonly present in individuals with EDs and substance abuse disorders, but are most frequently seen in women with co-occurring ED and SUD (21,22,39).

The role of childhood trauma in the etiology of EDs and SUDs has been the subject of numerous studies. Childhood sexual abuse predicts the onset of a myriad of psychiatric disorders, including but not exclusively EDs and SUDs (40–43). One study examining the differential rates of sexual abuse among the subtypes of EDs revealed that women with comorbid BN and substance dependence had the highest frequency and the most severe history of sexual abuse (44). However, some investigations suggest that sexual abuse is only one component of a larger and more complex etiologic picture (45).

Finally, the risk of co-occurring mood disorders is high in populations with EDs and SUDs. Depression has commonly been cited as a possible link between EDs and SUDs (15). A “self-medication” hypothesis suggesting that those with mood alterations and/or body dissatisfaction, coupled with impulsivity, might be predisposed to use substances in an attempt to alleviate these symptoms.

An Allostatic Model of Eating Disorders

Theoretic models for conceptualizing EDs as addictive disorders were proposed many years ago for AN by Szmukler (46) and for binge eating by Krahn et al. (47) and Lacey (48). More recently, Koob and LeMoal (32) proposed a model of dysregulation of the brain reward system for understanding drug addiction. This model has salient features applicable to conceptualizing the development of EDs. The model of Koob

and LeMoal was based on the homeostasis and allostasis hypotheses. Homeostasis, a self-regulating process for multisystem coordination of an organism’s response to an acute challenge, fails in alcoholism, drug addiction, and AN and BN, leading eventually to death or chronic impairment. The allostatic state as defined by McEwen and Steller (49) is a state of chronic deviation of the regulatory system from its normal homeostatic operating level. In other words, an allostatic state is a dysregulation of reward circuits with compensatory activation of brain and hormonal stress responses. The allostatic load is defined as the cost the body has to pay for adapting to adverse psychological and physical situations (49). It represents the presence of excessive demand on regulatory systems or the failure of these systems to relax when the demand is over. The latter may explain frequent relapses in both AN and BN. A vulnerable phenotype such as AN or BN may respond to various stresses by an allostatic maladaptation. The state of allostasis reflects both genetic and environmental factors and thus involves multiple brain mechanisms including dysfunction of neurotransmitters and aberrations of neuropeptides.

Examples of Neurobiologic Dysregulation in ED and SUD

Corticotropin-Releasing Factor (CRF) and Endogenous Opioid Peptides (EOPs)

There are similar characteristics in the EDs and SUDs. Individuals with SUDs have a compulsion to take drugs, and AN patients have a compulsion to exercise. SUD patients have a loss of control in limiting drug intake, and bulimics have a loss of control in limiting food intake. Individuals with both sets of diagnoses are characterized by engagement in repetitive dysfunctional behaviors without sufficient concern for the negative consequences (50,51) and are unable to change their behaviors. There are both positive psychological and physiologic reinforcements for restricting food for AN patients. Losing weight by restricting food makes those with EDs feel that they are in absolute control of themselves, and later these time-consuming weight-losing obsessions and compulsive behaviors provide a secondary reinforcement for avoiding perceived aversive or threatened environmental events (52). The physiologic reinforcement may reflect an increased secretion of CRF, which has an anorectic effect and a direct effect on the central nervous system mediating autonomic and behavioral responses to stresses (53,54). BN patients have a relief from dysphoria or anxiety with binge eating. Their purging behavior may produce a “high” related to EOPs and may actually become an addictive state (55).

Dopamine, Serotonin, and Neurobiologic Reward Systems

Dopaminergic neuronal function modulates feeding behavior, motor activity, reward-motivated behavior, and drug-seeking behavior (56). AN patients have restricted feeding, hyperactive stereotypic motor activity, anhedonic behavior,

negative affect, and reduced novelty seeking. BN patients engage in binge/purge behavior and have a high comorbidity with alcoholism and drug addiction (51).

There is evidence of altered dopaminergic function in AN. Increased binding of D₂/D₃ receptors in the anteroventral striatum, a region that involves optimal responses to reward stimuli, was found in patients who had recovered from AN (57). Another study showed a significant association between the frequency of functional polymorphisms of dopamine D₂ receptor genes and AN, suggesting that the D₂ receptor gene is a susceptibility factor in the development of this disorder (58). Women who were recovered from the restricting type of AN showed greater hemodynamic activation in the caudate compared to healthy women (59). AN patients may be vulnerable to dopaminergic aberrations because they sustain a greater-than-expected number of perinatal insults (60). Prenatal stress has long-term effects on the dopaminergic system (61).

Serotonergic neuronal systems are also involved in the modulation of appetite, motor activity, mood and obsessional behaviors, and impulse control. Features of anxiety, perfectionism, and obsessionality are present in both AN and BN; however, as noted, impulsivity is associated only with binge behavior. There is evidence for disturbances in the serotonergic neurotransmitter system in EDs. Recovered AN and BN individuals have reduced postsynaptic 5-HT_{2A} receptor activity relative to controls in the subgenual cingulate, mesial temporal, and parietal cortical regions (57,61). Recovered bulimic-type AN patients have increased 5-HT_{1A} postsynaptic activity in the subgenual cingulate and mesial temporal regions as well as frontal cortical regions and increased presynaptic 5-HT_{1A} autoreceptor activity in the dorsal raphe nucleus. Increased 5-HT_{1A} postsynaptic activity has been reported in BN patients (62). 5-HT_{1A} and 5-HT_{2A} receptors coexist and interact in the frontal cortex, amygdala, and hypothalamic regions and contribute to the modulation of dopamine neuronal activity. An aberration of serotonin neuronal modulation may be a vulnerability for developing either AN or BN during adolescence in response to stressful events.

The repetitive compulsive behaviors in EDs may involve the same neural circuits of the corticostriatal–thalamic loops that maintain the allostatic state of compulsive drug taking. These most likely involve dopamine, serotonin, opioid peptides, GABA, and glutamate.

Genetic Vulnerability for Allostasis in Eating Disorders

Genetic factors can act as trait mechanisms in an organism to produce differential sensitivity in the brain reward and stress systems that interact with environmental factors to produce a state of allostasis when activated (63). Individuals may be vulnerable to developing EDs because of intrinsic specific brain neurocircuitry that interacts with environmental life events and stresses. AN is highly familial, with a relative risk of 11.3 in family members of probands with AN (64).

Eating Disorders: An Addiction?

The high comorbidity of impulsivity and drug addiction with BN indicates the possibility of some common genetic factors in BN and drug addiction. The repetitive compulsive behaviors present in AN and BN may involve the same neural circuits of the corticostriatal–thalamic loops that maintain the allostatic state of compulsive drug taking. The neurotransmitter systems involved in the allostatic state of AN and BN may be similar to those in drug addiction and include dopamine, serotonin, opioid peptides, GABA, and glutamate.

SPECIAL CONSIDERATIONS IN EATING DISORDER—SUBSTANCE USE DISORDER COMORBIDITY

Assessment of Patients

Patients with ED–SUD comorbidity require careful and thorough assessment to identify and characterize the nature, extent, and temporal relationship of the symptomatic elements of both disorders. With respect to substance use, for each substance, patients should be directly asked about the age of first use, age of first regular use, age of first problems, age of first treatment, efforts to reduce use, longest periods of abstinence, patterns and quantity of use, and triggers for relapse. The interviewer should obtain details regarding the impact of each substance use on work, school, home, as well as familial and nonfamilial relationships. A recent investigation highlighted the importance of assessing consequences, in addition to use patterns, when examining substance use in individuals with EDs (65), particularly because the combination of problematic substance use and disordered eating is potentially deadly (66). Special attention should be paid to the use of substances while driving or in other physically hazardous situations. Similar inquiries should be directed toward the use of commonly misused over-the-counter substances such as laxatives, diet pills, appetite suppressants, diuretics, and stimulants. Syrup of Ipecac, an emetic designed for use in accidental poisoning, is commonly misused by bulimic patients. The agent is toxic to smooth and striated muscle and can lead to toxic, potentially fatal, cardiomyopathy (67,68). Another important area of assessment should focus on the misuse of prescribed medication by the ED patient. Some patients may take higher- or lower-than-prescribed dosages of medications that they believe may impact weight or appetite. Some examples of prescribed medications misused by ED patients include various anticonvulsants (e.g., topiramate and memantine) and hormones (e.g., thyroid). Topiramate, in particular, should be used with caution in patients with a history of AN or weight loss, in light of its tendency to induce weight loss in some patients (69). Diabetic patients may avoid taking prescribed amounts of insulin and/or oral hypoglycemic agents as a means of avoiding incorporation of sugars or to induce polyuria and diuresis (70).

Assessment of the patient with comorbid SUD and ED illnesses should include a family history focusing on mood and

anxiety disorders in addition to the primary illnesses in light of the strong heritability of both disorders. Family history should seek to obtain information about parental attitudes and behaviors in relation to weight, shape, physical appearance, and dieting. Similarly, a history of substance use (e.g., type and severity) in the family should be determined. In addition to developmental and childhood history, direct questions regarding emotional, physical, or sexual abuse should not be overlooked in light of data suggesting that childhood abuse is an extremely common antecedent of these disorders.

Treatment Delivery for Comorbid Patients

Despite the high rates of ED and SUD comorbidity discussed earlier in this chapter, there has been surprisingly little attention in the literature to the complex treatment planning and decision-making essential to effective treatment of this population. Patients must be motivated and ready to make radical changes in behavior. Patients with substance abuse must be motivated to abstain from alcohol and drugs, and patients with EDs must be motivated to abstain from bingeing and/or purging, or committed to normalizing restrictive eating behavior. The comorbid patient has the difficult task of attempting to do both. Unfortunately, to date, there has been little consensus and no clear guidelines regarding how to best manage co-occurring ED and SUD. Treatment delivery for patients with substance abuse and other psychiatric disorders is often described as sequential or integrated. Sequential treatment involves treating either the SUD or the ED first, without specific focus on and attention to treatment of the other disorder. Patients are then transferred to a different setting for treatment of the other disorder. While patients will often describe that they feel overwhelmed by simultaneous treatment of both disorders, sequential treatment can lead to a pattern of symptom replacement or substitution. Some patients describe a worsening of ED symptoms as they attempt to abstain from drugs and/or alcohol, and conversely, some patients describe exacerbation or relapse into substances as they attempt to normalize eating behavior. A second treatment delivery option would be parallel treatment in which a patient might receive treatment for both disorders concurrently, but by different providers or in different treatment settings. A third treatment delivery paradigm provides integrated, concurrent treatment of both disorders. While offering a number of potential advantages over sequential or parallel treatment, perhaps because of the resource-intensive nature of such settings, few integrated ED and SUD programs currently exist (71).

Elements of Treatment Integration

The recommended elements of independent multidisciplinary care for ED units have been described elsewhere (72). The integrated treatment of EDs and SUDs presents new challenges as well as new therapeutic opportunities. A number of forces that contribute to difficulties in treating co-occurring SUD and ED in sequenced treatments may be

avoided through the use of comprehensive, integrated treatment. Assessment should include a full inventory of symptoms of both illnesses for all patients. Often patients may conceal or minimize the elements of either the ED or the SUD. In nonintegrated programs, the treatment team may focus primarily or exclusively on their more comfortable area of primary experience. In this regard, the patient and therapeutic staff may consciously or unconsciously collude to avoid focus on the substance use problem. Often, patients with co-occurring ED and SUD do not receive structured assessment or treatment for EDs in addiction treatment programs, and similarly, substance abuse assessment and treatment may be lacking in many ED programs (73). A thorough medical evaluation should not assume that weight loss or various physiologic derangements result from either the ED or the SUD. Evaluation should address the interactive effects of ED pathology and substance use on cardiovascular, gastrointestinal, hematologic, and endocrine/metabolic systems (74). Laboratory evaluation can be of use in identifying surreptitious ED and SUD. Decisions regarding whether detoxification can occur on the integrated unit should be individualized and based on the degree of medical instability.

TREATMENT APPROACHES FOR CO-OCCURRING SUBSTANCE USE AND EATING DISORDERS

Patients who are in simultaneous, integrated treatment for SUDs and EDs require multidimensional therapies. The abrupt cessation of ED behaviors coupled with abstinence from alcohol and/or substances may be terrifying, with the creation of profound psychic stress and anxiety. This creates a therapeutic crisis for many patients. A number of therapeutic interventions, both pharmacologic and psychotherapeutic, may be utilized on the integrated treatment unit to provide support, reduce resistance, and facilitate sustainable change.

Pharmacologic Treatment

Medications may be useful adjuncts in the integrated treatment of EDs and SUDs. Cyproheptadine in high doses (up to 24 mg/day) can facilitate weight gain in anorectic restrictors and also provide a mild antidepressant effect (75). Although chlorpromazine was the first drug to treat AN, no double-blind controlled studies are available to show the efficacy of this drug for inducing weight gain and reducing anxiety in anorectic patients. In open-trial observations, chlorpromazine may be helpful in the severely obsessive-compulsive or agitated anorectic patient. It may be necessary to start at a low dose of 10 mg two or three times per day and gradually increase the dosage while monitoring blood pressure. Newer antipsychotics such as olanzapine have also been shown to be useful for severely obsessive-compulsive or agitated anorectic patients (76,77). Tricyclic antidepressants and serotonin reuptake inhibitors (SSRIs) are not particularly effective and have undesirable side effects for severely emaciated anorectic patients (78).

For patients with BN and out-of-control bingeing and purging, fluoxetine has been approved by the U.S. Food and Drug Administration (79). The only other SSRI studied in a randomized, controlled trial and shown to be effective is sertraline (80). In patients who do not respond to an SSRI, topiramate may be helpful (81). Since weight loss is a side effect of this medication, it should be used only in patients in the high normal or overweight range. It is necessary to begin this drug in very low doses of 25 mg/day, gradually increasing the dose to avoid adverse side effects such as paresthesias and cognitive word-finding difficulties. As mentioned previously, this drug has some abuse potential in individuals who are convinced that higher doses at more regular intervals might lead to greater degrees of weight loss.

There has been limited research on compounds that might simultaneously reduce or alleviate eating disturbance and substance abuse. Ondansetron, a 5-HT₃ antagonist, has been shown to be of potential benefit in the treatment of alcohol dependence (82) and in BN (83), but this agent has not gained widespread use in the treatment of either illness, nor has it been systematically evaluated in patients with comorbid ED and SUD, perhaps because of prominent side effects including abdominal pain. Naltrexone, an opioid antagonist approved for the treatment of alcohol and opioid dependence, has also been utilized in patients with BN despite the lack of systematic investigation. Extreme care should be undertaken in the pharmacologic treatment of patients with concurrent SUDs and EDs. The combined physiologic derangements of both illnesses render these patients even more vulnerable to cardiovascular, hepatic, gastrointestinal, and cognitive/neurologic effects than either disorder in isolation.

Psychological Treatments

Various psychotherapeutic interventions targeting motivation (e.g., motivational enhancement techniques), mood regulation and coping skills (e.g., dialectal behavior therapy and cognitive-behavioral therapy [CBT]), and relationship maintenance (e.g., interpersonal psychotherapy) benefit the patient with co-occurring ED and SUD. CBT is a well-researched and proven method for the treatment of BN (84). Although research on the effectiveness of CBT for the treatment of AN is much more limited, clinical evidence and data in support of its utility are emerging (85–87). Essentially, the cognitive-behavioral model for the treatment of EDs emphasizes the important role of both the cognitive (e.g., attitudes regarding the importance of weight, shape, and their control) and the behavioral (e.g., dietary restriction and binge eating) factors that maintain the ED and associated pathology. The treatment is presented in additive stages with an initial emphasis on stabilization of symptoms and behavioral change. As treatment progresses, the behavioral coping strategies are supplemented with cognitive restructuring techniques including work on interpersonal issues, body image, and affect regulation. The final stage of CBT concentrates on relapse prevention and maintenance planning. Many of the treatment

elements provided in CBT specifically target behaviors that may underlie concurrent substance abuse disorder and ED symptoms.

Although the CBT treatment model was designed as an outpatient intervention, the treatment has been utilized in a variety of settings, including inpatient and partial hospital programs. In this regard, given the high level of symptom severity for patients entering an inpatient program, CBT stands out as one treatment model that is particularly well suited for this population (88). CBT emphasizes early behavior change in a structured and systematic way. Additionally, once the patient begins to stabilize and is more receptive to any form of psychotherapy (5), the CBT focus shifts to address salient cognitive and emotional concerns, while maintaining symptom control.

It is recommended that patients with co-occurring illness receive intensive CBT in the milieu, in groups, and during individual psychotherapy. Therapists with highly specific training provide a variety of CBT-based group therapies including the following: Standard CBT for Eating Disorders, Body Image, Skills Training, Self-Esteem, Motivation to Change, and Coping Skills Training. These groups are based on salient elements of the standard CBT treatment protocols (89). Each of these important elements of treatment is expanded (and modified for adolescents vs. adults), creating separate and independent group therapies. The overall effect is that patients receive all elements of CBT, but in a more intensive dose during integrated treatment of the SUD and ED. Additionally, other more specialized groups, such as CBT-based Trauma Recovery Group, can be offered as appropriate.

Hospitalized patients also may benefit from intensive individual CBT where they can focus in a more specific way on their particular problems and conflicts. In this regard, it is recommended that all patients work individually on stabilization of symptoms through coping skills training, problem solving, and cognitive restructuring around ED and SUD beliefs and assumptions. For some patients, however, it may be necessary to expand beyond the standard CBT protocol to address, in a more intensive way, specific areas of concern such as body image, self-esteem, perfectionism, interpersonal difficulties, and emotion regulation (90). Typically, the individual therapist will concentrate on one or two of these particular areas. The goal is to provide effective, focused, and individualized therapy. While not yet substantiated by controlled investigation, clinical experience suggests that CBT is of great utility in the treatment of co-occurring SUD and ED.

Another therapy showing promise in the integrated treatment of this population is Dialectical Behavior Therapy (DBT) (91,92). With its focus on mindfulness, awareness of problems and choices of responses to those problems, coping skills training, and mood regulation techniques, this form of treatment concurrently benefits ED and SUD, as well as commonly occurring personality elements. Finally, in light of the powerful ambivalence notable in both illnesses independently, and the co-occurring patient, the motivational enhancement techniques (93,94) have been of great therapeutic value in

integrated treatment strategies. Further research into treatment strategies to address these disorders is greatly needed in light of their potential for relapse, morbidity, and mortality.

SUMMARY

The ED and SUD frequently co-occur, suggesting the possibility of shared etiologic and perpetuating factors, although this remains speculative. Regardless, the shared illnesses require diligent identification efforts through comprehensive medical and psychiatric assessment. Effective treatment should concurrently address the core vulnerabilities of each disorder. While more research is needed to identify the most efficacious treatment, integrated approaches using interventions such as CBT, DBT, and motivational enhancement strategies are currently recommended.

Elise E. DeVito ■ Marc Potenza

Gambling has a long history, spanning and likely extending beyond human written history. References to gambling in literature, including ancient religious texts (Old Testament, New Testament, and Mahabharata), as a common behavior as well as a potential source of moral downfall, suggest that problematic patterns of gambling have long been present alongside recreational patterns of engagement. However, there was limited research into gambling problems and possible forms of treatments until the 1970s and 1980s, with randomized clinical trials largely conducted within the past decade. Formal diagnostic guidelines for a gambling disorder (termed “pathological gambling” [PG]) were first included in the third edition of the *Diagnostic and Statistical Manual of Mental Disorders (DSM-III)* in 1980 and have been updated since. The core feature of PG is considered to be “persistent and recurrent maladaptive gambling behavior...that disrupts personal, family or vocational pursuits” (1). Increasing availability and participation in legalized gambling in the United States has been accompanied by increased interest into the factors associated with PG and the development, prevention, and treatment of the disorder.

TERMS AND DEFINITIONS

Gambling has been defined as “placing something of value at risk in the hopes of gaining something of greater value” (2). However, common perceptions of gambling typically involve either high risk, fairly rapid outcomes, or both, such that a long-term real estate or stock investment may be risky but may not be considered as gambling by the general public (2). “PG” is a clinical diagnosis in the *DSM-IV* defined by the presence of five or more inclusionary criteria related to gambling and the acknowledgment that the PG is not better accounted for by manic symptomatology (Table 25.1) (1). Other terms have been used to describe excessive patterns of gambling including the terms “compulsive gambling” or “problem gambling.” The former term was not used as a diagnostic entity when PG was introduced in the *DSM*, in part in order to avoid confusion with the distinct diagnostic entity of obsessive-compulsive disorder (OCD). The term “probable pathological gambling” is sometimes used when achieving threshold scores using screening instruments (e.g., South Oaks Gambling Screen [SOGS]) (3), rather than relying on meeting *DSM* criteria (e.g., through a clinical interview). Given that estimated rates of PG are often higher when a screening instrument was used compared with a full *DSM-IV*

clinical diagnoses, some cases of “probable pathological gambling” may not meet the *DSM-IV* criteria for “PG.” “Problem gambling” is typically used as a broader term for a pattern of gambling that still is related to difficulties in one’s life but may or may not meet the full criteria for PG (3). That is, “problem gambling” has been used at times inclusive of PG and at others exclusive of PG. In the gambling literature, problem gambling is often operationally defined as meeting three to four or, in other cases, one or more of the inclusionary diagnostic criteria for PG (4). “Disordered gambling” is a general term including both problem and PG. “Recreational gambling” describes gambling behavior that would not fall under disordered gambling, where the behavior is carried out in moderation without loss of control or marked negative consequences. However, a precise threshold for a difference between recreational and problem gambling has not been uniformly agreed upon.

DIAGNOSIS OF PATHOLOGIC GAMBLING

PG is included in the *DSM-IV* as an Impulse Control Disorder Not Elsewhere Classified (1). Impulse control disorders (ICDs) are characterized by a failure to resist performing an act that is harmful to oneself or others, increased feelings of arousal or tension prior to the act, and a feeling of pleasures or release of tension when performing the act (5).

A diagnosis of PG is made according to the *DSM-IV* based on the presence of at least 5 out of 10 indications of “persistent and recurrent maladaptive gambling behavior” which are not better accounted for by manic behavior (1). Indications of PG may include a preoccupation with gambling, repeated unsuccessful attempts to control or quit gambling, and irritability in the immediate setting of gambling cessation, attempts to recoup gambling losses with more gambling, a need over time to gamble larger amounts of money to achieve similar levels of excitement, gambling to modulate negative moods, being deceitful about one’s extent of gambling, relying on others or illegal acts to financially support the gambling, and damaging or jeopardizing important relationships or opportunities as a result of gambling (1).

As gambling behavior is considered to lie along a continuum, alternative conceptualizations of (and thresholds for) PG have been discussed (6,7). Some of the *DSM* inclusionary criteria for PG were modeled after those for substance use disorders (SUDs) (1), but while the *DSM* criteria for SUDs explicitly distinguish between grades of severity characterized

TABLE 25.1 DSM-IV-TR criteria for pathologic gambling

- A) Persistent and recurrent maladaptive gambling behavior as indicated by five (or more) of the following:
- 1) is preoccupied with gambling
 - 2) needs to gamble with increasing amounts of money in order to achieve the desired excitement
 - 3) has repeated unsuccessful efforts to control, cut back, or stop gambling
 - 4) is restless or irritable when attempting to cut down or stop gambling
 - 5) gambles as a way of escaping from problems or of relieving a dysphoric mood
 - 6) after losing money gambling, often returns another day to get even
 - 7) lies to family members, therapist, or others to conceal the extent of involvement with gambling
 - 8) has committed illegal acts such as forgery, fraud, theft, or embezzlement to finance gambling
 - 9) has jeopardized or lost a significant relationship, job, or educational or career opportunity because of gambling
 - 10) relies on others to provide money to relieve a desperate financial situation caused by gambling
- B) The gambling behavior is not better accounted for by a Manic Episode.

Adapted from American Psychiatric Association. *The Diagnostic and Statistical Manual of Mental Disorders*, 4th ed., Text Revision. Washington, DC: American Psychiatric Association; 2000.

by qualitative differences (substance abuse and substance dependence), PG is defined within the *DSM-IV* as a single diagnostic entity with no other specific gambling-related diagnosis (1). Some researchers and clinicians have cited evidence of clinically relevant factors associated with subsyndromal levels of PG to support either lowering the threshold to fewer than 5 out of 10 criteria, or formally recognizing a less severe form of gambling within the *DSM*.

EPIDEMIOLOGY OF GAMBLING: PREVALENCE

The vast majority of adults report having gambled at some point in their lives. Estimates of disordered gambling based on screening instruments suggest 2.5% of the U.S. population display problem gambling (4), while lifetime prevalence of PG is estimated to be between 0.4% and 3.4% of the U.S. adult population (1), with several large surveys using diagnostic assessments indicating past-year prevalence estimates in the United States in the range of 0.1% to 0.3% (8,9).

A study of probable PG in North America revealed that prevalence estimates for the general adult population (1.60%) were significantly lower than those for adolescent populations (3.88%). The general adult, adolescent, and college student (4.67%) rates have been found to be significantly lower than the estimated prevalence for adults who were either receiving psychiatric treatment (including treatment for SUDs) or were in prison (14.23%) (10).

Demographic variables such as sex, age, and race appear to influence gambling participation. Men are approximately two times more likely than women to develop PG (10), yet women may suffer from more physical and mental health complications than men at the same severity of disordered gambling (8). Compared to girls, boys make up a larger proportion of problematic or pathologic gamblers (estimated ratios range from 3:1 to 5:1), gamble more frequently and

wager larger amounts, begin at an earlier age, and more often prefer skill-based games (11).

African Americans are disproportionately represented in populations of disordered gamblers (12). Controlling for socioeconomic status, a U.S.-based telephone survey found black youths displayed higher rates of frequent gambling than did white youths (13).

Multiple different motivations may promote gambling, and there is some evidence for demographic differences based on individuals' gambling motivations (14). Recreational gamblers who report gambling for excitement (excitement-seeking) tended to be younger with more symptoms of impaired impulse control (e.g., SUDs, incarceration, larger wins and losses) and reported engaging in more forms of gambling and experiencing more gambling problems (15). Men are more likely to cite excitement seeking as their motivation for gambling, while women are more likely to report gambling as a form of escape or relief from dysphoria or boredom (15).

Various forms of gambling exist and differ in significant ways such as the level of skill required (e.g., electronic gambling machines versus poker), timing of the gambling sequence (e.g., fast-paced electronic gambling machines versus slower lotteries), and size of the wager (14). There has been debate regarding whether features of electronic gambling machines make them more "addictive" than other forms of gambling, and although there is little systematic research on this topic, the current data are mixed and thus do not on the whole support this contention (14).

SOCIAL AND ENVIRONMENTAL FACTORS

The acceptability and accessibility of gambling in the United States and around the world has typically increased recently, and although gambling was previously illegal in all but a few

regions of the United States, it is now legal in nearly every state. Gambling-related problems may increase with this greater availability of legal gambling outlets. Greater proximity and accessibility to gambling venues has been associated with increased gambling behavior, albeit not consistently, so increases in legal gambling venues should be carefully considered within a public health perspective (11,16).

The percentage of the general adult population reporting having gambled increased from 68% in 1975 to 86% in 1998 (17). Data from a meta-analysis of North American research studies between the years of 1974 and 1997 were consistent with an increase in rates of problem and PG across time within the general adult population, but not within the adolescent, college, or psychiatric treatment and prison-dwelling adult populations (10). One hypothesis is that increasing social acceptability with more legalized gambling venues relates to increasing gambling rates (10). Prevalence studies in the United States suggest that estimates of problem and PG in 12 to 17 year olds have increased from 1989 (median 10%, range 9% to 20%) to 1999 (median 14%, range 10% to 26%), while overall gambling rates rose from 45% to 66% in the juvenile population in the same time frame (11). Given the association between an earlier onset of gambling and more severe gambling problems in adulthood, increased rates of juvenile gambling have raised concerns that rates in adult populations may increase further with time (16). However, tempering these views are data that recent prevalence estimate surveys of problem and PG in the United States and Canada are similar to or lower than those reported in earlier prevalence estimate studies, despite increases in gambling availability. These findings suggest that increased availability of gambling does not alone predict rates of problematic or PG (9). Together, these findings indicate that at the population level, factors influencing engagement in gambling at multiple levels remain relatively poorly understood.

CO-OCCURRING PSYCHIATRIC DISORDERS

Gambling problems have been associated with increased odds of having Axis I psychiatric disorders (in particular depression, bipolar disorder, anxiety, and SUDs), and this association appears stronger in women as compared to men (7,8). Multiple Axis II disorders have also been associated with problem and PG (8,18). High frequencies of attempted suicide (17% to 24%) have been reported in individuals either receiving professional treatment for PG or regularly attending Gamblers Anonymous (GA) (19). Higher rates of disordered gambling are associated with psychotic disorders in community and clinical samples. Although high rates of co-occurrence have been found for multiple disorders across genders, women with PG appear more likely than men with PG to suffer from a comorbid mood disorder or to experience gambling-related anxiety while men appear more likely to suffer from comorbid SUDs (including alcohol dependence) (8). Juveniles with problem or PG appear more likely than their nonproblem gambling peers to report dissociative experiences while gambling (11). A U.S.-based telephone survey

of community-dwelling subjects found a high co-occurrence between gambling problems and alcohol problems in youths (age 14 to 21) (13).

The co-occurrence of psychiatric disorders appears to be related to the number of PG criteria met, rather than an association being restricted to individuals who qualify for the clinical definition of PG (i.e., ≥ 5 *DSM-IV* criteria). However, associations with advantageous health measures appear more mixed at lesser severities of gambling pathology. For example, recreational gambling is associated with increased odds of substance abuse or dependence in most cases except in samples of older adults where recreational gambling has been associated with better ratings of subjective general health (20).

The etiologies of co-occurring psychiatric disorders with PG are not well understood but may arise from common factors, such as impulsivity or risk-taking, and may include shared genetic and environmental contributions (16). Individuals with PG and co-occurring SUDs, such as nicotine dependence, have higher estimates of other psychiatric comorbidities at each gambling severity level (4), and first-degree relatives of individuals with PG display increased rates of mood disorder and alcohol dependence, findings that suggest common vulnerability factors between the disorders.

Another nonmutually exclusive explanation is that development of PG or other psychiatric disorders could contribute to the development of the other. For instance, debts and strained interpersonal relationships related to PG could increase the risk for developing depression, anxiety, or substance abuse, or alternatively depressed individuals may turn to gambling as a means of escape. One study has found that phobias, antisocial personality disorders, and most SUDs tend to temporally precede PG, suggesting that these disorders may represent risk factors or share vulnerability factors with PG, while depression and stimulant dependence tend to develop after PG, suggesting these disorders may represent a reaction to some aspect of PG (12). Despite generally high rates of lifetime co-occurrence of PG and alcohol dependence, one large study of gambling helpline callers found frequencies of reported current alcohol use problems to be approximately equal to general adult population rates, with most alcohol use problems being reported as not being active (21). While the studies used different assessment procedures and data from the helpline study have limitations including possible self-report and recall biases, the findings appear consistent with the notions that alcohol misuse may frequently precede PG and that individuals may “switch” addictive outlets over time (12).

As compared with recreational gamblers who do not abuse substances, those who do abuse substances are more likely to be younger, unmarried males who began gambling prior to the age of 18 and gamble for excitement or to win money (22). Comorbid alcohol use problems in problem gamblers are associated with reports of more forms of gambling performed, suicide attempts, gambling-related arrests, tobacco and drug use, and family histories of alcohol and drug use, further suggesting the potential contribution of poor impulse control across a broad range of behaviors (21).

SOCIAL AND PUBLIC HEALTH COSTS OF GAMBLING

Estimates of the amount of money spent on gambling in the United States (including payouts) rose from approximately \$17.4 billion in 1974 to \$860 billion in 2001, and costs attributed to problem and PG in the United States have been estimated in the 1990s to be approximately \$5 billion annually (17).

Gambling may have multiple personal and societal impacts. Individuals with PG typically gamble beyond their means, and may incur substantial debts and experience bankruptcies. PG may involve financial “bailouts” and the willingness to risk close relationships in order to pursue gambling. In more severe cases of PG, illegal behaviors (e.g., theft) may be committed in order to support the gambling behavior. Damaging behaviors such as domestic violence, child abuse, and child neglect may contribute to high rates of divorce and poor mental and physical health of family members of individuals with gambling problems (17).

Health problems such as hypertension, insomnia, gastrointestinal complaints, and cardiac arrests have been associated with disordered gambling (6). The presence of indicators of sustained stress in individuals with PG and indicators of acute stress during the act of gambling, such as increased salivary cortisol, hypertension, immune system changes, elevated heart rate, and higher levels of epinephrine and norepinephrine or their metabolites, suggest that stress may be a moderating factor in some of the health issues that commonly co-occur with PG (6).

Limited public education on the prevalence of and health impairments associated with excessive gambling behaviors may hinder attempts at prevention, early intervention, or treatment.

PATHOLOGIC GAMBLING AS ADDICTION OR IMPULSIVE–COMPULSIVE SPECTRUM DISORDER

Models of PG have primarily conceptualized it as a behavioral addiction, or as part of a spectrum of disorders lying along an impulsive–compulsive spectrum with such disorders as OCD (23). Evidence exists in support of both conceptualizations of PG, which are not mutually exclusive. Proposed core components of addiction including appetitive urges or cravings prior to the behavior, diminished self-control, compulsive or continued engagement in the behavior despite adverse consequences have been observed in both PG and SUDs, as have other aspects of addiction including tolerance, and withdrawal (23,24).

The phenomenology and clinical definition (according to the *DSM-IV*) of PG share similarities with both SUDs and OCD. Individuals with OCD, SUDs, or PG may experience motivations to perform behaviors (e.g., compulsive behavior, drug taking, gambling), may be preoccupied with thoughts of the behavior, and may demonstrate a diminished ability to resist drives to engage in excessive performance of the behavior.

In contrast with the individuals with OCD, individuals with PG or SUDs tend to experience the persistent thoughts about the behavior, anticipation of the behavior, and actual performance of the behavior as pleasurable or ego-syntonic, particularly in early stages of the disorders (25). In contrast, individuals with OCD tend to experience these motivations as ego-dystonic (i.e., inconsistent with the patient’s self-image and distressing) and engagement in the subsequent behavior as a relief or release (5). Since individuals with PGs or SUDs experience these behaviors as ego-syntonic, they may not believe they have a problem, or may deny or minimize problems, typically unlike individuals with OCD (6). Excessive risk aversion and overestimation of risk, characteristics associated with compulsive disorders including OCD, are not regularly observed in PG; rather, individuals with PG are more likely to display excessive risk-taking and underestimation of risks associated with other ICDs and SUDs (5). PG also resembles SUDs in that the severity of behavioral engagement runs along a continuum (abstinence to PG) (7), and it is possible for problematic behavior to resolve without formal treatment (26). Women display a similar “telescoping” effect with PG that has been observed with alcoholism and drug dependence, meaning that women tend to begin the behavior later in life but tend to progress to problematic stages at a faster rate than do men (6). Whether the phenomenon of “telescoping” in part reflects a gender difference in the willingness to seek treatment earlier in the course of illness is not entirely clear. While some ICDs such as trichotillomania are associated with elevated odds of OCD, PG is not; however, PG carries elevated odds of SUDs (5).

CANDIDATE MEDIATORS OF PATHOLOGIC GAMBLING

A number of candidate factors have been proposed to contribute to the progression to and persistence of PG including aspects of cognition, specific neurotransmitter systems and regional brain functioning, and genetic factors. These domains are not independent nor are their contributions mutually incompatible.

When viewing PG as a nonsubstance or “behavioral” addiction, it may represent an important model of addiction without the potentially complicating toxic effects of exogenous substances, ones that may or may not be linked to the core processes of addiction. One complicating factor of much addiction research is determining which factors in individuals with current SUDs represent pre-existing vulnerabilities and which result from repeated substance use or reflect changes arising during the course of addiction. Since gambling does not involve the introduction of exogenous substances, abnormalities in groups of individuals with PG are sometimes interpreted as pre-existing vulnerability factors, although longitudinal studies are needed to directly parse potential influences related to the progression of addiction. Neuroadaptation, the alteration of neural circuitry, can occur in response to repeated exposure to exogenous substances (e.g., drugs of abuse), but may also occur following high frequency

exposure to nonsubstance rewards (24). Tolerance and withdrawal, phenomena observed in PG as well as SUDs, are often conceived of as indications of neuroadaptation (10). As such, repeated engagement in gambling behavior may lead to the development of neuroadaptation or aberrant learning mechanisms that may themselves contribute to PG. A combination of premorbid vulnerabilities alongside changes resulting from repeated engagement in gambling behavior may account for the development of PG (10,27).

IMPAIRED COGNITION, IMPULSIVITY, AND COGNITIVE DISTORTIONS

Individuals with PG have been shown to be impaired on laboratory tasks of cognition including measures of cognitive control (e.g., Stroop), planning, attention, and timing (for review see (27)).

Individuals with PG have repeatedly been shown to report higher levels of self-rated impulsivity and to display impulsivity on laboratory measures, including impaired ability to withhold a prepotent response (impaired response inhibition reflective of response impulsivity) and steeper rates of temporal discounting of rewards (rapid delay discounting reflective of choice impulsivity) (27). Individuals with PG demonstrate less optimal decision-making on laboratory measures, for example, by showing greater preference for risky choices relative to their non-PG peers (27). Self-rated impulsivity has been associated with gambling severity in adults and juveniles, and adolescent impulsivity ratings are associated with later development of disordered gambling (for review see (27)). Poor impulse control on laboratory measures has been predictive of relapse in PG patients receiving treatment (28).

Impulsivity is a characteristic of multiple disorders associated with PG, including personality disorders, affective disorders, schizophrenia, SUDs, and neurologic diseases (16). Similarly, high rates of PG in adolescence have been proposed to be related to impulsivity, a feature of that developmental life phase (16).

Gambling-related cognitive biases or distortions have been shown in pathologic gamblers in interviews as well as during the “thinking aloud” method, where gamblers are asked to voice their thoughts aloud as they gamble. Some of these cognitive biases are based on a failure to appreciate the independence of trials or the randomness of outcomes. Many of these cognitive biases have been found in recreational as well as pathologic gamblers, raising questions regarding their centrality to PG. The “illusion of control” refers to the belief by the gambler that certain behaviors or rituals can increase their probability of success above that of the objective probability of the situation, or that one can control the outcome of a gamble. The “availability bias” occurs when individuals selectively recall large wins, which leads them to overestimate the likelihood or size of future “payouts.” The “gambler’s fallacy” refers to the belief that if an unlikely event has occurred that soon the reverse outcome will occur to even out the

probabilities (e.g., after consecutive “heads” coin tosses, a “tails” outcome is more likely). In reality, each event (e.g., roll of dice, spin of roulette wheel) is independent, and the probability of an outcome is not influenced by prior trials. The gambler’s fallacy could lead an individual to bet on a certain outcome that has not occurred in some time, believing it is “due.” On the other hand, a belief that a certain outcome has repeatedly occurred may be interpreted as meaning it could happen again (certain dice being “hot” and having repeatedly good outcomes). “Loss-chasing,” where an individual follows a gambling loss with continued gambling and an often riskier bet with the aim of winning back the amount lost, is observed in individuals who meet criteria for PG as well as those who do not. Interventions aimed at teaching independent odds have demonstrated that while individuals typically learn the mathematical concepts underlying gambling, impact on problem gambling behaviors have yet to be convincingly demonstrated, echoing findings in the drug abuse prevention field where education-based interventions alone appear insufficient to alter substance abuse behaviors (29).

NEUROTRANSMITTER SYSTEMS

Disruptions to several neurotransmitter systems, including those relating to norepinephrine, serotonin, dopamine, opioids, and gamma-aminobutyric acid, have been proposed to contribute to PG (30).

Physiologic arousal and excitement accompany the act of gambling, and subjective reports indicate that pathologic gamblers experience more intense gambling-related excitement than do recreational gamblers. Norepinephrine contributes to the regulation of arousal, attention, and aspects of impulsivity. Proximal measures of central norepinephrine levels (e.g., metabolites) are increased in men with PG as compared to those without (31). Pharmacologic challenge study results suggesting reduced sensitivity to postsynaptic alpha-2 adrenergic receptors in PG may be consistent with abnormally high norepinephrine secretion in PG (32). Levels of norepinephrine correlate with the gambling outcome and the urge to begin or continue gambling in problem gamblers, consistent with a role of norepinephrine in moderating gambling behavior (33). Norepinephrine and dopamine levels increase during the act of gambling to a greater extent in pathologic gamblers relative to recreational gamblers (33).

Lower levels of dopamine and higher levels of dopamine metabolites in the CSF of pathologic gamblers may indicate abnormal regulation of the dopamine system (31). PG has been observed in patients with Parkinson’s disease, a neurologic disease primarily characterized by loss of nigrostriatal dopamine neurons. Multiple factors have been reported as being associated with PG and other ICDs in Parkinson’s disease. These factors include ones related to clinical features of Parkinson’s disease (e.g., age at Parkinson’s disease onset), ones seemingly unrelated to Parkinson’s disease (e.g., personal history of an ICD prior to Parkinson’s disease onset), and ones related to the treatment of the disorder (e.g.,

dopamine agonists and other treatments for Parkinson disease, as well as the relative amount of dopamine replacement). Both drugs with prodopaminergic (amphetamine) and dopamine receptor antagonistic (haloperidol) properties have been found to promote gambling-related motivations and responses, suggesting that a role for dopamine in PG warrants additional investigation.

Serotonin has long been implicated in impulse control. Pathologic gamblers have decreased levels of serotonin metabolites and abnormal responses to serotonergic agonists like meta-chlorophenyl piperazine, in which they report a subjective “high” and demonstrate exaggerated prolactin increases, mirroring findings observed in alcoholic patients (34,35).

Casino gambling is associated with increased plasma concentrations of cortisol indicating activation of the hypothalamic-pituitary-adrenal (HPA) axis. During gambling, greater increases in heart rate and higher peripheral epinephrine and dopamine levels in problem gamblers may indicate exaggerated anticipatory autonomic arousal or increased sympathetic activity (33). Peripheral cortisol reactivity to stress has been demonstrated in problem gamblers, consistent with moderate levels of stress during gambling (33). Studies of beta-endorphin levels in problem gamblers have shown mixed results, leading to the suggestion that a role for endorphins may differ across forms of gambling (33).

GENETICS

Consistent with the studies of either central or peripheral neurotransmitter markers described above, genetic studies have preliminarily implicated genes involved in monoamine function. These genes include ones coding for dopamine D1, D2, and D4 receptors (*DRD1*, *DRD2*, *DRD4*), a tryptophan enzyme (tryptophan 2, 3-dioxygenase) involved in serotonin metabolism, and monoamine oxidase A, a protein relevant to norepinephrine, serotonin, and dopamine systems (36). One analysis indicated that genes important for norepinephrine, serotonin, and dopamine systems may contribute relatively equally to an additive risk for PG (36). An earlier study implicated the TaqA1 allele of *DRD2* in PG, but PG no longer showed an association with the TaqA1 allele after accounting for race and other DSM diagnoses (37). Additionally, more recent studies with sibling pair designs have not replicated an association with the TaqA1 allele, and the TaqA1 allele has also been shown to be in linkage disequilibrium with other genes (e.g., *ANKK1*) that might explain an association with addictive disorders (37).

Polymorphisms in the promotor region of *DRD1* have also been associated with SUDs and attention-deficit hyperactivity disorder as well as with PG, in preliminary studies, and D1 receptors have been implicated in reward processing and addiction, suggesting that *DRD1* may be important for the neurobiology of ICDs in general (16,37). Since many of the genes implicated in PG are also associated with other disorders consisting of impulsive-compulsive and addictive

behaviors, this may support the concept that an individual with a combination of these risk factors has a raised vulnerability to develop impulse control or addictive disorders, but the specific form of impulsive or addictive behavior may also be influenced by environmental factors (36). Consistently, studies of male twins have found significant overlaps in the genetic and environmental contributions to PG and alcohol dependence as well as to PG and other externalizing behaviors (38). Future studies using state-of-the-art approaches (e.g., genome-wide association studies) are needed in order to better understand genetic contributions to PG.

NEUROANATOMY

Few functional brain imaging studies have been conducted in individuals with disordered gambling. The findings show abnormal activation in frontal-striatal regions, brain regions implicated in impulse control and decision making, and draw similarities with and differences from SUDs and OCD.

Decreased activation of the right ventrolateral prefrontal cortex (PFC) during monetary wins and losses in problem gamblers was associated with poor performance (i.e., perseveration) on a task of probabilistic reversal learning, measuring components of reward learning, and cognitive flexibility (39). The same individuals with problem gambling demonstrated intact performance and normal dorsal frontostriatal brain activity during an executive function task measuring planning (39). These findings could be consistent with PG resembling OCD or SUD (39) since hyporesponsiveness of the ventrolateral PFC was found in individuals with OCD on the same task of reversal learning and hyporesponsiveness of the PFC to monetary reward has been observed in cocaine-dependent individuals (39).

Initial viewing (prior to self-reported onset of gambling urges) of gambling-related cues was associated with lower regional activity in the frontal cortex (e.g., inferior frontal cortex, superior frontal gyrus), basal ganglia (e.g., caudate), and thalamus in individuals with PG relative to control comparison subjects without the disorder; these regions previously have been found to show increased regional activity in OCD subjects during symptom provocation (25). After the self-reported onset of gambling urges, while viewing arguably more provocative gambling-related cues, the PG group relative to a control comparison group demonstrated hypoactivation in the ventral anterior cingulate portion of the ventromedial prefrontal cortex (vmPFC), a region associated with hyperactivation in cocaine-dependent individuals while viewing cocaine-related cues (25). A direct comparison in a male sample of the neural correlates of craving in cocaine dependence and gambling urges in PG found shared activation differences in the affected groups (as compared to control groups) during viewing of the diagnostic group-specific material (gambling tapes for pathologic subjects, cocaine tapes for cocaine-dependent subjects) with respect to relatively diminished activations in specific

brain regions including the ventral striatum and ventral PFC (30). Together, these findings suggest similarities between PG and SUDs as well as OCD (25). During a simulated gambling task, pathologic gamblers demonstrate diminished activity in the ventral striatum and vmPFC relative to healthy controls, and these regional functional magnetic resonance imaging (fMRI) BOLD signals correlated negatively with gambling severity ratings within the group with PG (40). Relative to healthy controls, pathologic gamblers displayed less brain activity in the vmPFC during performance of the Stroop task, a measure of cognitive control, selective attention and response inhibition (41), and individuals with SUDs with or without PG showed less activation of the vmPFC when performing a decision-making test (the Iowa Gambling Task). The ventral striatum is implicated in reward and salience processing and has also been shown to be hypoactive in substance-dependent individuals during reward processing, while the vmPFC has been implicated in impulse control and risky decision making (30). Pathologic gamblers watching a gambling scenario activated the dorsolateral prefrontal cortex more than did control subjects, and this regional increase in activation was associated with higher baseline and greater cue-induced increases in self-reported gambling urges (42).

Recent studies have investigated common gambling phenomena in healthy (nondisordered gambling) adults with fMRI. Loss-chasing was associated with increased activity in brain in regions including the vmPFC, while resisting the opportunity to loss-chase and quitting the gambling session was associated with activity in the ventral striatum, dorsal anterior cingulate cortex, anterior insula, and middle frontal gyrus. “Near-misses” occur when an unsuccessful outcome gives the appearance of coming close to winning, for example, when two out of three signals line up on a fruit machine and the third symbol is off by one, and have been proposed to promote gambling. Healthy individuals who felt they had more control over the situation reported near-misses as unpleasant but as increasing their desire to continue playing. Regional changes in brain activity during “near-misses” were similar to that following a monetary win (i.e., striatum, insula). Activation of the rostral anterior cingulate during near-misses was associated with healthy individuals’ degree of perceived control over the situation, while insula activity related to their motivation to continue gambling after a near-miss. The authors concluded that the ability for near-misses to recruit reward circuitry may underlie their ability to promote ongoing gambling (43). However, as these studies did not involve individuals with PG, their relevance to PG requires further, direct examination.

Taken together, a relatively consistent finding across studies involves diminished activation of the vmPFC and ventral striatum in individuals with PG. The majority of the imaging studies in PG only included men and excluded individuals with comorbid psychiatric disorders. Given the difference in the clinical profile and demographics of individuals with comorbid psychiatric disorders, it will be important to directly assess brain function in women and youth with PG before generalizing the findings in adult males to all individuals with PG.

TREATMENT

Numerous treatment options exist for PG including, but not limited to, pharmacotherapy and psychotherapy.

In practice, a number of pharmacologic approaches are employed to treat PG, although there are not yet any FDA-approved drugs with an indication for PG. Selective serotonin reuptake inhibitors (SSRIs), mood stabilizers, and opioid antagonists have demonstrated efficacy in treating PG in double-blind placebo-controlled trials (for review see Ref. (44)), with the strongest evidence in support of opioid antagonists, including naltrexone and nalmefene (45). Other medications spanning a range of pharmacologic classes (e.g., lithium carbonate, *N*-acetyl cysteine) have also shown efficacy in the treatment of PG. It has been suggested that clinicians should consider comorbid diagnoses when choosing the pharmacotherapy option for PG. For instance, individuals with co-occurring anxiety disorders may respond well to SSRIs like escitalopram, whereas those with co-occurring bipolar disorders may respond well to mood stabilizers like lithium. Other clinical measures may be used to guide the selection of pharmacotherapies. For example, positive responses to opiate antagonist treatment have been associated with positive family histories of alcoholism and strong gambling urges (44,46).

Evidence for the efficacy of psychotherapies such as cognitive behavioral therapy, motivational enhancement therapy, and imaginal desensitization in the treatment of PG has been observed in controlled clinical trials (44,47), and other forms of nonpharmacologic treatments such as aversion therapy, cognitive restructuring (of erroneous gambling-related beliefs), and personalized feedback have had encouraging results in preliminary studies. However, the psychological mechanism by which these treatments reduce gambling behavior remains unclear (3).

In addition, the majority of states in the United States with legalized gambling operate problem gambling telephone helplines. The 12-step program, GA, has meetings throughout the world. Such self-help treatment options are widely used and often encouraged by clinicians as an adjunct to professional treatment. Many individuals report success with GA, and GA attendance in a gambling treatment program has been associated with better clinical outcome (48). However, data suggest there is frequent discontinuation after attending one or two GA meetings and low rates of long-term abstinence (7.5% at 1 year), suggesting GA may not be efficacious as a stand-alone treatment for most individuals (48).

While historically PG may have been thought to follow a chronic, persistent course, recent studies suggest high rates of natural recovery from PG. These findings suggest that many individuals can shift from exhibiting PG to demonstrating controlled gambling or abstinence without the aid of formal treatment (26).

Only a small proportion of individuals with disordered gambling seek treatment, many of whom are identified by screening when being treated for other disorders (e.g., SUDs). One contributing factor to low rates of treatment seeking may be that only a small proportion of individuals with gambling

problems perceive themselves as having one. Furthermore, treatments for PG have traditionally focused solely on abstinence-based goals, which some individuals may be unwilling to pursue. However, some preliminary studies suggest a goal of controlled gambling may provide similar levels of success as abstinence-based goals (49).

Despite the wealth of treatment options for PG, the field of PG treatment lags behind treatment of SUDs in availability of empirically validated treatments with clearly demonstrated treatment efficacy. There have been relatively few controlled treatment trials or direct evaluations of the clinical efficacy of interventions like GA. Meta-analyses of PG treatment studies have shown substantial estimated effect sizes for both pharmacologic (0.78) and nonpharmacologic (2.01 posttreatment, 1.59 at longer term follow-up) treatments, yet one meta-analysis found the quality of study design to relate inversely to the effect size within cognitive and behavioral treatment studies for PG, such that the most poorly designed studies indicated the most robust treatment effects (50).

Many of the treatment trials should be interpreted with caution as they have only compared active treatments without a “no treatment” control arm, have been open-label, lacked pretreatment data, or used small samples. Of the controlled trials, many exclude patients with comorbid SUD including alcohol abuse or Axis I psychiatric disorders including depression and anxiety, all of which have high rates of comorbidity with PG. Many studies include solely or predominantly adult male subjects, raising questions of the generalizability of these results to women, juveniles, and patients with co-occurring disorders. Many of the longer duration clinical trials report a significant effect of time on treatment outcome, independent of treatment group, perhaps reflecting the tendency for gambling patterns to fluctuate over time and a possible influence of nonspecific factors or natural recovery in the clinical improvement.

CONCLUSION

The increased availability and social acceptance of legalized gambling throughout the world in the past few decades appears to have contributed to increased public and clinical awareness of PG. A growing body of research has furthered the understanding of neurobiologic, cognitive, and genetic factors that may contribute to the development or persistence of PG and contributed to the development of evidence-based treatments to address this potentially devastating disorder.

Virginia A. Sadock

INTRODUCTION

Sex addiction has been recognized implicitly by the culture in general and by the medical community in particular since classical times. The early names for sex addiction derive from Greek mythology: satyriasis for male sex addiction after the mythical satyrs who were characterized by uncontrolled sexual behavior, and nymphomania for female sex addiction, named for the nymphs who were driven by their desire for others. The problem has been portrayed through the ages in art, novels, plays, and films. The attention of psychiatrists was refocused on sex addiction in the late 1970s by James Orford's article on sexual dependency in the *British Journal of Sexual Addiction* and by the work of such clinicians as Patrick Carnes (1).

The concept of sex addiction has developed to refer to persons whose behavior is hypersexual, who compulsively seek out sexual experiences, and whose behavior becomes impaired if they are unable to gratify their sexual impulses (2). This concept derived from the model of addiction to such drugs as heroin or addiction to behavioral patterns such as gambling. Addiction implies psychological dependence, physical dependence, and the presence of a withdrawal syndrome if the substance (e.g., the drug) is unavailable or the behavior (e.g., gambling) is frustrated.

The phenomenon of a person whose entire life revolves around sex-seeking behavior and activities, who spends an excessive amount of time in such behavior, and who often tries to stop such behavior but is unable to do so in spite of adverse consequences is well known to clinicians. Such persons show repeated and increasingly frequent attempts to have a sexual experience, the deprivation of which gives rise to symptoms of distress. Compulsive sexual behavior is coupled with extreme sexual preoccupation and patients often incorporate diverse normal and abnormal practices in their sexual activities.

Awareness of this problem has been heightened by cultural changes. Accountability connected to sexual exploitation in religious, political, and business arenas has focused attention on the problem and the acquired immune deficiency syndrome (AIDS) epidemic has motivated patients to seek help in controlling self-destructive hypersexuality. The ubiquitous presence of sex on the Internet has escalated the prevalence of sex addiction and in some cases fostered the development of the pathology in vulnerable persons who otherwise might not have manifested the problem.

Other commonly used terms for this problem are hypersexuality, sexual compulsivity, and sexual impulsivity.

Hypersexuality is descriptive of the behavior but not the pathology of this condition. One study found one third of participants to have no significant pathology in addition to hypersexuality (3). The researchers also found no evidence of an addictive personality in the participants. These results, however, are contrary to the experience and findings of most clinicians and researchers. There are compulsive elements in addictive behavior, but differentiations can be made in the relatively ego-dystonic nature of compulsions and the ego-syntonic nature of sex addiction to many people. More importantly, compulsive behavior does not, in and of itself, provide pleasure in the activity, while sex addiction usually does. The term "sex addiction" discerns the difference between compulsively accessing the pleasure centers of the brain and the nonpleasure behavior that is more typical of obsessive-compulsive acts. Similarly, features of impulse control disorder are present in sex addiction. Impulsive behavior often is used to relieve the tension of an arousal drive about which the person may feel ambivalence, whereas addictions serve as a palliative or escape from a painful affect such as anxiety, depression, or narcissistic injury. In the author's view, sex addiction is a useful concept heuristically in that it can alert the clinician to seek an underlying cause for the manifest behavior.

DIAGNOSIS

Sex addiction is a behavior involving significant and destructive loss of control of the sexual impulse. Sex addicts are motivated to gratify their sexual impulses regardless of interference with relationships, work, or danger to reputation, status, and even physical well-being. In one study 38% of men and 45% of women contracted a sexually transmitted disease as a result of their behavior (4). Eventually, the need for sexual activity increases and the person's behavior is driven solely by the persistent desire to experience the sex act. Although there may be feelings of guilt and remorse after the act, they are not sufficient to prevent its recurrence, and usually sex addicts cannot refrain from their behavior, even when they attempt to do so. Most acts culminate in a sexual orgasm, although a sense of excitement (a high) usually accompanies the sex-seeking behavior even in the absence of an orgasm. The patient invests a great deal of time in the behavior, including fantasy, preoccupation, and preparation as well as engaging in sexual activity. Signs of sexual addiction are listed in Table 26.1.

TABLE 26.1 Criteria for sex addiction

Criteria

Recurrent failure (pattern) to resist sexual impulses to engage in specific sexual behavior
Frequent engaging in those behaviors to a greater extent or over a longer period of time than intended
Persistent desire or unsuccessful efforts to stop, to reduce, or to control behaviors
Inordinate amount of time spent in obtaining sex, being sexual, or recovering from sexual experiences
Preoccupation with the behavior or preparatory activities
Frequent engaging in the behavior when expected to fulfill occupational, academic, domestic, or social obligations
Continuation of the behavior despite knowledge of having a persistent or recurrent social, financial, psychological, or physical problem that is caused or exacerbated by the behavior
Need to increase the intensity, frequency, number, or risk of behaviors to achieve the desired effect or diminished effect with continued behaviors at the same level of intensity, frequency, number, or risk
Giving up or limiting social, occupational, or recreational activities because of the behavior
Distress, anxiety, restlessness, or irritability if unable to engage in the behavior

Adapted from Carnes PJ: *Don't Call It Love*. New York, NY: Bantam Books; 1991:181–266.

Diagnosis is complicated by the fact that patients usually are not forthcoming about their behavior (5). Patients feel shame and defend against that feeling with repression and denial. They exaggerate their ability to control their behavior, minimize the impact it has on others, or define themselves as having a strong sex drive rather than an addiction. Some cultures, such as those that emphasize machismo, facilitate this distortion.

In Oscar Hijuelos' Pulitzer Prize winning novel "The Mambo Kings Plays Songs of Love," the main protagonist, Cesar, suffers from dual addictions to alcohol and sex. A combination of denial and his internalization of the macho culture in which he was raised leaves Cesar unable to understand his wife's unhappiness about his constant philandering. He sees it as absolutely normal male behavior. Additionally, he is unable to sustain real intimacy with her (6).

The differentiation between a healthy, strong libido and sex addiction is determined by recognizing whether the sexual activity is kept secret and leads to the creation of a double life, whether there is an exploitative element to the sexual behavior, whether it is used as a palliative to painful emotions, and whether the person has difficulty with a truly intimate relationship.

There is a strong tendency for patients to compartmentalize or dissociate themselves from their behavior. Patients may present for treatment because of threats of divorce from a spouse, threat of loss of a job because they have been caught spending work time sexually interacting on the Internet or sexually harassing work colleagues, and confrontations with the legal system. Often, the patient will present the precipitating event as an aberration or rare occurrence.

Some patients present with anxiety or depression, and some seek treatment because their behavior has intensified to a degree that causes them conscious shame and they feel they

cannot continue with this way of life. The clinician should be particularly alert to the possibility of sex addiction if the patient gives a history of chronic affairs, compulsive masturbation, pervasive prostitution use, or habitual online surfing of sex sites.

ETIOLOGY

The incidence of sex addiction is unknown, but has been estimated to afflict 3% to 6% of Americans. It is more frequently seen in men in a ratio of men to women that has been reported variously as 3 to 1 and 4 to 1 (7). However, in cybersex the ratio is more equal, with more than 40% of participants being female (8). Sex addiction usually begins in adolescence when the hormonal changes of puberty and the psychological challenge of consolidating a sexual identity are normal developmental events in the course of a person's growth. The mastery of these adolescent challenges goes awry in the sex addict's development. The problem intensifies during the addicts 20s to 40s when the disorder becomes full-blown and affects the person's life in adverse ways. Some workers feel the intensity of sex addiction diminishes after age 40, but others disagree (9). The author's experience is that even if the behavior or acting out diminishes, the addict's fantasies and abnormally heightened preoccupation with sex continues. In general, the course of untreated sex addiction involves hypersexual behavior, interrupted by periods of abstinence when the addict tries to control the addiction, followed by relapses, and further episodes of compulsive sexual activity.

Research into biologic substrates for sex addiction is a new field, but studies have shown that sex addicts frequently come from families with multiple addictions. Addiction researchers have noted that the Taq 1A1 allele of the D2 receptor gene is

associated with increased risk of alcoholism, drug abuse, smoking, obesity, compulsive behaviors, and Tourette syndrome (7). Also, some workers hypothesize that increased orgasmic excitability or impaired orgasmic control may be a biologic contributant to sex addiction. Hypersexual activity of the type seen in sex addiction can sometimes be a symptom of organic pathology. Specifically, it can be the manifestation of a brain lesion, particularly a lesion in the medial basal-frontal, diencephalic, or septal region (10). Such behavior can also occur in the context of a seizure disorder, most often in association with temporal lobe epilepsy (11). Additionally, it can occur when cerebral functioning is impaired and normal inhibitory controls no longer function, as in the dementias.

Studies have found many families of sex addicts to be rigid or disengaged. Hypocrisy is another characteristic of these patients' families. That is, the families will proclaim a highly moral, even rigid set of values publicly, which they privately violate (12). For example, a parent may extol the sanctity of marriage while carrying on an affair. If the patient, often in adolescence, discovers the discrepancy, anger and rebellion frequently ensue. The rebellion may be covert, as in secret sexual activity, which starts the future sex addict on a path of leading a double life of which he or she is secretly ashamed. The dynamics in the families from which these patients come and the patients' resulting behavior prevent the learning and experiencing of intimacy. From a psychodynamic perspective, sex addiction can be viewed as an intimacy disorder.

Sex addicts report a disproportionately high incidence of childhood trauma and abuse; 72% report a history of physical abuse, 81% report a history of sexual abuse, and 97% report emotional abuse (5,12).

Many of the films of Francois Truffaut, the noted French director, present an excellent review of the etiology, symptoms, and effects of sex addiction, particularly if they are seen serially. For example, an early film, "The 400 Blows" is a portrayal of abuse that warps a child psychologically. Later films such as "The Man Who Loved Women" and "The Woman Next Door" portray, respectively, a man with sex addiction and a man obsessed with a former sexual partner, who ruins his current relationship by acting out his obsession. "Such a Gorgeous Kid Like Me" portrays a woman who continually seduces men for personal—sometimes criminal—gain. Finally, "Mississippi Mermaid" is an example of the destructiveness of uncontrolled sexual desire. Truffaut himself described it as "degradation by love."

It has been suggested that Truffaut's themes were informed by his personal experiences. Biographers note that his childhood was markedly unhappy, his mother having borne him illegitimately, and having remained extremely rejecting of him (13).

Some clinicians report that patients repeat significant emotional scenarios and actual behaviors from their abuse experiences in their sex addiction behaviors. Other sex addicts deal with their past traumas by indulging in high-risk behaviors. These may be looked at as a conditioned response linking sex or excitement with fear, or a counterphobic attempt to master engendered feelings of helplessness and danger.

A 44-year-old man presented for therapy after prolonged insistence by his wife that he do so. She wanted to engage in couple therapy, which he refused, but he eventually agreed to go for individual therapy. She suspected him of having an affair because of the late hours he kept and her frequent inability to get in touch with him, combined with a lack of sexual interaction between them.

He was a successful business man, prominent in his community as the head of numerous volunteer, civic activities. He was, in fact, sexually active on his many late nights, but his activities involved high-risk sex in questionable bars where he would seek out transgendered males. His preferred sexual behavior was oral sex with a man who had a penis, but had surgically or hormonally enhanced breasts.

His early history revealed an alcoholic mother and a father who was a martinet and forced him to take up boxing even though he was small for his age when he was a child and afraid of the sport. His first sexual experience was being taken with some friends at the age of 13 to a transgendered prostitute by an older, bullying schoolmate.

Aviel Goodman theorizes that vulnerability to the addictive process involves "impaired affect regulation, aberrant function of the motivational-reward system and impaired behavioral inhibition" (7). These three factors leave a person abnormally vulnerable to and easily destabilized by emotions that most people can cope with effectively. The person is prone to states of tension, emptiness, and anhedonia, and is largely incapable of resisting activities that provide immediate gratification or surcease from emotional pain, regardless of the destructive consequences of such behavior. Goodman believes that the selection of sex as the addiction of choice evolves from a combination of preference and opportunity. Other workers theorize that sex addiction is more likely to occur in an "eroticized child," defined as a child who has not been sexually abused, but has been covertly seduced. Carnes argues that the eroticized child is even more damaged than the overtly abused child (5). Patients who were eroticized children cannot clearly define parental behavior, doubt their perceptions, and often feel crazy. Sometimes, these patients through their sex addiction are identifying with a seductive mother who herself used sexualization as a defense against pain. In males, this serves the dual purpose of remaining attached to the mother from whom separation in childhood was particularly difficult, while at the same time asserting their maleness (14,15). Sex addiction sometimes has been explained as a way to deal with chronic separation anxiety and also as a way of protecting the patient from the fear of the final separation of death.

TYPES OF BEHAVIORAL PATTERNS

Carnes has developed a system of ten "archetypes" of sexual behavior that he believes help reveal the addict's arousal patterns (Table 26.2).

Half of these archetypes involve paraphilic behaviors. In fact, the paraphilias constitute the behavioral patterns most often found in the sex addict. As defined in DSM-IV-TR, the

TABLE 26.2 Sexual behavior patterns

Fantasy sex: sexually charged fantasies, relationships, and situations
Arousal depends on sexual possibility. Neglecting responsibilities to engage in fantasy or to prepare for the next sexual episode, or both, is common among fantasy sex addicts.
Seductive role sex: seduction of partners
Arousal is based on conquest and diminishes rapidly after initial contact. Arousal can be heightened by increasing risk or the number of partners, or both.
Voyeuristic sex: visual arousal
The use of visual stimulation to escape into an obsessive trance. Arousal may be heightened by masturbation, risk (e.g., peeping), or violation of boundaries (e.g., voyeuristic rape), but, for arousal to be maintained, it must be illicit somehow and must be visual.
Exhibitionistic sex: attracting attention to the body or sexual parts of the body
Sexual arousal stems from reaction to viewer shock or interest.
Paying for sex: purchase of sexual services
Arousal is connected to payment for sex, and, with time, the arousal actually becomes connected to money itself. Payment creates an entitlement and a sense of power over meeting needs, but the arousal starts with having money and the search for someone in the business.
Trading sex: selling or bartering sex for power
Arousal is based on gaining control of others by using sex as leverage.
Intrusive sex: boundary violation without discovery
Sexual arousal occurs by violating boundaries with no repercussions.
Anonymous sex: high-risk sex with unknown persons
Arousal involves no seduction or cost and is immediate. The arousal has no entanglements or obligations associated with it and often is accelerated by unsafe or high-risk environments, such as bars, beaches, parks, and restrooms.
Pain exchange sex: being humiliated or hurt as part of sexual arousal or sadistic hurting or degrading another sexually, or both
Arousal is built around specific scenarios or narratives of humiliation and shame.
Exploitive sex: exploitation of the vulnerable
Arousal patterns are based on target types of vulnerability. Certain types of vulnerable persons (e.g., clients or patients of professionals, children or adolescents, or distressed persons) become the focus of arousal.

essential features of a paraphilia are recurrent intense sexual urges or behaviors that are culturally unacceptable, including exhibitionism, fetishism, frotteurism, sadomasochism, voyeurism, cross-dressing, and pedophilia.

A 48-year-old lawyer presented for therapy because of marital problems and feelings of depression. His history revealed past alcohol abuse and a lack of sexual interaction with his wife since the birth of their youngest child 6 years previously. His current sexual activity was connected to visits to bars (which resulted in frequent lapses from his alcohol abstinence), both because alcohol relieved his sexual inhibitions and because he was sexually aroused by watching women smoke. Legally, bars were the only public venue where smoking was permissible and smoking was a fetishistic component of sexual arousal for him.

His early history involved an emotionally sadistic father who would smoke in the family car with the windows closed, not caring if the children got sick. He remembered being

attracted to a young aunt who smoked. His first cigarette was one he stole from a pack of cigarettes he found on his sister's bureau.

Paraphilias are associated with clinically significant distress and almost invariably interfere with interpersonal relationships, and they often lead to legal complications. In addition to the paraphilias, however, sex addiction can also include behavior that is considered normal, such as coitus and masturbation, except that is promiscuous and uncontrolled.

In the 19th century the psychiatrist Richard von Krafft-Ebing reported on several cases of abnormally increased sexual desire. One was that of a 36-year-old married teacher, the father of seven children, who masturbated repeatedly while sitting at his desk in front of his pupils, after which he was "penitent and filled with shame." He indulged in coitus three to four times a day in addition to his repeated masturbatory acts. In another case a woman masturbated almost incessantly and was unable to control her impulses. She had

frequent coitus with many men, but neither coitus nor masturbation was sufficient, and she eventually was placed in an institution (16).

In nonparaphilic sex addiction, the aim is constant physical gratification that many therapists interpret as an excessive need for an “orgasmic high” to alleviate unrecognized emotional pain. Women sex addicts frequently use sexual behavior to engage addictively in romantic relationships in order to fill unmet needs for love, attachment, dependency and admiration.

Many sexual behavior patterns express anger, sometimes called eroticized anger, that is a major component of most sex addictions. However, the patient notices only the sex component of the behavior, not the anger (17). For example, intrusive sex behaviors involve patients who are frotteurs (people who press their genitalia against others, usually in crowded situations such as subways), peeping Toms, obscene phone callers, and professionals such as doctors, dentists, therapists, or clergy who touch patients or congregants under the guise of performing professional tasks. The intrusion is sexual, but anonymous or masked, and leaves the sex addict unaccountable to the victim. In these cases the sex addict is putting something over on, or stealing sex from the victim. In seductive role sex, the excitement lies in the seduction and conquest, not in the sex act itself. This behavior pattern has also been called Don Juanism. The sexual conquests are used to mask a fear of rejection and deep feelings of inferiority. Some therapists believe that Don Juanism is a defense against fears of being homosexual. Most Don Juans have no interest in a woman after they have had sex with her (2).

A 41-year-old man presented for therapy because of the sexual dysfunction of ejaculatory inhibition. He was able to climax with masturbation or when he went to a massage parlor, but never with a woman in mutual sex play, whether manual, oral, or with intercourse. This was the case whether the patient was with his wife, or on one of his many one-night stands. He had experienced only two exceptions to this pattern. He was able to ejaculate once when he was having sex with two women at the same time, and once when he invited a woman into his home for sex, and there was real danger that his wife would walk in on the scene. The patient compulsively continued his pattern of seductions in spite of his dissatisfaction with his sexual experiences, stating that what he really enjoyed was the conquest. In fact, he kept a list of all the women he seduced which he would show to friends.

Sex addicts often act out in several clusters of behavior, moving from one to the other. Carnes states that “The key for clinicians is to understand the escalation factor. Addicts act out using more of the behaviors, add risk and danger, or seek new behaviors, often with great risk and danger. Escalation is tempered with plateaus, efforts to reduce risk, and sexually aversive periods. Most addicts are able to pinpoint moments of escalation and resulting consequences” (5).

In many cases sex addiction is associated with a variety of other disorders. In addition to the paraphilias that are frequently present, there may be an associated major mental disorder such as anxiety disorder, depressive disorder, bipolar

disorder, or schizophrenia. Antisocial personality disorder and borderline personality disorder are common. Paradoxically, persons with sex addiction may have a concurrent sexual dysfunction.

COMORBIDITY

Comorbidity (dual diagnosis) refers to the presence of an addiction that coexists with another psychiatric disorder such as those mentioned above. For example, about 50% of patients with substance-use disorders also have an associated psychiatric disorder. Similarly, many sex addicts have an associated psychiatric disorder (18). Dual diagnosis implies that the psychiatric illness and the addiction are separate disorders; one does not cause the other. The diagnosis of comorbidity is often difficult to make because addictive behavior (of all types) can produce extreme anxiety and severe disturbances in mood and affect, especially when addictive behavior is treated. If, after a period of abstinence, symptoms of a psychiatric disorder remain, the comorbid condition is more easily recognized and diagnosed than during the addictive period. Finally, there is a high correlation between sex addiction and substance-use disorders, up to 80% in some studies (7).

The centaur of Greek mythology is a perfect symbol of combined substance-use disorder and sex addiction. The centaur was a creature with the head, arms, and torso of a man and the lower body of a horse. Its weaknesses and downfall were lust and an inability to resist wine. When the centaurs drank, they were unable to control their impulses. Their physical depiction was reflective of their problems; the use of their human intellect and capacity for control was dissolved by wine and overpowered by their “animal” drives.

The term “fusion” is often used when two addictions are almost always indulged at the same time. For instance, cocaine use is almost always connected with sexual activity or intent, with both habits containing a compulsive element (19,20). Other instances of fusion can involve use of alcohol to enable the person to indulge in high-risk sex, or gambling to increase general excitement levels before having sex (21). An ironic comorbid diagnosis that is appropriate for a number of sex addicts is sexual aversion disorder. In these cases the patients are averse to and compulsively avoid sex with spouses or long-term partners, while addictively pursuing high-risk sex outside a relationship (22). This particular behavior transparently reflects intimacy problems, and is frequently the result of early family problems and traumas.

The classic French film, *Belle de Jour*, portrays this particular pattern. The main protagonist is an upper-middle class woman who has no interest in sex with her loving husband. However, she is preoccupied with masochistic fantasies in which she is whipped, reviled, and pelted with mud. Ultimately, she embarks on a double life, working a few hours each day at a small brothel. She is exposed to dangerous and sadistic men with whom she enjoys sex. We learn, during the course of the film, that she was repeatedly incestuously abused as a child.

Comorbidity not only complicates the task of diagnosis, but also complicates treatment.

CYBERSEX ADDICTION

Cybersex addiction has been called the crack cocaine of sexual addiction. The escalation of behavior that is inherent to the problem of sex addiction is exponentially increased when the Internet is used for compulsive sexual activity. Nonsex addicts may visit pornography sites on the Internet on an occasional basis, but they do not become sex addicts. However, persons already addicted to sexual behavior and persons who are vulnerable to the addictive process are quickly hooked by the Internet. Studies have shown that sex-related sites became the most profitable economic sector of the Internet in the past decade, exceeding sales of software and computers. Cybersex has become a problem in the workplace: 70% of Internet pornography surfing occurs during daytime work hours; and one in six workers is estimated to have a problem with sexual behavior online (5). The extraordinary addictiveness of cybersex is driven by what A.L. Cooper has called “the triple A engine: accessibility, affordability, and anonymity” or what other workers have called the ACE engine: anonymity, convenience, and escape (4).

A 48-year-old man, an accountant, presented for therapy after being fired from his job. He had worked for a small accounting firm for 22 years and had been a valued employee. The patient had always kept a stash of pornographic magazines, but did not give a history of excessive masturbation. However, after visiting pornography sites on the Internet, his traffic between numerous sites increased significantly and was accompanied by masturbation on a daily or twice daily basis. His risk-taking also increased. He began locking his office door frequently, sometimes not responding to knocks in order to indulge in cybersex. Although he was spoken to about locking his door, he continued the behavior. His risk-taking increased to the point that he would surf pornography sites on days spent servicing clients in the clients’ offices, even though he had no private space other than a separate desk on these occasions. One of the clients complained vociferously to his employer, which led to his being terminated.

Relationships are profoundly affected by Internet addiction. Patients report that they withdraw from close interactions with spouses, other family members, and friends. Their marital sex life decreases. The sex addicts invest their time as well as their emotional energy in their online relationships. They have little left to give to the real people in their lives and additionally may withdraw due to an unconscious sense of shame. Cybersex addicts escalate the frequency, the variety, and the risk of their behavior. Patients report becoming obsessed rapidly with behaviors that they never tried or never even knew about before their Internet experiences. They quickly find numerous sites: different types of pornography; paraphilia sites; e-mail partners, and chat rooms where they conduct virtual affairs.

The effect of these affairs on partners and family is as destructive as that of an actual affair. Spouses feel betrayed, hurt,

and angry. They experience a loss of self-esteem, feeling they could never compete with the online sex partners. Additionally, they report severe distress over being lied to repeatedly and experience a loss of trust. Children of the sex addict experience disillusionment. They may be exposed to objectification of women, and they may become involved in their parents’ conflict or suffer the break up of their parents’ marriage. One study reported a divorce rate of 28% following the discovery of an online affair, and consideration of divorce in over 60% of the couples where the sex addict’s behavior had been discovered (23).

It is estimated that 1% of the population in the United States suffers from Internet sex addiction (8). Studies of cybersex addicts report the majority to be male, heterosexual and married. However, the single and dating also form a significant segment of this population, as do persons who are homosexually oriented. Women are a larger proportion of addicts on the Internet than they are in the overall category of sex addicts. Some researchers theorize that women, like homosexuals, fall into the category of people who are disenfranchised sexually, and that the anonymity of the Internet provides them with an outlet for sexual behavior forbidden to them by the culture at large. This theory requires more research.

In addition to serving as a catalyst for persons who might never have become sex addicts without the Internet, cybersex can intensify existing addictive behavior and can precipitate new compulsive off-line behavior. Carnes discusses a theory to explain the escalation, intensity of arousal, and compulsive behavior set in motion by the Internet: “... through the internet patients”: “access the unresolved.” All people have sexual experiences that leave them unfinished. Sexual play as a child, for example, may leave the person with unfinished experiences. As a person matures, he or she realizes that he or she no longer has an interest in that behavior or that those experiences are no longer appropriate for adults. Yet a person might experience the right image or story that is an absolute overlay of something unfinished from childhood or adolescence. The nature of marketing pornography is to bombard potential clients with a variety of images to stimulate the purchase of memberships. When that which is unfinished is accessed, the individual begins to search for more of the same genre. The marketing loops of sex sites are literally labyrinthine; each choice may bring a person closer to the types of images that most closely fit the unresolved, unfinished aspect of the sexual self. Patients often report the phenomenon of a “burned in” image—a specific scene out of Internet about which they cannot stop thinking. This phenomenon is similar to the intrusive images that Post-Traumatic Stress Disorder patients describe (5).

TREATMENT

Sex addiction is a chronic disease. It usually has a relapsing, remitting course. The aim, as with all chronic disease, is to keep it in remission. In sex addiction this means enabling patients to control the destructive behavior, to help them evolve a healthier sexuality, and to mitigate the psychological distress associated with the disorder as much as possible. Numerous

treatment approaches are used in treating sex addiction, such as inpatient therapy, 12-step groups for sex addiction, other therapeutic groups, medication, psychodynamic psychotherapy, couple therapy, and sex therapy. Frequently, a combination of many of these modalities is necessary for treatment to be effective. Studies have evaluated the perceived helpfulness of a number of treatment options from the patient's perspective (Table 26.3).

The initial factor that is necessary for therapeutic engagement is the patient's recognition that there is a serious problem, whether this recognition is a result of the patient's insight, or imposed upon the patient by an intervention. The intervention can be initiated by spouse, family, colleagues, employers, or the legal system. The greater the acceptance by the patient of the presence of the pathology, the greater the chance of successful treatment. Similarly, the chances of success in treatment are paralleled by the degree of the patient's internal commitment to giving up the addiction. Even if treatment is imposed by threats of divorce, loss of job, or the law, recognition of the problem can be developed in treatment, along with a genuine desire to change.

Inpatient Therapy

Inpatient therapy involves institutionalization at a rehabilitation facility that may be freestanding or may be part of a larger psychiatric hospital or general hospital. Hospitalization as the first step in a treatment process is most appropriate for patients who are suicidal or dangerous to others. Paraphilias that involve victims such as pedophilia, frotteurism, or exhi-

bitionism may require that the patient be hospitalized. Some nonparaphilic patients who cannot refrain from excessive sexual activity even though they are participants in outpatient programs are also good candidates for hospitalization. Certainly, if a patient continues high-risk practices, such as promiscuous sex with strangers, or sex with numerous partners without utilizing safe-sex precautions such as condoms, inpatient therapy is indicated.

Treatment in these settings involves multiple approaches. In addition to the removal of the patient from the pervasive sexual stimuli of the general culture, he or she participates in a 12-step program, similar to the program developed for Alcoholics Anonymous. Education regarding the disorder is provided didactically and in therapy. Family meetings also educate family members about the problem and provide opportunities for the families and patient to reconnect in a moderated setting. Sometimes these meetings lead family members to enter therapy as well, not for sex addiction, but for support, introspection, and increased self-knowledge. Medication may be prescribed for the patient and individual therapy is a part of most programs. A follow-up program and plan for continuing treatment after discharge is essential for the ongoing recovery of the patient (24).

Group Therapy

There are several forms of 12-step programs available: Sex Addicts Anonymous (SAA); Sex and Love Addicts Anonymous (SLAA); Sexaholics Anonymous (SA); and Sexual Compulsives Anonymous (SCA). The first step in all these

TABLE

26.3

Treatment choices of 190 persons asked to note the helpfulness of various treatment options

Type of treatment	Helpful (%)	Not helpful (%)

From Carnes PJ. *Don't Call It Love*. New York, NY: Bantam Books; 1991:181–266.

groups requires personal acceptance of the problem by the addict, which is emphasized by the public profession of one addiction to the group. The patient receives immediate support for recognizing his or her problem. The next two steps address the addict's conflicts over dependency and control as the addicts admit their powerlessness to regulate their behavior and accept the necessity of help from a "higher power." The remaining steps emphasize spirituality, require the patients to further confront the problem by making an inventory of behavior that has harmed others and, where possible, make amends for that behavior (24). The final step advocates helping others who have the same problem. All the 12-step programs follow this format; their differences lie in their definitions of sobriety.

SAA members individualize this definition; with the help of other fellowship members, the recovering addicts individually identify the sexual behaviors that are destructive or lead them into problems and define such behaviors as "out of bounds" for themselves. SLAA has a similar approach and defines any sexual behavior or emotional act that is a trigger for out of control behavior as "bottom-line sex." Any act of "bottom-line sex" violates sobriety. In SCA sobriety is also highly personalized; members are encouraged to follow sexual recovery plans that reflect their own values, although these are shared with and affected by group input. SA has a very specific definition of sobriety as sex only with a spouse; masturbation or sex with any partner other than a spouse constitutes a lapse from sobriety. All programs encourage the adoption of a sponsor; a group member to whom the newly recovering addict can turn for support and counsel between meetings and in times of stress and potential or actual relapse (7).

Twelve-step programs have been extremely effective in counteracting sexual addiction and preventing relapse. Many workers believe that they are essential to recovery, even though empirical evidence reveals that many recovering addicts do not complete all the steps of such a program. The nature of these fellowships varies from group to group, reflecting the characteristics of the individuals who attend them. There is a danger that some sex addicts will use a group setting to connect with another group member in order to act out their addiction. However, the benefits of these groups appear to far out weigh the risks and constructive rehabilitation occurs significantly more than destructive behavior.

Other Therapy Groups

Participation in a therapy group of any type is beneficial to those who are addicted to sex. Support, confrontation, breakthrough of isolation, and the counteracting of denial and rationalization all aid the recovery process. Also, group acceptance is a significant factor in reducing the shame, conscious or unconscious, which contributes to perpetuation of the sex addiction cycle. The group provides a safe forum in which the addict learns to make meaningful connections with others. Groups can be educational and informational, cognitive-behavioral, supportive or psychodynamic in orientation (25). Cognitive-behavioral

groups are frequently used to treat sex addicts with paraphilias, and psychodynamic groups are useful for patients with comorbid personality disorders. Studies have shown that groups with structure are the most effective for persons with sex addiction disorder. The structure may somewhat counteract the threat of loss of self-coherence that many addicts suffer. Also group theory posits that the group ego is stronger than the ego of any individual member. In a structured group, the leader or the structure itself makes the greatest contribution to the group, which helps bolster the psychological frailties of the recovering patient. Additionally, groups function as a benign superego, providing nonshaming, nonpunitive controls for the addict who has insufficiently developed internal controls.

Pharmacotherapy

Pharmacotherapy is an important modality for reducing patient symptomology. The most commonly used medications are the antidepressants, particularly the selective serotonin reuptake inhibitors (SSRIs). Agents that have been found to be effective include fluoxetine (Prozac), sertraline (Zoloft), paroxetine (Paxil), and fluvoxamine (Luvox). The effectiveness of these medications derives from their side effect of reducing libido that has been reported in nonsex addict populations, from their use in treatment of obsessive-compulsive disorders, and also from their antidepressive effects. The last effect is important in those sex addicts who have comorbid affective disorder but also for most sex addicts who tend to respond to stress with intense feelings of dysphoria and addictive behavior. Studies report an effective response rate to these medications of 50% to 90% (26). Interestingly, a number of studies of paraphiliacs have found that SSRIs reduce the drive for pathologic sexual behavior in these persons, but not the drive for healthy sexual behavior (27). Other antidepressants that have proved effective in treating sex addiction include imipramine (Tofranil), nefazadone (Serzone), despramine (Norpramin), and clomipramine (Anafranil). However, clomipramine also has the paradoxical effect in some persons of producing spontaneous orgasms. Lithium is effective in the treatment of bipolar patients who evince hypersexuality in a manic episode. As is true in psychiatric disorders in general, pharmacotherapy is most effective when it is combined with other treatment modalities, particularly group or individual therapy.

Antiandrogens are sometimes used to treat sex addicts with paraphilic sexual behavior. This type of treatment is discussed below, in the section on paraphilias.

Cognitive-Behavioral Therapy (CBT)

Cognitive-behavioral approaches to sex addiction usually emphasize altering the maladaptive core beliefs that are thought to underlie the patient's addictive behavior. Cognitive-behavioral techniques for sex addiction are typically utilized in the context of therapy groups, although individual approaches are used as well (28–30).

A supportive, collaborative relationship is developed with the group or the therapist to keep patients engaged in therapy while they learn to correct their distorted beliefs and while they practice and master self-help skills to counter their addiction. The therapy is interactive and focuses on current problems and relapse prevention.

The goal in CBT is to have the patient recognize and stop the addictive behavior. In some cases, in addition to behavior modification, medication may be used to help the addict control hypersexual behavior. Instruction in anxiety reduction techniques, such as progressive relaxation, teaches patients to alleviate the anxiety that may precipitate the addictive behavior. In the group setting patient, recognition of the problem is publicly expressed to the group members, who similarly admit the same problem and provide support for one another. CBT requires a profession of commitment to the treatment process. This may be in the form of a promise to keep no secrets from the group members or therapist, or in the form of a contract made with therapist or the group about behavioral changes the patient wants to make. Such contracts are usually reviewed weekly and individuals share their thoughts about various successes and failures. In the group setting, members benefit from peer support and from confrontation by peers who are uniquely sensitive to manipulations by a patient who seems to be less than honest with himself or herself about addictive activities. An educational component is sometimes interwoven in the therapy with the therapist providing didactic material that informs the patient about the disorder. Members of the sex addict's family may become involved in therapy. The concept of sex addiction as a disorder rather than a lack of will helps diminish the shame felt by the addict. Patients may be instructed to keep journal entries as part of the therapy process. The journals provide a method for self-observation that keeps patients aware of impulses, fantasies, and affects, which they usually avoid by escaping into addictive behavior (31). CBT facilitates more adaptive social functioning through exercises in problem-solving and through assertiveness training (29). The compilation of factors that are significant in "triggering" a relapse is part of relapse prevention techniques. Patients are advised on how to deal with the triggers and how to deal with an episode of addictive sexual behavior should a lapse occur. Patients rehearse relapse prevention actions such as avoidance of triggering situations. For example, cybersex addicts are encouraged not to use computers. When such use is necessary for work, patients are instructed to position computers so the screens are clearly visible to others. In the group setting, contacting a group member for support when urges to act out occur is a crucial component of treatment. Rewards to prevent the addict from feeling excessively deprived are also an important part of the therapeutic process (5).

Psychodynamic Psychotherapy

Psychodynamic or insight-oriented psychotherapy to treat the sex addict is usually necessary to treat the dysfunctions of character or personality that are often comorbid with sex

addiction. Psychodynamic psychotherapy involves treatment in a dyadic setting with a therapist who is skilled in the use of transference and familiar with the use of psychodynamic constructs. Therapy has an open-ended time frame and the focus is on the patient's verbal associations, dreams, and fantasies, and the transference relationship to the therapist (32). The therapist is more interactive and directive than a traditional analytic psychotherapist.

Adding psychodynamic conceptualizations to behavioral techniques helps patients recognize affects of which they are unaware, helps them develop healthy defenses in place of the unhealthy defenses of denial, repression, dissociation or somatization, and frees them from the destructive behavior caused by unrecognized, unresolved inner conflicts, needs, and fears (33). Finally, it helps them correct distorted perceptions of themselves and others. Psychodynamic psychotherapy also provides the addict with what Franz Alexander called a corrective emotional experience (18).

An important concept in understanding the psychological development of a person's sexuality is the relationship between the child and his or her parents, particularly the mother.

Robert Stoller has explained:

Freud told us . . . that parents have the greatest possible influence on their children's development, that children create psychic structure in response, that adult sexual life can be traced back to effects in infancy, and that sexual desire and gratification find origins in infancy (34).

The first experience of intimacy occurs with the mothering person. That intimacy becomes the basis for subsequent experiences, including sexual experiences. Under positive circumstances, mothering experiences that gratify need appropriately and set boundaries on behavior are the basis on which future comfortable intimacy is established. Abusive, ambivalent, or neglectful mothering, in infancy, childhood, and later development, sets the stage for fear of hurt or loss and for reactive, retaliatory rage with subsequent, potentially intimate experiences. During their first year or recovery, many patients report painful memories from childhood that had been repressed and clarity about early wounds emerge (5). When past experiences and their associated affects become conscious, memories are expressed in words. Physiologic patterns, such as the development of psychosomatic disease, and behavioral patterns such as addiction that the patient used to cope with early hurts then become amenable to modification.

The replay of old reaction patterns, affects, and fantasies in a current time frame, and in a personalized context is the patient's expression of his or her transference. The transference resuscitates, in a moderated and safe setting, the patients unsatisfied claims for love, feelings of shame or humiliation, and prohibited aggressive feelings. This phenomenon offers an excellent opportunity for modification of distorted emotional responses and unhealthy behavior. Many sex addicts experience unrecognized, painful affects such as anxiety or unacceptable anger as the urge to act out sexually. Those affects are unconsciously translated into urges that often precipitate hypersexual

behavior. Addicts, because of neglectful or abusive caretaking in early childhood, never developed the skills to cope with uncomfortable affects and react to them as overwhelming threats that may cause psychological disintegration. The addictive behavior provides the patient, not just with a hedonic escape, but is unconsciously experienced by the patient as a necessary defense for his or her emotional survival (7,14).

In the context of the therapeutic relationship patients' shame about their behavior diminishes. They learn from the therapist that sex addiction is a disorder, not an inherent weakness or character flaw. At the same time they are confronted with the responsibility for dealing with it. The patients' capacity for coping with stress and for controlling hypersexual behavior develops as they internalize the therapist's caretaking functions and nonjudgmental attitude. They identify with and accept cultural standards for appropriate behavior. Goodman explains internalization as: "... a primary means by which psychotherapy promotes healing of impaired self regulation by providing new opportunities for patients to internalize self regulatory functions that they did not adequately internalize during childhood..." Self-care functions can develop through internalization of the message that the patient is valued as a person and worth taking care of. Healthy self-governance functions can develop through internalization of the therapist's integrity, respectfulness, nonjudgmental acceptance, and general stabilizing function.

In the course of therapy, patients recognize the stresses, both external and internal, that trigger addictive behavior. They learn to communicate with others more effectively as they become less ashamed and fearful, and they see themselves and the external world through a less distorted lens. Their expectations of themselves and others become more realistic, and they make greater use of such defenses as anticipation and suppression that help prevent relapse (33). Ideally these gains are used not just to deal with the sex addiction, but are applied both to the addict's personal relationships and to his or her work life.

Abstinence

Many sex addicts episodically refrain for all sexual behavior as a way of controlling their addiction. This has been called "acting in" (5). During these periods sexual impulses are dealt with by repression, which is ultimately ineffective. Without treatment the addictive pattern breaks through.

However, abstinence is usually prescribed in the initial phase of recovery. In the beginning of treatment it is easier for the patient to abstain than to transition from addictive sexuality to healthy sexual behavior. Many patients report relief at not having to deal with sex at all; they feel freed from an activity that has controlled them. Some treatment programs require the patient to write an abstinence statement that usually defines sexual behaviors to be curtailed, describes sexual behaviors to be cultivated, and includes situations, or triggers, for addictive behavior to be avoided (e.g., avoiding a red-light district in a town). These statements are discussed with a therapist or support group as part of treatment.

The majority of patients report that a celibacy period is a helpful component of treatment. Eventually, the addicts leave the shelter of abstinence and work on gratifying their sexual impulses in the context of healthy, intimate, and nonexploitative relationships. Couple therapy and sex therapy can be useful in this regard.

Couple Therapy

During the course of a patient's addiction his or her relationship with a partner is hurt by secrecy and lies that clearly interfere with intimacy. When the patient is recovering, he or she must deal with shame or guilt and vulnerability while the spouse or partner must deal with feelings of betrayal, rejection, anger, and loss. Couple therapy provides a controlled forum in which one has to confront and process these feelings. The therapist, through definite types of communication, attempts to reverse or change maladaptive patterns of interaction and behavior, and to encourage personality growth in both partners. Communication exercises may include setting regular times for talking together, and using the word "I", as in "I feel", "I think", "I need," as often as possible in order to promote the sharing of feelings and thoughts. Daily letter writing in which feelings are shared is another technique to improve communication. Sometimes partners immediately repeat their communications back to each other to make sure they have accurately heard each other. Couple therapy can elucidate pathogenic factors in the marital relationship (29). The emphasis is on restructuring the couple's interaction and sometimes exploring the dynamics of each partner. Also, this type of therapy can engage the spouse and the energy in the relationship as agents of therapeutic change in the recovery process (35). Major goals of couple therapy include improving the communication skills, the conflict resolution skills, and the problem-solving skills of the couple, usually with behavioral techniques. The addition of an insight-oriented approach can lead to improvement in the fulfillment of individual needs for attachment and intimacy, and to increase trust and equitability in the relationship (36).

Sex Therapy

Sex therapy may be necessary to help the patient's transition to a healthy mode of expressing sexual impulses or to augment couple therapy. Frequently, sex addicts suffer from a particular sexual dysfunction. This is not as ironic as it seems because the same developmental factors that are prevalent in the creation of a sex addict may lead to a sexual dysfunction. Any experience that hinders the ability to be intimate, that leads to a feeling of inadequacy or distrust, or that develops a sense of being unloving or unlovable may result in a sexual dysfunction (3).

The following factors have been found to be causative in erectile disorders: fear of punishment; castration anxiety, fear of injury as a result of opening up to others; fear of harming women through intercourse; and fear of retaliation from other men at successful sexual relations. The central conflict in inhibited male orgasm frequently lies in rivalry with and fantasized retaliations from other men (34).

Biologic factors may contribute to these dysfunctions and to premature ejaculation, but psychological or mixed factors are causative in 50% of cases. Psychological issues are causative in a higher percentage of cases in young and middle adulthood, particularly if there are no physical health issues (3).

Among women, dynamic factors that have been noted in sexual dysfunction include fear of direct injury to the vagina from the penis, inability to trust a sexual partner, reluctance to make oneself vulnerable related to previous experiences of loss, separation, or abuse, and fear of loss of control if sexual feelings are let loose.

Sexual difficulties have also been ascribed to flight from masochistic fantasies associated with sexual coitus. Freud postulated that girls in the oedipal phase of development assume they have lost a penis. Such assumptions of genital damage or insufficiency may give rise to wishes for vengeance that find expression in a variety of ways—for example, vaginismus with a denial of entry, fantasies of vaginal mutilation of the penis, the wish to disappoint the man and envy of male prerogatives (37).

Regardless of etiology, the final common pathway of sexual dysfunction is performance anxiety. A behavioral approach is utilized to minimize anxiety. Specific exercises, both in communication and for sex play are prescribed for the couple. The exercises are performed in the couple's own home and discussed weekly or twice-weekly in psychotherapy sessions. The aim of therapy is to establish or re-establish communication within the marital unit. Sex is emphasized as a natural function that flourishes in the appropriate domestic climate and improved communication is encouraged toward that end. To minimize performance anxiety, the couple are prohibited from any sex play other than that prescribed by the therapist. Beginning exercises usually focus on heightening sensory awareness to touch, sight, sound, and smell. Initially, intercourse is interdicted and the couple practice giving and receiving bodily pleasure without the pressure of having to achieve penetration or orgasm.

The individuals alternately invite each other for exercise sessions and alternate in caressing one another. This structure inherently confronts inhibitions about sexual approach in an intimate relationship and reinforces the idea that a person has to “give to get.” Exercises involving genital stimulation and quiet penetration (no thrusting) are added before the couple is advised to attempt intercourse. Psychotherapy sessions follow each new exercise period, and problems and satisfactions, both sexual and in other areas of the couple's lives, are discussed. The introduction of new exercises is geared toward the couple's progress.

One of the most effective treatment modalities is the use of sex therapy integrated with psychodynamic and psychoanalytically oriented psychotherapy. The material and dynamics that emerge in patients in analytically oriented sex therapy are the same as those in psychoanalytic psychotherapy, such as dreams, fear of punishment, aggressive feelings, difficulty trusting a partner, fear of intimacy, oedipal feelings, and the fear of genital mutilation. The sex therapy is conducted over

an extended period that allows for the learning of sexual satisfaction in the context of the patients' day-to-day lives.

The structure of sex therapy inherently involves the formation of a small group of three or four people; the therapist or cotherapists and the couple. Group dynamics, including the support and confrontation that are more easily possible in a group setting, enhance the effectiveness of the therapy. Also, the therapist or cotherapy team serves as a benevolent superego that helps to relax the inhibitions of the patients.

PARAPHILIAS

Paraphilic sex is an integral part of the behavior of a significant number of sex addicts. Paraphilias or perversions are sexual stimuli or acts that are deviations from normal sexual behaviors, but are necessary for some person's to experience arousal or orgasm (see listing of paraphilias above).

These individuals can experience sexual pleasure, but are inhibited from responding to stimuli that are normally considered erotic. A special fantasy with its unconscious and conscious components is the core element of the paraphilia, with sexual arousal and orgasm being associated phenomena that reinforce the fantasy or impulse (38).

John Money has explained that the love map (the ideal program for experiencing sexual pleasure) of the paraphiliac is that person's only way of salvaging his or her sexuality from the inhibitions that have interfered with responsiveness to normal sexual stimuli (39). Ethel Person has described the paraphiliac as possessing an abnormally narrow range of sexual responsiveness, since he or she remains unstimulated by the variety of stimuli that can arouse normal people. Some sex addicts indulge in several paraphilias, for instance fetishes, bondage, and voyeurism, or any other combination of perversions. Freud has described such people as polymorphous perverse (38).

There are nonparaphilic sex addicts and people with a paraphilia who are not sex addicts. However, it is not surprising for one person to suffer from both disorders since they share similar epidemiologies and etiologies. As is true for sex addiction, paraphilias are seen much more frequently in males in a reported ratio of 4 to 1. More than 50% of paraphilias have their onset before age 18, and patients with paraphilias frequently have 3 to 5 paraphilias, either concurrently or at different times in their lives. The occurrence of paraphilic behavior peaks between the ages of 15 and 25 and gradually declines. Few acts of criminal paraphilia (such as exhibitionism) are seen in men of 50. Many acts of paraphilia that occur are practiced in isolation or with a cooperative partner.

Psychoanalytic theory holds that persons with a paraphilia have failed to complete the normal developmental process toward sexual adjustment. The paraphilia is the method chosen by the person (usually a male) to cope with the anxiety caused by threat of castration by the father and separation from the mother. However bizarre its manifestation, the resulting behavior provides an outlet for the sexual and aggressive drives that otherwise would have been channeled into normal sexual behavior.

Learning theory proposes that children learn paraphilias through early experiences that condition them to perform the perverse act. The first shared sexual experience can be important in that regard. Experiencing molestation, as a child, can predispose a person to accept continued abuse as an adult, or conversely, to become an abuser of others. Also, early experiences of abuse that are not specifically sexual, such as spankings, enemas, or verbal humiliation, can be sexualized by a child and form the basis for a paraphilia (38). Learning theory indicates that because the fantasizing of paraphilic interests begins at an early age and because personal fantasies and thoughts are not shared with others (who could block or discourage them), the use and misuse of paraphilic fantasies and urges continues uninhibited through adolescence and early adulthood. Eventually, when the person realizes that his or her sexual urges and behavior deviate from societal norms, the repetitive use of paraphilic fantasies already has become ingrained as have the sexual thoughts and behaviors associated with these fantasies (38).

Some studies have identified abnormal biologic findings in persons with paraphilias, such as abnormal hormonal levels, hard and soft neurologic signs, and chromosomal abnormalities. However, these studies investigated only known paraphiliacs who were referred to medical centers; they did not use control groups or random samples.

Different modalities are used to treat persons with paraphilias. These include external control, chemical reduction of sexual drives, treatment of comorbid conditions such as anxiety or depression, CBT, group therapy, aversive behavioral conditioning, and dynamic psychotherapy.

Prison is an external control mechanism for sexual crimes (e.g., pedophilia) that usually does not contain a treatment component. Institutionalization at a rehabilitation center exerts external control plus treatment elements.

The use of antiandrogenic agents is usually limited to the treatment of criminal paraphiliacs (e.g., pedophiles or exhibitionists). Antiandrogens such as cyproterone acetate, which is used in Europe, and medroxyprogesterone acetate, which is used in the United States, may decrease paraphilic behavior by decreasing serum testosterone levels to subnormal concentrations. These agents decrease the sex drive but do not alter the paraphilic fantasy that propels deviant sexual behavior. Serotonergic agents (such as Prozac) have been used with limited success in treatment of paraphilias (7,27).

CBT is used to disrupt learned paraphilic patterns and modify sexual behavior. The technique seems most effective when used in the context of group therapy, although it can also be utilized in individual therapy. The interventions include social skills training, sex education, cognitive restructuring (confronting and destroying the rationalizations used to support the victimization of others or to support the acceptability of the paraphilia), and development of victim empathy. Imaginal desensitization, relaxation techniques, and learning what triggers the paraphilic impulse so that such stimuli can be avoided are also taught. Aversive techniques include imagining or seeing pictures of paraphilic behavior and concurrently being exposed to or imagining noxious stimuli

such as foul odors or vomiting (40,41). In modified aversive behavior rehearsal, patients are videotaped acting out the paraphilia with a mannequin. The patient is then confronted by a therapist and group members who ask questions about feelings, thought and motives associated with the behavior, and repeatedly try to correct cognitive distortions or point out lack of victim empathy (31).

Insight-oriented psychotherapy is particularly helpful to patients with comorbid anxiety disorders, mood disorders, or personality disorders. With this approach patients have the opportunity to understand their dynamics and the events that caused the paraphilia to develop (42). In particular, they become aware of the daily events that cause them to act on their impulses (e.g., fantasized or real rejection). Treatment helps them deal with life stresses better and enhances their capacity to relate to a life partner. Psychotherapy also allows patients to regain self-esteem, which in turn allows them to approach a partner in a more normal sexual manner. Sex therapy is an appropriate adjunct to treatment of patients who suffer from specific sexual dysfunctions when they attempt nondeviant sexual activities.

A poor prognosis for paraphilias is associated with an early age of onset, a high frequency of acts, no guilt or shame about the act, and substance abuse. The prognosis is somewhat better when patients have a history of coitus in addition to the paraphilia and when they are self-referred rather than referred by the legal system.

THE RECOVERY PROCESS

The recovery of a sex addict is a complicated, long-term process. It has been described by clinicians and researchers in terms of phases of recovery and in terms of behavioral and characterological changes seen through the spectrum of time. The phases that are defined include: recognition of the addictive problem; intervention with the aim of behavior modification; a period of stabilization that involves abstaining from addictive behavior and dealing with the affects that result from withdrawal from the addiction as well as the affects that are no longer masked or avoided by compulsive sexuality. Later phases of recovery involve focusing on underlying developmental issues including abuse, family-of-origin issues, and dealing with shame and unresolved grief. Recovery also requires addressing work, marriage, and family issues that may have arisen as a result of the addict's behavior. Relapse prevention is a necessary component throughout the recovery process (24).

Treatment methods can overlap and they can be utilized synchronously. As a rule directive, educative, chemical, and behavioral approaches such as didactic material about sex addiction, pharmacotherapy, and behavior therapies are utilized in the early phases of therapy. Psychodynamic psychotherapy that focuses on the healing of early wounds and trauma and includes goals of character change, the development of new values, and increased self-esteem is utilized in later phases of recovery, although CBT can be used for these purposes as well. Twelve-step programs are part of the therapeutic

regimen throughout recovery; first for support and guidance in stopping addictive behavior, and later as a method of continued support and relapse prevention.

Stages of progress also can be defined when the patient's improvement is measured against the parameter of time in recovery. The first year is a tumultuous one for most recovering addicts. Relief at having recognized the problem and having determined to address it is significant. However, the person experiences anxiety about life without addiction, a sense of loss, and accompanying feelings of numbness, confusion, and an inability to concentrate, as well as painful physical feelings associated with withdrawal. Most slips in behavior occur in the second 6 months of the first years of recovery. During this time, patients grasp the damage that their sexual behavior has wrought in their lives. Also, without the defense of addiction, they re-experience the pain of early developmental abuse or neglect. These emotions may push them back into destructive behavior patterns. In addition to lapses, accidents and illnesses occur frequently. This is a challenging time for the recovering addict. Nonetheless, most patients report feeling better than they did before they entered therapy.

The second and third years represent a stage of greater stability for the patient. With addictive behavior under improved control, the patient focuses on psychological restructuring through family, couple, and/or individual psychodynamic psychotherapy. Belief systems about self, sex, family, and values are reshaped. This work is reflected in improvements in the patient's ability to cope with stress, improved self-esteem, greater productivity at work, the deepening of bonds with others, and the assumption of more responsibility in both work and personal areas, including the realms of finance and health. Patients also report an increased sense of spirituality.

Beyond the third year the patients feel increasing confidence in their base of recovery and devote substantial energy to their relationships. Connections with partners, family, and friends go through a period of renewal. There are some cases where relationships with family of origin cannot be restored (usually because these families continue to be destructive), or where a marriage cannot survive the recovery process. For the most part, relationships improve substantially, including the development of a healthier expression of sexuality. In studies of this stage, addicts report expressing more compassion for themselves and others, and they experience a new sense of trust in the integrity of relationships. Not surprisingly, patients report a dramatic increase in overall life satisfaction.

Fortunately, the brain demonstrates plasticity, allowing persons the possibility of adapting and growing throughout their lives. This characteristic permits therapy for sex addiction to be effective and allows the patient to recover from his or her addiction (30). However, the emotional programming of the earliest years of life, when the developing brain is laying down synaptic patterns, has the greatest effect on a person. If, as is the case with most addicts, early development was hurtful and neglectful, the recovered addict will remain more vulnerable to life's vicissitudes than a normally nurtured person. That is why we speak of the treated addict as recovered, not

cured. He or she has to remain vigilant about relapsing into addictive behavior. Lifetime attendance at 12-step meetings (though with less frequency than is necessary at the onset of treatment) provides the addict with support to maintain recovery. Cognitive-behavioral techniques such as recognizing personal triggers for addictive behavior, avoiding tempting situations, and rehearsing corrective responses to small slips before they become full-blown relapses also are effective in relapse prevention. Similarly, developing an awareness of feelings of excessive stress, or developing an awareness of affects of depression or anxiety can precipitate seeking support through renewed participation in psychotherapy, use of medication, or by reaching out to sponsors.

A poor prognosis in sex addiction is associated with early age of onset, the presence of multiple addictions, a high frequency of hypersexual behavior, and an absence of anxiety or guilt about the behavior. A more favorable prognosis exists when the patient has a stable work life, good intelligence, the absence of nonsexual antisocial personality traits, and the presence of a successful adult attachment. As in therapy in general, the capacity for insight and a strong motivation to change augur a successful outcome. In spite of continued hypersensitivity to emotional stress, and vulnerability to relapse, the recovered addict can lead a productive life that includes an intimate sexual relationship and rewarding connections to others.

INTRODUCTION

A bulletin board flyer on Internet addiction posted in 2009 at Harvard's Science Center indicated that over 20% of Harvard undergraduate students report that computer or Internet use interferes with their academic performance, listed signs and symptoms of Internet addiction, and described how students could receive treatment for this condition. In South Korea, Internet addiction is considered one of the nation's major public health problems (1,2). In China, where medical experts report an epidemic of adolescent Internet addiction, involving one out of every eight youth, a total of approximately 10 million teenagers, concern about this problem led to the passage of laws in 2007 discouraging more than 3 hours of Internet use per day for playing games (2). Moreover, China is expected to become the first nation to recognize Internet addiction as a distinct disorder despite ongoing controversy about whether it merits a separate designation as a mental illness (3).

These examples illustrate that throughout the industrialized world, despite the enormous positive changes to society resulting from the Internet and other forms of electronic communication in the last 20 years, a small proportion but large number of users have experienced excessive and/or problematic involvement with these media, often associated with significant psychopathology. Although much needs to be learned about these phenomena and considerable debate exists among experts as to whether inappropriate applications of electronic media should be considered disorders in their own right, what is indisputable is that there are millions of individuals worldwide whose problematic use of these media is associated with significant psychopathology, clinical distress, and functional impairment. Mental health professionals, schools, and national governments have been inundated with the challenges of having to deal with the problems presented by such individuals, and the costs to society in lost productivity, increased morbidity, and rarely, cases of mortality resulting from the complications of Internet addiction, the most widely used term to describe these pathologic symptoms and behaviors, have been staggering. The recognition that mental health professionals are interested in this topic and are eager for information on how to properly diagnose and treat these syndromes is reflected by an emerging professional literature on topics related to Internet addiction and the fact that multiple journals such as *CyberPsychology and Behavior* and *Computers in Human Behavior* now exist, which feature research on understanding the impact of the Internet on behavior, human development, and society.

This chapter will review what is known about the clinical features of Internet addiction, beginning with a review of the relatively short history of these phenomena, how Internet addiction has come to be defined, and what is known of its epidemiology, which, for purposes of this review, will include all new types of electronic communication including not only use of the Internet but also texting, other uses of cell phones, and external device-mediated computer games, among others. This overview will show that, regardless of how one conceptualizes Internet addiction, these phenomena are associated with significant public health problems throughout the world.

Although excessive and problematic use of the Internet is most commonly labeled as an "addiction," many experts, notably those in the area of substance abuse and dependence, dispute the validity of labeling this syndrome as an "addiction." To put these concerns in context, we will examine the sparse literature that supports or refutes claims that patients with Internet addiction exhibit classic features of substance dependence such as tolerance, tachyphylaxis (the need for increasing dose to achieve the same effects) and withdrawal. In this regard, we will also describe current debates concerning whether Internet addiction might be better conceptualized as an impulse-control or compulsive disorder rather than as an addiction. In examining what is known about the determinants of Internet use in those with these syndromes and the extent to which these factors resemble and differ from those associated with other psychiatric disorders and syndromes like substance dependence, we will specifically consider neurobiologic and environmental factors.

We next review comorbid conditions frequently seen with Internet addiction. Here we grapple with the nosological confusion that surrounds various conceptualizations of Internet addiction as a "disease" process. Should Internet addiction be considered a disorder in its own right or primarily as a manifestation or symptom of another comorbid condition? For example, are individuals suffering from addiction to pornography on the Internet suffering from Internet addiction per se or using the Internet as a medium, the way a marijuana smoker uses a pipe, primarily to gain access to the substance or activity to which they are fundamentally addicted, that is a "pornography addiction"?

We then describe current evaluation techniques for these syndromes and review the very small research literature on treatment before offering our own recommendations on how to approach the evaluation and treatment of those suffering from Internet addiction. We conclude by discussing debates

regarding Internet addiction as a possible diagnostic entity in the *Diagnostic and Statistic Manual* (DSM) and by suggesting areas for future research that can better clarify Internet addiction's status as a potential disorder and lead to its more successful identification and treatment.

HISTORY AND DEFINITION

As technological advances for delivering content to a mass media have evolved, so have concerns for unintended psychological consequences resulting from these advances. For example, a 1927 article warned that radio was detrimental to listeners, who would no longer congregate and be gregarious (4). In 1954, Meerloo raised concerns that the new medium of television could have addictive properties (5), and a 1981 article first described "computer addicts" as compulsive computer users on college campuses, postulating that such users spent so much time on computers that their grades plummeted, their relationships suffered, and some even had health problems (6). The term "Internet addiction" has been attributed to Dr. Ivan Goldberg, a psychiatrist who in 1995 first proposed it as a hoax in order to parody the Diagnostic and Statistical Manual, 4th Edition (DSM-IV) (7). The fact that the term has been so extensively adopted reflects that it has captured a commonly held perception about a cultural development.

But when the "Information Superhighway" emerged and became increasingly accessed by the general population in the 1990s, Kimberly Young was the first serious investigator to actually coin the term "Internet addiction" in referring to what she believed to be the emergence of a new psychiatric disorder resulting from the problematic use of this new medium (8). She indicated that those with this syndrome had "a preoccupation with the Internet, an inability to control Internet use, and restlessness or irritability when attempting to cut down on Internet use" (9). Accordingly, most experts have credited Young as the first person to use the term "Internet addiction" as the name for these phenomena (8). Her 1996 presentation to an American Psychological Association meeting regarding Internet addiction, later published as an article (9), and her subsequent writings on the subject stimulated tremendous interest in this area (10,11). Other less commonly used terms for this syndrome and related problematic use of other electronic media have included "computer addiction" (12,13), "problematic Internet use" (14), and "compulsive Internet use" (15).

Generally, the term "Internet addiction" is most commonly used to describe a variety of dysfunctional behaviors involving computer use, even if the Internet per se is not being accessed (16). However, some have cautioned against using a single label to describe a complicated array of behaviors that is just beginning to be understood (17).

Nevertheless, because of its widespread use and recognition among both professionals and the lay public, we will use the term "Internet addiction" throughout this chapter to describe problematic use of all types of new electronic media developed for the general public in the last 20 to 30 years. It should be noted, however, that an increasing number of experts have argued for either broadening its definition to one

that does not presume any specific etiology or changing its name to one that better describes the full range of activities implied by the use of the label "Internet addiction". As cited by Pies, one definition of Internet addiction that does not imply any specific etiology and is consistent with the growing consensus of how to describe these phenomena is "the inability of individuals to control their Internet use, resulting in marked distress and/or functional impairment in daily life" (18,19). A more accurate term proposed by Pies, in an effort to reduce stigma and be more inclusive in describing the problems exhibited by individuals using the full range of electronic media, is "pathological use of electronic media" (PUEM) (18).

EPIDEMIOLOGY

General Population

According to Internet World Stats, a website that measures Internet usage with data supplied from the Nielsen Company and U.S. Census Bureau, 74% of the population of North America (in excess of 250 million people) were Internet users in the Spring of 2009 (20). These data suggest that even if prevalence rates for Internet addiction were small, the number of affected individuals would be quite large. The true prevalence of Internet addiction is difficult to ascertain since such great variability exists in diagnostic definitions, sampling methods, and other aspects of epidemiologic study designs (16). While more than a dozen studies have been published that address the prevalence of Internet addiction, most study samples have been restricted to a narrow demographic and/or geographical area and generally focus on students or other young people. Other studies with big sample sizes that have not oversampled young people have been criticized for gathering data exclusively online (17). Examples of these types of studies include one of the personal computer users between the ages of 16 and 24 years (so called "Net-geners") from Hong Kong, reporting that almost a third of the sample met criteria for Internet addiction (21). In China, estimates suggest that from 5 to more than 10 million of the country's 300 million Internet users have "Internet addictions" and that adolescents are especially vulnerable (2,22). Two studies from Iran yielded markedly different findings, with one study of high school students indicating a 3.7% prevalence rate of Internet addiction (23) while another, based on a sample of Northern Iranian Internet users, reported a 22.7% rate (24). An online UK study involving more than 300 university students reported an 18% prevalence rate of Internet addiction (25).

Data regarding gender differences in Internet addiction are also mixed with most studies finding a higher prevalence of affected males (26,27). In the Hong Kong-based "Net-geners" study noted earlier, however, more females than males were found to be addicted (21).

Methodologically, two studies stand out as being community based and reasonably representative, offering epidemiologic data regarding Internet addiction in the general populations of the United States and Western Europe. The first is a 2006 telephone survey of 2513 randomly selected representative U.S. adults (28). The authors employed four different symptom

criteria sets for their analyses. In this sample, Internet addiction ranged from 0.3% to 0.7% depending on which criteria were used. Of note, persons under the age of 18 were excluded from participating in the study. The authors did not report gender data.

The second, a 2009 study, reported data obtained from a random and representative sample of the adult population of Norway (29). The sample contained almost 3400 people between the ages of 16 and 74, of whom 87% indicated they were Internet users. In this sample, 1% of the subjects met criteria for Internet addiction. Male gender and young age were found to put respondents at highest risk for Internet addiction; 4.1% of men aged 16 to 29 were addicted to the Internet compared to only 1.7% of women in the same age group. The percentage of men meeting criteria for at-risk Internet use jumped to almost 20% for young men aged 16 to 29.

A cautious interpretation of these studies suggests that the general population prevalence of Internet addiction may be approximately 1%, that it affects more males than females, and that it tends to be found predominantly in younger people.

Children and Adolescents

Numerous cross-sectional studies have been published regarding the problematic use of electronic media in children and adolescents. Studies of these age groups are important because today's generation of youth is the first to be raised with extensive exposure to such technologies and, collectively, spend considerably more time than adults using the Internet and other electronic media for social interaction and other types of activities. Given the recent advent of these technologies, there has been little opportunity for longitudinal research examining how their widespread uses affect normal childhood development and the risk for Internet addiction, other psychopathology, and long-term functional impairment not only in the general pediatric population but also on vulnerable youth already suffering from or at elevated risk for psychiatric illness.

Video game use has become a major focus of study, given the increasing amount of time devoted to it by youth in recent years and concerns about the potential adverse impact of violent video games as well as the risk for "addiction" to playing these games (30,31). The first published study of the prevalence of video game addiction based on a large, national sample of youth representative of the general population employed an online survey methodology and criteria for problematic video game use based on DSM-IV criteria for pathologic gambling (31). The sample included 1178 youth between the ages of 8 to 18. Approximately 88% of the sample played video games at least some of the time. Approximately 8.5% met criteria for pathologic use of video games, and those receiving this diagnosis achieved significantly worse grades in school and had significantly higher rates of attention problems than those not found to be ill. In recent years, text messaging on cellular phones has also exploded in popularity among teenagers, raising concerns about its impact on youth. According to the Nielson Corporation, in the fourth quarter of 2008 teenagers sent an average of 2272 text messages per month, close to 80 per day, a doubling of the average from just 1 year earlier (32).

Phenomenology

In recent years researchers worldwide have variably described the symptoms of Internet addiction, resulting in multiple definitions, each with its own specific diagnostic criteria. Most include some combination of excessive and/or inappropriate use of the Internet or other electronic media associated with clinical distress and functional impairment. A major challenge in defining the syndrome has been the problem of conceptualizing exactly what types of disorders Internet addiction may represent.

Much of the debate concerns disagreement surrounding whether to label Internet addiction as a disorder in its own right as opposed to considering it to be just one manifestation of another, more inclusive disorder. Among those who advocate for Internet addiction to be included as a separate disorder in DSM-V, some propose that it is best viewed as akin to disorders of substance dependence, whereas others argue that it more closely resembles an impulse-control disorder. In fact, as described below, some of the diagnostic criteria for Internet addiction have been based on those for pathologic gambling, a DSM-IV impulse-control disorder that is often also referred to as a prototype of a "behavioral addiction," accompanied by psychologic withdrawal symptoms such as irritability and agitation, suggesting that the clinical features of impulse-control disorders and substance dependence may overlap to at least some degree. Notably, some of the most heated opposition to labeling Internet addiction as a type of "addiction" resembling that seen with substance dependence comes from substance dependence experts. Based on the limited research to date, they argue that insufficient evidence of physiologic markers of intoxication and withdrawal in individuals with Internet addiction renders problematic characterizations of Internet addiction as a true addiction (18).

These distinctions are important because they focus on the fact that Internet and computer use per se is generally not the end purpose of excessive users. Most Internet addicts demonstrate high specificity in the activities in which they become overinvolved, ranging from social involvements, problem solving, novelty seeking, information gathering, shopping, day trading, video gaming (including those with violent themes), and sexual stimulation and gratification, to name just a few. Lumping together all those who spend excessive hours online, such as Internet gamblers; Internet shoppers; Internet pornography addicts; lonely-hearts seekers on dating services; Wikipedia contributors; Second-Life participants; social-networkers; bloggers; texters; users of gaming consoles, Wii, bridge, or chess players; and those finding a myriad of other Internet-mediated activities to become preoccupying, may cause researchers to miss the trees for the forest. The Internet may simply serve as a common pathway and conduit through which all these individuals can more easily access their routes to a variety of "individual behaviors of excess." (33)

Nevertheless, taking into account the variable definitions of Internet addiction, as described in more detail later in this chapter, reports of impairment as a result of excessive Internet use indicate that these syndromes exact a high cost on individuals and society. There is considerable data showing that Internet addiction is associated with substantial functional impairment in affected individuals worldwide and in all age groups (1,31).

TABLE 27.1 Young's Diagnostic Questionnaire for Internet addiction^a

- 1) Do you feel preoccupied with the Internet (think about previous online activity or anticipate next online session)?
- 2) Do you feel the need to use the Internet with increasing amounts of time in order to achieve satisfaction?
- 3) Have you repeatedly made unsuccessful efforts to control, cut back, or stop Internet use?
- 4) Do you feel restless, moody, depressed, or irritable when attempting to cut down or stop Internet use?
- 5) Do you stay online longer than originally intended?
- 6) Have you jeopardized or risked the loss of significant relationship, job, educational or career opportunity because of the Internet?
- 7) Have you lied to family members, therapist, or others to conceal the extent of involvement with the Internet?
- 8) Do you use the Internet as a way of escaping problems or of relieving a dysphoric mood (e.g., feelings of helplessness, guilt, anxiety, depression)?

^aEndorsing five or more items results in classification as an addicted Internet user.

Evolution and Development of Diagnostic Criteria for Internet Addiction

The first formal attempt to establish identifying symptoms for addiction to the Internet was proposed by Young who in 1998 (9) modified the pathologic gambling criteria from the DSM-IV to develop an eight-item questionnaire that has been widely used to screen for Internet addiction (Table 27.1). After gathering data from clinicians who had treated the condition, Young et al. (34) in 1999 further delineated and proposed several subcategories of Internet addiction:

1. Cybersexual addiction: Compulsive Internet use to access pornographic material.
2. Cyber-relationship addiction: Maintaining online relationships to excess.

3. Net compulsions: Compulsive online gambling, shopping, or online trading.
4. Information overload: Excessive website surfing or search engine use.
5. Computer addiction: Using the computer to play games compulsively.

Young's criteria (9) have been criticized by Beard and Wolf (35), who noted that they are weighted too heavily on self-report and could also be applied to other behaviors that would appear to be more consistent with an impulse-control disorder rather than a true addiction. They also argue that Young's diagnostic criteria lack items that account for functional impairment secondary to the addictive behavior. Accordingly, Beard and Wolf (35) in 2001 expanded Young's criteria by adding three additional criteria (Table 27.2). These additional criteria

TABLE 27.2 Beard and Wolf's diagnostic criteria for Internet addiction

All of the following must be present:

- 1) Is preoccupied with the Internet (think about previous online activity or anticipate next online session).
- 2) Needs to use the Internet with increased amounts of time in order to achieve satisfaction.
- 3) Has made unsuccessful efforts to control, cut back, or stop Internet use.
- 4) Is restless, moody, depressed, or irritable when attempting to cut down or stop Internet use.
- 5) Has stayed online longer than originally intended.

At least one of the following:

- 1) Has jeopardized or risked the loss of a significant relationship, job, educational or career opportunity because of the Internet.
- 2) Has lied to family members, therapist, or others to conceal the extent of involvement with the Internet.
- 3) Uses the Internet as a way of escaping from problems or of relieving a dysphoric mood (e.g., feelings of helplessness, guilt, anxiety, depression).

TABLE 27.3 Shapira et al. diagnostic criteria for problematic Internet use

- A) Maladaptive preoccupation with Internet use, as indicated by at least one of the following:
- 1) Preoccupations with use of the Internet that are experienced as irresistible.
 - 2) Excessive use of the Internet for periods of time longer than planned.
- B) The use of the Internet or the preoccupation with its use causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.
- C) The excessive Internet use does not occur exclusively during periods of hypomania or mania and is not better accounted for by other Axis I disorders.

tap functional impairment due to Internet use, deceptive behavior regarding use of the Internet, and going online as a means of escape from problems or mood disturbance.

Shapira et al. (14) argued that both Young's and Beard and Wolf's sets of diagnostic criteria are inadequate. These authors conceptualize the phenomena as "problematic Internet use" (14). They also consider Internet addiction to be more closely aligned with impulse-control disorders than with an addiction per se. To that end, Shapira et al. proposed

a third set of criteria that identified problematic Internet use modeled on impulse-control disorders found in the DSM-IV-TR (Text Revision) (Table 27.3).

Several investigators have published psychometric instruments to assess Internet addiction (Table 27.4). Young developed the Internet Addiction Test (IAT) (11), a 20-item instrument, based on her original criteria. Subjects rate their Internet use and its consequences on a Likert scale. Most other instruments employ self-rated scales. We are unaware of any

TABLE 27.4 Psychometric instruments used to identify Internet addiction

References	Instrument	Number of items	Theoretical framework
Meerkerk et al. (15)	Compulsive Internet Use Scale (CIUS)	14	Conceptual underpinnings include DSM-IV criteria for substance dependence, pathologic gambling; behavioral addictions; compulsive Internet use
Caplan (36)	Generalized Problematic Internet Use Scale (GPIUS)	39	Based on cognitive-behavioral theoretical framework of Internet addiction; incorporates items from other instruments

commercially available measures of Internet addiction. Major drawbacks to the use of such instruments include the lack of a “gold standard” due to considerable disagreement regarding specific criteria for Internet addiction and the lack of generally accepted theoretical underpinnings for such a disorder. Indeed, one might heed the admonitions of Beard (43), who suggested that Internet addiction is best detected by a thorough clinical interview.

Determinants of Internet Use—Several features distinguish Internet use from that of other activities and from substance use that can evolve into an addiction: (a) Internet use offers a mechanism for accessing information and for various types of interactive activities, both constructive and maladaptive, and (b) Internet use constitutes an essential part of normal existence in the modern world. For those reasons, it is difficult to disentangle the extent to which spending large periods of time on the Internet represents evidence of a disorder specific to this medium, evidence of other mental illnesses, or simply variants of normal behavior. That is, how much “wheel spinning” or how many nonproductive activities manifesting distraction from primary tasks occurs when the individual is presumably engaged in an Internet-mediated functional activity is important to measure in determining whether use of such media is abnormal. Fortunately, recognizing this potential confound and the fact that, for many youth and adults, academic and occupational success is contingent on spending enormous amounts of time on the Internet, some researchers have controlled for this variable and still found that problematic Internet use is independently associated with functional impairment regardless of the amount of time engaged in a particular activity (31). Nevertheless, in contrast to syndromes of substance dependence where objective, physiologic evidence of tolerance and withdrawal can be noted with specific levels and duration of consumption, such signs and symptoms are neither as clear cut nor have they been systematically studied in Internet-related addictions.

Etiology and Predisposing Factors

Since intense debate exists about whether Internet addiction should even be considered a disorder, it is not surprising that no single cause has been identified (apart from the contributing factor of access to the Internet). However, as with most psychiatric disorders, etiologic factors are thought to be multifactorial (16).

Psychological Theories

Cognitive-Behavioral Theory—Several investigators have suggested that compulsive use of the Internet provides ultimately dysfunctional and ineffective methods for regulating negative emotions related to cognitions associated with low self-esteem and self-critical thoughts. Despite the short-term emotional alleviation and distraction, longer-term negative consequences include worsening relationships and poor school or work performance. This pattern then fuels a vicious cycle in which worsening self-esteem and poorer self-appraisal lead to further maladaptive use of the Internet,

culminating in social withdrawal and greater exacerbation of the psychopathology that led to excessive Internet use in the first place (44).

Social Skills Deficit Theory—Caplan (45) and others, as summarized by Shaw and Black (16), postulate that individuals with poor social competence who may also be anxious about social interactions are drawn to the anonymity of the Internet and the opportunities it affords for developing relationships in less threatening circumstances than those occurring face-to-face. Additionally, individuals have greater control regarding their self-presentations and their ability to construct more favorable images for those they may be trying to impress. While this feature of Internet-mediated communication may help depressed or socially anxious individuals overcome social inhibitions, it may also potentially contribute to an avoidance of true intimacy.

Family History—Little research exists in this area. In one small study, all but one of 20 individuals with problematic Internet use had a positive family psychiatric history (46). In this sample, depression was present in at least 65% of first- or second-degree relatives; 50% of relatives had bipolar disorder; and 60% had substance dependence. Unfortunately, no inquiry was made as to whether any relatives suffered from problematic Internet use.

NEUROBIOLOGY

Although research in this area is in its infancy, initial reports have revealed neurobiologic differences between individuals with Internet addiction and nonaffected controls. Many of the reported findings resemble those found in individuals suffering from substance dependence. For example, one preliminary study using position emission tomography showed evidence for release of striatal dopamine release resulting from video game playing (47). In addition, the dopamine D2 receptor gene allele polymorphism, *DRD2 Taq1A1* was found more frequently among 79 adolescents who played video games excessively compared to 75 normal controls (48,49), a potentially significant finding in that this allele has been hypothesized to increase vulnerability to addictive behaviors and, for example, is more prevalent in adults with methamphetamine dependence than in controls (50).

Preliminary research has also linked excessive Internet use in adolescent males with the homozygous short allelic variant of the serotonin transporter gene (*SS-5HTTLPR*), a genetic polymorphism previously associated with vulnerability to depression. In addition, compared to controls these adolescents scored higher on the Beck Depression Inventory, suggesting that they may have genetic characteristics and clinical features similar to those suffering from depression (51).

ENVIRONMENTAL FACTORS

Several investigators have found associations between family dysfunction and adolescent Internet addiction. In one South Korean cohort, for example, exposure to “violence” between parents or being a victim of “violence” perpetrated by the

parent was associated with adolescent Internet addiction (52). Similarly, a Chinese study of middle school students found strong associations between a history of physical abuse and meeting criteria for Internet addiction (53). In a study of almost 9000 Taiwanese adolescents, low family monitoring, low feeling of connection to school, high family conflict, having friends who were habitual alcohol drinkers, and living in a rural community were each associated with an increased likelihood of meeting criteria for Internet addiction (54). Among Chinese University students, being from a single-parent family and homesickness were associated with Internet addiction (55). Of course, access to the Internet is a significant environmental factor: in a cohort of almost 900 Greek adolescents, having access to the Internet at home and accessing the Internet to play games were predictors of Internet addiction, especially among males (56).

Pre-existing and Concurrent Psychiatric Comorbidities—

In a 2-year prospective study of 2293 Taiwanese adolescents (1179 boys and 1114 girls), hostility and attention-deficit hyperactivity disorder (ADHD) were found to be the leading risk factors for the occurrence of Internet addiction among males and female adolescents, and depression and social phobia predicted Internet addiction among female, but not male, adolescents (57). Several cross-sectional studies have shown that comorbidity is the rule rather than exception in individuals with Internet addiction. Block (2) has estimated that as many as 86% of patients with Internet addiction demonstrate at least one comorbid psychiatric condition, with many individuals suffering from multiple disorders. Those most commonly noted include mood disorders, anxiety disorders, impulse-control disorders, substance dependence, and ADHD (16,49). In China, which is experiencing an epidemic of Internet addiction, 30% of those diagnosed with Internet addiction have concurrent significant anxiety or depression, and 30% have ADHD (58).

Additional Complications—Abundant evidence suggests that individuals identified as suffering from Internet addiction and related disorders frequently suffer from significant psychiatric and medical complications. In 2006 the Korean government estimated that among the estimated 210,000 South Korean children and adolescents between the ages of 6 and 17 suffering from Internet addiction, about 80% required psychotropic medication and one fifth to one quarter required hospitalization (1,2). In fact, a major impetus in South Korea for identifying Internet addiction as a major public health problem was the report of 10 deaths resulting from cardiopulmonary causes, such as thromboembolism, occurring in Internet cafes among young healthy men who had played for more than 16 consecutive hours (2), and, in one case, a total of 80 hours (59). The increasing occurrence of this variant of thromboembolism has led to its being labeled “e-thrombosis” (60).

Sleep deprivation is another adverse consequence of excessive use of electronic devices. Among 100 adolescents 12 to 18 years of age, increased time using different forms of electronic devices after 9 PM significantly correlated with decreased sleep, increased consumption of caffeinated

products, and greater risk for daytime sleepiness, including sleepiness in the classroom (61). By means of a multitasking index devised to measure the amount of time teens spent engaged using various electronic devices including watching TV after 9 PM, being online, talking on the phone, listening to an MP3 player, text messaging, and playing computer games, the majority of the sample reported engaging in at least one activity, with the average using four electronic devices. The total average daily time spent using electronic devices was 5.3 hours. Teens getting 8 to 10 hours of sleep on school nights, considered optimal for teenagers, spent significantly less time using electronic devices whereas those sleeping less used these devices 1.5 to 2 times longer. These patterns of reduced sleep in teenagers have been associated with a variety of psychological and physical problems as well as decreased quality of life (61). For additional perspective, in a Chinese study of more than 3000 cases of Internet addiction, 80% of whom were adolescent males, the average amount of time spent on the Internet was 9 hours per day (58).

Numerous social, psychological, academic, and occupational complications of Internet addiction have been identified. In young people, poor academic performance sometimes leading to school failure, disrupted family relationships, and social isolation are among the more common. Other serious functional impairments resulting from problematic Internet use include legal difficulties and job loss (43,62).

Concerns have been voiced that playing violent video games may be associated with increases in violent behavior. This issue became a focus of national concern after the Columbine High School shootings in Littleton, Colorado, when it was learned that the teenage assailants were fascinated by violent video games including one licensed by the U.S. Military used for training soldiers to “effectively kill” (63,64). One representative study examining the psychological and behavioral effects of increasingly graphic violent video games on users found aggressive behavior and delinquency to be positively associated with playing violent video games (65). This association was stronger in previously aggressive individuals and in males, reflecting that psychologically vulnerable individuals and males may be at greater risk to act out violently in real life after engaging in such fantasy activities. In a second study by the same group, exposure to an extremely violent video game produced increases in aggressive thoughts and behaviors (65).

Decreased work productivity has been a major cause of functional impairment in adults with problematic Internet use. One review of this topic reported that one in four employees engage in problematic Internet use and estimated the annual costs to American corporations in lost productivity to range from 1 to 54 billion dollars (66). Because these problems are so widespread, employers at most large public and private institutions have instituted employee Internet use policies to address them.

Most concerning, certain dysfunctional behaviors occurring with electronic devices are associated with increased risks of harm to self or others. The use of cell phones and texting messages while driving results in decreased reaction

time and increased distractibility (67) leading to increased risks of motor vehicle accidents (68). These public health hazards have resulted in the passage by many localities of laws prohibiting hand-held cell phone use while driving. Nevertheless, despite using a methodology thought to underestimate cell phone usage and examining cell phone use only during daytime hours, the National Highway Traffic Safety Administration's 2007 annual survey of cell phone use while driving found significant increases in the use of cell phones and other handheld devices while driving compared to the previous year. At any given time approximately 6% of drivers were using handheld devices and 11% were using either handheld or hand-free devices, representing a total of more than 1 million vehicles at any given moment in which a driver was using a cell phone. The highest frequency of use, 8.8%, occurred in 16 to 24 year olds, an already high-risk group for automobile accidents (69). More disturbingly, a study of driver cell phone use at night found the highest rate of 12% to be among females 16 to 29 years old, much higher than the daytime rate among young people, especially concerning since young drivers are at most risk for having accidents at night (68).

The consequence of these worsening trends has been a public health crisis: a 2003 Harvard study estimated that there are more than 2500 traffic fatalities annually secondary to distractions caused by cell phone use (70). The U.S. Department of Transportation reported that driver distraction, mostly caused by cell phones, resulted in more than a doubling of this number of fatalities in 2008 (almost 6000), accounting for about one sixth of all fatal crashes; additionally, half a million people were injured in car crashes in 2008 as a result of driver distraction primarily caused by mobile phones (71). And research has shown that using a cell phone while driving is as dangerous as driving legally intoxicated with a blood alcohol level of 0.08% (70). Not surprisingly, the National Highway Traffic Safety Administration has officially recommended not using cell phones while driving.

Finally, the potential for exploitation and abuse by others, particularly among young people, is heightened by the increased social networking activities occurring via these media. Examples of situations that can result in unintended tragic ends include unsuspecting victims befriending sexual predators on the Internet and the perpetration of public humiliation, which has led to suicide, in the wake of a recent phenomenon called "sexting" in which typically teenagers send sexually explicit messages to friends on cell phones, sometimes including nude photos of themselves, which may then be maliciously more widely disseminated to others. In one notorious example, a teenage girl who had sent nude photos of herself to her boyfriend while they were dating was deeply humiliated when he subsequently forwarded embarrassing photos to her girlfriends after they broke up. The girlfriends responded by denigrating and "harassing" her, calling her a "slut" and a "whore," leading to her serious depression, school avoidance, and suicide by hanging (72). Notably, up to 20% of teens in surveys report sending or posting nude photographs of themselves (73). Furthermore, even teens who send and receive explicitly sexual messages

about themselves and their friends have been charged and on occasion convicted of disseminating and/or possessing child pornography (73).

EVALUATION AND TREATMENT

Due to ongoing debates about the definition and diagnosis of Internet addiction, no generally agreed-upon standards for assessment exist, nor have any evidence-based treatments been formally tested (16). In contrast to their Asian counterparts, who appear sensitized to the high prevalence of these disorders and routinely screen for them, few American mental health professionals at present seem to consider this syndrome in their differential diagnosis when evaluating patients presenting with other conditions, and few routinely ask about these issues in clinical practice (2).

Nevertheless, various psychosocial treatment programs have been proposed, and numerous Internet addiction treatment counselors and centers have emerged throughout the world. In South Korea, where Internet addiction is viewed as a public health crisis, as of June 2007 more than 1000 counselors had received training for this condition and more than 190 hospitals and centers were available to provide treatment for the syndrome (1,2).

To date most of the treatment literature concerning Internet addiction consists of case reports, case series, and occasional open-label medication trials. In China, treatments employed at the General Hospital of Beijing's Military Region's Addiction Medicine Center (AMC), a major treatment and research center for Internet addiction, have included behavioral training; medication treatment for patients with psychiatric symptoms; dancing and sports; reading; karaoke; and elements of the "12-Step" programs of Alcoholics Anonymous. Family therapy has also been included as an important treatment component. Unfortunately, some notorious treatment programs have also emerged in China. One such program, the Yang Yonxin Center for Internet addiction treatment at Public Hospital Number Four in Linyi, Shandong Province, reportedly used excessive doses of sedatives and prolonged courses of electroconvulsive therapy (ECT) (22).

Escitalopram has shown some promise in treating Internet addiction. After a case report described successful treatment of a condition characterized as severe Internet addiction with 10 mg/day of escitalopram (74), an open-label study was organized involving a sample of 19 adult subjects with "Internet usage disorder," defined as use of the Internet that was time-consuming, uncontrollable, distressing, and causing social, financial, or occupational dysfunction. A 10-week trial of escitalopram, 20 mg today, resulted in significant improvement on the two primary outcomes measures, the Clinical Global Impressions-Improvement scale (CGI-I) and total time spent per week in nonessential Internet activities. At the end of treatment, 64% of subjects were considered CGI-I responders, and weekly time on the Internet was reduced from 37 to 16.5 hours. In a subsequent double-blind discontinuation phase, no differences were found between the two groups; both the escitalopram and placebo groups maintained their improvements (75).

One case report alleged to indirectly support the conceptualization of Internet addiction as an addictive disorder focused on the successful treatment of a patient with “sexual addiction” involving the Internet (76). After a 7-year period during which this patient’s symptoms did not significantly improve following treatments with sertraline, individual therapy, group therapy, and involvement with Sexual Addicts Anonymous, his symptoms subsequently improved significantly following the addition of naltrexone, an FDA-approved treatment for alcohol dependence. In ongoing treatment akin to an ABA design fashion, his symptoms worsened again when the naltrexone was discontinued and improved again when treatment was resumed. Of course, this case raises several key questions: to exactly what was this patient “addicted”? Pornography? The Internet itself? Since the patient’s use of the Internet seemed limited to pornography, it is likely that the Internet primarily served as the vehicle for expressing excessive preoccupation with pornography rather than reflecting an “addiction” to using the Internet per se.

Does Treating Comorbid Conditions Impact Internet Use?

Preliminary studies suggest that problematic Internet use can be reduced through successful treatment of comorbid conditions commonly associated with Internet addiction.

Attention-Deficit Hyperactivity Disorder (ADHD)

An open-label study evaluated the efficacy of stimulant treatment on ADHD symptoms and Internet usage in Korean children, aged 8 to 12, who had ADHD and were video game players (49). One of the study’s aims was to assess whether improvement in ADHD symptoms correlated with a reduction of Internet addiction symptoms, since previous research has shown a high rate of comorbidity between the two syndromes and video game playing has been associated with release of dopamine, one mechanism through which stimulant medications operate. Based on the Korean version of the Young Internet Addiction Scale, YIAS-K, about 50% of the sample met criteria for Internet addiction. At the end of treatment, significant reductions were found for both ADHD and Internet addiction symptoms, and improvements in ADHD symptoms and decreased Internet use (i.e., time spent playing video games) were correlated. Of note, since playing videogames has been associated with improvements both in attention and visual spatial functioning, the authors speculate that video game playing in untreated ADHD individuals may represent attempts at “self-medication.”

Recommendations for Evaluation and Treatment of Individuals with Internet Addiction

For all the reasons regarding the lack of consensus about the nature of these somewhat heterogeneous conditions noted above, highly specific recommendations regarding how to treat this large group of patients are difficult to formulate. With this caveat in mind, in our view it is prudent to use a

flexible, biopsychosocial approach. Of key importance for all general psychiatric and mental health evaluations is that clinicians should routinely inquire about every patient’s use of the Internet, both to assess whether Internet use (and the use of other electronic media and devices) per se poses a major source of distress and impairment and to ascertain if problems associated with Internet use represent manifestations of some other psychiatric disorder requiring treatment. Unlike in Asian countries like China, Korea, and Taiwan where routine screening for Internet addiction is now commonplace, contemporary American psychiatrists appear to not routinely inquire about Internet use, and, as a result, many Americans with Internet addiction go undetected. In addition, the diagnosis of comorbid conditions associated with Internet addiction is delayed when questions about Internet use are omitted, since the primary manifestation of the comorbid syndrome, for example addiction to pornography, may be mediated only by activity on the Internet.

A good quality assessment includes asking the patient to describe and quantify how much he or she uses the Internet and other electronic media and whether the patient or family members feel that the patient’s use is a problem that interferes with relationships, school, and/or work. The inquiry should also investigate the various types of electronic activity in which the individual engages and the patient’s perception of what attracts him or her to using the Internet and other electronic media and the needs that such use seems to satisfy, in order to assess whether the patient uses the Internet and e-media as a vehicle for expressing clinically concerning preoccupations and urges, for example, cravings for violence manifested by playing violent video games, which may in turn lower inhibitions against behaving violently in the real world. For depressed individuals, “surfing the Net” or playing videogames may be a manifestation of social withdrawal related to difficulties coping with painful life circumstances. For shy and socially anxious individuals, such use may offer routes for engaging in social interaction in less anxiety-provoking circumstances than face-to-face encounters, but as mentioned above, may deleteriously perpetuate avoidance of more mature intimacy. Also, since Internet addiction has been described as having many features of both addictions and impulse-control disorders, patients should be asked if they experience cravings regarding using the Internet, difficulties resisting impulses to use the Internet, and the extent to which they become extremely irritable, anxious, and/or depressed when forced to stop using it.

The evaluation should also routinely include standard assessments for the major psychiatric disorders, in particular ADHD, mood disorders, anxiety disorders, substance dependence, and impulse-control disorders, all so commonly comorbid with Internet addiction and which frequently lead to it. In addition, assessment for personality characteristics, such as shyness, which place individuals at higher risk for problematic Internet use, should be performed.

A thorough clinical interview and/or the routine use of a screening questionnaire developed for detecting Internet addiction are all reasonable methods for conducting an assessment. Administration of an Internet addiction rating scale can

help determine the severity of impairment and provide a baseline against which to measure response to treatment. Obtaining collateral information from family, school personnel, and friends is necessary to complete an accurate clinical picture and assessment of severity of distress and impairment.

Treatment Approaches—An individualized approach is essential. To start, concrete behavioral interventions, including setting explicit goals for abstinence or for significant reductions of time spent in the dysfunctional activities may help alleviate the difficulties and offer opportunities for reversing the impairments they inflict. Treating common comorbid conditions such as mood and anxiety disorders and ADHD may frequently ameliorate Internet addiction. Interventions that have been efficacious for substance dependence and impulse-control disorders should be considered as well.

Gaining an understanding of the functions that problematic Internet use serve may help lead to successful interventions. For example, depressed individuals may reduce their reliance on the Internet when their mood improves and they have less need to withdraw from others. Particularly with children and adolescents, but with adults as well, addressing family problems that may be fueling the Internet addiction may help alleviate the disorder and may help support treatments to limit the patient's use of the Internet. Concerned family members may also be willing to confront the patient's problematic Internet use and encourage the patient to adhere to treatment.

Finally, outpatient and, recently, residential inpatient facilities devoted to treating this syndrome have appeared and in some locations proliferated. Clinicians dealing with patients presenting with these disorders will wish to learn about their treatment philosophies and other practical aspects of their programs and requirements.

SPECIAL CONSIDERATIONS

Should Internet Addiction Be Included as a Distinct Disorder in the DSM-V?

The debate as to whether Internet addiction should be recognized as a separate disorder in the DSM-V is unsettled at the time of this writing. Advocates for inclusion argue that Internet addiction manifests many of features of substance dependence or of impulse-control disorders (2,9). Detractors note that insufficient research data exists to support Internet addiction's legitimacy as a disorder in its own right at this time (18).

Although concepts of "tolerance" and "withdrawal" have been applied to "Internet addiction Disorder," these have referred only to psychological states. There is as of yet no research linking "cravings" to use the Internet and feelings of irritability that ensue when access to the Internet is denied to identifiable physiologic signs of tolerance and withdrawal in individuals suffering from Internet addiction (18). On the other hand, neurobiologic studies have shown that involvement with the Internet is associated with striatal dopamine release, suggesting links to mechanisms that contribute to the reinforcing effects of illicit drugs (47).

Arguments suggesting that Internet addiction should be conceptualized as an impulse-control disorder have also emerged. The DSM-IV-TR defines impulse-control disorders as conditions in which the major manifestation is "the failure to resist an impulse, drive, or temptation to perform an act that is harmful to the person or others." In addition, affected individuals frequently feel "an increasing sense of tension or arousal before the act and then experiences pleasure, gratification, and relief at the time of committing the act" (77).

Many aspects of the phenomenology of Internet addiction are consistent with this DSM-IV description of impulse-control disorders. Moreover, as summarized by Dell'Osso et al. (62), a DSM-V task force examining the impulse-control disorders for over a decade has considered creating four new disorders currently subsumed under "impulse control disorders not otherwise specified." Under the proposed nosological system, these syndromes would receive the new name of "compulsive-impulsive disorders" characterized by "... the impulsive features (arousal) that initiate the behavior, and the compulsive drive that causes the behaviors to persist over time." (62) The four new disorders identified by the task force are compulsive-impulsive (C-I) Internet usage disorder, C-I sexual behaviors, C-I skin picking, and C-I shopping.

CONCLUSIONS

Excessive and/or problematic use of the Internet and related electronic media has become a worldwide mental health problem of epidemic proportions in industrialized nations, and American pediatricians have raised concerns that Internet addiction might become a "new common chronic disease of childhood" and "major public health problem for the United States in the 21st century" (78). Although further research is needed to better define its boundaries and diagnostic criteria and to assess whether it merits inclusion in the DSM as a distinct disorder, abundant evidence exists that Internet addiction is associated with significant clinical distress, functional impairment, and high rates of comorbidity. In the 21st century, psychiatrists and other mental health professionals must consider this syndrome in the differential diagnosis of their patients' presenting problems and be able to utilize a flexible, biopsychosocial approach in understanding and treating this condition. Well-designed treatment studies of psychosocial interventions and medications are necessary to inform evidence-based practices that can reduce the considerable psychological and economic costs to society imposed by this new but rapidly proliferating syndrome.

Methadone Maintenance

Andrew J. Saxon ■ Karen Miotto

INTRODUCTION

Methadone maintenance is one of the most efficacious and cost-effective interventions in all of modern medicine. This chapter provides a comprehensive overview of methadone treatment for opioid dependence by reviewing the epidemiology, explaining the historical background, summarizing the regulations that govern methadone treatment, and describing the pharmacology and clinical use of methadone. The chapter will then cover a variety of practical issues that arise in the process of delivering methadone treatment in a licensed Opioid Treatment Program (OTP) including nonopioid substance use, management of co-occurring medical and psychiatric disorders, counseling and other behavioral interventions, urine testing, take-home medication, medication diversion reduction, managing problematic behavior, methadone in pregnancy, and medical and interim methadone maintenance.

EPIDEMIOLOGY AND HISTORY

During the early years of the 21st century, the purity of heroin sold in the United States generally remained higher than in previous decades, contributing to an increase in heroin-related emergency department visits from 33,900 in 1990 to 189,780 in 2006. Heroin users exhibit mortality rates 6 to 20 times those of age-matched populations (1,2). The past decade has also seen a surge in the illicit use of prescription opioid medications. In 2006, the number of emergency room visits related to nonmedical use of prescription opioids exceeded the number for heroin. Large numbers of overdoses on prescription opioids have also been noted. In 2007, as many people abused OxyContin in the past month (0.3 million) as used heroin, and 5.2 million abused some type of pain reliever (primarily hydrocodone and oxycodone) in the past month.

Methadone maintenance, available in the United States since the 1970s, is one of the primary treatment modalities for this burgeoning epidemic of opioid dependence. From 1919 until 1972, a ruling by the U.S. Supreme Court disallowed physicians from prescribing opioid medications to opioid-

dependent individuals for “maintenance” purposes. The federal methadone regulations (21 CFR Part 291) promulgated in 1972 and the Narcotic Addict Treatment Act of 1974 created the current regulatory system for methadone maintenance, which allowed prescribing of methadone to opioid-dependent patients through OTPs, which follow specific federal regulations and are licensed by both federal and state authorities. The Food and Drug Administration (FDA) and the Drug Enforcement Agency (DEA) oversaw these OTPs until 2000. The federal regulations governing methadone-maintenance treatment were amended slightly in 1980 and again in 1993. The changes in 1993 allowed the use of levo-alpha acetyl methadol (LAAM, which has not been manufactured nor available since 2003) and mandated counseling on preventing exposure to and preventing transmission of human immunodeficiency virus (HIV).

The federal regulations were altered once again in 2001. The oversight by FDA was discontinued, and the authority passed to the Center for Substance Abuse Treatment of the Substance Abuse and Mental Health Services Administration within the Department of Health and Human Services (42 CFR Part 8). In addition, these new regulations required triennial accreditation of all licensed OTPs by approved accreditation organizations. Finally, the 2001 regulations permitted more latitude in provision of take-home medications, allowing a maximum of 30 take-home doses of medication for stable, long-term patients. In 2003, the regulations again were slightly amended to allow the dispensing of buprenorphine and buprenorphine/naloxone through licensed OTPs.

Methadone treatment has undergone considerable expansion in the United States. In 1988, 650 programs treated about 100,000 patients. As of 2009, over 1200 programs existed. In 2007, 265,217 patients were treated in OTPs, the vast majority with methadone. Licensed OTPs are situated in every state in the United States except North Dakota, South Dakota, and Wyoming. Methadone treatment for opioid dependence has spread worldwide, and methadone and buprenorphine were included in the 2005 World Health Organization List of Essential Medications.

FEDERAL OPIOID TREATMENT STANDARDS GOVERNING METHADONE TREATMENT

These regulations are readily and publicly available, and only the key points will be summarized here.

Administration

Each licensed OTP must have a sponsor responsible for adherence to all regulations and a medical director responsible for administering all medical services. The OTP must maintain quality assurance and quality control plans focusing on patient outcomes and must have a diversion control plan. All staff must be qualified and comply with the credentialing requirements of their respective professions.

Patient Admission Criteria

Documentation of current opioid addiction of at least 1 year's duration is required for admission. These requirements may be waived by a program physician for patients recently released from incarceration or previously treated within the past 2 years in an OTP, or for pregnant patients. Patients under age 18 must have had two prior failed attempts at medically supervised withdrawal and have parental or guardian permission.

Required Services

Adequate medical, counseling, vocational, educational, and other assessment and treatment services must be provided. Each patient must receive a complete, fully documented physical evaluation by an authorized health care professional before admission. Special services for pregnant patients must be available. Each patient accepted for treatment must be initially and periodically assessed by qualified personnel to determine the most appropriate combination of services and treatment including the preparation of a written treatment plan. Programs must provide adequate addiction counseling and when clinically necessary provide counseling and education on HIV transmission and prevention. Programs must obtain at least eight random yearly drug tests for patients in maintenance treatment.

Medication Administration, Dispensing, and Use

Medication must be dispensed by an appropriately licensed health care professional. The only medications permitted for use in licensed OTPs are methadone, LAAM (not currently manufactured), and buprenorphine or buprenorphine/naloxone. The initial dose of methadone cannot exceed 30 mg, and the total dose for the first day cannot exceed 40 mg unless the physician documents that 40 mg did not suppress opioid withdrawal symptoms. The number of allowable take-home doses is specifically dictated by the regulations based on continuous time in treatment and patient stability.

Interim Maintenance Treatment

Interim maintenance treatment is allowable for a maximum of 120 days when patients cannot obtain entrance to comprehensive treatment. Interim maintenance involves daily dispensing of medication with no take-homes and does not require counseling or development of a treatment plan.

EFFICACY OF METHADONE TREATMENT FOR OPIOID DEPENDENCE

Numerous studies over nearly half a century have examined methadone treatment. Evaluating methadone through the most rigorous approach, double-blind, placebo-controlled randomized trials, poses some challenges. Since opioid withdrawal does not show much placebo response, it is difficult to maintain the blind. In addition, methadone has such obvious clinical utility for a condition causing extensive morbidity that the ethics of using a placebo are questionable.

These concerns have been surmounted in two studies that randomly assigned subjects in double-blind fashion to methadone maintenance versus a control condition of a blinded methadone taper followed by placebo. These two studies are included in a recent meta-analysis (3), which surveyed the literature through 2001 and found six trials involving a total of 954 subjects published between 1969 and 1993 that compared methadone maintenance to some sort of control condition. The analysis determined that subjects receiving maintenance were three times as likely as control subjects to remain in treatment and one third as likely to have used heroin.

This meta-analysis failed to show that methadone treatment reduces engagement in criminal activity. However, another meta-analysis (4), which included 24 studies conducted between 1964 and 1994, found that methadone maintenance had a large effect on drug-related crime, a small-to-moderate effect on drug- and property-related crime, and a small effect on non-drug-related crime. Most of the studies included in this analysis compared criminal behavior prior to entering methadone treatment to such behavior during methadone treatment. A more recent study, which randomly assigned subjects to interim methadone treatment versus referral to community methadone treatment, found that the referral group was much less likely to enter comprehensive methadone maintenance and received significantly more illegal income at follow-up than did the interim maintenance group (5).

A multitude of observational studies also show that methadone treatment reduces HIV risk behavior. The meta-analysis cited above (4) analyzed eight studies that looked at changes in HIV risk behavior both before and after entering methadone treatment and found that methadone treatment had a small but significant effect in reducing such behaviors. A more recent systematic review examined the literature on this topic from its inception through 2003 and found 28 relevant studies (6). Only two of these studies were randomized clinical trials. The studies consistently observed reductions in

both needle use and sexual risks during methadone treatment. Four of the studies looked at HIV seroconversion observationally and noted a protective effect of methadone treatment on seroconversion.

Opioid-dependent individuals exhibit mortality rates 6 to 20 times that of the age-matched population (2), but methadone treatment may partially reverse this risk. A controlled trial (7) that randomly assigned 34 heroin addicts to receive methadone treatment or to a control group that offered psychosocial treatment only showed a mortality rate of 11.8% in the control group within 2 years compared to 0% in the methadone group. Reduced mortality rates are also observed for opioid-dependent individuals in methadone treatment compared to those out of methadone treatment (8). A cost-effectiveness analysis found that the cost of methadone treatment per life-year gained falls well within the range of other commonly used medical treatments such as coronary artery bypass surgery or renal dialysis (1).

In summary, we have good evidence that medication-assisted treatment with methadone for opioid dependence keeps patients in treatment and reduces illicit opioid use better than does treatment without medication. We have a lower level of evidence that methadone treatment reduces HIV seroconversion, mortality, and criminal behavior.

METHADONE PHARMACOLOGY

Methadone possesses a unique and complex pharmacology. Its good oral bioavailability, gradual onset, and generally long half-life contribute to its efficacy, but the long half-life also confers risk of medication build up and inadvertent toxicity. Methadone also has several potential drug–drug interactions and effects on cardiac conduction. These safety issues moved the FDA to place a black box warning in the product label regarding respiratory depression and QT interval prolongation on the electrocardiogram (ECG).

Marketed methadone contains a racemic mixture of two stereoisomers, levo (L)-methadone and dextro (D)-methadone. The L-methadone enantiomer has the majority of pharmacologic activity, although the D-methadone has some antitussive action and may contribute to some side effects. Oral methadone is supplied as a solid tablet, a rapidly dissolving wafer, and a premixed liquid, all of which are basically bioequivalent.

Pharmacokinetics

Methadone is readily absorbed after oral ingestion (9), with an average bioavailability of about 80%, but interindividual variation ranging from 41% to 95% (10). Its initial effects can occur within 30 minutes, but peak effects and peak plasma levels occur on average about 4 hours following ingestion, with a range of 1 to 6 hours (11). Methadone has an average terminal half-life of 22 hours, with a range of 5 to 130 hours (12). The vast majority of methadone leaves the circulation and enters tissue stores in liver, kidneys, lungs, and brain. The tissue stores can be released back into the circulation typically

when serum levels fall but also potentially at unanticipated times and at unexpectedly rapid rates. The methadone remaining in the blood is 60% to 90% bound to plasma proteins, mainly to α 1-acid glycoproteins. The amount of free methadone available to tissues obviously varies with the amount of protein available for binding. For example, levels of α 1-acid glycoproteins increase during stress, which would increase the amount of bound methadone and reduce the amount of free methadone (10).

As might be anticipated from the wide variability in half-life, the metabolism of methadone is complicated and not yet entirely understood. An array of evidence suggests that metabolism is catalyzed primarily by the liver enzyme CYP 450 3A4 (13) with possible additional contributions by other enzymes (14) including CYP2B6, CYP2D6, and possibly, but to a smaller extent, CYP1A2, CYP2C9, and CYP2C19 (12). Recently, the primary role of 3A4 has come into question (15), but the important point is that all of these enzymes exhibit wide interindividual variation in activity based largely on genetics and to a lesser extent on environmental factors. Methadone can also induce its own metabolism so that serum levels and effects may decline over time.

Methadone is metabolized primarily to the inactive metabolite, 2-ethylidene-1,5-dimethyl-3,3-diphenylpyrrolidine (EDDP). Most parent drug and EDDP elimination occurs through the kidneys with some eliminated in the feces. As with other aspects of the body's handling of methadone, interindividual variation also occurs in clearance rates. In addition, renal elimination varies based on urinary pH. More acid urine leads to faster elimination.

The key message for clinicians is to appreciate the potential for tremendous variability in methadone absorption, metabolism, storage, and elimination both across individuals and within a given individual over time.

Pharmacodynamics

The primary pharmacodynamic target for methadone is the μ -opioid receptor, but methadone, unlike most other opioids, also antagonizes the *N*-methyl, D-aspartate (NMDA) receptor (16) and blocks the serotonin and norepinephrine transporters. In addition, methadone inhibits the cardiac potassium channel hERG that, as noted above, can cause a prolonged QT interval (17) on the ECG. Given acutely prior to the development of tolerance, methadone has typical μ -opioid agonist effects including miosis, analgesia, sedation, possible euphoria, decrease in gut motility, release of histamine, and respiratory depression.

In preclinical paradigms, methadone serves as a substrate of the transport protein, P-glycoprotein. P-glycoprotein activity varies both by genetic predisposition and environmental effects such as the presence of other drugs. P-glycoprotein activity could affect absorption of methadone from the gut but also, importantly, could have a substantial impact on the relationship between plasma and brain levels, reducing brain levels when it is more actively transporting methadone out of the central nervous system (CNS).

CLINICAL USE OF METHADONE

Methadone's unique pharmacology confers several clinical challenges. Each patient has a different response to a given dose of methadone, so careful individual attention is required in the monitoring and management of each patient. Due to incomplete cross-tolerance, dose conversion calculators can be misleading or erroneous when used to switch patients from other opioids to methadone. In addition, given its long half-life, several days are required in most patients to achieve a steady state. Although a patient may report an inadequate response initially, the ultimate response to a given dose cannot be immediately determined. Too rapid dose escalation can lead to unanticipated medication accumulation causing adverse events including most seriously respiratory depression, respiratory arrest, and death. These fatalities can occur particularly among individuals who have not developed any tolerance to opioids (18). The highest-risk period for fatal intoxication is during the first weeks of treatment and periods of dose adjustments (18).

One of the very characteristics that makes methadone potentially dangerous, its long half-life, is also an attribute that renders it a superb treatment agent for opioid dependence. For most patients, a once-daily oral dose is sufficient to prevent emergence of opioid withdrawal, which is a strong driver for ongoing illicit opioid use. Based on preclinical evidence, methadone's antagonism of excitatory NMDA receptors could reduce opioid tolerance, decreasing the need for a constantly escalating dose to obtain the same effect once stabilization is achieved (19). Methadone's blockade of serotonin and norepinephrine transporters may leave more of these neurotransmitters in the synapse thereby providing some mood-elevating effects.

Methadone Induction

The induction period encompasses the time from the first administered dose until the point when a stable dose is reached, typically a span of 2 to 4 weeks. Prior to inducing a patient onto methadone, specific elements of assessment must be completed. A medical history and physical examination should be completed including information on past and recent illicit opioid and other substance use as well as a record of all the patient's current medications. Information on the patient's experience with tolerance and withdrawal is important in determining the induction dose. The required (syphilis serology) and any other indicated laboratory tests should be obtained as well as a urine specimen for toxicology analysis to confirm the recent substance use history given by the patient. Informed consent should be provided so that the patient understands the risks of methadone treatment particularly the fact that physiologic dependence on methadone will occur. The patient should sign a consent document that also lays out all the expectations for methadone treatment.

Prior to administering the initial dose, the responsible clinician should ascertain that the patient is not exhibiting any clinical evidence of sedation or intoxication. Federal reg-

ulations specify that the initial dose of methadone can range from 5 to 30 mg with 30 mg being the maximum allowed first dose. An additional 10 mg can be added after a period of observation if 30 mg does not adequately suppress withdrawal. The maximum allowed total dose for the first day is 40 mg unless the program physician clearly documents in the record that 40 mg did not suppress opioid withdrawal. Clinical judgment about the initial dose depends on a variety of patient-specific factors including any history of prior response to methadone and prior methadone dose, type, amount, and frequency of recent opioid use, recent use of other substances such as sedatives or ethanol that could have additive or synergistic effects with methadone on level of consciousness or respiratory drive, and current medical conditions or concomitant prescribed medications that could alter the pharmacokinetics or pharmacodynamics of methadone. The patient's age should also be taken into consideration since older individuals generally metabolize methadone more slowly. If any question exists as to the appropriate initial dose, it is wisest to err on the side of a lower dose to avoid any potential risks of intoxication or overdose. For patients who have not used any opioids for three or more days prior to induction, 5 to 10 mg is the most appropriate initial dose. For patients with extensive recent use of heroin, the initial dose of 30 or 40 mg as a split dose will reduce withdrawal symptoms.

The clinician should evaluate the patient 2 to 4 hours following the initial dose. If the patient shows no signs of withdrawal or intoxication and reports feeling comfortable, the appropriate first-day dose has been achieved. If there are signs or symptoms of withdrawal, the clinician can administer additional doses of methadone to a maximum of 40 mg total for day 1. In the exceedingly rare instance when a dose higher than 40 mg for day 1 is contemplated, it must be clearly documented that a dose higher than 40 mg was required to manage opioid withdrawal. In the rare instance, when a patient appears sedated or intoxicated, 2 to 4 hours after the initial dose, the patient should at minimum be kept in the clinic for observation until the effects have resolved, or, if necessary, emergency measures such as naloxone administration to reverse intoxication and airway preservation should be instituted.

The patient will return to the clinic on subsequent days for evaluation and observed medication administration. The patient can then be assessed for signs and symptoms of withdrawal or intoxication. It is very likely that the initial dose did not completely suppress withdrawal symptoms over a full 24-hour period. Nevertheless, with the 22-hour average half-life of methadone and the fact that it takes four to five half-lives to achieve a steady state, it will typically require 4 to 5 days on a given dose to ascertain the ultimate effect of that dose. Even though the patient may experience some withdrawal symptoms during the 24-hour dosing interval, the most judicious approach is to increase the dosage in 5- to 10-mg increments every 4 to 5 days. Following this conservative titration schedule, dosages of 60 to 80 mg/day can be achieved within 4 weeks of initiation.

Determining the Stable Dose of Methadone

The overall goals for the induction period and beyond are to attain a methadone dose that (1) suppresses opioid withdrawal symptoms throughout the 24-hour dosing interval, (2) eliminates craving or desire for other opioids, (3) creates sufficient tolerance to prevent euphoria caused by self-administration of illicit opioids, (4) eliminates the use of illicit opioids as evidenced by self-report and urine toxicology testing, and (5) minimizes side effects so that the patient is not experiencing intoxication and can function normally. Frequently, all these goals cannot be met by doses that are safely reached during the induction period. In that circumstance, ongoing methadone dose increases in increments of 5 to 10 mg every 5 to 7 days should be continued until these goals are achieved. Once the daily dose exceeds 40 mg, 10-mg increments generally are quite safe and appropriate. Finding the stable dose involves a clinical balancing act since doses needed to establish sufficient tolerance and eliminate illicit opioid use often result in some side effects. Clinical trial evidence demonstrates that methadone doses of 80 to 100 mg/day are superior to lower doses in reducing illicit opioid use and retaining patients in treatment (20). For most patients, the stable dose will reside in the range of 80 to 120 mg/day, though as a consequence of interindividual differences, some patients do well on lower doses and some require higher doses. Within 60 to 90 days of starting methadone, most patients will stabilize on a daily dose that remains constant indefinitely.

However, considering the variety of pharmacologic, environmental, and physiologic factors that can arise over time to influence methadone's activity, including its ability to induce its own metabolism, it is not unusual for patients to develop symptoms or signs of instability after a period on a stable dose. The instability may come to light via patient self-report of withdrawal symptoms, side effects, or illicit opioid use, or illicit opioid use might be detected on urine screening. In these situations the clinician should re-evaluate the patient, seek to address any contributing factors (such as newly diagnosed medical conditions or introduction of concomitant medications that could be interacting with methadone), and consider changes in the daily methadone dose. The dose can again be increased in 5- to 10-mg increments every 5 to 7 days until the criteria for stability are once more achieved.

Patients may also miss methadone doses because of failure to attend the clinic. If more than 1 consecutive day is missed, the patient should receive a medical evaluation, and the methadone dose may need to be temporarily reduced if a loss of tolerance is suspected. A common practice after 2 or 3 days is to restart the patient at 50% of his or her established maintenance dose; however, the reduction should not be less than the original initial dose. Providing that the patient tolerates the reduced amount of methadone, the dose can be increased by no more than 10 mg/day. Slower dose escalation is recommended for patients who are medically compromised or have problematic alcohol or benzodiazepine use. After missing 4 or more days of methadone, the most cautious course of ac-

tion is to restart methadone at 30 mg or less, depending on the original initial dose. The methadone dose can then be re-titrated upward in a fashion analogous to induction to return ultimately to the stable dose.

Methadone Serum Levels

In the majority of cases, stability on methadone can be achieved with close clinical monitoring and dose adjustments as clinically indicated. Some patients in contrast may fail to achieve stability as evidenced by ongoing illicit opioid use or by complaints of opioid craving or withdrawal symptoms. For a few select cases, obtaining serum methadone levels may help to illuminate the problem. No firm agreement exists on thresholds for an adequate serum concentration. Suggested minimally therapeutic trough levels range from 100 to 400 ng/mL (21). Peak serum levels also vary widely among stable patients in methadone treatment. The best available evidence indicates that the rate of decline from peak to trough, rather than absolute levels, optimally predicts the presence of withdrawal symptoms and instability (22), but determining the rate of decline requires multiple samples over a 24-hour period, a sampling regimen not possible outside of a research context. Although not perfect, the ratio of peak to trough may serve as a surrogate for the rate of decline. A peak-to-trough ratio of greater than 2:1 may be an indicator of inadequate coverage throughout the 24-hour dosing interval leading to clinical instability. Patients who exhibit such a pattern may be rapid metabolizers of methadone, who would respond best to a split-dosing regimen rather than to an increase in daily dose. Thus, to evaluate serum methadone levels, a trough level should be obtained 24 hours after the last dose and a peak level obtained about 3 hours after the last dose. Consideration of the absolute levels, the ratio between them, and the clinical context may guide rational methadone dosing.

Methadone Drug Interactions

Table 28.1 lists important potential drug–drug interactions involving methadone. Additive or synergistic effects can occur between methadone and other opioids or sedatives that also suppress respiratory drive leading to toxicity or overdose.

Given the numerous potential pathways for methadone metabolism, multiple drug–drug interactions are theoretically possible. Drugs that inhibit the enzymes involved in methadone metabolism could cause elevated methadone serum levels and increased opioid effects. For the most part, these types of expected interactions have not usually caused much in the way of clinically concerning effects. For example, a human laboratory study found that fluconazole (a CYP 3A4, 2C9, and 2C19 inhibitor) significantly increased methadone serum levels without causing any clinically observable effects (23). However, there is one case report of concomitant administration of fluconazole leading to methadone toxicity (24). Similarly, there is one case report of concomitant fluvoxamine (an inhibitor of CYP enzymes 3A4, 1A2, 2C9, and 2C19) administration leading to methadone toxicity (25).

TABLE 28.1 Common potential methadone drug–drug interactions

Class or specific drug	Interaction	Putative mechanism	Notes
Antiretrovirals			
Efavirenz, lopinavir, nevirapine	Reduction in serum methadone levels	Induction of CYP 450 enzymes	Clinically significant opioid withdrawal symptoms likely
Abacavir, etravirine, nelfinavir, ritonavir, squinavir, tipranavir	May reduce serum methadone levels	Induction of CYP 450 enzymes	Clinically pertinent opioid withdrawal symptoms usually not seen with these agents
Didanosine	Reduction in didanosine plasma concentration	Decreased bioavailability	Possible decreased efficacy of didanosine
Zidovudine	Increase in zidovudine plasma concentration	Unknown	Risk of zidovudine toxicity
Antidepressants			
Tricyclics: amitriptyline, clomipramine, desipramine, doxepin, imipramine, nortriptyline, protriptyline, trimipramine	Increases risk for constipation and sedation; increases risk for QT prolongation and arrhythmia	Anticholinergic effects; blockade of hERG channel	Clinical experience with combination indicates it is generally safe with careful clinical monitoring
Serotonin reuptake inhibitors: citalopram, escitalopram, fluvoxamine, fluoxetine, paroxetine, sertraline	May increase serum methadone levels; increased risk for serotonin syndrome	Inhibition of CYP enzymes; blockade of serotonin transporter	Clinical experience with combination indicates it is generally safe with careful clinical monitoring
Monoamine oxidase inhibitors: isocarboxazid, phenelzine, selegiline, tranylcypromine	Increased risk for serotonin syndrome	Inhibition of serotonin metabolism	Use with extreme caution and careful clinical monitoring
Serotonin/norepinephrine reuptake inhibitors: duloxetine, desvenlafaxine, venlafaxine	Increased risk for serotonin syndrome; increases risk for QT prolongation and arrhythmia (venlafaxine)	Blockade of serotonin transporter/blockade of hERG channel (venlafaxine)	Clinical experience with combination indicates it is generally safe with careful clinical monitoring
Antibiotics			
Ciprofloxacin, clarithromycin, erythromycin, azithromycin	May increase methadone serum levels; increases risk for QT prolongation and arrhythmia	Inhibition of CYP enzymes; blockade of hERG channel	One case report of sedation (ciprofloxacin); clinical monitoring required
Rifampin	Reduction in serum methadone levels	Induction of CYP enzymes	Severe opioid withdrawal can occur; will need increased methadone dose

Antifungals					
Ketoconazole, fluconazole	May increase methadone serum levels	Inhibition of CYP enzymes	Little evidence for important clinical effects		
Anticonvulsants					
Carbamazepine, phenytoin	Reduction in serum methadone levels	Induction of CYP enzymes	Severe opioid withdrawal can occur; will need increased methadone dose		
Antiarrhythmics					
Procainamide, quinidine	Increases risk for QT prolongation and arrhythmia	Blockade of hERG channel	Careful clinical monitoring required		
Amiodarone	May increase methadone serum levels; increases risk for QT prolongation and arrhythmia	Inhibition of CYP enzymes; blockade of hERG channel	Careful clinical monitoring required		
Benzodiazepines	Additive CNS and respiratory depressant effects	Increased GABA activity	Careful clinical monitoring required		
Barbiturates	Additive CNS and respiratory depressant effects	Increased GABA activity	Careful clinical monitoring required		
Cimetidine	May increase methadone serum levels	Inhibition of CYP enzymes	No evidence of major clinical effect		
Naltrexone	Precipitated opioid withdrawal	Displaces methadone from μ -opioid receptors	Contraindicated		

Drug–drug interactions that are clinically significant induce the enzymes catalyzing the metabolism of methadone resulting in a decrease in the methadone serum level and emerging opioid withdrawal. Drugs known to cause this effect include the anticonvulsants, phenytoin, and carbamazepine; the antibiotic, rifampin; and antiretroviral medications, lopinavir, efavirenz, and nevirapine. These medications are best avoided in methadone-treated patients, but if their use is essential, often fairly substantial increases in the methadone dose are required to eliminate the emerging withdrawal symptoms. Other antiretroviral medications may alter methadone pharmacokinetics but do not appear to result in clinically observed withdrawal.

Finally, as described below, methadone can prolong the QT interval on the ECG. Numerous other drugs also have a similar effect. Although the issue has not been well studied, it seems probable that the combination of methadone with other drugs that prolong the QT interval could have additive effects increasing the risk for QT prolongation.

Managing Methadone Side Effects

Table 28.2 lists common methadone side effects. If troublesome side effects are present, and the patient has stopped illicit opioid use and does not have withdrawal symptoms,

many side effects can be managed by incremental methadone dose reductions of 5 to 10 mg every 5 to 7 days until side effects are resolved, tolerable, or until withdrawal symptoms occur. If dose reductions are not reasonable because the patient has continued illicit opioid use or still has withdrawal symptoms, other interventions can be applied to manage some of the commonly occurring side effects.

Constipation is one of the most frequent and bothersome side effects in patients on methadone. Constipation can be managed by encouraging patients to drink more water, eating a diet higher in fiber content, and engaging in modest exercise. If these measures are ineffective, psyllium or other bulk-forming laxatives can be used but should be used with caution unless adequate fluid is maintained. Other patients respond to emollient laxatives such as docusate, or to stimulant laxatives (bisacodyl) or osmotic laxatives (lactulose). Although constipation is generally benign, it can obviously progress to impaction and small bowel obstruction, so early intervention to address it is warranted. Methylnaltrexone is an opioid-receptor antagonist that blocks the peripheral gastrointestinal opioid receptors, but does not cross the blood–brain barrier. It has been recently approved by the FDA as a subcutaneous preparation for the treatment of opioid-induced bowel dysfunction; the oral forms remain under investigation.

TABLE 28.2 Potential methadone side effects

Body system	Side effects
Body as a whole	Asthenia (weakness), edema, headache
Cardiovascular	Arrhythmias, bigeminal rhythms, bradycardia, cardiomyopathy, ECG abnormalities, extrasystoles, flushing, heart failure, hypotension, palpitations, phlebitis, QT interval prolongation, syncope, T-wave inversion, tachycardia, torsade de pointes, ventricular fibrillation, ventricular tachycardia
Digestive	Abdominal pain, anorexia, biliary tract spasm, constipation, dry mouth, glossitis
Metabolic and nutritional	Hypokalemia, hypomagnesemia, weight gain
Nervous	Agitation, confusion, disorientation, dysphoria, euphoria, insomnia, seizures
Respiratory	Pulmonary edema, respiratory depression, sleep apnea
Skin and appendages	Pruritis, urticaria, other skin rashes, and, rarely, hemorrhagic urticaria, diaphoresis
Special senses	Hallucinations, visual disturbances
Urogenital	Amenorrhea, antidiuretic effect, reduced libido, erectile dysfunction, urinary retention or hesitancy

Edema can also be an unpleasant side effect of methadone (26). How methadone causes edema remains unknown. Edema seldom responds to sodium restriction. It sometimes responds to a decrease in methadone dosage if the patient is sufficiently stable to undergo a decrease. If severe edema does not respond to these measures, diuretics, such as furosemide, often prove helpful. If a diuretic is prescribed, potassium levels should be checked periodically to assure that potassium depletion is not occurring.

Methadone can cause hormonal alterations related to sexual functioning. Methadone acts at the hypothalamus altering the release of gonadotropin-releasing hormone, leading to a reduction in follicle-stimulating hormone (FSH) and luteinizing hormone (LH) and subsequent suppression of testosterone levels. In men, reports of methadone side effects include orgasmic and erectile dysfunction, and decreased sexual desire. The reductions in FSH and LH normalize after several years of methadone treatment despite a persistent decrease in testosterone in some individuals (27). Sexual dysfunction may respond to a methadone dosage reduction. If that is not possible or does not help, erectile function often improves with use of phosphodiesterase type 5 inhibitors (presuming contraindications for this class of medications such as cardiac conditions are not present). Testosterone replacement can ameliorate sexual dysfunction among methadone treated men with low serum testosterone levels.

For women on methadone, depressed libido and oligomenorrhea or amenorrhea have been reported; however, some improvements are also noted after stabilizing in treatment. Irregular menses may lead some women to believe incorrectly that they cannot become pregnant or are pregnant when they are not. For symptomatic female patients, a medical workup is indicated that includes a discussion of the possibility of becoming pregnant without regular menses and about the use of birth control. Referral to an endocrinologist or gynecologist can identify or rule out other medical conditions that can cause amenorrhea or oligomenorrhea.

A hormonal effect of methadone that persists in some individuals after years of treatment is altered prolactin release. Rather than the normal diurnal variation, prolactin release becomes reactive to the peak level of methadone (27). The clinical symptoms associated with hyperprolactinemia include galactorrhea, menstrual disturbance, erectile dysfunction, or long-term loss of bone mineral density. A cross-sectional study found that three quarters of methadone-maintained patients had low bone mineral densities. Hormone levels were not measured in this study, but other modifiable factors contributing to low bone mineral density were lower body weight and heavy alcohol consumption (28).

Hyperhidrosis or excessive sweating (29) is another common complaint among patients on methadone. One potentially effective intervention is to lower the methadone dose if possible. In patients treated with additional drugs that induce hyperhidrosis such as cholinesterase inhibitors, selective serotonin reuptake inhibitors, or tricyclic antidepressants, using an alternative to one of these medications can decrease the severity of sweating. Methadone and other opioids induce

release of histamine by degranulation of mast cells, which is implicated in the side effects of sweating and itching. Antihistamines are mast cell stabilizers, and two case reports suggest that antihistamines may alleviate sweating in methadone patients. The newer nonsedating antihistamines do not incur a risk of increase in the QT interval.

As noted above, methadone has a black box warning for QT interval prolongation. Some evidence suggests that a corrected QT interval longer than 500 msec increases the risk for torsades. At the present time, insufficient information on the cardiac effects of methadone is available to make definitive recommendations about how to handle this issue. It is reasonable to consider obtaining ECGs on methadone patients who have known structural heart disease or who have a history of syncope or a family history of sudden cardiac death, since there can be genetic predisposition to a prolonged QT interval. If patients on methadone have a corrected QT interval above 500 msec, consideration should be given to discontinuing other medications that also prolong the QT interval, to stopping illicit cocaine use, correcting electrolyte imbalances, and reducing the methadone dose if clinically feasible.

Methadone Medically Supervised Withdrawal and Tapering

Medically supervised withdrawal or tapering from methadone may be performed for several reasons. In the majority of cases, it should be avoided because relapse rates to dependence on illicit opioids tend to be high (30). If medically supervised withdrawal must be done, slower tapers lead to superior outcomes (31). Justifications for medically supervised withdrawal include patients who do not qualify for maintenance because they have had less than a 1-year history of opioid dependence, patients who must enter a controlled environment such as incarceration where methadone is not available, administrative tapers for patients who do not comply with program policies, and voluntary tapers for patients who evince a personal desire to be off methadone.

Patients who do not qualify for methadone maintenance because of less than a 1-year history of dependence may be appropriate for medically supervised withdrawal. One reasonable approach is to use a 180-day schedule to perform induction and stabilization, similar to what would be done for a maintenance patient and continue a stable dose to the 120-day mark. At that point, the dose can be tapered over 60 days with the understanding that the rate of taper should slow in the latter part of this interval. Shorter tapers can be conducted in analogous fashion.

For patients receiving an administrative discharge, the usual custom is to perform a taper over 21 days. Although this time frame almost universally militates against success, it does balance the patient having an opportunity to make alternative plans against the need to have the patient leave the program relatively quickly.

For patients requesting a voluntary taper, a number of signs of stability should be in place before considering a taper, including a substantial period without illicit drug use, a stable

living situation, stable relationships, a stable source of income, and the absence of unstable medical or psychiatric conditions. The rate of taper should be adjusted to the patient's needs and expectations. It is not unusual for these types of tapers to require many months or even years depending on the starting dose. A typical rate would be a decrease of 5 to 10 mg from the daily dose every 1 to 2 weeks. It helps to inform the patient that a successful taper makes the patient feel better by reducing methadone side effects. If the patient starts to feel worse, the taper is going too rapidly. A good option is to allow the patient to halt the taper or regain the previous higher dose upon request if the patient experiences any instability. The taper should definitely be stopped if any obvious signs of instability such as a positive urine specimen or failure to comply with program rules occur. As the daily dosage drops below the 40 to 60 mg/day range, the rate of taper usually has to be decreased. Patients who successfully complete the taper should be encouraged to continue counseling and to make a decision to resume methadone if relapse seems imminent. Some patients may want to begin opioid antagonist therapy with naltrexone once they no longer have physiologic dependence, to protect themselves from relapse.

NONOPIOID SUBSTANCE USE

Patients who enter methadone-maintenance treatment for opioid dependence also have high rates of misusing other substances. Since methadone specifically targets only opioid dependence and since problematic use of other substances usually undermines stability in methadone maintenance, misuse of other substances oftentimes requires additional active interventions.

Alcohol

Among patients seeking treatment for opioid dependence, rates of alcohol dependence range from 24% for a current to 50% for a lifetime diagnosis (32,33). Excessive alcohol use causes serious medical and psychiatric morbidity, and particularly worsens the prognosis in chronic hepatitis C. Alcohol can act additively with methadone and other opioids to suppress CNS activity and respiratory drive, increasing the risk of overdose. Alcohol can also induce the activity of cytochrome P-450 enzymes (34), thereby enhancing the metabolism of methadone and destabilizing the patient. Patients who have indicators of alcohol problems tend to have poorer methadone treatment retention and more illicit drug use than patients without alcohol problems (35).

Monitoring for excessive or problematic alcohol use can prove challenging since alcohol is eliminated fairly rapidly via zero-order kinetics. Breathalyzers and routine urine tests for alcohol will only detect recent alcohol use but can and should be utilized. Tests for alcohol metabolites in urine such as ethyl glucuronide can screen for more remote alcohol use but are expensive and positive results can occur from the use of hand sanitizers, medications, and other products that contain even trace amounts of alcohol.

Active alcohol abuse or dependence when recognized in methadone maintenance should be treated aggressively. The mainstay of treatment involves one or more behavioral interventions including contingency management, motivational interviewing, relapse prevention, and 12-step facilitation with referral to Alcoholics Anonymous. Using the latter intervention would require some alterations for methadone patients who could experience stigmatization at 12-step meetings because of their methadone prescription. Pharmacologic interventions for alcohol dependence should also be considered, although naltrexone, as a μ -opioid antagonist, is contraindicated in methadone patients (as an acute dose of it will precipitate withdrawal in an opioid-dependent person). However, monitored disulfiram is used frequently. A study that compared monitored and required disulfiram to unmonitored disulfiram in methadone patients who were failing treatment because of severe alcohol dependence showed a dramatic and significant reduction in alcohol use in the monitored group (36), though a randomized-controlled trial found no difference in outcomes between disulfiram and placebo (37). Acamprosate has not been studied in methadone-maintenance patients.

Benzodiazepines

The prevalence of current benzodiazepine abuse in methadone-treated patients has been estimated between 24.9% and 50.6% (38). Patients use benzodiazepines for multiple reasons including to alleviate anxiety, to decrease restlessness or insomnia produced by stimulants, or to boost the effects of methadone, making it feel more like heroin. The respiratory depressant effects of methadone and benzodiazepines are synergistic. Use of benzodiazepines may require methadone dose reductions in the event of oversedation. If the benzodiazepines are prescribed for anxiety or insomnia, ideally the care can be coordinated and an alternative agent may be used. In the case of benzodiazepine dependence, it may not be realistic or safe to demand immediate abstinence from the benzodiazepine use. Abrupt cessation of benzodiazepines can cause a medically significant withdrawal syndrome. Options for treating benzodiazepine dependence among methadone patients include a slow outpatient taper, or admission to an inpatient unit for medically supervised withdrawal of benzodiazepines. Outpatient tapers often prove difficult because patients become symptomatic and continue use of illicit benzodiazepines. Experimental methods still undergoing study involve the substitution of anticonvulsants, which act through the gamma-aminobutyric acid (GABA) system, such as gabapentin, topiramate, or valproic acid for benzodiazepines. Use of sedatives other than benzodiazepines has become rare among methadone patients, but it should be addressed in a similar fashion to benzodiazepines.

Cocaine and Amphetamines

A diagnostic study of 716 patients who recently entered methadone treatment showed a lifetime rate of cocaine dependence of 64.7% and a current rate of 40.7% (32). In addition to

the multitude of well-known toxic effects of cocaine, it can also exacerbate the risk for cardiac arrhythmia already potentially present during methadone treatment. Cocaine use during methadone treatment increases the likelihood of heroin use (39).

Behavioral treatments, particularly contingency management and cognitive-behavioral therapy, effectively reduce cocaine use among methadone patients (40). Several specific pharmacotherapy interventions for cocaine dependence among methadone patients have been tested with generally disappointing results with the exception of disulfiram, which shows considerable promise even among patients who do not have alcohol dependence (41). Disulfiram inhibits the enzyme dopamine- β -hydroxylase that catalyzes the transformation of dopamine into norepinephrine. This action potentially alters the balance between these two neurotransmitters in the brain, and thereby may mitigate the desire for and/or the effects of cocaine.

Because methamphetamine and other stimulant use among methadone patients seem to be infrequent, a paucity of data exists on this topic. Behavioral interventions would be similar to those used for cocaine.

Cannabis

Cannabis use among methadone patients is reported to range from 54% to 78.5% (42). In contrast to the very deleterious effects of alcohol, benzodiazepines, or cocaine use on methadone patients, cannabis use itself does not have a measurable negative effect on typical methadone treatment outcomes such as treatment retention, illicit opioid use, or employment. In fact, many methadone programs do not test for cannabis. Undoubtedly, some methadone patients with cannabis dependence suffer from the low motivation and cognitive disruption seen with that disorder and could benefit from cannabis abstinence. However, there is a growing body of experimental literature suggesting that stopping regular cannabis use may be difficult because of withdrawal symptoms including anxiety, depression, irritability, craving, decreased quantity and quality of sleep, and decreased appetite (43). As with other forms of substance dependence, patients with cannabis dependence usually respond to cognitive-behavioral therapy and contingency management (43). Methadone clinics can also approach the problem of cannabis use by giving positive rewards, such as take-home doses, preferential dosing, reduced fees, or counseling appointment times, for abstinence from cannabis.

Tobacco

The rate of tobacco smoking among methadone patients is about 80%, and many evince interest in quitting (44). Since methadone patients have a high prevalence of diseases caused or exacerbated by tobacco smoking, smoking cessation could have a substantial impact on health outcomes in this population. Also, heavy smoking strongly predicts cocaine and illicit opioid use among methadone patients (45). Long-term quit

rates fall in the range of 5% when transdermal nicotine and intensive behavioral interventions are used. Other forms of smoking cessation pharmacotherapy such as bupropion, varenicline, or combination of transdermal nicotine with immediate release forms of nicotine replacement like gum or lozenge have not been investigated in methadone patients. Clearly, more research on both pharmacologic and behavioral interventions as well as more active application of clinical interventions known to work for tobacco dependence is needed among methadone patients.

CO-OCCURRING PSYCHIATRIC DISORDERS

Opioid-dependent patients on methadone maintenance exhibit high rates of co-occurring, non-substance-related, psychiatric disorders. Two large studies have used structured psychiatric interviews to assess psychiatric illness in opioid-dependent patients. Major depression ranged from a low of 8.7% for men in one study (32) to a high of 69% for women in the other study (33); rates of bipolar disorder ranged from 0% for women in one study to 10.8% in the other, with men falling in between; rates of anxiety disorders ranged from 6.1% to 25.4%. Rates of schizophrenia were similar to what is seen in the general population, about 1%. As for Axis II psychiatric disorders, overall rates of personality disorders range from 25.3% to 40.5% with antisocial personality being by far the most common. Neither of these studies assessed patients for posttraumatic stress disorder, but rates of posttraumatic stress disorder were determined to be 20% for women and 11% for men among methadone patients in a separate study of this specific disorder (46). Eating disorders and attention-deficit hyperactivity disorder have also been reported to occur not infrequently in methadone patients (47,48).

Assessment for co-occurring psychiatric disorders usually requires a thorough psychiatric interview. High rates of substance-induced psychiatric disorders obviously also occur among methadone patients. Ideally, observing a patient through a several week period of abstinence to see if symptoms remit may demonstrate that the disorder is not a primary psychiatric disorder and obviate the need for specific treatment. Particularly with depressive symptoms, many patients show improvement during their first week of methadone treatment (49).

It is generally believed that patients with substance dependence and co-occurring psychiatric disorders perform worse in treatment than do patients with only substance dependence, but few studies specifically examined this notion among methadone-maintenance patients. Nevertheless, active treatment directed at the non-substance-induced co-occurring disorders is recommended. In general, the treatment for these disorders should be identical to that provided to any psychiatric patient, including pharmacotherapy and psychotherapy.

Depression is one specific co-occurring disorder for which treatment among methadone patients has undergone rigorous investigation. Two double-blind, placebo-controlled trials of tricyclic antidepressants for depression among

methadone patients showed that doxepin (50) in one study and imipramine (51) in the second study improved depressive symptoms significantly more than placebo, while having minimal effect on other treatment outcomes such as illicit drug use. Conversely, two placebo-controlled trials of serotonin reuptake inhibitors showed that neither fluoxetine (52) nor sertraline (53) was superior to placebo in treating depression in this population.

Aside from depression, a randomized-controlled trial of methylphenidate, bupropion, and placebo for attention-deficit hyperactivity disorder among methadone patients did not show differences on any outcomes for active medications compared to placebo (48).

Professional psychotherapy has not received rigorous investigation for specific disorders among methadone patients, but when psychiatric severity is assessed dimensionally rather than categorically, patients with low psychiatric severity derive no added benefit when psychotherapy is added to basic counseling, whereas patients with moderate or high psychiatric severity show significant improvements in outcome with the addition of psychotherapy to counseling (54).

CO-OCCURRING MEDICAL DISORDERS

Medical disorders are prevalent among opioid-addicted populations in part due to the route of drug administration. Injection drug users are at risk for infectious diseases such as pneumonia, tuberculosis, endocarditis, sexually transmitted diseases, soft tissue infections, bone and joint infections, CNS infections, and viral hepatitis. Clearly, HIV infection and acquired immunodeficiency syndrome pose a massive problem among injection drug users. Drug smoking also leads to medical complications, particularly pulmonary concerns. Cocaine and methamphetamine, taken by any route, can also cause myocardial ischemia and/or infarction as well as cardiac arrhythmias, cerebrovascular accidents, seizures, gastroduodenal ulceration, and acute renal failure. Excessive alcohol use has the potential to damage nearly every organ system. Methadone-maintenance patients need attention to these co-occurring medical disorders.

Both acute and chronic pain are not infrequent consequences of these co-occurring medical disorders or traumatic injury. A key principle in managing pain in methadone patients is that the daily methadone dose, which is intended to prevent withdrawal symptoms and opioid cravings, will not provide relief from either form of pain. When pain occurs, conservative measures such as nonsteroidal anti-inflammatory medications can be tried, but opioid analgesics should not be denied to patients on methadone if they have a painful condition for which a clinician would normally prescribe opioids. In fact, since patients on methadone may have opioid-induced hyperalgesia as well as a high level of opioid tolerance, higher doses of opioid analgesics may be required to control pain than would be used in an average, nonopioid-dependent individual with the same condition. Acute pain requiring opioids can be treated with any short-acting opioid to which the patient has a history of a good response. Chronic pain often responds well

to additional amounts of methadone in pill form prescribed for pain and given in divided doses throughout the day, although other opioids can also be prescribed. If morphine is prescribed, it can conceivably confound interpretation of urine testing since heroin shows up on toxicology testing as morphine, one of heroin's major metabolites.

PSYCHOSOCIAL AND ANCILLARY SERVICES

Many patients with opioid dependence do not completely respond to methadone treatment alone. They may continue some degree of problematic substance use or struggle with core life issues such as relationships and employment. Some patients benefit from psychosocial interventions directed at the areas in which difficulties persist, although uncertainty remains as to the optimal intensity or modality of psychosocial treatments for these patients.

Studies of various intensities of psychosocial services in OTPs indicate that patients who receive minimal psychosocial services do not fare as well as those who receive moderate or high levels of services (55). However, the lower cost-effectiveness of more intensive services may nullify any slight advantage they hold over moderate services.

The accumulated general knowledge on modalities of psychotherapy indicates that individual therapist's skill at creating a therapeutic alliance has a stronger effect on outcomes in psychosocial interventions for substance dependence than the specific modality applied. Nevertheless, a variety of specific modalities have been applied to patients with opioid dependence such as individual drug counseling, cognitive-behavioral therapy, supportive-expressive psychotherapy, relapse prevention, contingency management, and medical management. A recent meta-analysis of psychosocial interventions for substance use disorders, that included interventions for opioid dependence, found that both cognitive-behavioral therapy and contingency management had positive moderate effects with contingency management holding a slight advantage (56). Psychotherapy performed better than drug counseling for patients with high psychiatric symptomatology (54).

Contingency management shapes behavior (e.g., illicit drug use) in a preferred direction (e.g., towards abstinence) by offering desired rewards contingent on behavior change, and numerous studies demonstrate its benefit in methadone maintenance (57). An approach that is already frequently applied in methadone programs, provision of methadone take-home doses contingent upon negative urine specimens, clearly increases abstinence rates (58). Another approach that shows tremendous promise grants vouchers that can be redeemed for goods or services contingent upon negative urine specimens but has not yet gained a strong foothold in clinical settings. This voucher-based contingency management approach leads to cocaine abstinence in 50% of methadone-maintained cocaine-abusing participants compared to none of the participants who receive vouchers that are not contingent upon a negative urine specimen (59). Reductions in opioid use also occur when vouchers are earned for cocaine

abstinence. Using a technique in which patients who provide negative urine specimens draw vouchers from a bowl containing many vouchers of varying value significantly reduced stimulant use among methadone patients at an average cost for the awarded goods and services of \$10 per week per participant (60). Ideally, in light of its efficacy, voucher-based contingency management will receive increasing use in methadone-maintenance programs.

As a consequence of long periods of opioid dependence, methadone-maintenance patients tend to have deficits in several life areas in addition to substance dependence and medical and psychiatric problems. They are likely to have legal difficulties, educational, vocational and financial problems, relationship and family issues, and an absence of healthy recreational activities. There is some evidence that targeting ancillary psychosocial services specifically to address these patient problem areas is beneficial (55). If such services are not available onsite, a referral network that facilitates connecting patients to needed services is desirable.

URINE TESTING

Drug testing identifies ongoing or sporadic drug use and potential safety issues. The results should be used as part of the treatment plan; a negative test should be used to discuss successful strategies, and a positive test to explore obstacles to abstinence and to identify additional recovery resources. Positive tests for illicit drugs may result in loss of take-home privileges. To avoid confusion between licit and illicit drugs, programs generally require the patient to report or bring in all prescriptions for controlled substances and to coordinate care with the prescriber. In the case of prescription opioids for pain, a confirmatory test can be obtained to distinguish the prescription opioid from heroin. The frequency of urine testing can be increased after a positive test result in order to clarify a lapse from a more extensive relapse.

Fear of sanction such as loss of take-home doses may lead a patient to avoid testing positive for drugs of abuse by tampering with the urine sample. Tampering methods include diluting the sample, adding substances designed to mask a positive test and substituting with a sample not containing drugs of abuse. To discourage tampering, programs are required to test on a random schedule. Reliance on urine observation to minimize falsification is not required, although at times it may be necessary. Temperature testing is less intrusive and can also identify altered specimens. A laboratory can check the validity of a urine sample by performing a urine creatinine analysis. The concentration of creatinine can be used to determine if the sample has been diluted by adulteration or by drinking an excessive amount of liquid.

Testing for methadone and methadone metabolite serves as an important diversion safeguard. Patients who are positive for methadone but negative for metabolite need to be evaluated. This result suggests that the methadone was put directly into the urine sample. Patients may legitimately provide a negative screen for methadone if they have a rapid metabolism or are on very low doses, or have missed doses. To avoid

a false result, the commonly used less costly enzyme immunoassay can be confirmed with gas chromatography–mass spectrometry analysis.

TAKE-HOME STATUS

Regulations allow take-home doses of methadone for stable patients and, in fact, can ultimately be advanced to a maximum of a 1-month supply of take-home doses for patients in continuous treatment for 2 years or longer. Since patients highly value take-home doses, take-home privileges can be effectively used in a contingency management plan as described above. Patients who comply with program rules and responsibilities including abstinence from illicit drug use get rewarded with additional take-home doses. Patients who do not comply and/or supply positive urine specimens get punished by rapid removal of take-home doses. Such procedures actually reduce illicit drug use (58).

OTP physicians must consider the patient's ability to store, take, and transport take-home doses safely. Friends and family members other than the patient are susceptible to accidental overdose from take-home medication. Federal criteria for take-home privileges include: (1) absence of recent abuse of drugs (opioid or non-narcotic) including alcohol; (2) regularity of clinic attendance; (3) absence of serious behavioral problems at clinic; (4) absence of known recent criminal activity, for example, drug dealing; (5) stability of the patient's home environment and social relationships; (6) length of time in comprehensive maintenance treatment; (7) assurance that take-home medication can be safely stored within the patient's home; (8) determination that the rehabilitative benefit to the patient derived from decreasing frequency of clinic attendance outweighs the potential risk of diversion. Many programs are closed for dispensing on Sundays and holidays. Typically, it does not pose an undue risk to provide a take-home dose once per week on days the clinic is closed for patients who do not strictly meet all of these criteria. Occasionally, an individual patient may be so unstable that arrangements must be made to provide observed methadone dosing 7 days per week.

DIVERSION RISK REDUCTION PLAN

Physicians must weigh the risk of diversion against the benefits to the patient. For instance, when a urine drug test result is negative for methadone or metabolite, additional analysis is needed to determine if there is a logical explanation or indication of urine tampering or methadone diversion. Although diversion of take-home doses of methadone to individuals for whom it is not prescribed certainly occurs, few data exist to indicate the frequency of such events. A study of methadone medical maintenance (see below) in which subjects received either 5 or 6 days versus 27 days of take-home medication used random monthly medication callbacks by which subjects are notified to return to the clinic within 24 hours with all outstanding medication (61). In this scenario, if individuals do not have all expected medication in hand,

diversion can be inferred. The study found that over a 12-month period of treatment 0.9% to 5.0% of subjects possessed an incorrect amount of medication at the time of callback, and 1.7% to 5.6% failed to return for the callback. In a survey in Australia of patients receiving methadone maintenance at community pharmacies, 12.6% admitted to ever having diverted or trying to divert their methadone, and 2.2% admitted to diverting or trying to divert methadone in the past 12 months (62). The number of take-home doses did not differ between diverters and nondiversers.

Thus, from the data available, methadone diversion is not an exceedingly common event, but some diversion of methadone will inevitably occur, so programs must develop and apply diversion reduction plans. Unfortunately, no data exist to guide programs toward the optimum approach. Diversion reduction plans must therefore rely on practicality and common sense. Careful application of criteria for take-home eligibility and removal of take-home privileges quickly with evidence of instability as enumerated above constitute the foundations of diversion reduction. Instituting a random callback system is also feasible and creates an additional safeguard. As conveyed by King et al. (61), programs can randomly phone a few patients each week and ask them to return within 24 hours with all methadone expected to be in their possession. Rare events of diversion will be detected by the callbacks, and all take-home privileges can be revoked from patients who fail the callbacks. Equally important, the callbacks may have a deterrent effect whereby patients who might be tempted to divert methadone refrain from doing so because of concern about failing a callback and losing their take-home privileges.

MANAGING PROBLEMATIC BEHAVIOR

Since methadone patients are by definition illicit drug users, since the prevalence of antisocial personality is high in this population, and since federal regulations stipulate certain requirements for the patients such as attendance at counseling, provision of urine specimens, and meeting specific criteria to obtain take-home doses, problematic behaviors by patients are bound to arise. Problematic behaviors include loss or misuse of take-home doses, loitering, drug possession or dealing on the premises, methadone diversion, theft, falsification of urine specimens, intoxication in the clinic, and, most seriously, verbal abuse, threats, or actual violence such as fighting.

Prevention of problematic behavior represents a necessary first step. Establishing a clear program structure and conveying to all patients a set of expectations and rules both orally and in writing at the outset and throughout treatment and then enforcing the expectations consistently and fairly will encourage patients to keep their behavior within appropriate boundaries. Reinforcing compliant behavior by provision of program privileges such as take-home doses and preferential dosing or appointment times will also support desired behavior. Regular counseling sessions provide patients an opportunity to adopt alternative, more functional coping strategies

when they are faced with stressors that might lead them to engage in problematic behaviors.

When problematic behaviors do occur, the program has essentially two sanctions available as a consequence: (1) removal of take-home privileges or denial of take-homes for some specified time into the future and (2) program discharge. Oftentimes a dynamic tension exists between the direct interests of the patient and maintaining the integrity and safe milieu of the program necessitating difficult clinical and administrative decisions. Frequent discharge, even if it is not beneficial to the patient, becomes the only realistic option.

Occasionally patients return to the clinic to report theft, loss, or misuse of their take-home doses. Generally, unless the patient can provide a police report documenting that the take-homes were stolen, missing take-homes should not be replaced. If lost take-homes are replaced, diversion could be inadvertently encouraged. If the patient has admitted loss of take-home doses, there is clear evidence that the patient is not sufficiently responsible to manage take-home doses, and the patient should be placed on daily observed ingestion for some period of time. Similarly, if a patient reports running out of take-home doses because of taking a larger dose than prescribed, take-home privileges should be suspended, and the patient should be evaluated for a methadone dose increase.

Loitering can usually be handled through repeated warnings and removal of take-home privileges. Rarely would loitering require program discharge.

In contrast, drug possession or dealing on the premises, methadone diversion, and theft all involve criminal activity. Criminal activity seriously contaminates the milieu and interferes with the welfare of compliant patients. In most cases when such criminal activity is detected, program discharge is the most reasonable response. Falsification of urine specimens falls somewhere in between. A patient who attempts to falsify by, for example, bringing in someone else's urine or adulterating or diluting the specimen, presumably is motivated by a desire to obtain or maintain take-home doses that would be lost because of a drug-containing specimen. In that case, removal of take-home privileges for a specified time such as several months may be an adequate response to deter such behavior in the future. Repeated attempts at falsification may render discharge necessary.

A patient appearing intoxicated in the clinic poses both safety and liability concerns and requires several immediate actions. The patient should be evaluated by medical staff to determine if the methadone dose should be withheld or if it is safe to provide a partial dose such as 50% of the usual dose or less. If the intoxication appears serious, the patient should be transferred to an emergency room for monitoring and possible administration of naloxone if the intoxication is due to opioids or flumazenil if due to benzodiazepines. If the intoxication appears to be mild, the patient should be observed in the clinic until the intoxication resolves. If alcohol is involved, ideally a breathalyzer reading should be obtained, and the patient not released until below the legal limit. If the patient drove a vehicle to the clinic, the keys should be taken from the patient and not returned until the intoxication has

resolved. Should the patient be noncompliant and attempt to drive while still intoxicated, the police should be called to protect public safety. Assuming the patient is cooperative, once the intoxication resolves, medical staff can determine if it is safe to give the patient methadone that day and initiate a plan to prevent further episodes of intoxication.

A repeated pattern of appearing intoxicated in the clinic raises the issue of whether the patient can be safely treated with methadone in an outpatient setting. If inpatient treatment is available, it should be strongly considered. If inpatient treatment is not available or is tried and fails to eliminate the episodes of intoxication, after ample warnings in writing with the patient as a signatory, discharge from methadone treatment may be the only option.

Verbal abuse, threats, or actual violence create a direct safety risk to other patients and staff, and, if permitted, make attending treatment or working at the program untenable. In these instances program, discharge is almost always the only reasonable course to pursue. Patients who incur an administrative discharge for any of these reasons would usually be given a 21-day methadone taper. In rare cases because of safety concerns, an immediate termination of methadone may be needed. Also, all clinics need to have an appeal or advocacy process whereby the patient can present any evidence that the purported infraction was not actually committed or that extenuating circumstances place the infraction in a different perspective. Even if a decision to remove take-home doses or discharge is not reversed, this process can be therapeutic for the patient by attempting to show that the program staff care about the patient as a person while not tolerating the behavior. Oftentimes, depending on the nature of the problematic behavior, transfer to another clinic can be facilitated or readmission at a later date can be planned contingent on resolution of the problematic behaviors.

METHADONE IN PREGNANCY

Methadone maintenance is the preferred treatment for opioid addiction during pregnancy. Because of its long duration of action, methadone provides reasonably constant opioid effects, thereby preventing the fetus from undergoing repeated cycles of excessive effect punctuated by periods of withdrawal that would occur in a pregnant woman using short-acting, illicit opioids (63). Case studies suggest that compared to no treatment, to treatment without medication, or to medically supervised withdrawal, methadone maintenance along with prenatal care reduces the risk of maternal and fetal complications (64). A recent study specifically examined outcomes for pregnant women receiving ongoing methadone maintenance compared to methadone withdrawal and found that those receiving maintenance stayed in treatment longer, attended more obstetrical visits, and more often delivered at the program hospital (63).

The basic approach to methadone treatment is similar for pregnant women as for other patients, but the physiology of pregnancy does demand careful attention to methadone dose adjustment. During the latter stages of pregnancy, particularly

the third trimester, increasing blood volumes in pregnant women almost always creates the need for an increased dose of methadone. The need for this increase should be anticipated so that withdrawal symptoms and instability related to inadequate dose do not occur and create added stress on the fetus or lead to illicit opioid use. At times a single daily methadone dose does not fully prevent emergence of opioid withdrawal in a pregnant woman. In that case the patient should receive a split dose of methadone if it is logistically possible for the patient to attend the clinic twice daily or if the patient qualifies for take-home doses (64).

Methadone should be continued during and after delivery. For most women, the methadone dose needs to be reduced postpartum guided by careful clinical monitoring, generally either to a dose similar to the stable dose prior to pregnancy or, for women who began methadone maintenance during pregnancy, at approximately half the dosages they received in the third trimester (64).

Although methadone is excreted in breast milk, most mothers maintained on methadone should be encouraged to breast-feed because the health advantages of breast-feeding outweigh the risks of infant exposure to methadone. Exceptions occur for women who are HIV positive and/or who have ongoing use of illicit drugs or alcohol. Hepatitis C infection does not pose a contraindication to breast-feeding (64).

Methadone use during pregnancy predisposes the newborn to the neonatal abstinence syndrome (NAS), characterized by signs and symptoms of central and autonomic nervous system regulatory dysfunction (65). High variability occurs among infants in both incidence and severity of NAS, neither of which appear to be directly related to the maternal methadone dose level or duration of methadone exposure (65). Caretakers sometimes can treat infants with NAS solely with nonpharmacologic treatment, which generally involves reduction in external stimulation and physical soothing (66). Most, however, require pharmacologic treatment, which typically involves some form of opioid medication. Protocols vary from center to center, and no data currently support one strategy over another.

MEDICAL MAINTENANCE

Over the past 25 years, U.S. experimental models of methadone treatment for opioid dependence have been evaluated in which patients who have already stabilized in an OTP transfer their methadone care to a physician practicing in an office-based setting, otherwise known as medical maintenance. Typically, these patients come in to pick up their methadone once per week to once per month, see the physician, provide a urine specimen, and receive take-home doses until the next appointment. Both uncontrolled trials and randomized-controlled trials indicate that the majority of already stabilized patients succeed in medical-maintenance treatment and that patients randomly assigned to medical maintenance have equivalent outcomes to clinic-based patients (61). The studies also show that patients who do poorly in medical maintenance can readily return to routine

clinic-based treatment (61). On a pragmatic level, while such medical-maintenance treatment of stabilized methadone patients is legally permissible in the United States via an exception to the methadone treatment regulations, the process to obtain such an exception is sufficiently cumbersome that very few medical-maintenance practices have been established outside the research setting.

INTERIM MAINTENANCE

In some areas of the United States, methadone treatment services are not readily and immediately available to all individuals seeking such treatment. Interim methadone maintenance is designed as a service that provides medication-only treatment as an alternative to having individuals who desire methadone treatment wait with no treatment until a slot in comprehensive treatment becomes available. As per federal regulations, interim methadone provides methadone induction and then a daily, stable observed dose of methadone with no take-home doses and no other services except emergency counseling. Although, as noted above, comprehensive methadone treatment shows superior outcomes to medication-only treatment, interim methadone compared to a wait-list control in at least three randomized-controlled trials demonstrated reduced illicit drug use and higher rates of subsequent entry into comprehensive methadone treatment (5).

CONCLUSION

Methadone maintenance has a long history of efficacy in the treatment of opioid dependence. Federal regulations provide specific requirements necessary to deliver methadone maintenance. Methadone has several pharmacologic characteristics, particularly its slow onset and long half-life, which make it ideal as a medication to treat opioid dependence but which also demand extensive knowledge and care for it to be prescribed safely. Medical personnel in OTPs must know proper procedures for methadone induction, how to determine an appropriate stable dose of methadone, how to manage side effects, and about methadone drug interactions.

Opioid-dependent patients treated with methadone often have complex presentations, with use of multiple substances in addition to opioids, and with a high prevalence of co-occurring medical and psychiatric disorders. Specific treatments directed toward these other disorders along with a moderate level of ongoing counseling can improve outcomes. Careful clinical monitoring including urine testing and a diversion risk reduction plan help to determine when take-home doses of methadone are indicated and can also help to prevent problematic behavior by patients which must be actively addressed when it occurs.

Methadone is a well-established treatment for pregnant women with opioid dependence and leads to improved fetal outcomes compared to no treatment. Increasing evidence shows that less restrictive forms of methadone maintenance, such as medical maintenance, and less intensive forms, such as interim maintenance, are safe and effective to treat the individ-

ual and address the public health and public safety aspects of opioid addiction. As the knowledge base about evidence-based practices in methadone maintenance continues to grow, this well-established modality should diversify and expand to treat an increasing number of opioid-dependent individuals throughout the 21st century.

Buprenorphine in the Treatment of Opioid Dependence

D. Andrew Tompkins ■ Eric C. Strain

INTRODUCTION

Opioid abuse and dependence remain substantial public health problems throughout much of the world. The United Nations estimates that between 15 and 21 million persons between the ages of 15 and 64 used illicit opioids in 2007, with the greatest use in Asia and Europe (1). In the United States, the 2008 National Survey on Drug Use and Health (NSDUH) estimated 1.7 million persons aged 12 and older were dependent or abusing prescription pain relievers and that 282,000 persons were dependent or abusing heroin (2). Prescription opioids have become widely available for the treatment of pain, and consequently have become more likely to be abused than heroin in the United States. Individual and societal costs of opioid dependence include incarceration, infectious diseases, increased health service utilization, loss of productivity, and death. Up until 1996, methadone, levomethadyl acetate, and naltrexone were the only pharmacologic agents approved to treat opioid dependence; in that year, France was the first country to approve the use of buprenorphine for this treatment. Since the late 1990s, buprenorphine has gained widespread use in the world. This chapter describes the history of buprenorphine, its associated pharmacokinetic and pharmacodynamic properties, the efficacy of this treatment, its optimal use in clinical practice, safety concerns, regulatory issues, and its use in special populations.

HISTORY

The chemical compound known as buprenorphine, 17-(cyclopropylmethyl)-alpha-(1,1-dimethylethyl)-4,5-epoxy-18,19-dihydro-3-hydroxy-6-methoxy-alpha-methyl-6,14-ethenomorphinan-7-methanol, hydrochloride, [5-alpha,7-alpha (S)], was first synthesized in 1966 (Reckitt and Colman, Hull, UK) and quickly found use as a potent analgesic agent (3). Jasinski and colleagues learned about the unique partial agonist qualities of buprenorphine and hypothesized that this agent might also be used in the treatment of opioid dependence. In experiments they conducted at the Addiction Research Center, adult males with prior opioid dependence were maintained on 8 mg/day of subcutaneous (SC) buprenorphine; when these individuals were given acute doses of morphine, they experienced an attenuated euphoric response (4). When three of these same individuals were given acute doses of 4 mg SC naloxone, they had on average fewer withdrawal signs and symptoms than seven individuals maintained on

morphine 30 mg SC four times daily, prompting the researchers to conclude buprenorphine had less risk of misuse and showed promise as a pharmacologic agent in the treatment of opioid dependence. These early results were substantiated when buprenorphine was shown to decrease heroin self-administration in heroin-dependent individuals (5). Buprenorphine was also shown to have a ceiling for euphoric effects, and it could almost completely block acute opioid effects for 24 hours with residual blockade of acute effects lasting for 98 hours after drug administration (6,7).

After these promising results, a sublingual (SL) version was developed for human clinical trials. Studies examining the efficacy of 8 mg SL buprenorphine as compared to low and high doses of methadone for maintenance therapy initially were conducted. One trial did not show a positive effect in terms of reducing relapse and improving retention in treatment over 52 weeks (8), whereas two other trials showed equivalence of buprenorphine with methadone (9,10) in terms of retention and opioid positive urine samples. Except for the flexible dosing strategy used in one study (10), these initial trials only tested a fixed 8 mg daily SL buprenorphine dose. Further trials showed superiority of 12 mg (11) and 16 mg doses of buprenorphine (12) to low dose methadone. In a major clinical trial (13), 220 opioid-dependent persons according to Diagnostic and Statistical Manual of Mental Disorders, 4th edition (DSM-IV) criteria (14) were randomized to low-dose methadone (20 mg), high-dose methadone (60 to 100 mg), buprenorphine (16 to 32 mg), or levomethadyl acetate (LAAM) (75 to 115 mg). Study retention rates were much greater and opioid use was much less in the high-dose methadone, LAAM, and buprenorphine treatment arms as compared to the low-dose methadone group. High-dose methadone had the highest retention rate (73%) followed by buprenorphine (58%) and LAAM (53%), although these results were not statistically different. LAAM had the lowest rate of opioid positive urinalysis per week (53%) followed by buprenorphine (62%) and methadone (62%). Given the preponderance of evidence, the U.S. Food and Drug Administration (FDA) gave approval for the use of buprenorphine (Subutex) and buprenorphine/naloxone (Suboxone) in the treatment of opioid dependence in the United States in October 2002, 6 years after approval in France.

As a partial agonist with a longer time to peak effect relative to morphine, buprenorphine has many useful features as a pharmaceutical treatment for opioid dependence. However, it is an opioid and has potential for abuse. Case reports of buprenorphine diversion and illicit use from New Zealand

were published as early as 1983, where buprenorphine was marketed for analgesia as Temgesic (15). More reports came from other countries throughout the 1980s and early 1990s. Given a growing concern of diversion, a combination product with buprenorphine and naloxone was developed to decrease the risk of illicit use by injection. The abuse liability of the combination product was examined in a double-blind, randomized within subject study of persons maintained on low-dose methadone. The study showed that administration of SC buprenorphine 0.2 mg + naloxone 0.2 mg as well as buprenorphine 0.3 mg + naloxone 0.2 mg had similar subjective and objective effects as naloxone alone (16). These results suggested that the combination of the two medications had low abuse liability. However, the 1:1 ratio needed refinement, as there were many unpleasant opioid withdrawal effects in the sample.

To discover the optimal ratio of buprenorphine to naloxone, Mendelson and colleagues looked at ratios of buprenorphine to naloxone in morphine-maintained individuals (17). They found that ratios of 2:1 and 4:1 provided the maximum decrease in euphoric effects of morphine with the minimum amount of withdrawal effects. A further study confirmed that the optimal ratio was 4:1 buprenorphine to naloxone (18). Efficacy studies showed that the naloxone was not well absorbed when given in a SL formulation, and that the combination product (given in 16/4 mg daily doses for 4 weeks) produced similar reductions in illicit opioid use as buprenorphine 16 mg alone (19). An observational study demonstrated longer-term utility in 53 opioid-dependent persons treated in a primary care setting, but retention was still 38% at 2 years (20).

PHARMACOKINETICS

Buprenorphine has low oral bioavailability due to substantial first-pass metabolism in the small intestine and liver, so the medication has been administered intravenously (IV), intramuscularly (IM), sublingually, and transdermally (TD). Original efficacy studies in the treatment of opioid withdrawal and dependence used a SL buprenorphine solution dissolved in 30% ethanol, whereas buprenorphine is currently marketed as a SL tablet with and without the addition of naloxone. The most widely used buprenorphine formulations in the United States for opioid dependence are SL buprenorphine hydrochloride (Subutex) or buprenorphine hydrochloride combined with naloxone hydrochloride in a 4:1 ratio (Suboxone), both manufactured by Reckitt Benckiser Healthcare Ltd. (Hull, UK). A generic formulation of buprenorphine came onto the U.S. market in October 2009 and is manufactured by Roxane Laboratories (Columbus, OH).

Pharmacokinetic studies of the SL tablet (8 mg) compared to the SL buprenorphine solution (8 mg/mL) revealed a relative bioavailability of 49% (based on area under the curve [AUC]) in an acute dosing model of nondependent volunteers (21), but this could range between 60% and 70% (AUC) after 7 to 14 days of daily buprenorphine dosing (22,23). There is large intersubject variability in the SL

absorption of buprenorphine, but there seems to be less intrasubject variability especially when examining the SL tablet formulation. SL absorption usually is dependent on saliva pH and length of time held under the tongue, but one study failed to find a clinically significant difference in buprenorphine absorption at differing saliva pHs and at times greater than 2.5 to 3 minutes held under the tongue (24). In clinical practice, patients are told to hold the tablet under their tongue until it dissolves, which occurs on average after 5 minutes. In some people, tablet particles can still remain after 10 minutes, but this does not affect bioavailability of buprenorphine.

Buprenorphine is highly lipophilic and therefore has a large volume of distribution. In plasma, it is usually protein bound but readily crosses the blood–brain barrier. Buprenorphine is metabolized by enzymatic transformation, mainly through the cytochrome P450 3A4 isozyme to the active metabolite norbuprenorphine (25). After glucuronidation, buprenorphine and its metabolites are excreted primarily through the fecal route (70%) as unconjugated buprenorphine or the metabolite norbuprenorphine. Around 30% is excreted in urine in the conjugated form, and dose adjustments usually do not need to be made in persons with severe renal impairment or who are on dialysis. Buprenorphine and its major metabolite are inhibitors of cytochrome P450 3A4 and 2D6 and could show significant drug–drug interactions if concomitant drugs that affect these enzymes are taken (26).

The addition of naloxone does not interfere with buprenorphine's pharmacokinetics but is mainly used as a deterrent against diversion and parenteral misuse of buprenorphine. There is very little absorption ($\leq 10\%$) of SL administered naloxone. Naloxone is metabolized using similar enzymatic transformation and glucuronidation as buprenorphine, although its elimination half-life is much shorter (1 to 2 hours) when compared to buprenorphine. Naloxone can cause withdrawal effects if the tablet is crushed and injected in persons dependent on opioids (16,27). Likewise, as a partial agonist, buprenorphine itself can precipitate withdrawal if given to individuals maintained on other full mu-opioid receptor agonists, as buprenorphine has higher affinity to the receptor. This is a rare occurrence but has been seen, especially when transitioning high-dose methadone-maintained individuals to buprenorphine.

PHARMACODYNAMICS

Buprenorphine is a synthetic derivative of the morphine alkaloid thebaine and has approximately 25 to 40 times the analgesic potency of morphine when administered IV, and is 15 times more potent than intramuscular morphine when administered SL. Unlike morphine, buprenorphine displays both typical mu-opioid receptor agonist and antagonist properties, making it an ideal candidate for the treatment of opioid dependence. The agonist effects—miosis (clinically insignificant), respiratory depression, decreased gastrointestinal motility, euphoria, and sedation—occur at lower doses of the drug while antagonist effects occur only with increasing doses of buprenorphine given to persons maintained on another

primary mu-opioid receptor agonist. These properties allow for a “ceiling effect” on respiratory depression, making for a better safety profile than pure mu-opioid receptor agonist (28).

The onset of buprenorphine’s drug effect is slower than morphine, with mean peak effect seen between 40 and 60 minutes (producing a lower peak euphoric rush compared to other opioids), but the duration of action is longer, with a terminal half-life of 32 to 37 hours (4). Most likely this is a route of administration effect, as IV administered buprenorphine produces similar drug liking responses as IV morphine in persons with an opioid abuse history. The long terminal half-life allows for once daily or even less frequent dosing patterns (29). Buprenorphine’s receptor binding properties help explain its partial agonist profile; it binds to mu-opioid receptors with greater affinity and can displace other agonists from these sites (30). Higher doses of an antagonist (3 and 10 mg/70kg IM naloxone or 3 mg/70 kg PO naltrexone) are required to displace buprenorphine from mu-opioid receptors as compared to methadone (31). Buprenorphine is also a weak kappa-opioid receptor antagonist, delta-opioid receptor antagonist, and opioid receptor-like 1 (ORL-1) agonist, but the full understanding of these actions is not yet known. It is currently hypothesized that one or more of these receptors could be involved in or mediate buprenorphine’s bell-shaped dose–response curve. Buprenorphine’s ORL-1 activity especially shows promise as the mechanism behind its ceiling effect for respiratory depression, as activation of this receptor antagonizes acute effects of morphine; however, more research into this area is needed.

EFFICACY IN THE TREATMENT OF OPIOID DEPENDENCE

This section examines the peer-reviewed papers reporting on results regarding the efficacy of buprenorphine and buprenorphine/naloxone in the treatment of opioid dependence (both maintenance and detoxification treatment). While the utility of detoxification as a treatment intervention has been called into question, detoxification followed by significant psychosocial rehabilitation does have proven benefit (32). It is with that overall treatment goal that opioid detoxification with buprenorphine is discussed.

Buprenorphine/naloxone and buprenorphine have been shown to provide greater suppression of opioid withdrawal symptoms in both inpatient and outpatient detoxification settings as compared to clonidine (33), dihydrocodeine (34), and lofexidine (35), and show similar results as methadone (36). Retention rates in these clinical trials have usually been higher in the inpatient as compared to outpatient setting, but one multisite trial conducted by the National Institute on Drug Abuse Clinical Trials Network did not find a significant difference between setting types (37). Drug abstinence at the end of outpatient detoxification is achieved at relatively low rates (17% to 29%) (38). Higher treatment success following opioid detoxification (as defined by study completion and drug-free urinalysis on the last day of study) is associated with better control of withdrawal symptoms during treatment,

fewer comorbid substance use disorders (SUD) including nicotine dependence, and higher baseline anxiety levels (33). Long-term abstinence following detoxification, however, is rarely achieved or sustained unless significant ongoing rehabilitation and treatment is continued.

Consensus treatment guidelines advocate long-term maintenance therapy as a first-line strategy in adult opioid-dependent participants. In one of the first randomized controlled clinical trials of buprenorphine maintenance, daily SL buprenorphine (8 mg) was shown to be as effective as 60 mg methadone in terms of retention and opioid-negative urines, and superior to 20 mg methadone (9). Further double-blind clinical trials replicated these early results using a clinically relevant flexible dose schedule (10), although a Swiss multisite trial showed higher dose methadone (60 to 120 mg) had better retention rates than moderate dose buprenorphine (12 to 16 mg) (39). These early trials defined maintenance treatment as lasting between 8 and 16 weeks. Studies of longer duration (6 to 12 months) initially showed results favoring high-dose methadone compared to buprenorphine in terms of retention, opioid-free urine toxicology screens, and withdrawal symptoms (8,11). A recent meta-analysis by the *Cochrane Review* examined 24 randomized and controlled clinical trials and concluded that buprenorphine is less effective at retaining patients in treatment than methadone delivered at adequate doses (40). However, results for opioid-free urines showed no inferiority of buprenorphine and the authors concluded that buprenorphine is an effective intervention for the maintenance treatment of opioid dependence. Buprenorphine/naloxone combinations have also shown to be as effective as buprenorphine alone (19). Longer-term effectiveness trials in primary care clinics have shown buprenorphine to be a safe and successful treatment not only in the United States but also in over a dozen countries on six continents (41–45). These studies have shown that there is a large dropout rate in the first 3 months of treatment, but that this can be reduced somewhat by a quick induction phase to eliminate withdrawal symptoms. Given this large dropout rate, more research is needed into optimally choosing candidates for buprenorphine treatment. Patient variables such as gender, age, lifetime opioid use, and the particular opioid abused (heroin, methadone, or other prescription opioids) could be predictors of treatment outcomes as a few studies have shown.

OPTIMAL USE OF BUPRENORPHINE

The use of buprenorphine (most commonly buprenorphine/naloxone in the United States) in an outpatient medical practice for opioid dependence consists of three main phases: induction, stabilization/maintenance, and (if necessary) withdrawal. Induction onto buprenorphine, defined here as the first 24 to 72 hours of starting on buprenorphine, requires first a comprehensive medical evaluation to establish a diagnosis of opioid dependence, drug use history and any complicating medical, psychiatric disorders or SUD, concomitant medications, and drug allergies. There are no absolute contraindications to buprenorphine, except for documented previous

allergic reactions to the medication or naloxone. The medication is not approved for children (<16 years of age) or pregnant women, but ongoing clinical trials are assessing safety and efficacy in these populations.

There are two separate induction strategies for persons previously on short-acting opioids (e.g., heroin or oxycodone) versus long-acting opioids (e.g., methadone). This discussion will first focus on buprenorphine induction for dependence on short-acting opioids. Patients should be told to come to the office in mild opioid withdrawal, usually 4 to 12 hours after their last dose of opioid. A clinician should verify the withdrawal syndrome with a standard rating scale such as the Clinical Opiate Withdrawal Scale (COWS) (46,47). Depending on the level of prior opioid use, the patient should be given 2/0.5 or 4/1 mg of SL buprenorphine/naloxone and monitored in the office for any side effects, including worsening opioid withdrawal or opioid toxicity. The patient should be instructed to place the tablet(s) under the tongue and keep them there for 3 to 5 minutes without talking or swallowing. If the mouth is dry, the patient should be instructed to drink water first before being administered the medication. If side effects occur, they should be treated with the appropriate medications. If withdrawal is not relieved by the initial buprenorphine dose, the patient can be redosed up to a recommended maximum total dose of 8/2 mg buprenorphine/naloxone on the first day. Previous research has shown that rapid induction of buprenorphine and buprenorphine/naloxone is safe and leads to better retention (42), so a patient should usually reach their maintenance dose (12 to 16 mg) on the second day. If the patient requires >16/4 mg per day, further titration can occur to a maximum dose of 32/8 mg on days 3 to 4.

There were some initial fears that giving persons already in mild opioid withdrawal SL naloxone in the form of buprenorphine/naloxone would worsen withdrawal, so the U.S. guidelines published in 2004 recommended using buprenorphine (without naloxone) during the initial induction and then switching to buprenorphine/naloxone (48). However, clinical experience and a recent clinical trial has shown that SL naloxone does not induce further withdrawal (49), and most practitioners start induction with buprenorphine/naloxone without sequelae. Buprenorphine/naloxone should be used for all phases of maintenance unless the subject has a documented allergy to naloxone; buprenorphine alone should be rarely used.

When the patient is dependent on long-acting opioids, the induction phase ideally requires an initial taper of the long-acting opioid. In the case of methadone, a person should be tapered to 30 to 40 mg daily dose if possible before buprenorphine induction (48). The patient should be instructed to present to the office 24 to 36 hours after the last methadone dose in order to show some mild opioid withdrawal. They should be told there is a small risk for worsening withdrawal symptoms after starting buprenorphine/naloxone. The rest of the induction phase is the same as with short-acting opioids. The patient should take no more methadone after the first dose of buprenorphine/naloxone. In case there are fears that a protracted methadone taper may trigger relapse before starting

buprenorphine/naloxone, there is a study that has shown that there can be safe transition to buprenorphine/naloxone in some persons maintained on 100 mg of methadone (50). Results from that study suggest that small repeated doses of buprenorphine/naloxone (2/0.5 mg) spaced approximately 2 hours apart will decrease the risk of buprenorphine-precipitated withdrawal.

Although opioid dependence is typically required for buprenorphine maintenance, one exception requires more discussion. A physician may decide to prescribe buprenorphine to a person who is not currently opioid dependent but at high risk for relapse or developing opioid dependence; for example, a recently released prisoner with opioid dependence prior to incarceration or person using opioids after a recent detoxification attempt. This induction should start with a smaller buprenorphine/naloxone dose (2/0.5 mg) and should be titrated up to clinical effect more slowly (e.g., dose increases every 3 to 7 days).

Stabilization is the phase where the patient is maintained on the same dose of buprenorphine/naloxone and is referred/engaged in concurrent psychosocial counseling/rehabilitation. At this point, the patient may choose to take buprenorphine on alternate days, but this is not the general recommendation and is done rarely in clinical practice. Twice-daily dosing may also be required, especially in patients with comorbid pain.

Withdrawal from buprenorphine can be accomplished rapidly in an inpatient setting (≤ 3 days) or during a protracted outpatient taper. In the past, 0.3 mg IM buprenorphine was given two to three times daily for a rapid 3-day withdrawal. However, this treatment is no longer recommended and IM buprenorphine is not approved for opioid-dependent treatment. Instead, inpatient settings may use a SL buprenorphine taper. The superiority of moderate or long-term taper of buprenorphine has not yet been fully determined, although most studies show a substantial increase in opioid positive urines after any buprenorphine taper (33). Whether or not to stop buprenorphine treatment should be decided on a case-by-case basis by the physician and patient, weighing the risks of continued treatment against the risks of relapse following withdrawal.

LEGAL ISSUES

Office-based treatment of opioid dependence with buprenorphine did not come easily in the United States. Pharmacologic treatment of opioid dependence had been hindered by the Harrison Narcotic Act of 1914, which was interpreted by courts after 1917 to forbid physicians from prescribing opioids specifically for the treatment of opioid dependence. Prosecution of physicians violating this act and subsequent legislation continued until the American Medical Association and American Bar Association issued a joint report questioning these policies in 1958 (51). Methadone subsequently became available for the treatment of opioid dependence, and has proven to be a reliable and beneficial treatment. However, administrative fears of diversion,

overdose, and physician prescribing practices led to very stringent and convoluted policies that governed its use, including an ability to dispense methadone only at approved clinics and hospital pharmacies. These policies, codified in the Narcotic Addict Treatment Act (NATA) of 1974, as well as a cadre of various state and local regulations, governed the medical treatment of opioid dependence up until 2001.

As stated earlier, buprenorphine showed early promise as a treatment for opioid dependence. However, it required an act of Congress in the United States to approve its use by individual physicians in an office-based setting. That bill was the 2000 Drug Addiction Treatment Act (DATA), which had taken 5 years of political maneuvering to become law (52). DATA allowed physicians to prescribe narcotics in an office-based setting and pharmacists to dispense certain narcotics (currently only buprenorphine) for the treatment of opioid dependence. The wording leaves open the possibility of “any approved narcotic drugs in schedule III, IV, or V ... for maintenance or detoxification treatment,” so other medications may also be used in the future in office-based settings under DATA. DATA did specify requirements before physicians could legally prescribe buprenorphine for opioid dependence (Table 29.1). If a physician meets those requirements, he or she must apply for and receive a Department of Health and Human Services waiver (DHHS) waiver (<http://www.buprenorphine.samhsa.gov>) and

be given a specific Drug Enforcement Agency (DEA) number before writing the first prescription.

Given concerns over diversion, DATA limited the number of buprenorphine-approved patients (initially 30 per physician group/institution) and prescribed a 3-year monitoring phase after buprenorphine was approved by the FDA for treatment of opioid dependence. In 2005, the effects of DATA on opioid dependence received a good review; thus DHHS expanded the number of potential buprenorphine patients per individual prescriber to the current levels (100 per year after the first year of approval) and removed the group practice restriction. Nevertheless, DHHS and DEA still have the authority to repeal the law without Congressional approval if those organizations are concerned about buprenorphine’s effects on public health, making it easy to end office-based treatment of opioid dependence in the future.

In the United States, the rate of physicians applying for and receiving an DHHS waiver to prescribe buprenorphine has not been as quick as first predicted. As well, about half of all the physicians qualified to prescribe buprenorphine are addiction specialists (53). This indicates that primary care doctors are not expanding access to buprenorphine by becoming prescribers in the numbers that were originally projected. Reasons for this hesitation include lack of qualified counseling services, staff training, visit time required for in-

TABLE 29.1 Requirements for DATA Waiver

- Be a licensed physician (MD or DO)
- Possess a current DEA Number
- Have completed one of the following:
 - 1) Subspecialty Board Certification in Addiction Psychiatry from the American Board of Medical Specialties
 - 2) Addiction Certification from the American Society of Addiction Medicine
 - 3) Subspecialty Board Certification in Addiction Medicine from the American Osteopathic Association
 - 4) Not less than 8 hours of training on the treatment and management of opioid-addicted patients^a
 - 5) Participated as an investigator in one or more clinical trials leading to the approval of a narcotic drug in Schedule III, IV, or V for maintenance or detoxification treatment
 - 6) Other training or experience as the State medical licensing board (of the State in which the physician will provide maintenance or detoxification treatment) considers to demonstrate the ability of the physician to treat and manage opioid-addicted patients
 - 7) Other training or experience as the Secretary of the Department of Health and Human Services (DHHS) considers to demonstrate the ability of the physician to treat and manage opioid-addicted patients (only a 3-year waiver)
- Have the capacity to refer patients to counseling and ancillary services
- Agree to have no more than 30 patients prescribed buprenorphine for opioid dependence in the first year after receiving a waiver and up to 100 patients after the first year
- Notify the Center for Substance Abuse Treatment in writing of the intent to begin dispensing or prescribing buprenorphine

^aSponsored by the American Society of Addiction Medicine, the American Academy of Addiction Psychiatry, the American Medical Association, the American Osteopathic Association, the American Psychiatric Association, or any other organization that the Secretary of DHHS determines is appropriate.

Figure 29.1. Countries where buprenorphine is prescribed for opioid dependence.

duction phase, lack of buprenorphine availability in local pharmacies, and pain medicine concerns (54). Future campaigns should address these needs in order to increase access to buprenorphine maintenance treatment.

Outside of the United States, countries have various legal restrictions on the prescribing and dispensing of buprenorphine and buprenorphine/naloxone. (See Fig. 29.1 for countries currently allowing the use of buprenorphine for the treatment of opioid dependence.) The following is not meant to be an exhaustive description of policies regulating buprenorphine in every country, as that would be beyond the scope of this chapter, but does illustrate the parameters of buprenorphine's use in non-U.S. countries. In France, the initial country to approve the use of buprenorphine for the treatment of opioid dependence, a national policy places physicians in primary care or specialized drug treatment facilities as the “gatekeepers” of patients' access to buprenorphine and allows community pharmacies to dispense it. Physicians can prescribe buprenorphine with up to a 28-day supply, but patients can only get up to 7 days of medication from the pharmacy unless the physician allows for longer periods (55). This system has led to buprenorphine being the primary medication used in opioid replacement therapy (ORT) throughout the country. Unlike France, Australia has both national and state laws that govern the use of buprenorphine for ORT (56). In this country, community pharmacists are the “gatekeepers” of patients' access to buprenorphine. Both physicians who prescribe buprenorphine and at least one pharmacist in the pharmacy that dispenses it must receive specialized buprenorphine training. States set up differing laws regarding take-home availability; but in general, all buprenorphine must be taken by the patient and witnessed by a staff member in a community pharmacy. National law does offer every other day or thrice-weekly dosing to stable patients who do not want to

come daily for treatment. Finally, the “gatekeepers” in Italy (physicians) can only be found in specialized ORT facilities, and these prescribers must have received specialized training for buprenorphine (56). The medication is then dispensed daily in these facilities and must be witnessed, similar to methadone. In conclusion, eligibility criteria for buprenorphine, its prescribing and dispensing authority, or even the ability to offer ORT are governed by statutes that are essentially unique to each country where this medication is available.

SAFETY CONCERNS

The most common side effects from buprenorphine result from its opioid agonist properties and are seen when given to a non-dependent person. These can include nausea, vomiting, sedation, and dizziness. Respiratory depression from buprenorphine, a serious and often fatal complication of other opioids, has been examined extensively in humans and animals. Studies concluded that there was a ceiling effect for respiratory depression unlike pure mu-opioid receptor agonist, and that this depression was not clinically significant (57,58). If severe respiratory depression does occur in the community, it is usually due to concurrent use of benzodiazepines and/or alcohol. This rare respiratory depression is difficult to treat with standard opioid antagonists; the best recommendation is to provide a continuous naloxone infusion until the buprenorphine has been cleared from the patient (59). However, case reports have also shown benefit from high-dose single injection of naloxone (4 to 6 mg IV bolus given within a correct dose window) (60) and doxapram, which stimulates respiratory drive via peripheral and central means (61).

There has also been particular interest on the cognitive and psychomotor effects of buprenorphine, especially as ORT is

meant to help facilitate a person's return to employment, family involvement, and other important societal functions. However, many of the published studies examining acute and chronic dosing effects on cognition have methodologic problems that make conclusions difficult; for example, not matching groups on characteristics known to influence cognitive performance like premorbid IQ and allowing persons with active substance use to participate in studies. Nevertheless, some conclusions may be drawn that appear consistently throughout the literature. First, with a decrease in use of heroin or other illicit opioids while on buprenorphine maintenance, a person's executive function, selective attention, and concentration usually improve (42). Second, there appears to be relatively slower acute reaction time when comparing persons maintained on methadone to persons on buprenorphine (62). Third, buprenorphine seems to have less of an effect on decision-making skills than methadone (63). Finally, researchers have demonstrated that driving is not significantly impaired during buprenorphine maintenance; and, the addition of small amounts of alcohol (0.05% blood alcohol concentration) to chronic buprenorphine dosing does not show any worse performance than in non-drug abusing controls (64). Thus, the majority of the peer-reviewed studies indicate that buprenorphine may have less cognitive side effects than methadone; but like methadone, buprenorphine may help increase functioning to baseline by decreasing illicit substance use. However, better designed, prospective research is needed in this area to validate these conclusions.

In light of the growing concern over cardiac arrhythmias from QTc prolongation in methadone maintenance, studies have examined the risk for electrocardiogram abnormalities with buprenorphine and buprenorphine/naloxone. Researchers have concluded that buprenorphine does not significantly prolong the QTc at clinically indicated dosing ranges and may be safer than methadone (65). However, if patients are taking known inhibitors of cytochrome P450 3A4, such as certain medications to treat HIV, there is a slightly increased but not clinically significant risk of QTc prolongation (66).

Deaths associated with buprenorphine have received increased public scrutiny recently, especially as methadone-related overdoses have increased. The number of calls to U.S. Poison Control Centers after buprenorphine exposure has gone from 13 in 2000 to almost 6200 in 2008 (67) and a similar increase has been reported in France (68). In some countries, the number of reported deaths related to buprenorphine increased after its introduction, especially if combined with benzodiazepines. Whether this trend improves as physicians and patients become more knowledgeable about the medication remains to be seen. The experience in France, which approved buprenorphine in 1996, has shown that the death rate related to buprenorphine is lower than methadone (69), and there is early evidence for this same finding in Australia (70).

Diversion of buprenorphine was one of the original feared effects of office-based treatment. As the use of buprenorphine for opioid dependence has risen, diversion of supplies onto the black market has increased. In some locations outside of the United States where the heroin supply has been curtailed, this diversion is more frequent per capita than methadone (71). In

the United States, a survey of 1000 patients seeking drug-abuse treatment at standard drug-abuse clinics showed that 35% of individuals self-reported misuse of buprenorphine to get high during the initial 2 years of treatment and this number fell to below 20% by the end of the survey period (72). In that same study, less than 3% of all persons presenting for ORT in 2007 gave buprenorphine as their drug of choice to get high. Vigilance should be maintained in the United States to prevent more diversion while not restricting this valuable pharmacotherapy from reaching patients in need.

Following diversion, illicit injection of buprenorphine (8 to 16 mg daily) has been associated with several cases of hepatitis, all in persons with underlying liver disease (i.e., hepatitis C and alcoholic hepatitis) (73). There is also evidence that hepatitis can occur in persons taking SL buprenorphine as prescribed (74,75), but these individuals also had underlying risk factors. Physicians should check liver function tests before induction and after maintenance has been achieved in those persons with known or at risk for liver dysfunction. Other side effects associated with the injection of SL buprenorphine are similar to most other illicit IV drugs, and include infectious endocarditis (76), myositis (77), acute limb ischemia sometimes requiring amputation (78), and embolic stroke (79).

Even with these risks of buprenorphine, two elegant studies have shown an overall decreased mortality in persons exposed to and compliant with ORT—including buprenorphine (43,80).

SPECIAL POPULATIONS

Although the FDA and most international governments have approved buprenorphine only for adults, recent research has shown promising results for buprenorphine's use in adolescents, pregnant women, and incarcerated populations. These populations are covered in depth elsewhere but deserve brief comment in this chapter. First, there is no FDA-approved treatment for opioid dependence in adolescents (<16 years old). However, one clinical trial showed promise for this medication's longer-term use in this population. Researchers randomized 152 persons aged 14 to 21 years with DSM-IV opioid dependence to either a 14-day buprenorphine detoxification and subsequent counseling or 12 weeks of buprenorphine maintenance along with counseling (81). Primary outcomes examined were opioid positive urine toxicology and treatment retention. At week 12, only 20.5% of adolescents randomized to detoxification remained in the study versus 70% in buprenorphine maintenance. There was no statistical difference in opioid positive urines between the groups at week 12, but there were significantly lower positive urines in the maintenance group at weeks 4 and 8. Maintenance participants had lower self-reported cocaine, marijuana, and injection drug use, and attended more counseling sessions than the detoxification group. During 12 month follow-up, the detoxification group was over twice as likely (OR 2.65) to have an opioid positive urine as the maintenance group. Overall, this trial pointed to the potential value of longer-term buprenorphine treatment for adolescents with opioid dependence. More research is

needed on buprenorphine for this population, but it is likely to show value in including opioid agonist treatment for adolescents.

Buprenorphine (and buprenorphine/naloxone) is an FDA pregnancy category C medication, indicating not enough studies have been done to advise the use of this medication during pregnancy. The standard of care for opioid-dependent pregnant women has been methadone in a specialized treatment facility. There have been many peer-reviewed articles published on buprenorphine treatment of opioid dependence in pregnancy. In reviewing outcomes of these studies, authors examined birth weight, prematurity, neonatal abstinence syndrome (NAS), perinatal complications, and some long-term follow-up data on women and their offspring. In two studies comparing women without substitution therapy to buprenorphine and methadone, buprenorphine had less incidence of NAS compared to methadone (82,83), although other studies did not replicate this finding (84,85). When NAS was present, it had a later onset than methadone but seemed to be shorter in length. There was no difference in neonatal weight, length of hospitalization, or frequency of birth defects/neonatal demise in buprenorphine as compared to methadone-treated women (85–87). If women are to be prescribed buprenorphine currently, they should be informed that research is still ongoing into the neonatal and maternal outcomes. As well, induction onto buprenorphine may be complicated by precipitated withdrawal if the woman has been using long-acting opioids, but the maintenance phase typically has fewer dose adjustments (88). Finally, breastfeeding can usually continue if the mother remains on buprenorphine as there is low oral bioavailability of the medication. However, this recommendation is not yet backed by definitive studies.

The use of opioid agonist treatment in the prison system has been advocated by the Centers for Disease Control and Prevention (CDC) and the World Health Organization (WHO) due to the high incidence of substance use in the year prior to incarceration and obvious benefits to individual and public health (89,90). However, only 55% of facilities in the United States offer methadone currently, usually only for chronic pain and in pregnant women with opioid dependence; an even lower percentage of facilities offer buprenorphine (14%) (91). Internationally, 29 countries or territories offered ORT to prisoners in 2008, which was an increase over previous years (92). Most facilities prefer a drug-free detoxification environment to opioid agonist treatment. These facilities also do not always refer inmates to postrelease methadone or buprenorphine providers, doing so in less than half of all cases. Research is ongoing into the cost savings, decreased recidivism, decreased HIV transmission, and effects on substance relapse postrelease. This research is needed to help sway prisons and jails to treat opioid dependence just like any other disease during incarceration.

CONCLUSION

Buprenorphine provides patients and health care providers a new medication for the treatment of opioid dependence. It is often preferred over methadone by patients for its ease of use

and safety/side effect profile. This chapter has shown the intense work done by researchers, lawmakers, physicians, advocates, and patients themselves to bring this treatment to the market. It does have unique risks and benefits, which should be weighed for every potential patient; it also appears to be roughly equivalent in many outcomes compared to methadone. Long-term data are still being collected, but the French experience shows the great benefits can occur with buprenorphine's widespread use. Hopefully, these results will be reproduced in the United States and worldwide for the benefit of all.

INTRODUCTION

Naltrexone hydrochloride is a nonselective, competitive opioid receptor antagonist which binds at the mu-, kappa-, and delta-opioid receptors and prevents opioids from binding at these receptors. Naltrexone is approved by the Food and Drug Administration (FDA) as a pharmacotherapy for the treatment of opioid dependence and for alcohol use disorders. While originally developed for use in opioid use disorders, its *clinical* effectiveness has been disappointing for opioid-dependent individuals. Instead, opioid *agonist* therapy with methadone or with the more recently approved mixed agonist/antagonist buprenorphine is usually the treatment of choice. Nevertheless, naltrexone continues to have a role in the treatment of opioid dependence, as an adjunctive medication during detoxification to shorten the course of detoxification or as maintenance therapy in highly motivated individuals. In contrast to the literature of naltrexone's efficacy in opioid dependence, a rich literature, including both clinical trials and laboratory studies, supports naltrexone's use in individuals with alcohol use disorders. Although not all patients benefit from its use, new research has suggested that certain patient characteristics such as family history of alcoholism and certain genetic polymorphisms are associated with the greatest efficacy. Naltrexone has also been evaluated as a potential treatment for other psychiatric disorders, such as pathological gambling and eating disorders, but its efficacy in these disorders has not been definitively established. This chapter reviews the clinical uses of naltrexone and the research evaluating its efficacy.

PHARMACOLOGY

The opioid receptor was first characterized in the 1970s and has subsequently been widely studied. Three types of opioid receptors have been identified and include the mu-, delta-, and kappa-opioid receptors. The opioid receptors are found primarily in the central nervous system and in the gastrointestinal tract, and mediate both the effects targeted by medications and the side effects of these agents. Opioids are chemicals that work by binding to the opioid receptors; they include medications (e.g., Percocet, oxycodone, OxyContin), drugs of abuse (notably heroin), and even occur endogenously (e.g., beta-endorphin). *Opiates* are those opioids which are either found in the resin of the opium poppy or are generated from its derivatives. Table 30.1 presents common opi-

oids and opioid antagonists. Opioids when used medicinally are used primarily for their analgesic effects since they decrease the perception of pain, the reaction to pain, and pain tolerance (1). Other effects include sedation, constipation, and suppression of cough.

Extensive research has shown that substance use and abuse is mediated via the so-called reward circuit of the brain, which is a neurochemical pathway that connects mesolimbic and mesocortical structures. Dopaminergic neurons connect the midbrain ventral tegmental area via a mesolimbic dopaminergic pathway to cortical regions including the nucleus accumbens, amygdala, the hippocampus, and the prefrontal cortex. The reward potential of drugs of abuse is related to their ability to stimulate dopamine release in the mesolimbic pathway. Opiates are of particular interest in substance use disorders because activation of the opioid receptors results in dopamine release in the nucleus accumbens and is related to increased euphoria and feelings of well-being.

Naltrexone hydrochloride was first synthesized in the 1960s for use in the treatment of heroin dependence (2). Naltrexone has several routes of administration, including oral administration, implants, and suspended release injection. It is marketed under the trade names Revia and Depade; the extended release under the trade name Vivitrol. Naltrexone has a half-life of about 4 hours and the active metabolite 6-beta-naltrexol has a half-life of about 12 hours (3). Two related drugs include naloxone and methylnaltrexone bromide. Naloxone is shorter acting than naltrexone and not absorbed orally; it is the treatment of choice for opioid overdose and is part of the formulation of Suboxone, a combination treatment of buprenorphine and naloxone for opioid maintenance therapy. Methylnaltrexone bromide (Relistor) is marketed as a treatment for opioid-induced constipation.

Naltrexone and its active metabolite, 6-beta-naltrexol, are competitive antagonist at mu, kappa, and delta receptors. This competitive antagonism means naltrexone binds to the opioid receptor competing with opioid drugs (e.g., heroin and morphine). Naltrexone acts by reversibly blocking the physiological and subjective effects of opioids, thereby attenuating the euphoric effect of opioid drugs, rendering them less rewarding and less reinforcing. Naltrexone can also be used in opioid detoxification; however, it can precipitate opioid withdrawal and should be used with care in opioid-dependent populations. Although its mechanism of action suggests it would be an ideal medication for opioid dependence, its clinical utility is not supported by clinical studies.

TABLE 30.1 Opioids and opioid antagonists

Generic name	Trade name(s) ^a
Opioids	
Codeine	No trade names
Morphine	Astramorph, Avinza, Duramorph, Infumorph, Kadian, MS Contin, Oramorph, Roxanol
Diacetylmorphine (heroin)	No trade names
Hydrocodone	Vicodin, Lortab, Lorcet, Hycodan, Vicoprofen
Hydromorphone	Dilaudid
Oxycodone	Tylox, Percodan, Oxycontin
Oxymorphone	Opana, Numorphan, Numorphone
Fentanyl	Actiq, Fentora, Duragesic

Naltrexone is also used in the treatment of alcohol dependence. Alcohol produces a wide variety of pharmacological effects on a number of different neurotransmitter systems including the dopamine, opioid, glutamate, serotonin, and GABA (gamma-aminobutyric acid) systems. Like all drugs of abuse, alcohol stimulates dopamine release in the mesolimbic pathway and dopaminergic release contributes to its reinforcing effects. However, dopamine release is not critical in promoting continued alcohol consumption. The rewarding effect of alcohol is also related to its ability to stimulate the opioid system. After preclinical evidence showed that naltrexone reduces alcohol euphoria and consumption in laboratory animals, naltrexone was examined as a possible treatment for alcohol use disorders in humans. Given the complexity of the reward circuitry and of alcohol's complex effects on multiple neurotransmitter systems, questions remain about the exact mechanism of action of naltrexone's effect on alcohol reward (4).

EFFICACY OF NALTREXONE

Opioid Dependence

Opioid dependence is a serious clinical problem leading to significant morbidity and mortality. It has been estimated that 0.1% to 0.4% of the population has opioid dependence; however, the number of individuals using opioids has increased dramatically with the availability of prescriptions such as Vicodin and OxyContin (1). Clinically, it is a syndrome manifested by continued use of opioids despite physical, social, or psychological consequences; usually individuals are physically dependent. The hallmarks of physical dependence include tolerance and withdrawal upon abrupt discontinuation of use. Abrupt cessation of opioids in an individual who is physically dependent leads to a well-characterized syndrome manifested by dysphoria, nausea, vomiting, rhinorrhea, watery eyes, mydriasis, and muscle aches, hence the term

“kicking.” Some of the symptoms are mediated by a hyperactivity of the noradrenergic system, particularly in the locus coeruleus. Detoxification from opioids can be accomplished by substitution and gradual tapering of a longer acting opioid (such as methadone). Alternatively, adrenergic agents, such as clonidine or lofexidine, are used to treat some of the symptoms of the opioid withdrawal syndrome by dampening the noradrenergic hyperactivity of the locus coeruleus. However, these agents do not alter its course (5). An alternative to detoxification is *agonist maintenance* therapy with methadone or the partial agonist buprenorphine, but that is beyond the scope of this chapter.

Naltrexone for Opioid Withdrawal/Detoxification

Since naltrexone binds to opioid receptors, administration of naltrexone in an opioid-dependent individual precipitates opioid withdrawal. Nevertheless, it has been used in the treatment of opioid withdrawal as an adjunct medication in order to accelerate the detoxification process. Naltrexone can be administered in combination with the α -adrenergic agent clonidine and other medications in an outpatient setting to produce rapid opioid withdrawal. In this application, naltrexone-assisted clonidine detoxification may reduce the time required for opioid detoxification from about 14 days down to 4 to 7 days (6). It should be noted that naltrexone can increase patient discomfort and reduce treatment compliance.

Naltrexone is also used in ultrarapid opioid withdrawal procedures. This accelerated withdrawal process occurs under general anesthesia in order to reduce the unpleasant effects of opioid withdrawal (7). As with rapid withdrawal, naltrexone is administered in combination with other medications (e.g., clonidine). The ultrarapid withdrawal process occurs over a 4- to 6-hour period, substantially shorter than the rapid withdrawal process. Ultrarapid opioid withdrawal is a significant medical procedure since it confers the risk of general anesthesia. Due to possible respiratory complications during and immediately postwithdrawal, an experienced anesthesiologist should be available (5). The opioid antagonist naloxone is used more commonly than naltrexone in ultrarapid opioid withdrawal (7).

Although patients are physiologically no longer dependent on opioids after withdrawal, craving for opioids occurs and could precipitate relapse. Following rapid and ultrarapid opioid withdrawal, maintenance with naltrexone (50 mg/day) is recommended to reduce levels of craving (5). However, following ultrarapid detoxification, rates of relapse are not substantially better than rates after more conventional methods of detoxification (8). Therefore, the risk/benefit ratio of ultrarapid detoxification seems to increase the risk without substantial benefit, when compared to more conventional methods.

Naltrexone for Maintenance Therapy

After abstinence is achieved, naltrexone can be used for maintenance therapy in order to prevent relapse. Due to the risk of precipitating withdrawal, abstinence from opioids is a pre-

requisite for the use of naltrexone as a maintenance pharmacotherapy. For patients who have not undergone documented detoxification, it is recommended that patients successfully complete a naloxone or naltrexone challenge to confirm abstinence prior to dosing. Naltrexone prevents relapse by blocking the effects of opioids, serving as a deterrent to further use.

Oral naltrexone was approved for use in opioid dependence in the United States by the FDA in 1984. Although in theory, naltrexone should be an ideal candidate for the treatment of opioid dependence, clinical data supporting naltrexone's efficacy in opioid dependence is not robust. Some reviews have suggested that naltrexone is not superior to placebo for retention or relapse rates. However, the studies are plagued by poor retention rates, which have been as low as 4% (1). Nevertheless, some evidence does suggest that naltrexone use is associated with lower heroin use and decreased criminal activity. When examining treatment studies with high retention rates, naltrexone decreased opioid use, craving, and even psychiatric symptoms compared to controls (1). Naltrexone seems to be particularly beneficial for patient populations who are highly motivated to remain opioid-free, such as health care professionals and legally mandated opioid-dependent individuals (1).

Doses and Routes of Administration

The standard prescribing dose of naltrexone is 50 mg/day, which is a dose that is sufficient to block the pharmacological effects of 25 mg of IV heroin for 24 hours (5). The frequency of naltrexone oral administration can vary from 50 mg/day to 100 mg/every other day to 150 mg/every third day: for every 50 mg dose, the duration of action extends by 24 hours. Therefore, a naltrexone dose of 100 mg is effective for 2 days and 150 mg for 3 days. Since higher doses can be taken less frequently, medication may be administered by others and this has the potential to improve compliance. Compliance is a major issue, as patients who want to resume opioid use can skip doses to resume drug use. Naltrexone use is not associated with tolerance or withdrawal.

While oral administration is currently the only approved route of administration for naltrexone, other routes under investigation include naltrexone implants and injectable sustained-release naltrexone. The advantage of the implants and sustained-release injections is the potential increase in compliance, compared to oral administration. Neither of these new routes of administration is currently approved by the FDA for the treatment of opioid dependence. Naltrexone implants typically last up to 4 to 6 weeks (however, some are formulated to last 4 to 6 months). Doses range from 1.1 to 2.2 to 3.3 g. The location of the implant is subcutaneous, in the abdomen or lateral chest wall (9). Individual variations in plasma naltrexone concentrations have been observed (10).

The first randomized clinical trial examining the safety and efficacy of naltrexone implants as maintenance treatment has recently been completed (11). In the study, 56 heroin-

dependent patients received either a 6-month 2.2-g naltrexone implant or standard care. No placebo implant group was included. Opioid use was reduced in the naltrexone group, compared to the standard care control group. Although the majority of side effects were minimal, three patients experienced adverse events that necessitated the removal of the implant.

Injectable sustained-release naltrexone is another new development in naltrexone administration. A recent randomized clinical trial supports this route of administration as safe and well-tolerated (12). In the 8-week trial, 60 heroin-dependent participants were randomly assigned to receive sustained-release injections of 192 mg, 384 mg, or placebo naltrexone. These doses were selected because they are efficacious in the treatment of alcohol use disorders (13). Following detoxification, all participants successfully completed an oral naltrexone challenge test. Injections occurred at weeks 1 and 5. Although no significant reduction in heroin-positive urine samples was observed in the study, retention in treatment was dose dependent and participants were most likely to stay in treatment at the highest naltrexone dose. More research is needed to determine whether injectable sustained-release naltrexone should be considered a viable treatment for opioid dependence.

Opioid-Dependent Patients for Whom Naltrexone Is Optimal

As mentioned above, naltrexone is best for highly motivated patients who are interested in opioid abstinence. The addition of effective psychosocial treatments which address compliance can increase the effectiveness of naltrexone pharmacotherapy (14). For example, the inclusion of psychosocial treatments targeting compliance, involvement of the family, and family therapy all increase compliance (1). External motivation, such as risk of loss of license for health care professionals or those who are under legal mandate to remain abstinent, also increases compliance and therefore effectiveness of naltrexone.

Alcohol Use Disorders

Alcohol use disorders are one of the most common psychiatric disorders and are thought to affect 8% of the general population (15). Alcohol dependence is characterized by a pattern of continued drinking despite physical, psychological, or social consequences. Many, but not all individuals will have physical dependence, including tolerance to alcohol and withdrawal symptoms after abrupt cessation of alcohol use. Alcohol abuse is less serious, but characterized by a pattern of drinking that results in situations that are harmful: drinking in situations that are physically dangerous (i.e., driving while intoxicated), failure to fulfill work, school or home responsibilities, or continuing to drink despite relationship problems worsened by drinking. While alcohol dependence and abuse are the most serious of the alcohol use disorders, a far greater number of people exhibit hazardous drinking,

or drinking that is associated with physical or psychological harm. While most treatments traditionally focus on alcohol abuse or dependence, emphasis on preventing hazardous drinking has become an increasingly important focus of treatment and research.

Pharmacologic management for alcohol use disorders can be characterized as treatment for detoxification from alcohol, treatment for the prevention of relapse, and treatment of comorbid psychiatric disorders. Medications for detoxification from alcohol and for comorbid psychiatric disorders are beyond the scope of this chapter. Naltrexone is one of the three medications approved by the FDA as a medication to prevent relapse alcoholism; the other two are disulfiram and acamprosate, and are reviewed elsewhere. Naltrexone is used to prevent relapse in abstinent individuals and to decrease heavy drinking in nonabstinent individuals. More recently it is being explored as a potential treatment for non-alcohol-dependent individuals who exhibit hazardous drinking.

Clinical Trials

In humans the efficacy of naltrexone treatment for alcohol use disorders was first demonstrated by Volpicelli and colleagues (16). In this landmark study, 70 alcohol-dependent male patients were randomized to receive 50 mg/day naltrexone or placebo for 12 weeks; all patients received outpatient psychotherapy. Patients receiving naltrexone reported less craving for alcohol and also reported fewer drinking days. In those individuals who drank alcohol, naltrexone slowed the rate of relapse to heavy drinking, defined as five or more alcoholic drinks in a day. These promising findings were replicated and extended by O'Malley and colleagues (17). In this study, 97 alcohol-dependent male and female patients were randomized to receive either 50 mg/day naltrexone or placebo for 12 weeks. They were also randomized to receive either cognitive behavioral therapy (emphasizing relapse prevention and coping skills) or supportive therapy. An interaction of naltrexone and therapy was observed, where abstinence from alcohol was more likely to occur in patients receiving active naltrexone and supportive therapy. However, in patients who drank alcohol, the combination of naltrexone and cognitive behavioral therapy was more efficacious. Together these two hallmark studies led to the FDA's approval of naltrexone for the treatment of alcohol use disorders in 1994. Since this approval, the majority of randomized clinical trials examining naltrexone have had positive results.

The first multisite study was conducted in the late 1990s (18). Patients ($N = 169$) received either 50 mg/day naltrexone or placebo for 12 weeks. All patients received psychosocial treatment and had been abstinent from alcohol for 5 to 30 days. The primary outcome of interest was the time to first heavy drinking day. No effect of naltrexone was observed when all patients were included in the analyses. However, when only compliant patients were included (defined by 80% medication consumption, and attendance at all follow-up appointments), naltrexone decreased the amount of alcohol consumed but did not change the time to the first heavy

drinking day. The authors concluded that compliance is crucial in naltrexone treatment, indicating that naltrexone is best for highly motivated patients.

Several meta-analyses have examined the efficacy of naltrexone (19–21). Kranzler and Van Kirk (19) examined nine naltrexone studies. All studies were randomized clinical trials. The meta-analysis only considered data from intention-to-treat samples. The length of treatment varied across the included studies. They observed several indications that naltrexone is an efficacious treatment for alcohol use disorders. The effect size for naltrexone (12% to 19% better than placebo) was modest. Naltrexone decreased the percentage of drinking days, increased the likelihood of alcohol abstinence during study participation, and decreased the risk of relapse to heavy drinking. They concluded that naltrexone was a viable treatment for alcohol use disorders. Streeton and Whelan (20) examined seven naltrexone studies. All studies were randomized clinical trials that included 12 weeks of outpatient treatment, with varied psychosocial therapy. They concluded that naltrexone reduced relapse to heavy drinking and improves alcohol abstinence while on medication. At 6-month follow-up, no benefit of 12-week naltrexone, over placebo, was observed (21).

A more recent meta-analysis review of naltrexone as a treatment for alcohol use disorders was completed in 2005 by Srisurapanont and Jarusuraisin (22). Twenty-seven trials, spanning from 1992 to 2003, were included. All studies were randomized clinical trials. Eighteen studies compared naltrexone to placebo while others compared naltrexone to other medications such as acamprosate, disulfiram, nefazodone, and ondansetron. Five studies also included comparisons of psychosocial treatment length. The authors concluded that naltrexone reduced rates of relapse by 36% and reduced the rates of returning to alcohol drinking by 13% in short-term randomized clinical trials.

Some studies have reported negative findings with daily oral naltrexone. The largest negative study was the 52-week multisite VA Cooperative Study (23), which found no advantage of naltrexone over placebo. Participants were randomly assigned to one of three medication conditions: (a) 50 mg/day naltrexone for 12 months, (b) 50 mg/day naltrexone for 3 months, followed by placebo for 9 months, or (c) placebo for 12 months. Medication was offered as an adjunct treatment to individual counseling and programs, and attendance at Alcoholics Anonymous. Naltrexone, compared to placebo, did not delay or prevent relapse, decrease the percentage of drinking days, or decrease the number of drinks per drinking day in mostly male (98%) sample. In comparison with patients in other trials, patients in this study exhibited more severe and chronic alcohol dependence. This difference, among other characteristics, has been suggested as a rationale for the negative results (24). A secondary analysis of the data suggests that naltrexone might have been beneficial for those alcohol-dependent patients with a consistent drinking pattern (25).

In the largest study to date, Project COMBINE examined the efficacy of naltrexone, in combination with combined behavioral intervention (CBI) and with another medication for

alcohol use disorders (3 g/day acamprosate) in 1383 subjects (26). The study consisted of 16 weeks of treatment and the drinking outcomes of interest were the percentage of days abstinent and the time to first heavy drinking day. Participants were randomly assigned to naltrexone (100 mg), acamprosate (3 g), placebo, the combination or to no pill condition and to two psychosocial conditions that included medical management (MM), an intervention that could be modeled in a primary care or cognitive behavioral intervention (CBI). Randomization resulted in nine groups and the participants in groups 1 to 8 received MM, the ninth received CBI. The mean dose of naltrexone was 88 mg/day. The best outcomes were with those individuals who received MM and naltrexone or MM and CBI. Results supported the use of naltrexone in the treatment of alcohol dependence, but with a modest effect size.

An emergent use of oral naltrexone in young nondependent adults with hazardous drinking has been targeted administration of naltrexone, sometimes in combination with daily dosing. Patients are instructed to use the medication when they are expecting exposure to alcohol and alcohol-related cues. A recent study of early problem drinkers examined the efficacy of targeted naltrexone (27). In the study, 153 patients were randomly assigned to one of four groups: (a) 50 mg naltrexone daily, (b) placebo daily, (c) 50 mg naltrexone targeted, or (d) placebo targeted. The instruction for targeted naltrexone administration was to self-administer the medication in anticipation of a heavy drinking situation. Targeted naltrexone decreased both drinking and heavy drinking. This line of research continues in an ongoing randomized clinical trial (RCT00568958) in young adults, which is examining the efficacy of a low dose of targeted naltrexone (25 mg) in addition to daily naltrexone (25 mg) and counseling.

Concern about rates of compliance with oral naltrexone led to the development of 4-week extended-release injections. This formulation is marketed in the United States as Vivitrol. The FDA approved intramuscular naltrexone in 2006 for alcohol dependence. A 6-month randomized clinical trial examined the efficacy and tolerability of Vivitrol in 627 alcohol-dependent adults (13). Participants were randomly assigned to receive 380 mg naltrexone, 190 mg naltrexone, or placebo, and all received standardized psychosocial support. Both naltrexone doses were well tolerated. The 380 mg dose reduced heavy drinking more effectively than the 190 mg dose. Retrospective analyses of early treatment response indicated that Vivitrol was clinically effective within 2 days of injection (28) and was more efficacious if patients were already abstinent from alcohol (29). Gender effects were observed in this trial and a positive effect of naltrexone over placebo was observed in males, but not in women. The reasons for this gender difference are unclear and will be examined in future studies.

Laboratory Studies

Laboratory-based investigations have been conducted to further understand how naltrexone improves clinical outcomes for alcohol dependence. Several studies have suggested that

naltrexone might reduce alcohol drinking by altering the subjective effects of alcohol. For example, Swift and colleagues (30) examined the effect of an acute dose of naltrexone on alcohol intoxication. Naltrexone decreased subjective ratings of alcohol-induced stimulation while increasing ratings of alcohol-induced sedation. In another study, chronic naltrexone (50 mg/day) administration led to decreased alcohol craving prior to drink consumption and decreased subjective alcohol-induced stimulation after consumption (31). Naltrexone has also been included in examinations of alcohol cue reactivity and is associated with decreased reactivity to alcohol cues compared to placebo (32).

Drinker characteristics such as family history of alcoholism have also been examined as possible predictors of response to naltrexone. A recent study explored the effect of chronic naltrexone administration and family history of alcoholism in a laboratory model of alcohol drinking (33). The study enrolled alcohol-dependent individuals and randomly assigned them to receive either 50 or 100 mg/day naltrexone or placebo. In the laboratory paradigm, participants consumed a priming dose of alcohol (equivalent to one alcoholic beverage) and then participated in an ad-lib drinking session for several hours. Naltrexone (100 mg/day) decreased the number of drinks consumed in family history positive males. These findings indicate that family history of alcoholism affects response to naltrexone and suggests that this effect might also be linked with gender.

Individuals with a family history of alcoholism can be about three times more likely to have a particular version (G allele vs. A allele) of the mu-opioid receptor gene (OPRM1) (34). A recent study investigated whether differences in this gene might influence the effect of naltrexone on response to alcohol. Forty participants received either 50 mg oral naltrexone or placebo. They then received intravenous alcohol to reach three targeted breath alcohol levels (0.02, 0.04, 0.06 g/dL). Under placebo, participants with the G allele variant reported greater subjective high from the alcohol. Under naltrexone, patients with the G allele reported greater blunting of alcohol-induced high, compared to patients with the A allele (35). These findings further strengthen the relationship between family history of alcoholism and response to naltrexone.

Doses and Routes of Administration

Oral naltrexone is marketed in the United States as Revia. The standard prescribing dose of naltrexone is 50 mg/day. This dose was first selected because it was efficacious in the treatment of opioid dependence. Some investigations have suggested that a higher dose (100 mg/day) results in better clinical outcomes. Naltrexone may be better tolerated if patients receiving oral naltrexone initiate treatment with 25 mg/day and then increase to 50 mg/day across 7 days. While the optimal length of treatment has not been determined, a typical length of treatment is 12 weeks. Oral administration is best for highly motivated patients, as the efficacy of naltrexone oral administration in the treatment of alcohol use disorders is enhanced in individuals who have high rates of medication compliance.

Another way to prescribe oral naltrexone, targeted administration in anticipation of exposure to alcohol, in combination with daily dosing is currently being evaluated.

Naltrexone is also available in a 4-week extended-release injection which is marketed in the United States as Vivitrol. Patients receive an intramuscular gluteal injection of serum that contains microspheres of encapsulated naltrexone (380 mg/injection). The microspheres degrade over time and naltrexone is continuously released. An advantage of this route of administration is that some side effects that some patients report with the rapid uptake of naltrexone when administered orally are minimized (13).

Naltrexone in Combination with Other Medications/Therapies

In most of the randomized clinical trials, naltrexone has been combined with some form of psychotherapy. Naltrexone has been evaluated with cognitive behavioral therapy, 12-step facilitation, supportive therapy, and medical management. It is recommended by the FDA that naltrexone be prescribed *in conjunction* with an adequate psychosocial intervention. In one of the landmark studies, naltrexone (vs. placebo) was paired with either cognitive behavioral therapy or supportive therapy (17). The interaction of naltrexone with therapy suggested that careful consideration of therapeutic styles should be considered when naltrexone is used as an adjunct pharmacotherapy.

Interest has grown, perhaps because of naltrexone's modest effect size, in combining naltrexone treatment with other medications to enhance alcohol use outcomes. Naltrexone has been given with other FDA-approved medications to treat alcoholism including acamprosate in the COMBINE trial (26), disulfiram in a multisite study in 254 dually diagnosed alcohol-dependent veterans (36) and with serotonin reuptake inhibitors as adjunctive medications (37). However, the addition of other medications does not seem to result in improved alcohol use outcomes compared to naltrexone alone. Studies evaluating naltrexone in combination with other medications, such as the anticonvulsant topiramate (NCT00769158) and the serotonergic agent ondansetron (NCT00027079), which have shown promise in treating alcoholism, are ongoing. Naltrexone has also been given safely to patients who are on psychiatric medications, including antipsychotics (38), antidepressants (23,39), and mood stabilizers (36,40).

Alcohol-Dependent Patients for Whom Naltrexone Is Optimal

Naltrexone is recommended for highly motivated patients, since efficacy rates seem to be highest among compliant patients (18). Recent studies have suggested that certain patient characteristics such as family history of alcoholism can also be a predictor of success with naltrexone (33). Some recent genetic research has indicated that a functional polymorphism of the OPRM1 (mu-opioid receptor) is associated with better naltrexone response (41). However, another study did

not support this association (42). Differences in study sample characteristics have been suggested as a possible explanation for the mixed results.

SAFETY OF NALTREXONE

Side Effect Profile

Naltrexone is generally well tolerated. The most common side effects with 50 mg/day oral administration are nausea, headache, dizziness, fatigue, vomiting, anxiety, and sleeplessness; less common side effects include anxiety and sleepiness (20). Use of extended-release injections can reduce symptoms, such as nausea, that are associated with oral dosing. Some side effects specific to injections include pain, tenderness, induration, swelling, erythema, bruising, and pruritus at the injection site (13). Some side effects specific to naltrexone implants include infection of the implant site, pain at implant site, and allergic reactions (11).

Naltrexone is metabolized by the liver and can be associated with hepatotoxicity, although usually if given in much higher doses than the 50 mg currently recommended. Nevertheless, liver function tests should be evaluated before the use of naltrexone and periodically during treatment and it is generally recommended that individuals whose liver function tests are three to five times normal should not be prescribed naltrexone.

Questions have been raised about whether long-term therapy with naltrexone may be associated with dysphoria. Theoretically, dysphoria could occur because naltrexone, as an opioid receptor antagonist, competes with endogenous opioid peptides. A recent review, however, indicated that most studies have not found evidence of dysphoria with long-term naltrexone therapy (43).

Contraindications

It should be remembered that naltrexone is an opiate antagonist and as such is contraindicated in those patients with chronic pain who are being treated with opiates as it will precipitate withdrawal. In addition, worsening of pain has been reported with naltrexone (16). Before starting naltrexone, patients should discontinue narcotics for a minimum of 7 to 10 days. Patients taking naltrexone should be provided with a wallet card explaining that they are currently prescribed naltrexone. This safety measure will reduce complications for treatment in cases of emergency when opioid administration could be advisable. Naltrexone is contraindicated in pregnant and lactating women. As mentioned above, naltrexone should not be used in individuals who have seriously compromised liver function.

Use of Naltrexone in Other Populations

A growing body of literature is evaluating naltrexone's efficacy in dually diagnosed alcohol-dependent patients. This literature includes pilot studies, retrospective evaluations,

secondary analyses, and a few randomized clinical trials. Naltrexone's efficacy is an important clinical issue since some evidence suggests that clinicians who treat patients with alcohol use disorders preferentially prescribe medications to individuals with comorbid psychiatric disorders. Utilization of naltrexone in the VA system nationally, despite a very low overall rate of prescribing (less than 2% of 194,001 patients with alcohol dependence were prescribed naltrexone), was higher in those patients with the presence of a comorbid mental disorder (44).

Several studies have suggested that naltrexone is both safe and effective for treating alcohol use disorders in individuals with comorbid psychiatric disorders. In a retrospective study on 72 psychiatric patients treated with naltrexone for their alcohol use disorder, 82% of patients significantly reduced their drinking (45). Naltrexone also decreased alcohol use and improved depressive symptoms in an open study with patients manifesting alcohol dependence (46). It has been hypothesized that patients with well-controlled psychiatric conditions might find naltrexone effective or that naltrexone might work synergistically with psychotropic medications in improving drinking outcomes (47). In a secondary analysis of the VA Cooperative Study of naltrexone, those subjects treated with antidepressants for depression and anxiety during the trial, naltrexone-treated individuals had better alcohol use outcomes than did individuals on placebo (48).

The first controlled, randomized clinical trial with naltrexone in patients with schizophrenia and comorbid alcohol dependence ($N = 31$) showed that naltrexone-treated individuals had fewer drinking days and heavy drinking days and reported less craving in comparison to individuals treated with placebo (38). All subjects were on stable doses of neuroleptic medication. Overall, naltrexone was well tolerated and did not cause a worsening of psychosis. A larger study evaluating naltrexone versus placebo in patients with comorbid schizophrenia has been recently completed (49,50), and results suggest that among patients who were compliant with medication, those on naltrexone had better outcomes than those who were on placebo (50). In patients with bipolar disorder ($N = 50$), naltrexone-treated patients had a trend toward better alcohol use outcomes than those on placebo (40).

A 12-week randomized clinical trial of naltrexone and disulfiram in individuals with Axis-I disorders and alcohol dependence, who were stable on psychiatric medications ($N = 254$), showed that individuals had better outcomes if treated with active medication compared to placebo. However, no difference in outcome in those treated by naltrexone compared to disulfiram and no advantage of the combination were observed (36). In evaluating outcome by diagnosis, individuals with posttraumatic stress disorder (PTSD) ($N = 93$) did particularly well on active medication, but again no differences between naltrexone or disulfiram and no advantage of the combination were observed (51). Individuals with psychotic spectrum disorders ($N = 61$) had worse overall alcohol outcomes than individuals with nonpsychotic spectrum disorders. They had better alcohol outcomes if treated with either

naltrexone or disulfiram, compared to placebo, but again there was no clear advantage of the combination of disulfiram and naltrexone over either alone (52). Individuals with depression did not fare as well as those who had PTSD or psychosis (39).

Naltrexone has been evaluated for dually diagnosed patients with opioid dependence; however, opiate agonists such as methadone and buprenorphine have proven more effective for long-term treatment. Literature describing the use of agonist pharmacotherapies in opioid-dependent dual diagnosis patients is beyond the scope of this chapter.

Other Uses

Naltrexone has been evaluated for a number of other addictive and impulsive spectrum disorders, including cocaine dependence, tobacco dependence, problem gambling, kleptomania, and eating disorders. It has also been evaluated as an adjunctive medication in other psychiatric disorders and to treat opiate-induced adverse events.

Naltrexone has been evaluated for cocaine dependence, and given the high comorbidity with alcohol dependence, particular emphasis has been on treating those with both alcohol and cocaine dependence. In an early study, naltrexone was found to be less effective than disulfiram for cocaine- and alcohol-dependent individuals (53). For individuals with alcohol dependence who also use cocaine, doses higher than the standard 50 mg/day could be more effective than the standard dose. A recent study examining 50 mg/day naltrexone in 80 patients with cocaine and alcohol dependence did not observe a significant reduction in either cocaine or alcohol use (54).

Some randomized clinical trials have examined the effect of naltrexone on smoking cessation rates. In addition to examining naltrexone alone, the drug has also been used as an adjunct pharmacotherapy to other established treatments, such as nicotine replacement therapy (55). In general, findings have been inconsistent. The primary benefits of naltrexone for smoking cessation include that it might limit weight gain (56), and that it is useful in treating polydrug abuse (57).

Impulse Control Disorders: Problem Gambling and Kleptomania

Recent evidence suggests that chronic naltrexone administration reduces gambling urges and behaviors. An 18-week randomized clinical trial enrolled 77 problem gamblers who received either 50, 100, or 150 mg/day naltrexone, or placebo (58). Naltrexone improved clinical outcomes with no difference between doses. Family history of alcoholism has been identified as a clinical predictor of naltrexone response for problem gambling (59). However, naltrexone in the concurrent treatment of problem gambling and alcohol use disorder is not supported (60). In this 11-week randomized clinical trial, 52 participants received either naltrexone or placebo, and all received cognitive behavioral counseling. The dose of naltrexone started at 50 mg/day and was increased by 50 mg/day if patients reported no therapeutic effect; the actual mean

dose for the naltrexone group was 100 mg/day. Naltrexone neither improved symptoms of problem gambling nor outcomes for the alcohol use disorder.

Naltrexone has also recently been used in the treatment of kleptomania. Doses have typically been higher than those used in the treatment of alcohol use disorders. An 8-week randomized clinical trial of naltrexone, compared to placebo, observed that naltrexone decreased stealing urges and behaviors (61). The naltrexone dose range was 50 to 150 mg/day, and the mean study dose was 116 mg/day. In another similar study, the mean effective dose was 135 mg/day (62).

Eating Disorders: Bulimia, Anorexia Nervosa, Binge Eating Disorder

Recent studies examining the efficacy of naltrexone in treating eating disorders have had mixed results. These studies used chronic naltrexone administration, with a standard 1-week medication lead-in period. Evidence for naltrexone's use in the treatment of eating disorders is limited. While there have been some indications that naltrexone improves clinical outcomes in the treatment of bulimia (63), other studies have had negative results (64). Limited evidence also suggests that naltrexone might be beneficial in the treatment of binge eating disorder (63). A report suggests that naltrexone can improve clinical outcome for anorexia nervosa in some patients (65).

MISCELLANEOUS

Naltrexone has been evaluated with limited success as an adjunctive treatment for schizophrenia (66) and depression (67) in individuals *without* comorbid substance use disorders. Naltrexone has also been used to alleviate opioid-induced adverse events. Low doses of naltrexone (6 mg/day) have been shown to reduce opioid-induced constipation and pruritis, without reversing analgesia (68).

CONCLUSIONS

Naltrexone is an oral opioid antagonist that competes with opioids to bind at opioid receptors. Although naltrexone was originally developed for the treatment of opioid dependence, research indicating that opioid receptors are involved in the effects of alcohol has led to the use of naltrexone for the treatment of alcohol use disorders as well. Naltrexone is safe and has clinical uses in both treatment of opioid dependence and alcohol dependence. Its role in opioid dependence is predominately as an adjunctive medication for opioid detoxification or for maintenance in highly motivated populations. In alcohol use disorders, naltrexone's efficacy is supported by most of the clinical trials, but it has a modest effect size. The standard starting dose of naltrexone is 50 mg/day for both opioid dependence and alcohol dependence. This dose is sufficient to block opioid receptors for 24 hours and has been found to be effective in treating alcohol use disorders. However, research evaluating the efficacy of different doses, particularly

in alcohol use disorders, is underway. While oral administration is the most common route of administration, newer routes of administration include extended-release injections and implants. In opioid dependence, improving compliance is likely to improve its efficacy, and research into the use of extended-release injections is of high priority. In alcohol dependence, not all patients are sensitive to its therapeutic effects. Consideration should be given to patient characteristics that can increase positive outcomes, including family history of alcoholism. Further research on identifying characteristics, such as genotypes, of patients who most benefit from naltrexone therapy is also underway.

INTRODUCTION

Vaccines for substance abuse offer a new and very different approach for treating for cocaine, nicotine, methamphetamine, heroin, and phencyclidine abuse. The socioeconomic problems of substance abuse are discussed in detail in other chapters; therefore, this chapter will discuss the influence of specific antibodies on drug pharmacodynamics and the experimental and clinical status for each of these abused substances. The basic concept for vaccine effects on the pharmacology of drugs is that antibodies can slow the rate of drug entry into the central nervous system (CNS), potentially reducing total drug concentrations. This is achieved through antibody binding of the substance in the bloodstream, since antibody molecules are too large to pass through the blood–brain barrier under normal conditions. This should result in a reduction in the reward sensations from drug ingestion, making the vaccinated-user less susceptible to psychological and physiologic reinforcement responses, so that the bonds of addiction might be more easily loosened.

Numerous issues remain to be fully investigated, but sufficient progress has been made in both experimental animal and human studies that more advanced clinical trials for the major abused substances will be conducted in the next few years. As will be discussed in detail, there are three distinct areas of limitation on vaccine effects relating to the influence on drug distribution and metabolism: the amount and persistence of antibody ordinarily elicited by vaccines, and the affinity of the antibody for the drug (1). The advantages of vaccines as a treatment for substance abuse, in contrast to conventional drug therapy approaches, are that if persistent, high levels of antibody can be elicited by a vaccine, compliance failures will be much less of a problem, and undesirable CNS side effects of the treatment itself would not be a concern, as they often are with small molecule agonists or antagonists. This chapter will discuss the effects of antidrug antibodies on drug pharmacodynamics in terms of both the quantitative and the qualitative properties of the antibodies, and will also review the current stages of vaccine development for nicotine, cocaine, methamphetamine, phencyclidine, and heroin. Vaccination resulting in long-term inhibition of the pharmacologic actions of abused drugs has great potential for assisting motivated addicts to begin and sustain abstinence from their specific abused substance.

CONCEPTUAL BASIS FOR DRUG VACCINES

Drugs associated with substance abuse enter the CNS following absorption or injection and occupy receptors that modulate neuron signaling, thus leading to the reward/reinforcement sensations associated with use of the specific drug. These sensations are dependent on the number of receptors occupied, as well as, in many cases, the rate at which receptor occupation occurs (2). Cocaine, for example, targets dopamine transporters and methamphetamine binds several different receptors (3), while morphine and heroin metabolites bind mu-opiate receptors. Preventing the rapid rise of receptor occupation in the brain will inhibit the maximal pleasurable and reinforcing effects of many abused drugs (4).

In order to influence drug pharmacodynamics, substance abuse vaccines must elicit high levels of specific IgG antibodies with good binding affinity, so that these antibodies can bind and hold most of the drug molecules within the circulation, reducing and delaying drug access to the brain. Antibody binding to target antigens has been extensively studied over the past several decades, and small molecule (hapten) binding in particular is quite well understood. The interactions between a small molecule (such as a drug of substance abuse) and an antibody can thus be accurately characterized as predominantly a function of antibody quantity and affinity, because antibody binding to a hapten does not result in significant changes in the structure or subsequent function of the antibody, in contrast to antibody binding to complex antigens. In the latter case, binding can create immune complexes, with alterations in the structure of the heavy chain portion of the antibody exposing complement binding sites, leading to activation of the complement cascade. Such changes in structure also result in attachment of the bound antibody to antibody receptors on cells of the reticuloendothelial system so that these complexes can be cleared from circulation. This clearance process can also cause activation of other immune functions that may lead to inflammatory responses in various tissues. Since binding of abused drugs, for example, cocaine, methamphetamine, or morphine, does not cause alterations in antibody structure, the half-life of the antibody is essentially unaffected. In fact, the half-life of the drug is often significantly prolonged as a result of binding to the antibody, except in the case of cocaine (discussed later).

To determine the initial, necessary goals for vaccine elicitation of antibody in terms of quantity and binding properties (affinity), the simple model of mass action equilibrium

can be used, where K_a represents the association constant, $[A]$ the free antibody concentration, $[H]$ the concentration of free hapten, and $[AH]$ the concentration of bound complex of drug and antibody at one combining site:

$$K_a = \frac{[AH]}{[A] \cdot [H]}$$

This equation is, for our purposes, sufficient to describe the basic interaction of a single drug molecule and a single antibody combining site, since the combining sites (two on IgG, for example) do not interact when bound with small molecules, either on the same antibody or between antibody molecules. At 50% occupancy of available antibody binding sites, the K_a predicted is accurate for IgG (5), the antibody isotype that dominates the antibody response with vaccines currently being studied. A more extensive discussion is provided elsewhere (1), detailing the alterations that occur at the extremes of antibody/drug concentration differences. In order to evaluate this equation, one must know the expected concentrations of free drug that are typically found in substance abusers depending on the drug of interest. Most of the drugs used achieve peak concentrations in the 0.5 to 1 μM range drug (6–8), although in heavy abusers, concentrations can sometimes be much higher (e.g., with morphine (9)).

From this information, and making reasonable assumptions about the expected binding affinity of the antibody responses, it is straightforward to determine the amounts of antibody required for binding a desired proportion of administered drug. Figure 31.1 shows a set of plots graphing the amount of antibody needed over a range of affinities for different doses to bind 75% of the peak concentration of the

Figure 31.1. Affinity and dose effects on antibody requirements for 75% drug binding. The amount of antibody (Y axis, $\mu\text{g/mL}$) required to bind 75% of a specific peak drug concentration (Z axis, μM) is plotted for the specific antibody binding affinity, K_a (X axis, μM^{-1}).

drug. As compared to the usual antibody responses needed for complete protection against toxins and microbes using standard vaccines, such as those against tetanus (1 to 2 $\mu\text{g/mL}$) or the *Haemophilus influenzae* b bacterium (0.15 $\mu\text{g/mL}$), the concentrations of antibody required for drug binding are quite high, up to 100 $\mu\text{g/mL}$ or more for higher doses of drug. However, these levels are achievable in only a proportion of human patients using standard vaccine techniques (10). One interesting aspect of this plot is that it shows the relative independence of binding at affinities 30 μM^{-1} or higher (affinities that are typical of antibody in secondary (boosted) immune responses (11)). This is due to the fact that the specific concentrations of the target drug drive the response at a high proportion of binding. Each band in the figure flattens out beyond 30 and remains quite flat as the curve moves toward the right to higher affinities beyond that point. The binding at each higher dose then would require a step up in antibody concentration as can be appreciated on the right side of the figure. On the other hand, antibody affinities below 10 (typical of antibodies in primary immune responses (11)) are problematic for binding because much higher concentrations of antibody would be required with higher doses of drug (left side of figure). Although the actual requirements have not been precisely determined in clinical settings, the results from clinical trials for both nicotine (12) and cocaine vaccines (13) have shown that these estimates are clinically relevant. For both drugs, the higher 30% or so of high antibody responders showed significant reductions in drug use (cocaine) and quit rates (nicotine).

Simple binding to block uptake, however, is not the only consideration that affects drug pharmacodynamics. The speed with which the antibodies can bind to a drug will also influence its inhibition of drug entry into the CNS. As with many drugs of abuse, physiologic and subjective (the “rush”) effects from smoked cocaine or methamphetamine are detectable within a few minutes of exposure (6). The antibody–antigen binding characteristics for haptens have been carefully studied over the years, and the initial attachment of an antibody combining site to its specific target molecule (the “on” rate) has been empirically determined in several model systems (14). Fortunately for substance abuse vaccine applications, these studies indicate that such initial antibody binding rates for small molecules are quite rapid and should not prove a hindrance to the effectiveness of vaccines, if they elicit a sufficiently high concentration of antibodies. IgG antibodies will bind the target molecules in a fully mixed sample essentially to equilibrium in less than 1 second (5), and consequently for ordinary administration routes and doses, the on rate of antibody binding is expected to be fast enough that maximal possible drug binding will occur in the bloodstream well before transfer of the drug to the brain is expected to take place. Achieving the high level responses necessary in vaccine recipients by optimizing vaccine design and administering with improved adjuvants should greatly reduce both the rate and the total drug accumulation in the brain from single doses.

Finally, although the above considerations do account for many of the clinical and experimental observations made

with substance abuse drugs and vaccines thus far, some data from experimental animal studies suggest further effects of drug vaccines that are not fully understood. With nicotine vaccines in mice, for example, entry of a bolus dose of nicotine into the brain was blocked in vaccinated rats not previously treated with nicotine (15). Chronic nicotine treatment of such rats, however, which should result in some reduction of binding capacity of the antibody, showed lower levels of the nicotine bolus retained in the blood, but the mice still had a reduction in brain concentrations equivalent to the vaccinated mice without nicotine treatment. This might be explained in part by an increase in fat uptake (16), though the mechanisms for this observation remain obscure. Similarly, Owens' group has observed unexpected reductions in brain uptake of phencyclidine in experimental animals given a passive antibody infusion and then administered phencyclidine later at doses well above that expected to saturate the residual antibody (3). Thus some benefits of vaccination on drug pharmacodynamics may be operative, even at suboptimal antibody response levels.

ANTIBODY EFFECTS ON DRUG PHARMACODYNAMICS AND PHARMACOKINETICS

Most current ideas about reward from addictive substances combine aspects of "rate" and equilibrium binding pharmacologic theories to explain observations relating to drug action. The influence of both drug concentrations and pharmacodynamic features for cocaine, nicotine, methamphetamine, and opioids are important for their physiologic and subjective effects. Thus, a marked reduction in free-drug concentration in the blood by binding to specific antibodies would significantly inhibit drug action in the brain (e.g., if 75% to 90% of the drug is bound by high affinity antibody), since IgG-bound drug cannot readily cross the normal, non-inflamed blood-brain barrier. In addition, it is well known experimentally that the rate of increase in receptor occupation in the CNS has a profound influence on the subjective effects of each of these drugs (17). Thus, less dramatic binding of the drug even by lower affinity antibody (e.g., resulting in 50% binding, perhaps) could still have a substantial influence on the rate of entry of free drug into the CNS. Even if the eventual total accumulation in the brain is similar to what would be achieved in the absence of antibody, the subjective CNS effects of the drug may be substantially or completely blunted, since the rate of receptor occupancy would be significantly reduced.

The pharmacokinetics of antibody-bound drug are thus related to the effects of antibody binding on a drug's metabolism, tissue distribution, and elimination pathways, as well as the antibody's intrinsic half-life and the effect of drug binding on antibody half-life through changes in the antibody structure, if any. Antibody binding to morphine, for example, prolongs morphine's terminal half-life in the bloodstream of experimental animals by two- to threefold (18), with essentially no effect on drug metabolism. In a vaccine study in rats,

on the other hand, antibody binding of cocaine was shown to have little effect on cocaine half-life or metabolism, due in part to ongoing ester hydrolysis in the bloodstream, as well as no effect on clearance of the antibody (19).

Some antibodies can display catalytic properties, however. Selected monoclonal antibodies can enhance cocaine hydrolysis thus speeding the metabolic degradation of this drug *in vivo* (20). However, a vaccine that would elicit such catalytic antibodies from active immunization would be very difficult to design, given the broad variation in the structural features of the polyclonal antibodies elicited through immunization. Similar to morphine and in contrast to cocaine, antimethamphetamine antibodies have been shown to decrease methamphetamine clearance, prolong methamphetamine concentrations in serum, reduce conversion to amphetamine, and increase uptake in reticuloendothelial tissues like the liver (21). These features may well be related to the longer biologic half-life displayed by methamphetamine in comparison to cocaine, and especially to the fact that a substantial fraction of methamphetamine is not metabolized, but rather excreted unchanged in the urine. Nicotine also has a longer half-life in the body than cocaine, and the effects of antibodies on nicotine pharmacokinetics have been shown to resemble those on methamphetamine, with higher plasma concentrations after nicotine doses (22), and a half-life that is prolonged three- to sixfold.

A theoretical concern is that the potentially high affinity of the antidrug antibodies for drug metabolites, which, if present in high concentrations, may reduce the amount of antibody available for native drug binding. This is particularly a concern with cocaine. Benzoyllecgonine is produced by hydrolysis of cocaine's methyl ester moiety, is structurally very similar to cocaine, and is essentially inactive pharmacologically. Heavy use of cocaine will result in substantial concentrations of benzoyllecgonine in plasma, up to 10-fold higher than peak cocaine concentrations (23). Other metabolites, such as ecgonine methyl ester, and norcocaine are present in concentrations lower than cocaine itself. The half-life of benzoyllecgonine is longer than that of cocaine, contributing to the high concentrations observed. Nicotine and its major metabolites, for example, cotinine, also present concerns regarding antibody binding competition. On the other hand, significant cross-reactivity of antimethamphetamine antibodies with amphetamine, a major methamphetamine metabolite, would be very desirable since amphetamine itself is pharmacologically active. Similarly, heroin is rapidly metabolized to 6-acetylmorphine and morphine in both the periphery and in the CNS. Both of these heroin metabolites are pharmacologically active. Fortunately, morphine conjugate vaccines can elicit antibodies capable of recognizing all three compounds (24).

NONTRADITIONAL VACCINE CONSTRUCTS

An alternative vaccine design is being developed at the University of Melbourne in David Jackson's laboratory in which a completely synthetic, self-adjuncting epitope-based

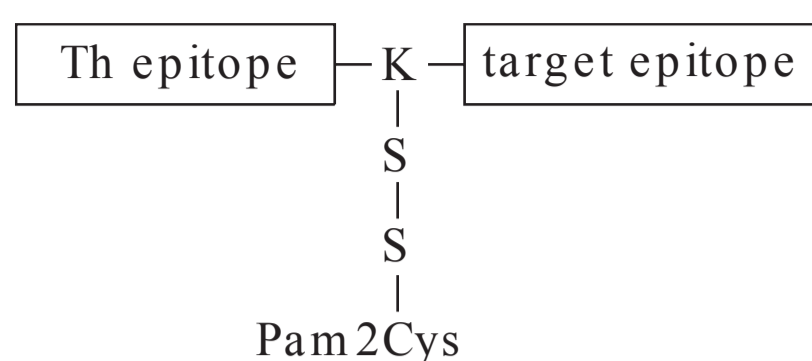

Figure 31.2. Self-adjuvanting vaccine structure. The helper T cell epitope and target epitope are attached to the lysine, and the internal adjuvant is the lipid moiety dipalmitoyl-*S*-glyceryl-cysteine (Pam2Cys) attached to the lysine through the serine residues.

vaccine is used to stimulate immune responses (25). The target epitope of the vaccine (in this case a substance abuse drug) is conjugated to a helper T cell (Th) epitope that also has the lipid moiety dipalmitoyl-*S*-glyceryl-cysteine (Pam2Cys) attached to it to function as the costimulatory signal for immune activation. The schematic design of this vaccine structure is shown in Figure 31.2.

A number of candidate antibody-inducing vaccines based on this design have been constructed, such as epitopes of either luteinizing hormone releasing hormone, gastrin, or a neutralizing epitope of group A streptococcus, and each has shown good responses in animal models (26). Epitopes from influenza virus, *Listeria monocytogenes* and tumor antigens that are recognized by cytotoxic T lymphocytes have been successful in demonstrating protection in various experimental animal systems. For antibody-inducing epitopes, the specific antibody levels elicited by the self-adjuvanting vaccine constructs in lab animals can be similar to that elicited by more traditional vaccines with standard adjuvants, such as complete Freund adjuvant (CFA), but without the toxicity associated with the latter agent. As a completely synthetic construct, the generic vaccine structure described here could have significant advantages in evaluation and development for rapid progression to human trials and clinical use. One such lipopeptide vaccine is expected to soon be in clinical trials in Australia.

Haptens like nicotine, cocaine, morphine, and methamphetamine are obvious potential immunogenic epitopes for such lipopeptide vaccine constructs using standard chemistries on a peptide synthesizer. Early experiments by Dr. Jackson in collaboration with our laboratory have shown that vaccines against amphetamine and cocaine elicited satisfactory levels of antidrug antibodies in mice. Once effectively formulated, a novel antidrug lipopeptide vaccine construct of this type would be inexpensive to produce with likely fewer side effect risks than the potentially toxic additional adjuvants traditionally required for most other vaccines. If so, it could be a real advance in vaccine design for clinical applications in substance abuse.

STATUS OF SPECIFIC DRUG VACCINES

Clinical trials with nicotine and cocaine vaccines have shown considerable promise, but still need improvement in the magnitude and consistency of the antibody responses to enhance

clinical effectiveness. Antibody strategies for methamphetamine, morphine, and phencyclidine are still in preclinical development.

Nicotine

Cigarette smoking kills almost 5 million per year worldwide and further contributes to a worse clinical outcome in a variety of diseases. Successful escape from nicotine addiction in long-term smokers remains low despite the availability of several medications, counseling programs, and other treatments. Polls have shown that an overwhelming majority of tobacco users would like to quit the habit, which is fueled mainly by a strong physical dependence on nicotine. Given the widespread prevalence, adverse health consequences, motivated population of addicts, and failure of currently available treatments (27), nicotine is a critical therapeutic target for an effective vaccine.

Significant strides are being made in the area of nicotine vaccines, which will provide a new therapeutic option to help motivated individuals to finally break free of nicotine addiction. A number of these vaccines have successfully progressed to late Phase II and early Phase III clinical trials. Drug vaccines rely on the elicitation of specific antibodies that bind the drug in the bloodstream and thus prevent it from reaching specific receptors in the brain. This process effectively decouples the act of taking the drug and receiving the “reward” of the drug’s effects. The antibodies must be present in sufficient quantities to deal with the majority of the drug amounts delivered. Whereas cocaine, heroin, and methamphetamine abuse is typically sporadic and taken in one bulk dose, nicotine is commonly delivered with frequent small doses. This can result in high plasma concentrations over a long duration. Furthermore, relapse to smoking after a period of abstinence frequently results from an ex-smoker being reacquainted with as little as a few puffs on a single cigarette, or even being in a smoky room occupied by current smokers. The presence of antibody at this precarious juncture could prevent any reward effect of the nicotine absorbed and thus help to prevent a relapse from occurring.

The effectiveness of eliciting antibodies targeting nicotine has been clearly demonstrated in animal models (12,15). In humans, three unique nicotine conjugate vaccines have completed Phase I clinical trials. All were well tolerated and able to elicit nicotine-specific antibodies, and cross-reactivity to human signaling molecules such as neurotransmitters was not observed. Following the NicVAX (Nabi Biopharmaceuticals) Phase I vaccine trial, a number of participants quit smoking for 30 days or more. This is particularly remarkable given that the trial was based around dosing and safety, not monitoring efficacy in smoking cessation. The majority of those individuals who quit were from the highest dose group, potentially linking dose/antibody response to successful smoking cessation. The NicVAX Phase IIB trial showed a 12-month continuous abstinence rate of 16% for the 400- μ g schedule and 14% for the 200- μ g schedule versus only 6% for the placebo group. Additionally, an improved immunization schedule was recently released based on the 400- μ g dose, with an increase of subjects reaching the target antibody level from 50% to 80% at 14 weeks (12).

Substantial antinicotinic antibody levels were also achieved utilizing the NicQb/NIC002 vaccine (Cytos Biotechnology AG). This was illustrated in the impressive quit rates attained for the upper third of antibody responders when compared to the placebo group (57% vs. 31%) (12). Data from the NIC002 Phase IIB trial was broken into three subgroups based on the antibody response to the vaccine: low, medium, and high responders. The 6-month continuous abstinence data showed 32% for the low, 32% for the medium, and 57% for the high responder groups compared to 31% for the placebo group, confirming the principle that only those with adequate antibody responses benefit significantly from immunization. After 12 months, the groups exhibited continuous abstinence rate of 26%, 21%, and 42%, respectively compared to the 21% of the placebo group. A second dose optimization trial, increasing the dose of conjugate from 100 to 300 μg , showed a 4.2-fold increase in specific antibody with up to 87% of patients achieving the antibody target level. Novartis purchased the rights to this vaccine, and the ongoing Phase IIB trial in smokers motivated to quit has been recently completed (28).

The trial involving the TA-NIC vaccine (Celtic Pharma, London) showed a similar positive response when the 12-month quit rate was compared between the highest dose group and the control group (38% vs. 8%) (29). A TA-NIC Phase IIB trial is currently planned. These studies show that vaccination against the nicotine molecule has immense potential to aid in the vast numbers of people seeking smoking cessation, especially if the quantity of specific antibodies induced can be optimized.

Cocaine

Cocaine continues to be a major problem in the United States and elsewhere in the world, resulting in both individual and family difficulties from the medical and legal perspectives, and economic and political disruptions from the local to the international level are pervasive (30). At least 14.5% of Americans (35.9 million) have tried cocaine at least once in their lifetimes as of 2007, and 2.3 million admitted to cocaine use in the past year, including 2.1 million in the prior month (31). The societal costs of this abuse are considerable as discussed in more detail elsewhere (see Chapter 14), but include the health care costs for up to 30% of drug-related emergency room (ER) visits that are up over 1% of all ER visits (32) as well as the direct health complications for individuals such as acute psychotic reactions, acute coronary syndromes, and strokes. Even though most individual abusers come to realize the dire consequences of their dependence, they often lack the ability to discontinue this highly addictive substance.

Medications to treat cocaine abuse have been sought for many years, but none has yet been sufficiently successful to achieve the status of approval. Behavioral therapies have been shown useful for a small percentage of cocaine addicts, but it is clear that new approaches are needed to complement those treatment programs. A therapeutic vaccine could be just an additional treatment, with or without new medications that are currently under study, since a vaccine would function via

an entirely different and potentially complementary mechanism of action. Studies in experimental animals have shown that cocaine-specific antibody will significantly inhibit the accumulation of cocaine in the brain of rats and mice, demonstrating a reduction in locomotor activity induced by pharmacologic doses of cocaine, as well as an inhibition of the reinstatement of cocaine self-administration (19,33). This latter finding, as an accepted model of human cocaine addiction, may be the most pertinent for therapeutic applications of the clinical vaccine, since reinstatement of cocaine craving after a period of abstinence is one of the most difficult problems preventing the success of cocaine treatment programs (25). Complete avoidance of all exposure to the drug is certainly the best approach, but this is difficult to achieve, since even the most motivated individual may succumb to the temptation for cocaine use under a particularly stressful circumstance or in the context of social pressures for drug use. Thus, blocking the transient pleasure ordinarily felt from cocaine use may reduce or eliminate the craving response usually engendered in the previously abstinent individual.

A cholera toxin B conjugated COC preparation (TA-CD) has been developed and undergone preliminary clinical trials demonstrating safety and immunogenicity (34) and some clinical effectiveness (13). A 14-week Phase IIA trial, in which 18 cocaine-dependent subjects in early recovery were studied, the vaccine was well tolerated at two dose levels (100 $\mu\text{g} \times 4$ injections or 400 $\mu\text{g} \times 5$ injections). Cocaine-specific antibodies were detectable in immunized individuals for at least 6 months. Those subjects receiving the higher dose of vaccine developed significantly higher anticocaine antibody titers than those in the low dose group and were also more likely to maintain cocaine-free urines. In the Phase IIB double-blind placebo controlled trial, Martell et al. found that the TA-CD vaccine was able to stimulate specific antibody in almost all 57 immunized subjects (with none found in the 57 control subjects), but only about 30% of those immunized were able to produce levels of IgG antibody high enough to be expected to bind a major fraction of the cocaine that would enter the circulation after administration of a typical recreational dose of the drug. In addition, after booster dosing was completed at 12 weeks, antibody titers peaked at 16 weeks and then began an inexorable decline in virtually all subjects. Nonetheless, of those subjects who did achieve such antibody concentrations, a marked reduction in cocaine use was documented in thrice weekly urine tests for cocaine metabolites (13). For these subjects, more than 50% of their urine tests indicated no new use of the drug as determined by the Preston Rules during the period when their antibodies were present. In contrast, subjects who did not develop high levels of anticocaine antibody had no significant change in their cocaine use in the same period of the study.

One concern regarding cocaine vaccines, as well as other substance abuse vaccines, is that a vaccinated individual might be tempted to use increasing doses of drug to overwhelm the antibody block in order to achieve adequate concentrations in the brain to get the high sought from the substance. Theoretically, such increasing doses might result in higher risks of drug overdose toxicity, although higher

doses in animal studies in our laboratory usually appear to overcome the block in a satisfactory pattern in relation to antibody. Interestingly, higher cocaine use did not appear to happen in most of the individuals with high antibody concentrations as documented by quantitative benzoylecgonine monitoring of urine samples in the Martell study. This may indicate that cocaine vaccines will be best applied clinically to those individuals who are motivated to quit their substance abuse. The implications of these preclinical and clinical studies are that cocaine conjugate vaccines may have a significant role to play in reducing cocaine abuse for those who wish to quit, especially with improvements in the vaccine design or administration methods that result in higher and more persistent cocaine-specific antibody levels.

A novel complementary therapy for vaccines that produce specific antibody to cocaine has been proposed as well. One of the two principal pathways for degradation of cocaine is through the enzyme butylcholinesterase, a nonspecific detoxifying hydrolase in circulation. This enzyme degrades cocaine by hydrolyzing the benzoyl ester of cocaine to produce benzoic acid and ecgonine methyl ester. Brimijoin et al. (35) and Zheng and Zhan (36) have markedly enhanced the hydrolytic function of this enzyme. Recent work on this enzyme has resulted in enhanced activity up to 50,000 times faster than the native enzyme. Although passive administration of the enzyme can be overcome by increasing doses of cocaine, combining a vaccine to produce antibody to bind the drug, and gene therapy to produce low to modest levels of the enzyme might be sufficient to block CNS entry by even very high doses of drug. Such an approach, while still relegated to the future clinically, is being actively developed in animal models.

Phencyclidine

Phencyclidine (PCP, “angel dust”), an *N*-methyl-D-aspartate (NMDA) receptor antagonist, is representative of a number of designer drugs that continue to be abused in some areas of the United States and around the world, despite the severe psychotic reactions that can occur with its use. Actual PCP dependence has been relatively uncommon, and as a result, vaccine development for PCP has been oriented primarily toward production of therapeutic antibodies, especially monoclonals, that can be used for passive, acute administration in emergency situations (37). The goal of eliciting monoclonal antibodies with a broad specificity for binding to a variety of PCP-related compounds has been challenging, although some progress has been made in that regard. Animal studies with PCP conjugate vaccines have shown that substantial quantities of induced antibodies can reduce the accumulation of PCP in the brain (38). Such antibodies can block the behavioral effects of PCP on locomotor activity and posturing, and passively administered polyclonal and monoclonal anti-PCP antibodies can also reverse the toxic effects of high PCP doses, suggesting that they may prove useful in treating patients who overdose on this drug (37). Unlike antibody blocking of other drugs thus far, infused monoclonal antibody against PCP has been found to block CNS effects of the drug much longer and at lower

doses than would be expected based simply on predictions from drug pharmacokinetics and the antibody half-life (3). The mechanism by which this effect occurs remains unknown, although protection has been shown to persist in experimental animals for up to a month after administration, despite doses of PCP administered far in excess of the antibody binding capacity. Clinical application of this immunologic therapy to PCP overdose situations may be available in the near future.

Methamphetamine

Methamphetamine is a stimulant that is abused broadly in the United States, particularly in rural and suburban areas, with 1.3 million current year users in 2007 (39,40). The effects of methamphetamine to increase energy, a sense of well-being, and euphoria make this substance highly addictive, and once addiction is established it is very difficult to overcome (see Chapter 16 for more details). Unlike cocaine, which is rapidly hydrolyzed to inactive compounds, methamphetamine has a long half-life and is in part demethylated to amphetamine, which is itself an addictive stimulant. Much of the parent compound and its major metabolite are cleared by the kidney with a biologic half-life of 9 to 15 hours, depending on urinary pH. The effects of this stimulant are complex, because it affects multiple neurotransmitters in the nervous system, including dopamine, norepinephrine, serotonin, histamine, and gamma-aminobutyric acid, both blocking monoamine transporters and causing the release of monoamines from synaptic vesicles (3). As a result, it is likely to be less amenable to a specific drug antagonist, or even a substitute agonist agent, than cocaine, heroin/morphine, or nicotine.

Although a very small molecule near the lower limit of size for recognition of epitopes by the immune system (molecular weight of 149), antibodies can be made against it as a hapten when conjugated to a carrier protein like the other drugs discussed in this chapter. Owens et al. have characterized an extensive number of antibodies against methamphetamine (3). When a monoclonal antibody preparation is administered to rats, it is able to reverse the effects of 1 mg/kg methamphetamine given 30 minutes before the antibody, as might be useful in a drug overdose situation (41). Furthermore, methamphetamine self-administration in rats and locomotor activity in rats given high dose methamphetamine could also be inhibited by administration of monoclonal antibodies (3).

Active immunization with methamphetamine conjugate vaccines produces polyclonal antibodies, which will develop even with ongoing administration of methamphetamine (42), demonstrating that the immune responses to the conjugate vaccine were not inhibited by drug exposure during the vaccination process. This is particularly important considering the clinical application of the vaccines to active substance abusers. These experiments did not show inhibition of methamphetamine pharmacologic activity at the high doses administered; however, more recent studies have demonstrated that some blockade of methamphetamine activity by active immunization can be achieved (43). In these experiments, a phenyl ring linkage to the drug was used to conjugate

to fused peptides (C5a, a complement component fragment that binds to dendritic cells, and a tetanus toxoid peptide sequence recognized by helper T cells). Rats were immunized with the conjugate vaccine weekly for 5 weeks, and in the absence of any other adjuvant, the resultant immune response showed modest antidrug IgG antibody by 6 weeks (1.7 $\mu\text{g/mL}$ in sera). Nonetheless, vaccinated rats had to self-administer more methamphetamine than controls to overcome the presence of the antibody, which eventually became saturated with the drug, and the amount of measurable free antibody did not return to baseline until 34 days after administration of the drug was stopped. Conjugate vaccines constructed with more typical carrier proteins injected with conventional adjuvants in our laboratory, however, have been able to elicit much higher levels of specific antimethamphetamine IgG, up to 2 mg/mL, as measured by ELISA at 16 weeks after the original immunization and a booster dose at 3 weeks. As shown in Figure 31.3, the amount of specific antibody measured in the sera for each group of mice in the study is roughly proportional to the degree of inhibition of locomotor activity stimulated by single dose methamphetamine administration, similar to the observations cited above for passive monoclonal antibody administration. For the individual mice, 8/10 of vaccinated mice had a marked inhibition of methamphetamine-induced locomotor activation with a change in distance traveled of <500 cm. In contrast, 8/9 control mice had a difference in travel distance >1000 cm. These promising results suggest that a clinical vaccine that induced adequate levels of antidrug antibody would be expected to have a substantial impact on single doses of methamphetamine, and in combination with cognitive behavioral or other treatment regimens could provide an effective treatment tool to help prevent relapse to abuse of this highly addictive substance by motivated patients.

Figure 31.3. Specific IgG inhibits single dose methamphetamine increases in locomotor activity. Groups of mice were immunized with succinylmethamphetamine conjugated to ovalbumin using either alum or complete Freund's adjuvant (CFA) and boosted at 3 weeks. After 16 weeks, immunized and control groups were challenged with 5 $\mu\text{g/mL}$ methamphetamine IP and locomotor activity was assessed as compared with saline injections. Mice immunized with CFA had over 2000 $\mu\text{g/mL}$ anti-METH IgG and showed complete inhibition of locomotor activity. Partial inhibition was achieved with alum adjuvanted vaccinated mice as compared with controls having no antibody in circulation.

Heroin and Morphine

The concept of immunization against drugs of abuse was first realized in experimental animals more than 35 years ago with morphine (44,45). However, the discovery and development of synthetic narcotic derivatives such as methadone and buprenorphine shortly thereafter, and the successful implementation of these drugs in heroin abuse treatment programs, reduced the enthusiasm for narcotic vaccines, at least in developed countries. Unfortunately, the cost of these programs, and the resurgence of heroin/morphine abuse in recent years, especially in developing countries have illustrated clearly the limitations of this pharmacologic approach to the problem.

Narcotics abuse worldwide is dominated by heroin, especially, and morphine. In developed countries, however, there is an increasing problem with prescription drug abuse using synthetic narcotic derivatives (46), even including methadone which, as a partial mu-receptor agonist with a prolonged half-life, had not been considered initially to have a high abuse potential. The number of related compounds with narcotic abuse potential and the activity of heroin metabolites, as well as the extremely broad dose range of these drugs when actively abused pose special problems for a therapeutic immunization approach for these substances. Thus, the design of the conjugate vaccines in terms of linkage of the drug hapten to the carrier protein may be critical to their usefulness. Cross-reactivity with the major metabolites of heroin is crucial for antibody effects, since heroin is a prodrug that is rapidly converted to the pharmacologically active opiates 6-acetyl morphine and morphine by esterases present in both the periphery and the CNS (47). Early studies demonstrated that conjugate vaccines with a linkage through the 6-hydroxyl group elicited antibodies capable of binding heroin, 6-acetylmorphine, and morphine itself, the dominant compounds of interest, and similarly produced antibodies were later shown to bind glucuronide metabolites (48) that also have significant narcotic activity.

Early studies of morphine conjugate vaccines through a derivative of its 6-hydroxyl group elicited a polyclonal antibody response that bound heroin and 6-acetylmorphine, as well as morphine itself (49). The bound drug could be displaced from this binding by later addition of new morphine, indicating that bound molecules are eventually released for metabolism and elimination. In these studies, the authors also demonstrated that the antibodies were saturable, so that higher doses of drug could overcome the binding capacity of circulating antibodies. Of most clinical relevance, self-administration of heroin was reduced in actively immunized rhesus monkeys (45). Berkowitz et al. (24) showed that sequestration of the drug in the blood by antibody binding prolonged morphine half-life to explain at least a part of this effect. Anton et al. in recent studies (50) have shown that a conjugate vaccine using morphine linked through its 6-hydroxyl moiety to tetanus toxoid was capable of binding both morphine and heroin sufficiently so that rat reinstatement behavior for either morphine or heroin was inhibited. The antibodies could bind *in vitro* to heroin, morphine, and the active metabolites, similar to the findings in earlier studies, but they showed no binding to synthetic narcotics used in treatment,

such as methadone and buprenorphine (50). Similar studies in our laboratory have demonstrated that conjugate vaccines to morphine through the 6-hydroxyl group are able to elicit high levels of antibody that are also able to inhibit the nociceptive action of morphine using hotplate assays in mice.

As discussed in the earlier section on antibody quantitation, the amount of antibody that may be expected from a very effective vaccine would be in the hundreds of micrograms/mL range, which, in molar concentration terms would be a few micromoles per liter. Due to tolerance in heavy users, heroin doses of up to 1600 to 1800 mg can be “safely” injected by some subjects, which would result in up to a 2 mM acute concentration (50). As a result the target population for vaccination in heroin/morphine abuse will have to be motivated addicts who have been withdrawn or are being withdrawn from opiates. Withdrawal leads to a reversal of tolerance so that the pharmacologically active drug dose will be within the range able to be inhibited by achievable antibody concentrations.

The well-known socioeconomic costs of narcotics abuse and especially the associated health complications of injected heroin abuse, including the spread of the human immunodeficiency virus (HIV), the hepatitis C virus, and other sexually transmitted diseases in many countries such as China, India, and Russia (1), has reestablished considerable enthusiasm for development of alternative therapeutic approaches for abuse of these substances, including active immunization. A successful vaccine against heroin abuse that could slow or even reverse the addiction would have profound effects on criminal behavior, social stability, and the transmission of HIV/AIDS and other blood borne or sexually transmitted diseases.

CONCLUSIONS

A number of addictive drugs have pharmacokinetic and pharmacodynamic characteristics that make them viable targets for vaccine development. On a theoretical basis, from the known properties of antibodies and the drug concentrations in blood expected for the abused drugs discussed, the quantity and quality of antibody elicited by an effective vaccine should be sufficient to reduce or block drug effects, often by both reducing and slowing the accumulation of drug in the brain. Animal studies with several conjugate drug vaccines and human studies with nicotine and cocaine vaccines have all shown promising results. Blocking immediate behavioral and toxic drug effects is valuable in itself, but even more promising from the addiction perspective is the inhibition of drug reinforcement, or craving, which is necessary to help prevent relapse to drug use by individuals motivated to quit. According to some animal experiments, the effects on reinforcement may not require levels of antibody blocking as high as would be expected for inhibition of the acute drug effects, a property that could dramatically extend the benefits of this approach to therapy. Drug vaccines should also effectively complement current counseling programs and potential future small molecule medications that may be developed to treat the growing worldwide problems posed by the addictions. Advances in vaccine conjugate design, carrier protein use, and especially adjuvant optimiza-

tion will significantly enhance the quantity and quality of the antibodies produced, allowing drug vaccines to become useful clinical tools for the treatment of substance abuse.

INTRODUCTION AND HISTORY

Acupuncture (derived from the word *aces*, meaning a sharp point, and *puncture*, meaning to pierce) can be defined as a technique of inserting and manipulating fine filiform needles into specific points on the body to relieve pain and for various therapeutic purposes. The original acupuncture technique uses up-and-down and rotating maneuvers, termed as manual needling. In modern times, new methods of stimulating the acupuncture points (acupoints) include applications of electric current to needles inserted in the acupoints (electroacupuncture, EA), skin electrodes placed over the points (transcutaneous electrical acupoint stimulation, TEAS), injections into the points, or finger-pressure massage of selected points (acupressure), etc. In addition to the original 361 points, many new points have been described on specific body parts, leading to, for instance, scalp acupuncture, hand acupuncture, and (of particular interest for addiction treatment) ear acupuncture, also known as auricular acupuncture.

Although acupuncture and related acupoint therapies are most commonly known for their analgesic effects, it may be indicated for other medical applications such as nausea and vomiting of various etiologies (1). While a consensus on the clinical efficacy of acupuncture for the treatment of addictions has not yet been achieved unanimously, it has been amply demonstrated that acupuncture is an addiction treatment service now being sought by many potential patients.

Serendipitous Clinical Practice

The application of acupuncture in the treatment of opioid addiction originated from a serendipitous observation made by Dr. H. L. Wen in Hong Kong in 1972. A 50-year-old man was admitted to the Neurosurgical Unit of the Kwong Wah Hospital in Hong Kong, because of a brain concussion. He was a known opium addict of 5 years' duration. After the cerebral concussion had improved, the patient was asked whether he would agree to cingulotomy to relieve his drug-abuse problem. He agreed, and was then scheduled for surgery. During the operation for surgery, instead of local anesthesia being injected under the scalp (where the incision was to be made), acupuncture anesthesia (analgesia) was used. After stimulation for 15 to 30 minutes, the patient voluntarily stated that his withdrawal syndrome had completely cleared up. Physical examination revealed that he was free of withdrawal syndrome. The operation was canceled and the patient returned

to the ward. The next day, two other patients, both of whom were opium abusers, appeared in the orthopedic wards. When they learnt of the experience of the previous patient, both agreed to the procedure. Both responded well to the half hour of acupuncture and electrical stimulation on the ear and body points and their withdrawal symptoms stopped. After the above observation, Dr. Wen and his colleague, Dr. Cheung subsequently reported that, in a study of 40 heroin and opium addicts, acupuncture combined with electrical stimulation (now being termed "electroacupuncture") was effective in relieving the symptoms of opioid withdrawal (2).

This method was later adopted in many clinical settings in Western countries, including the Lincoln Hospital in New York City. However, the body acupuncture points originally used by Wen and Cheung on the arm and hand were gradually omitted, retaining only the ear points for acupuncture and doing without additional electrical stimulation in drug-abuse treatment (3). The protocol developed at Lincoln Hospital by Dr. Michael Smith and his colleagues was subsequently promulgated by the National Acupuncture Detoxification Association (NADA) on a national basis, with formalized training and standards for the application of ear acupuncture in a group setting. This has been the predominant approach studied by clinical trials and practiced in the United States since then.

Translation from Basic Studies on Acupuncture Analgesia

The use of acupuncture as a method of anesthesia and/or analgesia for surgery in China in the late 1950s raised a great deal of interest among the public and the biomedical community. This led to exploration of the biologic mechanisms underlying the actions of acupuncture. Starting in 1965, the Department of Public Health of China sponsored extensive research in this area. The discovery of morphine-like substances (endorphins) in the mammalian brain in 1975 (4) had a great impact on modern concepts of pain and analgesia. It was soon clear that acupuncture (manual needling)-induced analgesia can be blocked by the opioid receptor antagonist naloxone, suggesting the involvement of endogenous opioid substances (5). Manual acupuncture or EA was shown to accelerate the production and release of endorphins which could then interact with various opioid receptors to relieve or prevent pain (6). Endorphins are a group of peptides possessing a variety of specific characteristics.

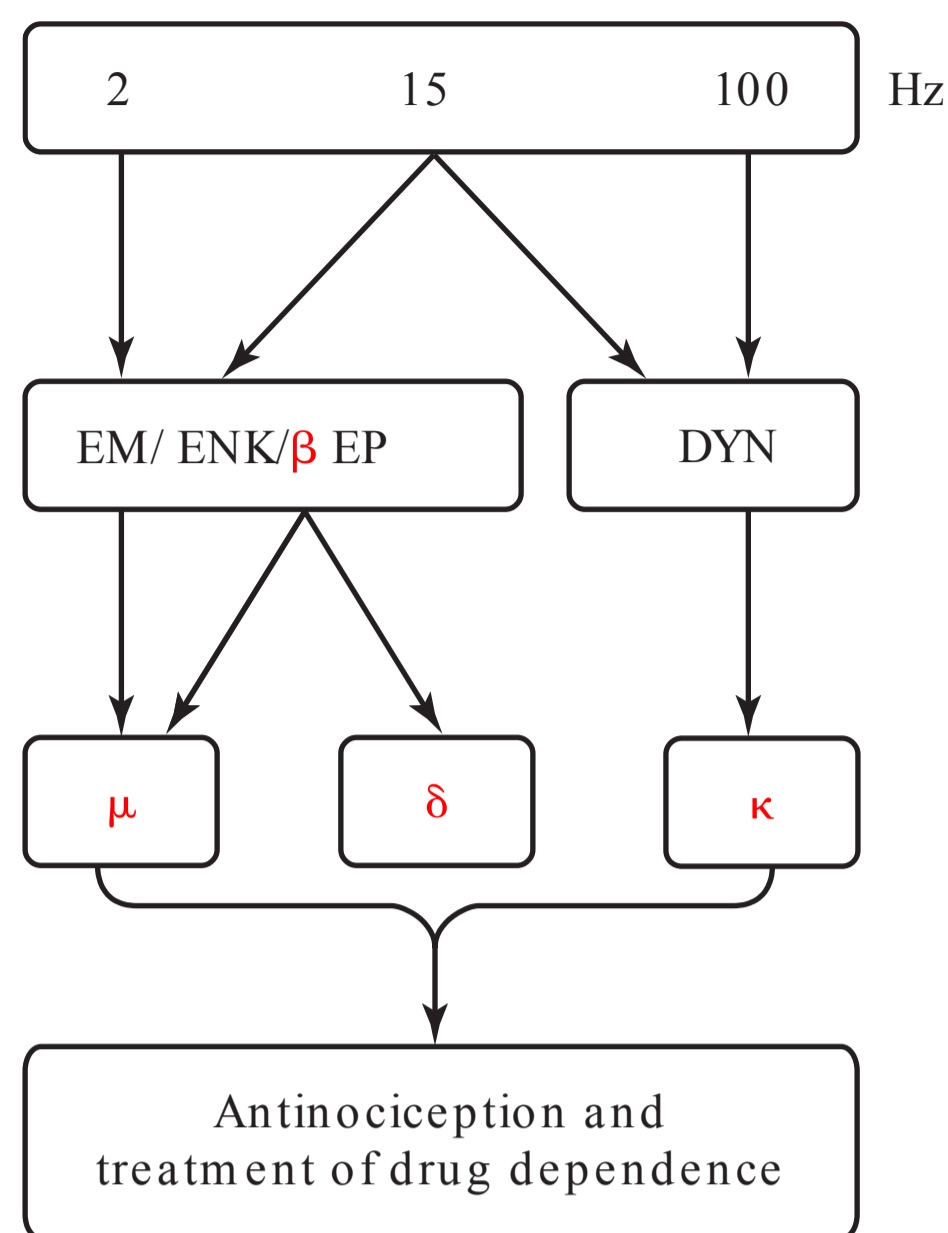

Figure 32.1. Frequency-dependent release of opioid peptides in the central nervous system. Four kinds of opioid peptides: EM, endomorphins; ENK, enkephalins; β EP, β -endorphin; DYN, dynorphins. Three kinds of opioid receptors: μ , δ , κ . Representative frequency of electroacupuncture: 2, 15, and 100 Hz.

Among those peptides, β -endorphin and enkephalin are primarily agonists of the μ - and δ -opioid receptors, whereas dynorphin is the agonist for the κ -opioid receptors. Interestingly, electrical stimulation of different frequencies can specifically induce the release of different endorphins. For example, low-frequency (2 to 4 Hz) EA stimulates release of the enkephalins that interact with μ - and δ -opioid receptors, whereas high-frequency (100 Hz) EA can stimulate the release of dynorphin to interact with κ -opioid receptors (7). These findings provided a biochemical explanation for the traditional acupuncture practice (see Fig. 32.1) and suggested that the usefulness of acupuncture might be much broader than pain control.

FROM PAIN MANAGEMENT TO OPIOID DEPENDENCE

China significantly suffered from problems of opiate addiction in the 1800s and early 1900s. This problem was minimized from 1949 to 1951 because of the complete closure of overseas trade involving opioids. However, concurrent with the implementation of the “open door policy” of the 1980s, large amounts of opiates began to be smuggled into border areas and increasing problems were seen with heroin addiction. It was natural to think that if acupuncture can release endogenous opioids in the brain to ease pain, why not make use of it to relieve opiate withdrawal symptoms? This idea was initially tested in rats made dependent on morphine. The withdrawal symptoms were significantly reduced by high-frequency (100 Hz) EA administered at the hind limbs. This effect was found to be much greater than

that induced by low-frequency (2 Hz) stimulation (8). Encouraged by the experimental results, EA was applied clinically to previous heroin addicts to see if it suppressed withdrawal symptoms. Preliminary results were promising. However, it was soon found that it was not always feasible for patients to visit the clinic to obtain professional treatment one or more times a day, and, as a result, patients might drop out. Technology for self-administration (SA) of the stimulation was developed to see whether it would be possible for patients to treat themselves by using electrical acupoint stimulation without a needle, as part of the treatment program for their addiction problem.

Experimental findings obtained in the rat model showed that electrical stimulation applied to the surface of the skin overlaying the acupoint could produce analgesic effects similar to that produced by EA through the penetrating needles (9). Satisfactory results were also obtained for the treatment of heroin withdrawal in humans using the same method of electrical acupoint stimulation via skin electrodes (10). Later it was found that this device was also useful in suppressing the conditioned place preference (CPP) to morphine in the rat (11). This is an animal model mimicking craving for drugs of abuse. Subsequent human studies revealed that this form of stimulation could also inhibit the craving for heroin in addicted patients (see below).

ACUPUNCTURE AND VARIOUS KINDS OF MODIFICATIONS

Manual Needling

As discussed in the previous paragraphs, classical acupuncture involves the piercing of the skin by a sharp metallic needle and manipulation by up-and-down (plug-drag) and twisting (twirling) movements. The correct placement of the needle at the acupoint and the optimal manipulation are generally characterized by feedback from the patient concerning a subjective feeling called *de-qi*. This sensation, reported by patients to include heaviness, soreness, numbness, and sense of swelling, occasionally also involves the trembling of the local muscles. In the meantime, the operator of the needle (the acupuncturist) often has a feeling resembling that experienced during fishing when a fish is nibbling at or swallowing the bait. This is likely the result of the rhythmic contraction of muscle fibers surrounding the needle. According to the traditional acupuncturist, it takes years to really master the particular modes of manual stimulation, for example, to produce a feeling which is “warm” (like the whole mountain is burning), or, to produce a feeling which is “cold” (like the whole sky is freezing).

Electroacupuncture (EA)

It has been made clear that the analgesic effect induced by acupuncture can be completely blocked by local procaine injection deep into the acupoint, but not by its subcutaneous injection, suggesting that the signal of acupuncture originates

mainly from nervous tissues (or tissues susceptible to procaine blockade) located in deep structures rather than in the superficial layer of the skin (12). Using single nerve fiber recording technique to record the afferent impulses of the nerve innervating the site of stimulation, it was found that the nerve fibers responsible for transmission of acupuncture signals belong to the group II (A β) fibers (13). Since the analgesic effect induced by manual needling can be totally abolished by local nerve blockade (12) or nerve transection, a neural mechanism is strongly implicated. It is thus rational to use electrical stimulation administered via the metallic needles in lieu of its mechanical movement. This has been called *EA*. The advantage of EA is that the frequency, amplitude, and pulse width of the electrical stimulation can be determined precisely and objectively, and therefore it can be replicated by other acupuncturists or experimenters without any difficulty. Moreover, the procedure of inserting the needle at a precise skin location, and changing the direction and the depth of the needle to an optimal status in order to achieve a maximal *de-qi*, is just the same as in manual needling. It is only at the end of the needle-placement procedure that the patient is connected to the electrical stimulator in place of further manual stimulation. This is exactly the procedure described by Dr. Wen in his first report, that is, “acupuncture and electrical stimulation” (2). Having said that, it should be mentioned that EA should optimally be given daily, or even several times per day during the period of detoxification, which may be difficult for outpatients who are at a distance away from the clinic. A procedure that can be operated by the patient at home under the supervision of the physician might be a desirable alternative to daily treatment in the clinic or inpatient care. In addition, because drug-addiction patients have a high incidence of blood-borne viral infections, it may be more convenient for invasive procedures to be replaced by noninvasive methods that do not produce sharp biohazardous waste.

Transcutaneous Electrical Acupoint Stimulation (TEAS)

An alternative to the use of EA is to take a transcutaneous route of electrical administration. However, since the skin has a very high impedance, which is more than 10 times that of the muscle tissue, it is necessary to use a constant current output device to assure a constant level of stimulation without being affected by the degree of moisture of the skin surface or the change of blood flow rate within the skin. Because the tip of the needle goes several millimeters or even centimeters below the skin, the placement of the skin electrodes should ensure the maximal stimulation of the deep structures underlying the acupoint. For example, to stimulate the Hegu point (coded as Large Intestine 4 [LI-4]) located in the thenar muscle of the hand, the correct placement of the skin electrodes should be one on the dorsal side and the other on the palm side of the point, so that the current is forced to pass through the thenar muscle with little deviation.

Regarding the frequency of stimulation, it is commonly accepted that conventional transcutaneous electric nerve stimulation (TENS) is based on the gate-control theory (14) that high-frequency (e.g., 100 to 200 Hz) low-intensity stimulation is preferable to activate the large-caliber nerve fibers in order to suppress the pain mediated by the unmyelinated small-caliber fibers. On the other hand, “acupuncture-like” stimulation is characterized by low-frequency (e.g., 2 to 4 Hz) high-intensity stimulation. The new approach of TEAS attempts to combine the TENS-like and the acupuncture-like stimulation to create what is hoped to be an optimal mode of stimulation to maximize the release of both classes of endorphins. A device that possesses these features was designed and named Han’s Acupoint Nerve Stimulator (HANS), and used in a series of animal and clinical experiments, the details of which are given below.

NEUROBIOLOGY OF ACUPUNCTURE TREATMENT (ANIMAL EXPERIMENT)

Physical Dependence

Systemic studies reveal that the mechanism of acupuncture analgesia is attributed mainly to the increased release of endogenous opioid peptides in the central nervous system (CNS) (6,7). A rational extrapolation is that the activation of endogenous opioid systems by acupuncture should be useful to ease opiate withdrawal symptoms.

Early in the 1970s, it was reported that transauricular electrostimulation suppressed the naloxone-induced morphine withdrawal syndrome in mice and in rats. Auriacombe et al. (15) demonstrated that TENS with an intermittent high-frequency current effectively attenuated the abstinence syndrome in the rat after abrupt cessation of morphine administration. The mechanisms of action remained obscure. Based on our previous findings that low-frequency EA (e.g., 2 Hz) accelerated the release of β -endorphin and enkephalin in the CNS, whereas high-frequency EA (e.g., 100 Hz) accelerated the release of dynorphin (7,16) in the spinal cord, we tested the effect of EA in a naloxone-precipitated morphine withdrawal model of the rat. The results showed that 100-Hz EA was far more effective than 2-Hz in suppressing withdrawal syndrome (8). This outcome is hypothetically compatible with the previous reports that (a) 100-Hz EA accelerated the release of dynorphin in spinal cord (7) and (b) spinal dynorphin can suppress the withdrawal syndrome in heroin-dependent humans (17) and morphine-dependent rodents (18,19).

Recent study showed that chronic morphine treatment resulted in serious damage of the dopamine (DA) neurons in the ventral tegmental area (VTA) of the rats, manifested as shrinkage of the cell size, swelling of the rough endoplasmic reticulum, and blurring of the mitochondria. The electrophysiologic response of these DA neurons to morphine (1 mg/kg, i.v.) was also markedly reduced. When 100-Hz EA was given to these rats 24 hours after the last injection of morphine twice a day for 10 days, the morphine withdrawal

syndrome were diminished, accompanied by a recovery of the VTA dopaminergic neurons, as compared to rats without EA treatment (20–22).

Psychic Dependence

There are several animal models (23) that can be used to study the psychic dependence on drugs of abuse, which is a central issue in addictive disorders. CPP is one of the frequently used models (24). In a two-chamber or three-chamber experimental apparatus, the drug (unconditioned stimulus) is injected in the animal in one of the chambers. Thus the drug effects become associated with the environmental stimuli unique to that chamber (e.g., color of the surroundings and texture of the floor). After repeated training, the rat will choose to stay longer on the drug-associated side than in a chamber associated with normal saline injection or no injection. The ratio between the time spent in the drug-associated side and the saline-associated side can be taken as an index for the degree of “craving.” Using this model, experiments were conducted to test whether acupuncture suppresses the expression of the CPP.

Wang et al. (11) were among the first to explore the effect of EA on morphine CPP in the rat. CPP was significantly suppressed by a single session (30 minutes) of EA at 2 Hz and 2/100 Hz, but not 100 Hz. The results suggest that it is the low-frequency component of the EA that suppressed the morphine CPP. Since the effect of EA can be completely reversed by the opioid receptor antagonist naloxone at a dose of 1 mg/kg, which is sufficient to block the opioid μ and δ , but not the κ , receptors, it seems evident that the effect of EA is mediated by endogenously released μ - and δ -opioid agonists, most likely endorphins and enkephalins, to ease “craving” for exogenous opioids (in this case, the morphine).

In practical life, craving and relapse can be easily induced by stress or by a very small dose (priming dose) of opioids. This phenomenon can be reproduced in animals using the CPP model (25), and this reinstated CPP can also be suppressed by EA (26).

For simplicity and clarity of analysis, previous studies observed only the effects produced by a single session of EA. However, in clinical practice, acupuncture, or HANS is delivered daily in consecutive days or even several times a day. To mimic the clinical situation, animal experiments were designed using EA once a day for 3 or 5 consecutive days. In this case, not only 2-Hz, but also 100-Hz EA is effective in suppressing morphine CPP (27,28). The finding suggests that the efficacy of EA to suppress morphine-induced CPP depends not only on the frequency of EA (2 Hz better than 100 Hz), but also on the total number of sessions of EA being administered (5 times > 3 times > single session). This may be related to the degree of activation of the genes encoding opioid peptides. It was found that 2 and 100 Hz EA can selectively elevate preproenkephalin (PPE) and preprodynorphin (PPD) mRNA level, respectively (29,30), as well as an increase of the tissue content of DA in the nucleus accumbens (NAc) of morphine-induced CPP rats (31).

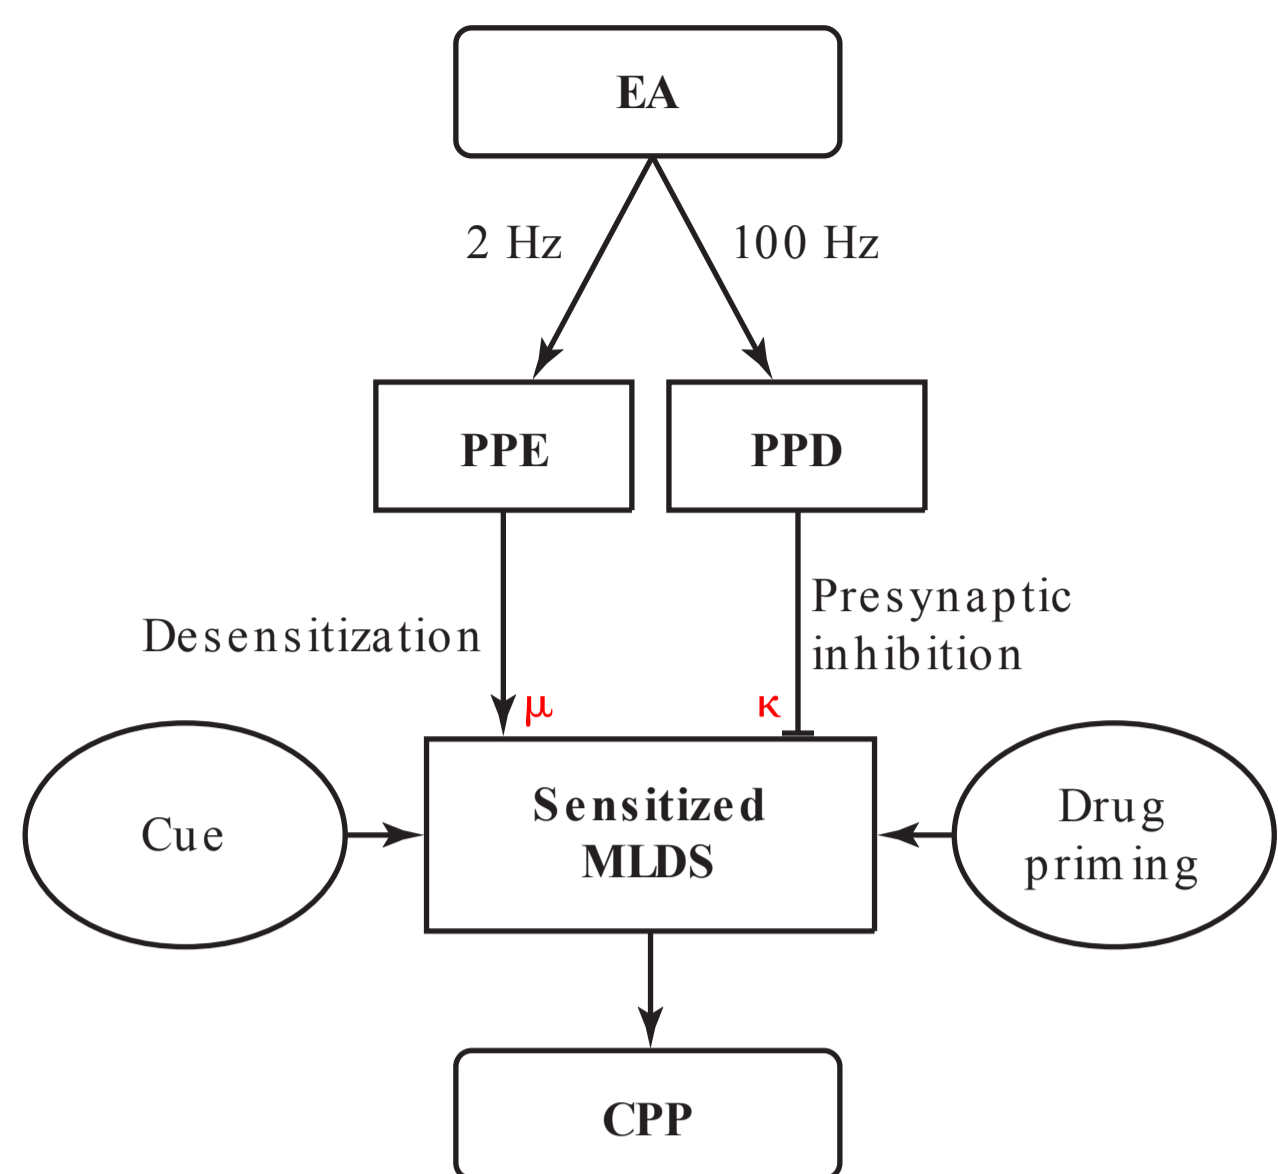

Figure 32.2. Diagram showing that the cue-induced CPP for morphine or drug priming-induced reinstatement of CPP can be suppressed by electroacupuncture of different frequencies. See details in the text. EA, electroacupuncture; PPE, preproenkephalin; PPD, preprodynorphin; MLDS, mesolimbic dopamine system.

The results mentioned above can be summarized in the diagram shown above. An environmental cue or small dose of drug can induce CPP or cause reinstatement of extinguished CPP by activation of the mesolimbic dopamine system (MLDS). The sensitized DA neurons can be suppressed by EA via different mechanisms: low-frequency EA activates the PPE neurons thereby desensitizing the DA neurons via μ -opioid receptors, whereas high-frequency EA activates the dynorphin system and causes the presynaptic inhibition of DA neurons via κ -opioid receptors (Fig. 32.2).

EFFICACY (HUMAN STUDIES)

Effect on Withdrawal Syndrome

For the treatment of the withdrawal syndromes in heroin addicts, HANS was used once a day for 30 minutes for a period of 10 days in a drug-addiction treatment center (32). Apart from the subjective answer to a standard questionnaire, two objective parameters were measured, that is, the heart rate and body weight of the patients.

Single Treatment

To observe the immediate effect of HANS on the heart rate of patients in withdrawal from heroin, the two pairs of output leads of the HANS were connected to four acupoints in the upper extremities. One pair at Hegu point (LI-4, at the dorsum of the hand on the thenar eminence) and Laogon (P-8, opposite to LI-4, on the palmar side), another pair on Neiguan (P-6, located at the palmar side of the forearm, 2 inches proximal to the palmar groove, between the tendons of the palmaris

Figure 32.3. Heart rate of heroin addicts receiving HANS treatment once a day for 10 days. $P < 0.01$ compared with the mock acupuncture (“control”) group.

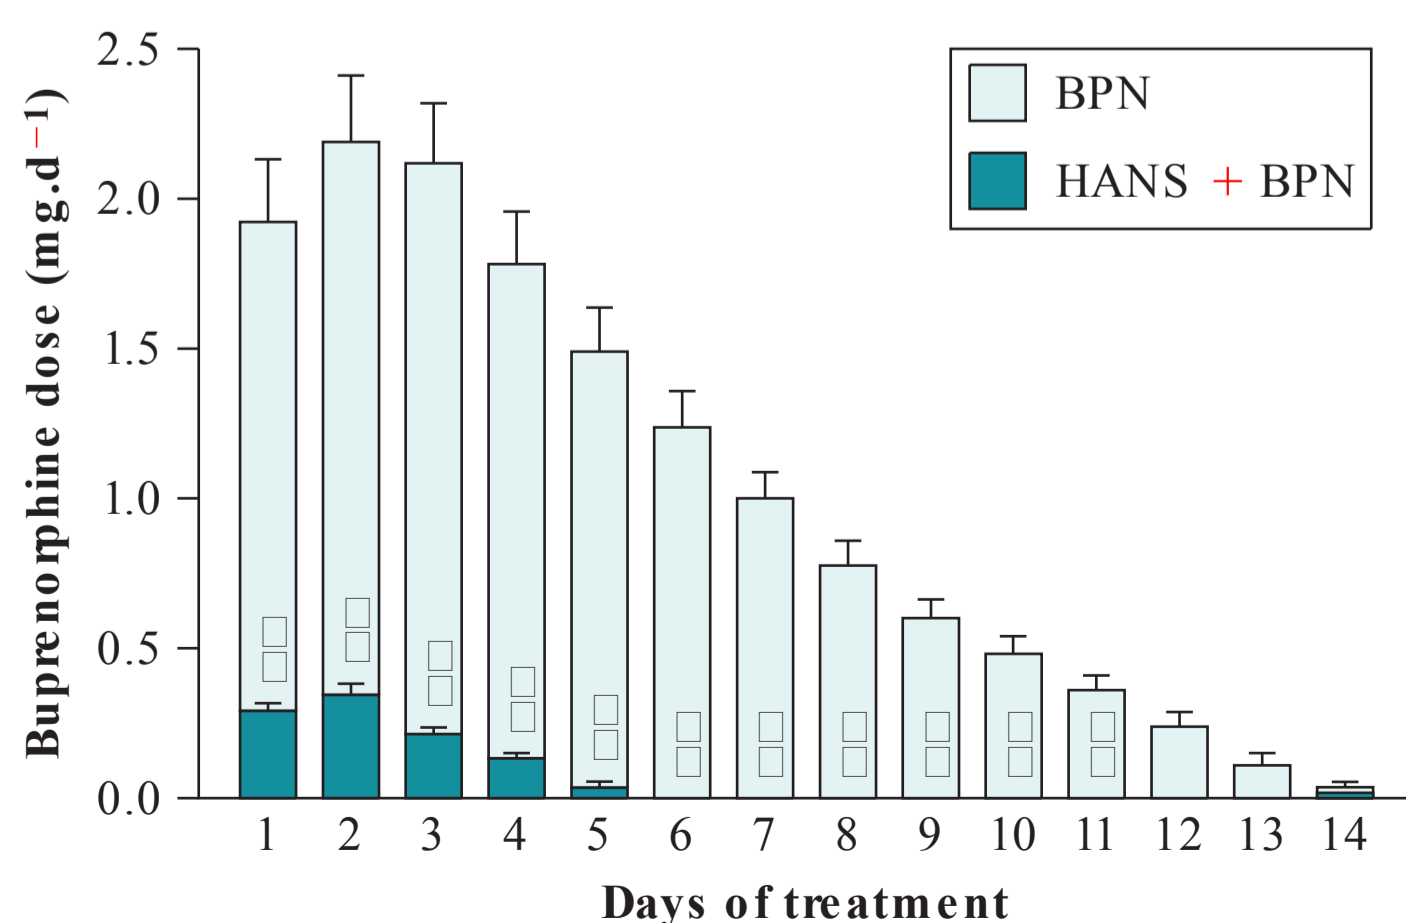

longus and flexor carpi radialis) and Waiguan (TE-5, on the dorsal surface of the forearm opposite the P-6). A “dense-and-disperse” mode of stimulation was administered, in which 2-Hz stimulation alternated automatically with 100-Hz, each lasting for 3 seconds. This mode of stimulation releases all four kinds of opioid peptides in the CNS (7). The control group received the same treatment, except that the electrodes were disconnected from the electronic circuitry. The average heart rate of the patients in opioid withdrawal was 109 beats per minute before treatment, significantly higher than the normal value of below 70. The dense-and-disperse mode stimulation for 30 minutes reduced the heart rate to 90 beats per minute. The full effect remained for only 20 minutes after the stimulation, and returned to its original level thereafter. So the effect was robust but short lasting.

Multiple Treatments

To observe the cumulative effect of multiple daily treatments with HANS, heroin-addiction patients were randomly divided into four groups, receiving HANS of 2, 100, or 2/100 Hz (“dense and disperse”). The control group received mock stimulation, with the electric circuitry disconnected. The treatment was delivered 30 minutes a day for 10 consecutive days.

Figure 32.4. Influence of 2/100 Hz transcutaneous electric acupoint stimulation (with HANS device) on the requirement of buprenorphine (BPN) for heroin addicts during the period of detoxification. $P < 0.01$ compared with the corresponding control group (BPN alone).

In the control group receiving mock HANS, heart rate did not come down to a level of 100 beats per minute until 8 days after the treatment. Repeated daily EA treatment was effective in reducing the tachycardia of heroin withdrawal, with an effective order of dense-and-disperse > 100 Hz > 2 Hz (32) (Fig. 32.3). This result is compatible with the findings obtained in rats that the withdrawal syndrome is more effectively reduced by 100 Hz rather than 2 Hz stimulation, while the dense-and-disperse mode is always the best because of synergistic interaction between opioids.

In order to obtain a quantitative estimate of the effect of HANS in reducing withdrawal syndrome, the following protocol was established (33): HANS was used three times a day for the first 5 days and reduced to twice a day for the second 5 days and then once a day for a total of 14 days. Buprenorphine (Buprenex) i.m. was used as a supplement to HANS when the patient experienced withdrawal distress. To quantify the role of HANS in a combined HANS/buprenorphine treatment, 28 heroin-addiction patients were randomly divided into two groups, receiving buprenorphine only, or HANS plus buprenorphine. The results shown in Figure 32.4 indicate that the total amount of buprenorphine used in the HANS group was only 8.3% of that needed in the pure

Figure 32.5. Effect of Han's Acupoint Nerve Stimulation (HANS) on craving scores in heroin addicts ($N = 29$ to 30 in each group). HANS of 2 and 2/100 Hz accelerated the decay of craving scores during the 10-day treatment period.

buprenorphine group. This can be taken as a quantitative estimate of the effect of HANS on opioid withdrawal symptoms. This is apparently a result of an accumulation of the therapeutic effect produced by repetitive treatments in the period of 14 days. Similar observations were made in another group of heroin-addicted subjects using a methadone reduction protocol as control group and HANS (2/100 Hz) plus methadone as the experimental group (34). The total dose of methadone used in the HANS group was only 25% of that in the control group.

Effect on Craving and Relapse

Drug addiction is a chronically relapsing disorder in the CNS. The cardinal behavioral feature of drug addiction is continued vulnerability to relapse after years of drug abstinence (35). Therefore, long-acting opioid (methadone, levo-alpha-acetylmethadol [LAAM], or buprenorphine) maintenance is the principal choice to prevent relapse to heroin. Alternately, for some patients, especially those with strong resources for social support, one may try to become drug free for the rest of their life. The following sections explore whether acupuncture helps to reduce craving and postpone or prevent the relapse.

Effect of HANS on Opiate Craving in Humans

To obtain a quantitative estimate of possible suppression of craving in response to acupuncture or related techniques, we used a visual analogue scale (VAS, 0 to 100 mm) to represent the degree of craving in a group of heroin-addicted patients who had completed the process of detoxification more than 1 month earlier. A total of 117 subjects with an initial VAS score higher than 20 were recruited, and were randomly assigned to four groups, receiving HANS treatment once a day for 10 days. This treatment period was preceded by a control pretreatment period for 10 days, and followed by another 10 days for the observation of after

effects. Three groups were subjected to HANS treatment at frequency of 2, 100, or 2/100 Hz, respectively, and one group to mock HANS of minimal stimulation (using 5 mA threshold intensity at the beginning for 5 minutes and then switched off). There was a very slow decline of the VAS in the mock HANS control group. A dramatic decline of the degree of craving was observed in the groups receiving 2 or 2/100-Hz electric stimulation, but not in the group receiving 100-Hz stimulation. In summary, the results observed in humans coincided with the findings obtained in the rat that low-frequency HANS is more effective than high-frequency HANS in reducing the craving for opiates (26) (Fig. 32.5).

Drug Free for 1 Year as a Standard for Successful Prevention of Relapse

Heroin addiction is characterized by a high rate of relapse even after a long abstinence. Without taking special measures, the chance of complete drug abstinence for a period of 1 year is minimal. Consequently, we accept 1 year as a criterion of successful prevention of relapse. Based on the findings shown in the previous study concerning the effect of HANS on opiate craving, we encouraged detoxified addiction patients to take with them a unit of portable HANS when they were discharged from the detoxification center. It was strongly recommended to have at least one session (30 minutes) before going to bed to facilitate sleep. It was also suggested that they use the device anytime when there was a strong drug cue or a robust episode of craving. The anticraving effect was usually reported to appear within 20 minutes.

A follow-up study (2000 to 2001) was conducted on a group of 56 patients in Hainan island of south China, who used HANS at home with weekly consultation and a urine check twice a month. At the end of 12 months, only 9 were drug free based upon urine test results, so the 1 year relapse rate was 83.9% (16.1% success rate). A later study in Shanghai (2003) found a 1 year success rate of 26.8% (60 out of 224).

Compared with a 95% to 99% relapse rate at the end of 1 year in the majority of reports on heroin addiction in China (without methadone maintenance) (36), the above-mentioned results were encouraging.

SAFETY

Aversive Side Effects

Relatively few complications have been reported for acupuncture. Serious events including organ puncture and lung collapse are very rare, since most of the acupoints are located in the extremities. In fact, acupuncture is well known for its low rate of aversive side effects and high safety (1), compared with many standard pharmacologic treatments. The risk of acupuncture-mediated infection is minimized by strict adherence to the instructions for single use needle. For those still concerned, the use of skin electrodes rather than needles will reduce this risk from minimal to zero. The serendipitous electric shock is prevented by the design of the stimulation device such that once the modulatory keys are set, the whole device will be locked to avoid the incidental touch of the parameter keys.

Dependence Liability

Given the established finding that acupuncture and related techniques would increase the release of opioid peptides in the CNS (7), one may be concerned that acupuncture per se might produce dependence. While we have not heard of any report of this kind, this is a rational issue deserving careful exploration. In an experimental setting in the rat we tested the hypothesis that if EA produces pleasurable experience, repeated EA in a fixed experimental environment might cause CPP. This was verified by the finding in rats that EA of 2 Hz indeed cause significant, although mild, CPP (28,37). Translating into human behavior, one may expect that acupuncture or a related technique would be welcome by the patients, or at least to neutralize the possible inconvenience caused by needle punctures and to keep patients adhering to the acupuncture treatment schedule.

SPECIAL CONSIDERATIONS

Alcohol

Acupuncture was considered quite promising for the treatment of alcohol addiction in the 1980s (38). The same orthodox ear points suggested in the Lincoln Hospital/NADA protocol were used, and points 3 to 5 mm apart were used as nonspecific points for control. However, this result could not be replicated by Worner et al. (39) in the United States (56 cases) or by Sapir-Weise et al. (40) in Sweden (72 cases). In a recent randomized, placebo-controlled study of auricular acupuncture, Bullock et al. (41) conducted a large-scale clinical trial that included 503 cases. The outcome, however, was quite different from the original hypothesis. All four groups

showed a significant improvement. These authors concluded that ear acupuncture did not make a significant contribution over and above that achieved by conventional treatment alone in the reduction of alcohol use.

Data show that the euphoric effect of alcohol is mediated by endogenous opioid peptides and the opioid antagonist naltrexone has been used to assist cognitive-behavioral therapy for alcoholics (42). Therefore, modulation of the endogenous opioid system should be considered as one of the approaches for the treatment of alcohol craving in alcoholic patients. Yoshimoto et al. (43) reported that rats subject to repeated restriction stress consume more alcohol than the control animals. EA at hind limb points zusanli (ST-36) significantly reduced the alcohol-seeking behavior, whereas the lumbar point Shenshu (BL-23) was not effective. The effect of EA stimulation at ST-36 was accompanied by an increase in DA level in the striatum, compared with that produced by EA at BL-23. These findings provide new information for understanding alcohol-drinking behavior and for treating human alcoholics. This was supported by a recent study of Overstreet et al. (44) who did an experiment in the P rats that showed special favor for alcohol consumption. EA applied at ST36 and SP6 of the rat with 2/100 Hz stimulation caused a significant reduction of alcohol consumption, which was reversed by naltrexone, a long-acting opioid receptor antagonist, suggesting that this effect is mediated by opioid receptors.

Smoking

A recent Cochrane review concluded that despite the relatively high number of studies, there was no consistent evidence that acupuncture was effective for smoking cessation. Lambert et al. (45) evaluated the efficacy of a standardized protocol of TEAS in alleviating the urge to smoke in nicotine-dependent individuals, during a 26-hour abstinence period. Electrical stimulation was applied on the Hegu (LI 4)/Laogon (PC 8) points of the hand, and Neiguan (PC 6)/Waiguan (TE 5) points of the upper arm, using 2/100 Hz alternating frequency and 10 mA intensity as the effective stimulation, and no stimulation or intermittent 5 mA minimal stimulation as the control. The results showed that 10 mA stimulation, but not the minimal stimulation, significantly reduced the craving for smoking. The results warrant further large-scale clinical trial.

Cocaine

Cocaine addiction is one of the most important challenges of substance abuse treatment for two reasons. First, according to the 2007 WHO report, cocaine has approached heroin in terms of drug users in the whole world (14 vs. 16 million persons), and surpassed heroin in terms of illicit drug market (71 vs. 65 billion dollars). Second, there is no effective pharmacologic treatment available for cocaine addiction.

Compared with heroin addiction, cocaine addiction shows a minimal withdrawal syndrome upon cessation of use, yet more prominent and longer-lasting craving, serving as one of the most important cues leading to its relapse. Therefore

the most important issue is whether acupuncture can have an effect in suppressing and/or preventing cocaine craving. Data obtained from animal experiments with cocaine are discussed first, followed by a discussion of results from clinical trials.

Experimental Studies

In the last three decades, the SA technique has commonly been used to assess the degree of psychic dependence to cocaine in rats. In recent years, CPP has also been used for this purpose. Ren et al. (46) studied the expression of cocaine-induced CPP in rats, which was maintained for as long as 4 weeks at weekly checking, or for 13 days at a daily checking schedule. High-frequency (100 Hz) EA applied at hind leg points for 30 minutes was found to significantly reduce the CPP, whereas low-frequency (2 Hz) was without effect. This is in sharp contrast to opioid-induced CPP, where 2-Hz EA is much more effective than 100 Hz in suppressing its expression. The attenuation of cocaine CPP by 100-Hz EA may involve a κ -opioid mechanism. Indeed, the effect of 100 Hz EA can be blocked by the opioid antagonist naloxone only at a high dose (10 mg/kg). This dose is sufficient to antagonize all three subtypes of opioid receptors, including κ receptor. On the other hand, the lower doses (1 and 5 mg/kg) that are only able to inactivate μ - and δ -, but not κ -opioid receptors was not effective. These results may suggest a role for 100-Hz EA to reduce cocaine craving and to prevent relapse. Clinical trials of this approach are certainly warranted.

Clinical Trials

Ear acupuncture is often used for the treatment of cocaine addiction in the United States, using the same four to five ear points originally developed at Lincoln Hospital for use in the treatment of opioid addiction and promulgated by NADA for general use in addiction programs. Using this protocol, Smith et al. observed a series of 226 cases of users of cocaine or crack cocaine and found that 149 (65%) had more than 80% negative urine tests during the entire treatment period (47). While there was no control group, the success rate by itself was felt to be quite encouraging. This was supported by the work of Margolin (1993) and Avents (2000) with an observation population of 32 and 82, respectively.

Encouraged by the aforementioned results, a randomized, controlled, single-blind, multisite large-scale clinical trial was conducted from 1996 to 1999. The results were published in *JAMA* in 2002 (48). A total of 620 cocaine-dependent adults were randomly assigned to receive auricular acupuncture (four needles schedule), a needle-insertion control (four needles inserted into the helix of the ear), or a relaxation control. Treatments were offered five times weekly for 8 weeks. Main outcome measures were cocaine use during treatment and at the 3- and 6-month follow-up based on urine toxicology screening and retention in treatment. The conclusion was that within the clinical context of this study, acupuncture was not more effective than a needle-insertion or relaxation control in reducing cocaine use. The authors concluded that the results do not support the use of acupuncture as a stand-alone treat-

ment for cocaine addiction, yet it may play an ancillary role for the treatment of cocaine addiction. This conclusion is apparently in contrast to that derived from the animal experiments, as well as results from the preceding pilot study. It seems that the psychosocial and rehabilitative services made available for patients during the second study were fairly minimal, while in the first, the services had been considerable (49).

Finally, in the planning of future large trials of acupoint therapy for cocaine addiction, attention should also be directed to the results obtained in rat experiments showing that the therapeutic effect of EA is frequency-dependent, that is, 100-Hz, rather than 2-Hz stimulation can suppress the cocaine-induced CPP. Therefore, it may be worthwhile to include 100-Hz EA (and possibly body EA) stimulation in future trials of acupuncture-related therapy for the treatment of cocaine addiction.

TECHNICAL COMMENTS ON USING ACUPUNCTURE IN THE TREATMENT OF ADDICTION

Ear Acupuncture versus Body Acupuncture

Although the ear concha is not included in the classical 14 meridians, there is no reason not to use ear points. On the other hand, there seems no reason to avoid the use of body points either. The original protocol of Dr. Wen in treating drug abuse in Hong Kong used four points in the hand and arm (connecting to electrical stimulator) and two points on the ear. Besides, while the sensation produced by piercing the ear is almost pure pain, pain is not a component of the typical experience of *de-qi* in the body acupuncture. In other words, ear acupuncture and body acupuncture should have equal chance to be used in the treatment of drug abuse.

Needle Staying versus Manual Needling

The results obtained in human studies (Fig. 32.6) suggest that manipulation of the needle produces a stronger physiologic effect than does needle staying (i.e., no manipulation) in the acupoint, at least when pain modulation is measured (50).

Acupuncture and Electroacupuncture versus Transcutaneous Electric Stimulation

A series of studies showed that the manipulation of the needle triggers a train of nerve impulses transmitted along the afferent nerve fibers to the CNS. The physiologic effects produced by acupuncture (e.g., the antinociceptive effect) can be readily blocked by the injection of local anesthetics deep into the acupoint (12), or along the afferent nerve. If nerve activation accounts for the transmission of the acupuncture signals, then similar effects should be induced whether nerve impulses are generated by manipulation of a needle (manual acupuncture, MA), or by electrical stimulation via the needles inserted into the point (EA), or even by electrodes placed

Figure 32.6. Influence of manual needling at ear acupoint Shenmen ($N = 16$) or Shenmen plus lung ($N = 18$) on pain threshold of the skin over the chest and abdomen in humans. The pain threshold increased during the period of needle manipulation and started to decrease when the needle stayed in situ.

on the surface of the skin over the point, forcing the current to pass through the underlying tissue (TEAS). In an experiment performed in the rat, the analgesic effects induced by EA (via needles) and by transcutaneous stimulation (via skin electrodes) were compared. No significant difference was found between the two approaches in the efficacy of inducing an antinociceptive effect (9). It is interesting to note that a similar mechanism seems to underlie the two analgesic effects. Thus, no matter whether the electrical stimulation is delivered via needles or skin electrodes, the opioid antagonist naloxone at a 2 mg/kg dose produced a complete reversal of 2-Hz stimulation-produced analgesia, a partial reversal of 15-Hz stimulation-induced analgesia, and no reversal on 100-Hz stimulation-produced analgesia (9), unless the dose of naloxone is increased to 10 to 20 mg/kg (7).

Opioid- versus Nonopioid-Mechanisms

The mechanism of acupuncture or EA relies, at least partly, on the frequency-dependent release of opioid peptides in the CNS (7). For example, high-frequency (100 Hz) stimulation is more efficacious in reducing opiate withdrawal syndrome, whereas low-frequency appears to be more effective in reducing opiate craving. In contrast to opiate addiction, effects on cocaine addiction may work through a slightly different mechanism, such that CPP for cocaine in the rat, a rodent model of cocaine craving, can be suppressed only by 100-Hz, but not 2-Hz, stimulation (46). These findings should be considered in the future study.

Design of Appropriate Control Group

Acupuncture, as a procedure (or group of related procedures), is far more difficult to subject to a double-blind clinical trial than is a drug. In this respect, clinical trials of acupuncture should be compared with trials for different types of psychotherapy or surgical procedures, rather than drug trials. In recent years, considerable methodologic progress has been made that will better answer many ques-

tions about acupuncture's efficacy. For example, the design of a mock needle that looks like it is penetrating the skin, but actually withdraws into a hollow space leaving a touch sensation on the skin mimics the *de-qi* experience (51). This is a single-blind design, because the acupuncturist knows the difference between the conventional needle and the mock needle.

To use EA at threshold intensity with intermittent trains is another option. For example, using a constant current device, the threshold intensity for a 4 × 4-cm skin pad is 5 mA for most subjects. A desirable intensity is two times the threshold, that is, 10 mA. On the other hand, one can use a minimal stimulation by (a) reducing the stimulation intensity to the threshold level (5 mA), and (b) reducing the time of stimulation by using an intermittent (on/off) schedule, that is, 10 seconds on and 20 seconds off, so that the stimulation time is cut by 2/3, yet the subject still feels the stimulations come and go (45).

SUMMARY

Acupuncture is an emerging treatment for drug abuse. This approach is different from that of pharmacologic treatments. For example, while methadone maintenance treatment is aiming at long-term replacement of methadone for heroin, acupuncture or TEAS attempts to strengthen the endogenous opioid system and eventually get rid of the drug. From a technical point of view, there is still considerable room for improvement, and more evidence of efficacy remains to be shown. For example, apart from the reduction of protracted withdrawal symptoms and craving, two further changes in body function help the patient to build confidence in maintaining abstinence. One is the disappearance of injection marks, and the other is the recovery of the depressed sexual function (52). The complicated network underlying drug abuse can be unraveled only through combined physiologic, neurobiologic, and psychological endeavors, and acupuncture may play a role at least as one of the tools in a comprehensive treatment approach.

Richard N. Rosenthal

INTRODUCTION

For the most part, the treatment of alcohol dependence has been conceptualized by clinicians and the general public as a behavioral intervention, whether through involvement in mutual self-help groups such as Alcoholics Anonymous, or through intensive in- or outpatient rehabilitation, or through professional alcohol counseling. This reality is striking in that there have been effective medications available to assist in recovery from alcohol dependence since the early 1950s. Even with the fact that there at least five medications, four of which are currently FDA-approved, that contribute clinically useful impact in the treatment of alcohol dependence, the acceptance and implementation by the treatment community remains low (1,2). In general, medications for the treatment of alcohol dependence achieve their effect through either of two proposed mechanisms—stabilizing systems that have adapted to chronic alcohol exposure and which have become dysregulated with a reduction in alcohol intake, or interfering with the reinforcing effects of alcohol consumption.

HISTORY OF MEDICATION TREATMENT

Disulfiram

History of the Treatment

Disulfiram was a medication originally explored for use as an antiparasitic, and discovered to have aversive qualities in the context of alcohol drinking by Danish researchers Hald and Jacobsen in 1948 (3). In the United States, it was approved by the FDA for the treatment of alcohol dependence in 1951.

Pharmacology of the Medication/Treatment

Its mechanism of action is to block the oxidation of alcohol to acetate through the irreversible inhibition of the enzyme acetaldehyde dehydrogenase, which can increase plasma level of acetaldehyde 5 to 10 times than under normal circumstances of drinking. The buildup of acetaldehyde, which is the oxidation product of ingested alcohol via alcohol dehydrogenase, produces highly unpleasant symptoms in the patients, such as nausea, vomiting, throbbing headache, tachycardia, dysphoria, flushing, hypotension, vertigo, diaphoresis, and dyspnea (4). As such, the actual mechanism of disulfiram in the reduction of alcohol intake lies in its aversive qualities, and thus its ability to increase motivation for sobriety through potential or more rarely, actual punishment.

Efficacy of the Medication/Treatment

Although disulfiram has been in use for 60 years, there have not been a substantial number of well-controlled efficacy studies, and those that have been performed used various outcome measures with differing results (5). Some studies show an improvement in days drinking and reduction in quantities of alcohol consumed. In the largest ($N = 605$) clinical trial, a double-blind, placebo-controlled, 1-year, multicenter cooperative study by the Department of Veterans Affairs, there were no significant differences in the intention-to-treat analysis of abstinence rates among the three treatment groups receiving a daily dose of disulfiram 250 mg, disulfiram 1 mg (an inactive dose), or a vitamin (6). However, those in the disulfiram 250 mg group had significantly fewer drinking days than subjects in the other two groups. Only the groups who received disulfiram were told they might have an aversive reaction if they drank. Nonadherence was a confounding factor in this study, in that 80% of subjects did not take the study medication regularly. Interestingly, the small subset of patients across groups who were adherent with the protocol demonstrated reductions in their alcohol consumption.

A later randomized clinical trial took the adherence issues into consideration and put supervision of daily dosing of the study medication into the procedure, demonstrating significantly less drinking with 200 mg disulfiram compared to a vitamin C control (7). An open randomized 8-month clinical trial ($N = 100$) conducted a head-to-head comparison between disulfiram and acamprosate in subjects screened for good family support for adherence and follow-up (8). The disulfiram group had greater maintenance of abstinence (88% vs. 46%, $P = 0.0002$) and had increased time to relapse to heavy drinking (123 vs. 71 days, $P = 0.0001$), compared with the acamprosate group. Overall, disulfiram decreases drinking days, but there is not strong evidence that it supports maintenance of abstinence (10), and the lack of this stronger evidence is most likely due to patients' poor adherence with the study medication in the existing data sets.

Safety of the Medication/Treatment

Disulfiram is associated with rare but serious side effects such as hepatotoxicity, cholestatic and fulminant hepatitis, optic neuritis, peripheral neuritis, polyneuritis, and in high doses, psychotic symptoms (9). Contraindications to the use of disulfiram include ischemic heart disease and pregnancy. Disulfiram inhibits the induction of hepatic enzymes and thus may interfere with the metabolism of concomitantly

administered medications. As such, disulfiram enhances the effects of the coumarin anticoagulants and the phenytoin anticonvulsants (4). In general, disulfiram is used safely in patients who clearly understand the need to avoid consumption or skin contact with all alcohol-containing materials, as even a small dose of alcohol can lead to a buildup of acetaldehyde. This means, in addition to abstaining from consumption of beverage alcohol, the patient must avoid contact or ingestion of alcohol found in foods, over-the-counter cold and other medications, mouthwashes, colognes, and lotions in order not to have an aversive reaction (10). Certain patients with poor control of impulses or poor judgment may be at higher risk for drinking when on disulfiram. Clearly, clinical judgment is a factor in choosing an optimal candidate, but diagnoses alone, while suggestive of potential problems in using disulfiram, are not sufficient as a contraindication against disulfiram use. For example, recent research has demonstrated that patients with co-occurring disorders that may impair cognition or judgment such as schizophrenia, depression, or post-traumatic stress disorder, can still make effective use of disulfiram therapy (11–13).

How the Medication/Treatment Is Optimally Used

Disulfiram is available in 250-mg tablets, and patients should start with an initial oral dose of 250 mg daily, and may be built up to 500 mg daily. Disulfiram should not be taken unless the blood alcohol concentration is zero or until the patient has not consumed any alcohol for at least 12 hours. In addition, as disulfiram is an irreversible aldehyde dehydrogenase inhibitor, the potential for a disulfiram reaction continues until new enzyme is synthesized, which may be up to 2 weeks after discontinuation of treatment. Typically, disulfiram is used for treating patients with prior failure of one or more courses of psychosocial treatment (10) and who are motivated to achieve complete abstinence (6). In patients newly diagnosed with alcohol dependence, disulfiram has not been recommended as a first-line medication, as there are other FDA-approved medications for the treatment of alcohol dependence with more benign side-effect profiles and ease of use. However, there are instances where it is imperative to demonstrate sobriety, such as in legal agreements and consent decrees, where the supervised use of disulfiram, combined with proper toxicologic evaluation, can increase the likelihood that a particular patient will be abstaining from alcohol over a given interval.

Adherence to the medication regimen is an important negative predictor of relapse since patients typically stop disulfiram if they are planning to start drinking again. As such, it is useful to investigate strategies that are likely to optimize exposure to the medication. Disulfiram in an implantable form has been investigated, but currently, the data are limited. As subject adherence with disulfiram dosing has been identified as an important factor in revealing its efficacy, several studies appear to support that supervised administration is an important strategy to optimize efficacy. In the 1986 VA study (6), across groups, those that demonstrated improvements in maintenance of abstinence were those who were adherent with the

study medications. Since disulfiram works as an aversive contingency, rather than through neuromodulation, all subjects who took active or placebo medication were subject to the contingency. Supervision of disulfiram has been reported as a superior strategy for decades and even limited supervised administration appears to increase disulfiram's efficacy (14,15). In the open clinical trial comparing acamprosate to disulfiram described above, disulfiram generally had no specific effect unless its use was monitored and supervised by clinicians or significant others (8).

Special Considerations

A well-researched and effective behavioral strategy that optimizes the adherence to disulfiram is Behavioral Couples Therapy (BCT), which provides contingency for sobriety and increased social support for the patient's efforts to change. In BCT, a couple signs a contract stipulating that the partner will watch the patient taking a daily dose of disulfiram and record it on a calendar, then the patient and partner thank each other for their efforts, and will not argue or even discuss the patient's drinking behavior (16). A meta-analysis of randomized studies of BCT showed superior impact on frequency of alcohol use, consequences of use, and relationship satisfaction over individual interventions for alcohol and drug abuse (17).

Oral Naltrexone

History of the Treatment

Naltrexone is a μ -opioid antagonist that was approved in 1994 by the FDA for the prevention of relapse to heavy drinking in alcohol-dependent individuals (Table 33.1). As an opioid antagonist, it was originally approved and marketed as a treatment for opioid dependence. The use of oral naltrexone for opioid dependence, although pharmacologically active, has fallen into disuse due to high rates of medication nonadherence and treatment dropout (18).

Pharmacology of the Medication/Treatment

Endorphins and enkephalins, which are naturally occurring opiates, are released as a result of alcohol consumption (19). Dopamine (DA) is released from the nucleus accumbens (NAc) when these opiates bind to brain receptor sites, resulting in some of the pleasurable effects of alcohol. There may also be opioidergic but non-DA-mediated reward circuitry (20). Investigations of animal models of the role of opioids in alcohol-mediated reward have demonstrated that alcohol-preferring animals have reduced opioid peptides in their brains, and that alcohol is not self-administered by μ -opioid knockout mice (21). In research with humans, as compared to non-alcohol-dependent persons and their family members, a family history of alcoholism is associated with decreased baseline beta-endorphin levels and an exaggerated increase in beta-endorphin as a response to alcohol (22,23). This suggests that at least one component of the vulnerability to the development of alcohol dependence is based upon an increased sensitivity to alcohol-induced endorphine release and subsequent reinforcement. Naltrexone

blocks the opioid-mediated release of DA in the NAc that is typically induced after alcohol consumption (24,25), thus diminishing alcohol's positive reinforcing effects. In addition, alcohol craving is reduced by naltrexone in both social drinkers (26) and alcohol-dependent patients (27), which may be another mechanism of action that is beneficial in recovery from alcohol dependence.

Efficacy of the Medication/Treatment

Two early trials demonstrated that when combined with psychosocial treatment, naltrexone was efficacious in treating alcohol dependence by reducing relapse to heavy drinking (Table 33.2). Volpicelli and colleagues (28) conducted a 12-week double-blind RCT in alcohol-dependent men ($N = 70$) who were postdetoxification and receiving outpatient psychosocial treatment, and compared naltrexone 50 mg/day versus placebo. Compared to 25% in the naltrexone-treated group, about 50% of the placebo-treated patients had relapsed to heavy drinking, defined as ≥ 5 drinks/day. The group treated with naltrexone also had significant reductions in alcohol craving over the 12-week period. O'Malley and colleagues (29) found similar results in an RCT of naltrexone 50 mg/day or placebo in male and female subjects with alcohol dependence ($N = 97$) who received either alcohol-targeted individual coping skills and relapse-prevention therapy or supportive therapy. Results of a later 12-week trial of naltrexone

50/mg a day compared to placebo in alcohol-dependent patients ($N = 97$) who were receiving psychosocial therapy, demonstrated that the rate of relapse to heavy drinking was significantly reduced only in naltrexone group patients who were adherent to the medication regimen (30).

Although most RCT of naltrexone demonstrate significant reductions in drinking behavior, a few have not (31,32). In a meta-analytic approach examining 14 RCTs of naltrexone and placebo, Bouza and colleagues found that administration of naltrexone over the short term (< 12 weeks), significantly decreased the rate of relapse to heavy drinking (odds ratio, OR: 0.62 [0.52, 0.75], $P < 0.001$), but did not have a significant effect on the rate of abstinence (OR: 1.26 [0.97, 1.64], $P = 0.08$) (33) (Table 33.2). A Cochrane collaborative study performed a meta-analysis of 24 RCTs of naltrexone and placebo, finding that in short-term studies the rate of relapse to heavy drinking was reduced by 36% by naltrexone (relative risk, RR: 0.64, 95% CI 0.51 to 0.82). A smaller effect size was demonstrated for maintenance of abstinence (RR: 0.91, 95% CI 0.81 to 1.02) (34). There were too few studies ($N = 8$) to demonstrate benefits for prevention of relapse to heavy over the medium-term trials (> 12 weeks), but some evidence for decreased craving over time and increased time to first drink were obtained. Project COMBINE, a 16-week multisite U.S. RCT ($N = 1383$), evaluated the effects of different combinations of acamprosate, naltrexone, and several behavioral

interventions in alcohol-dependent patients. The main result was that all treatment groups, including placebo, substantially reduced drinking (35). Secondary analyses demonstrated that relapse to heavy drinking was significantly reduced by naltrexone, but not acamprosate. This is an outcome that was present in most of the RCTs of naltrexone, and for which a significant effect was demonstrated in the meta-analyses described above.

Taken together, the evidence suggests that the main clinical effect of naltrexone, with respect to the treatment of alcohol dependence, is reduction in relapse to heavy drinking. This finding has implications based upon severity of symptoms, patient capacity and patient goals, as to how naltrexone should be included in treatment planning. There is a lesser effect on maintenance of complete abstinence.

Safety of the Medication/Treatment

Typical dosage for naltrexone is 50 mg once daily as an adjunct to psychosocial treatment of alcohol dependence. Naltrexone has a $t_{1/2}$ of only several hours in the plasma, but a major metabolite, 6-hydroxy- β -naltrexol, accumulates with regular dosing and demonstrates mild μ -opioid antagonism. Since naltrexone is an opiate antagonist, patients receiving naltrexone should be screened for opiate use so that administration does not precipitate acute withdrawal symptoms. Naltrexone-associated side effects are more frequent in the first days of therapy. The most common side effects are central nervous system symptoms (headache, dizziness, and fatigue) and gastrointestinal-related (nausea) symptoms (36). Naltrexone has few interactions with other medications as it is metabolized by a hepatic nonmicrosomal oxidase system. As μ -opioid receptors are blocked by naltrexone, naltrexone-treated patients will generally find opioids ineffective for analgesia. Therefore, patients taking naltrexone who are in acute pain, and who require an overriding dose of opioid medications for acute treatment should have this administered under the guidance of an anesthesiologist or a qualified clinician who can provide appropriate clinical support (37). A “black-box” warning exists for naltrexone in high doses, but at the recommended doses there is no evidence for hepatotoxicity. Reported hepatotoxicity in alcohol-dependent patients was attributable to elevations of liver enzymes that were reversible.

The optimal treatment duration with naltrexone has not been specified, but 3- to 6-month studies demonstrated low risk of treatment-emergent adverse events (AEs) or what is termed in systematic reviews a favorable harms profile (34,38). In addition, retention in treatment is not adversely impacted by naltrexone and may be improved (33,34).

How the Medication/Treatment Is Optimally Used

Pharmacogenetic considerations: The role of genetic markers in the clinical response to naltrexone for alcoholism has been examined. A particular single-nucleotide polymorphism (SNP) has been identified in exon 1 of the gene encoding for the μ -opioid receptor (*OPRM1*), which is a missense A-to-G (A118G) substitution coding for the amino acid aspartate instead of asparagine (Asn40Asp). This SNP is associated with altered μ -

receptor response to endogenous opioids and to μ -opioid receptor antagonists, such that individuals carrying at least one copy of the Asp40 allele demonstrate increased alcohol-induced reward (39) and a greater decrease in the rewarding effects of alcohol in the context of naltrexone (40). Therefore, in certain cohorts of patients, naltrexone may be more efficacious, suggesting that better characterization of these higher responders is an appropriate venue for exploration. Several studies have examined in alcohol dependent subjects the effect of the Asn40Asp SNP on the clinical response to naltrexone (41–43) and have found that, compared to subjects homozygous for the Asn40 allele, carriers of the Asp40 allele in fact demonstrate superior response to naltrexone (41–44). In addition, Mitchell and colleagues conducted an RCT in heavy drinkers who were not seeking treatment for alcohol dependence (45). The studies by Oslin et al. (41) and Anton et al. (43) and a haplotype analysis by Oroszi et al. (44) on the Anton et al. (43) data set found that the μ -opioid receptor Asp40 allele predicted a positive clinical response to naltrexone, while the studies by Gelernter et al. (42) and Mitchell et al. (45) did not demonstrate that finding. In addition, a meta-analysis of 28 samples from 19 publications ($N = 8096$) of predominantly opioid- or alcohol-dependent subjects compared to controls showed no evidence for an association of the Asn40Asp polymorphism with alcohol dependence (46).

Ethnic and Racial Differences in Naltrexone Response

One factor in the varying results for the association of Asn40Asp SNP and clinical responsivity to naltrexone may be the ethnic differences in the tested subjects with regard to the frequency of the Asp40 SNP. The frequency of the Asn40Asp SNP is estimated to be less than 5% in individuals of African descent, whereas it is about four times greater in those of European descent, and up to 58% in Asians (47). If the *OPRM1* Asp40 polymorphism renders increased response to μ -receptor antagonism, then those of African ancestry may be less likely to benefit from naltrexone. A secondary outcome analysis of the COMBINE study examined the effects of naltrexone among African Americans ($N = 100$) during the 16-week treatment and indeed found, when controlling for the behavioral interventions and acamprosate, that the beneficial effects attributed to naltrexone in the overall COMBINE sample, such as percent days abstinent and time to first heavy drinking, were not seen in the ethnic subsample (47). Whereas these data are initial and as yet unique, they offer a compelling hypothesis that a low frequency of a particular allele variant may have differential impact on responsivity to alcohol pharmacotherapy.

Special Considerations

It is reasonable to expect that due to adherence and judgment issues in patients with co-occurring disorders, treatment outcomes with naltrexone might be adversely affected. However, in an RCT, patients with schizophrenia treated with naltrexone for alcohol dependence had significantly fewer drinking days and heavy-drinking days (>5 drinks) and reported less craving (48). Petrakis and colleagues demonstrated in a second RCT that compared with placebo a replication in which

naltrexone reduced heavy-drinking days as well as increased abstinent days in patients with schizophrenia (49). Therefore, the presence of co-occurring disorders should not be a barrier to use of naltrexone.

Injectable Naltrexone

History of the Treatment

Naltrexone was approved by the U.S. FDA in April 2006 in an injectable, extended-release formulation for the treatment of alcohol dependence (50,51).

Pharmacology of the Medication/Treatment

For the purposes of injection, 380 mg of naltrexone is encapsulated in biodegradable microspheres that slowly release naltrexone over a 30-day period after injection. The naltrexone released has the same μ -opioid antagonist properties as orally administered naltrexone. The microspheres are composed of a polylactide-co-glycolide polymer that is used extensively in other extended-release drugs, such as in absorbable sutures as well as in long-acting risperidone (Risperdal Consta). A pharmacokinetic analysis after injection of naltrexone 380 mg demonstrated sustained therapeutic plasma levels for 30 days, without significant drug accumulation (51). Plasma levels of naltrexone show peak concentrations 2 to 3 days after an intramuscular (IM) injection and demonstrate a slow decline for the next 30 days. Since oral naltrexone is dosed at 50 mg/day, over 30 days the monthly cumulative dose is 1500 mg, whereas an IM injection of naltrexone given every 30 days results in a lower monthly dose of 380 mg. In addition, injectable long-acting naltrexone also does not demonstrate the typical daily fluctuations in plasma concentrations as associated with daily oral dosing of naltrexone (52).

Efficacy of the Medication/Treatment

In a multisite RCT in alcohol-dependent subjects ($N = 315$) of a depot formulation of naltrexone different from the one that is currently FDA-approved, treatment with depot naltrexone compared to placebo injection significantly increased the time to the first drink, decreased the number of drinking days during treatment, and supported a significantly greater rate of abstinence (18% vs. 10%) (53).

A 6-month, multisite, double-blind RCT evaluated the efficacy and safety of long-acting injectable naltrexone 190 or 380 mg (Vivitrol) in alcohol-dependent subjects ($N = 624$) over 24 weeks of treatment (50). Alcohol abstinence was not required of subjects at study entry and there was no lead-in with oral naltrexone prior to naltrexone injection. Patients received 12 sessions of psychosocial support. The primary outcome, targeted at the expected main effect of naltrexone in alcohol dependence, was the event rate (number of drinking days/total number of days at risk) of heavy drinking (≥ 5 standard drinks/day for men and ≥ 4 standard drinks/day for women). IM naltrexone reduced the rate of heavy drinking by 25% ($P = 0.03$) in the 380 mg group and by 17% ($P = 0.07$) in the 190 mg group, compared to placebo. Heavy-drinking days were reduced by 48% by long-acting injectable naltrex-

one including those actively drinking and patients who were abstinent at treatment entry. For subjects abstinent before injection, injectable naltrexone treatment effects were greater—compared to those actively drinking at injection who had a 21% decrease in the event rate of heavy drinking, those who had a period of 7-days abstinence prior to first injection had an 80% reduction ($P = 0.02$). Secondary outcomes included the event rates of risky drinking (>2 drinks/day for men and >1 drink/day for women) and of any drinking days. Injectable naltrexone was not associated with a significant reduction in risky drinking or rate of any drinking days (complete abstinence) compared to placebo.

In a subgroup of patients with at least 4 days of abstinence before injection ($N = 82$) IM naltrexone 380 mg prolonged abstinence (median time to first drink: 41 days vs. 12 days) and reduced the number of drinking days and heavy-drinking days. The rate of continuous abstinence at end of the study was 32% versus 11% ($P = 0.02$) (54). IM naltrexone 380 mg compared with placebo had beneficial effects on alcohol volumes and frequencies as well, with substantially increased time to first heavy-drinking event (>180 days vs. 20 days; $P = 0.04$), a 90% decrease in the median drinking days per month (0.7 vs. 7.2; $P = 0.005$), and a 93% decrease in heavy-drinking days per month (0.2 days vs. 2.9 days; $P = 0.007$). Taken together, IM naltrexone appears to have a positive effect even in actively drinking patients, but has stronger effects in abstinent individuals. However, there was no significant treatment outcome effect of subjects having abstinence as a treatment goal.

A 1-year open-label extension study was conducted with subjects consenting to continue after completing the initial 6-month study (55). Heavy drinking was significantly reduced in subjects receiving IM naltrexone. Compared to subjects who received naltrexone 380 mg IM during both the 6-month RCT and extension study, subjects who had been treated initially in the placebo arm of the study for 6 months who were switched to 380 mg IM naltrexone during extension study demonstrated the largest reduction in days of heavy drinking.

There appears to be a dose-response effect for IM naltrexone, with outcomes for 190 mg ($N = 26$) generally intermediate between that of the approved 380 mg IM dose and placebo (50,54).

In the intention-to-treat sample, an analysis of quality of life measures with the medical outcomes study 36-item short form demonstrated that compared with IM placebo, IM naltrexone 380 mg was associated with significant improvements in mental health ($P = 0.0496$), social functioning ($P = 0.010$), general health ($P = 0.048$), and physical functioning ($P = 0.028$) (56).

Overall, the clinical outcomes for long-acting injectable naltrexone in alcohol-dependent patients are consistent with the meta-analyses of RCTs of oral naltrexone in demonstrating reduction in relapse to heavy drinking. IM naltrexone has advantages over oral naltrexone in that it has less potential for hepatotoxicity, once-monthly administration is sufficient to sustain therapeutic plasma levels for a month, and the route of administration likely improves adherence in clinical populations.

Safety of the Medication/Treatment

Compared to the oral formulation of naltrexone, an advantageous pharmacokinetic property of IM naltrexone is its reduced first-pass elimination, which exposes the liver to less of the drug cumulatively and thus reduces the potential for hepatotoxicity. Pharmacokinetic studies comparing plasma concentrations after a single IM dose of naltrexone found similar levels of naltrexone and its primary metabolite 6 β -naltrexol, and similar cumulative exposure over 63 days in subjects with mild (Child-Pugh grade A) and moderate (Child-Pugh grade B) hepatic impairment and in matched control subjects (57). Thus, this route of administration may be advantageous in using naltrexone with patients who have chemical or infectious hepatitis, or other liver impairment. Given the risk of hepatotoxicity with continued drinking, subjects treated with 380 mg IM naltrexone experience greater improvement in gamma-glutamyl transpeptidase levels compared to controls ($P = 0.03$) (54).

In the 6-month multisite RCT of treatment with long-acting injectable naltrexone, AEs occurring in at least 10% of subjects were nausea, headache, fatigue, decreased appetite, dizziness, and injection site pain. Discontinuation due to AEs occurred in 14% in the 380 mg and 6.7% in the 190 mg group and 6.7% in the placebo group (50).

How the Medication/Treatment Is Optimally Used

The greatest advantages of the long-acting IM formulation of naltrexone are the low dosing frequency, the more or less continuous exposure of μ -opioid receptors to naltrexone, and the high intrinsic medication adherence. The low dosing frequency can be helpful in supporting patients to return for the next dose. The nature of the formulation ensures that the patient will be exposed to the effects of the medicine for at least 30 days, until they return for the next dose administration. The fact that the medication can more easily be framed as a background for recovery can allow clinicians to focus upon delivering or providing for convergent (e.g., CBT to reduce acting on craving as the drug reduces craving) or complementary (self-help groups to support abstinence) psychosocial interventions that work synergistically with naltrexone's main effects on drinking behavior (58).

Acamprosate

History of the Treatment

Acamprosate was approved for use by the U.S. FDA in July 2004 for the treatment of alcohol dependence in conjunction with psychosocial support. Its indication is for the maintenance of abstinence from alcohol in alcohol-dependent patients who are abstinent at treatment initiation (Table 33.1).

Pharmacology of the Medication/Treatment

Acamprosate is a taurine analogue that, similar to taurine, activates glycine receptors (GlyRs) in the NAc and also acts as a weak partial *N*-methyl-D-aspartate (NMDA) receptor antagonist. In animal models, strychnine-sensitive (competitive an-

tagonist) GlyRs in the NAc and nicotinic acetylcholine receptors (nAChRs) in the ventral tegmental area are involved in regulating DA release and mediating alcohol-induced DA elevation in the mesolimbic DA system (59,60). In animal models of direct and systemic administration, acamprosate appears to decrease alcohol intake through primary interactions with GlyRs in the NAc and secondarily with the ventral tegmental nAChRs, both of which increase extracellular DA in the NAc (61,62).

In addition, acamprosate is believed to modulate glutamatergic hyperactivity associated with changes in the balance of excitatory and inhibitory neuroregulation in the context of chronic alcohol exposure. The normal balance between the neuronal excitation and inhibition that is regulated through gamma-aminobutyric acid (GABA), glutamate/NMDA, and other receptor systems is disrupted by acute alcohol exposure, leading to a net amplification of inhibitory process (63). However, chronic alcohol consumption elicits upregulation of excitatory NMDA receptors as a neuroadaptive mechanism to counterbalance the chronic inhibition. This resulting net excitation is a homeostatic mechanism compensatory to the chronic inhibitory action of alcohol, which restores the neuronal balance toward normal. When the chronic alcohol is precipitously removed in the chronically compensated state, such as when an alcohol-dependent person becomes acutely abstinent, the upregulated glutamate/NMDA receptor system functions unopposed, which results in a hyperexcitable state that is associated with acute withdrawal, as well as postwithdrawal phenomena (64,65). It has been proposed that acamprosate may modulate both ionotropic and metabotropic central NMDA receptors at regulatory sites, such as m-glu-R5 receptors, to normalize NMDA glutamatergic hyperexcitability and reestablish homeostasis in the absence of alcohol (66–70).

Efficacy of the Medication/Treatment

An analysis of outcomes in a clinical trial database consisting of data from double-blind RCTs—one short-term of 13 weeks (71) and two long-term of 48 weeks (72) and 52 weeks (73), were the basis of U.S. FDA approval of acamprosate in 2004 (Table 33.1). In all three RCTs, acamprosate (1332 and/or 1998 mg/day) was tested against placebo in the context of psychosocial support in abstinent subjects with a diagnosis of alcohol dependence who were detoxified. The short-term trial comparing placebo or acamprosate (1332 or 1998 mg/day) was a multisite study of French and Belgian subjects ($N = 188$). There was a significantly greater rate of complete abstinence in the acamprosate group at the end of the study (1998 mg/day acamprosate, 38%, vs. placebo, 13%, $P = 0.001$), as well as increased percent days abstinent (1998 mg/day acamprosate, 67%, vs. placebo, 29%, $P < 0.001$) and time to first drink (1998 mg/day acamprosate, 52.5 median days, vs. placebo, 17 median days, $P < 0.001$) (74). Similarly, in the long-term trials, complete abstinence rates were significantly greater in the acamprosate group in both the 48-week German study (72) ($N = 272$; pooled 1332/1998 mg/day acamprosate, 28%, vs. placebo, 13%, $P = 0.002$) and in the 52-week multisite French study (73) ($N = 538$; 1998 mg/day

acamprosate, 16%, vs. placebo, 9%, $P = 0.044$). Both studies also demonstrated significant increases in percent days abstinent and time to first drink (74). In a 12-month medication-free follow-up evaluation of the German long-term RCT subjects, those previously randomized to receive acamprosate showed double the rate of abstinence at 1 year off of study medications (acamprosate, 39%, vs. placebo, 17%, $P = 0.003$) (72). The French 52-week RCT also showed that a significantly higher percentage of acamprosate-treated patients compared to placebo were able to regain abstinence after relapse to any drinking (acamprosate, 46.4%, vs. placebo, 34.6%, $P < 0.05$), demonstrating a relapse recovery effect (75).

Mason and colleagues compared against placebo the effects of acamprosate 1 g either twice daily or three times daily in a 6-month RCT in the United States ($N = 601$) and found no significant between groups difference in the percentage of abstinent days in the main analysis (54.3% for placebo, 56.1% for 2 g, 60.7% for 3 g) (76). However, there were differences in methodology and subject cohort between this study and the European trials described above. Unlike prior efficacy trials, the subjects in the U.S. trial were not required to be abstinent from alcohol prior to study entry, nor were they excluded by age limitation or elevated liver function tests. In addition, there was a higher percentage of polysubstance abuse among the subjects of the U.S. trial. Any of these factors may have contributed to the outcome differences between the U.S. and other studies. When the investigators performed a secondary analysis of the data from a subset of 241 subjects who initially had abstinence as a goal at study entry, controlling for baseline variables and treatment exposure, they found that compared to placebo, acamprosate was associated with a higher percentage of abstinent days (70.0% for 2 g, 58.1% for placebo; $P = 0.02$). These data suggest that for acamprosate treatment, motivation for abstinence may be an important factor in promoting a positive outcome.

A 26-week multisite RCT in Spain tested the efficacy of acamprosate that was administered at the beginning of medically supervised alcohol withdrawal rather than postdetoxification in patients with alcohol dependence ($N = 296$). Compared to the placebo-treated group, the acamprosate-treated group had a cumulative abstinence duration (CAD) 19 days longer at the study endpoint ($P = 0.0006$), and 16 days longer duration of abstinent days between the last episode of any drinking to the study endpoint (stable recovery duration) ($P = 0.021$) (77).

A secondary analysis of 15 European studies suggests a cumulative effect of acamprosate in reducing both the frequency of relapse and the amount of drinking during a relapse interval (78). The investigators evaluated relapse severity by defining it as the product of quantity and frequency of drinking by subjects at four intervals (30, 90, 180, and 360 days) across studies and found that compared to placebo, acamprosate was associated with less drinking among the subjects who relapsed ($P < 0.001$), and that the between-groups difference increased over time.

Two recent meta-analytic approaches support that acamprosate is efficacious in helping patients with alcohol dependence to maintain abstinence from alcohol (Table 33.2) (33,79). Pooled data from 17 placebo-controlled trials determined for acamprosate a significantly higher proportion of subjects maintaining complete abstinence and a relative benefit of 1.47 over placebo of attaining 6 months of complete abstinence, a moderate to strong effect (Mann et al. (79)). Similarly, in a different meta-analysis of 12 RCTs, acamprosate treatment was associated with a significant increase in the abstinence rate (OR: 1.88 [1.57, 2.25], $P < 0.001$) and the CAD (weighted mean difference, WMD: 26.55 [17.56, 36.54], $P < 0.001$) (33). Further, data from these systematic evaluations suggest that acamprosate has moderate benefits on overall treatment adherence and a small positive impact upon treatment retention (33,79).

Taken together, there is a good evidence base to conclude that acamprosate compared to placebo increases abstinence and decreases drinking days in patients with alcohol dependence. However, two large recent U.S. studies did not find similar results for the efficacy of acamprosate, and have dampened clinical enthusiasm for the medication (35,76). There may be differences in study methods and the characteristics of the populations being studied that may account for some of these striking and consistent differences in outcome. Nonetheless, there are strong data supporting acamprosate efficacy in long-term studies and its strongest effects have been demonstrated in subjects who have been recently detoxified.

Safety of the Medication/Treatment

Acamprosate, which does not undergo hepatic metabolism, is excreted entirely in the urine as unchanged drug (80), and does not interact significantly with other medications (81,82). When acamprosate is used with other medications such as disulfiram, diazepam, or even alcohol, there are no pharmacokinetic interactions (80). Acamprosate has a favorable safety and tolerability profile supported by the extant clinical trial data (83). Acamprosate was demonstrated to be safe, well tolerated, and compared to placebo, without significant discontinuation due to AEs in a meta-analysis of 10 RCTs (33). More recently, Rosenthal and colleagues (83) assessed the safety and tolerability of acamprosate by analyzing data from 13 short- and long-term RCTs ($N = 4234$). The incidence of treatment-emergent AEs was 61% for acamprosate and 56% for placebo ($P < 0.01$), the majority of which were reported across groups as transient, of mild or moderate severity, and were attributable to comparable discontinuation rates. For acamprosate compared to placebo, the highest frequency AEs were respectively, diarrhea (16% vs. 10%, $P < 0.01$) and flatulence (3% vs. 2%, $P < 0.01$), which occurred relatively infrequently. Transient diarrhea typically occurs in the first 4 weeks of treatment, with decreasing incidence over time, and is of mild to moderate severity (83). There were no increases in AEs among subjects taking additional medications frequently used to treat alcohol dependence.

How the Medication/Treatment Is Optimally Used

Acamprosate is formulated in a tablet containing 333 mg, which is recommended to be taken as two tablets three times a day. Given the strength of evidence for optimal response in already-abstinent patients, initiation of acamprosate treatment should begin as soon as possible after abstinence is achieved and the period of acute withdrawal has passed. Given recent research data demonstrating the benefit in study subjects who had lost abstinence, treatment should be continued even if a patient relapses (78).

Special Considerations

Patients with Impaired Renal Function Subjects with varying degrees of renal impairment were compared with healthy adult subjects in a pharmacokinetic study that measured total plasma clearance, renal clearance, C_{max} , and T_{max} after a single dose of acamprosate. Subjects with renal impairment differed significantly from healthy subjects on all measures, and a linear correlation between decreases in the clearance of creatinine and that of acamprosate was demonstrated (80). These data suggest that patients with impaired renal function could accumulate acamprosate with prolonged dosing. Therefore it is recommended that in patients with moderate renal impairment (creatinine clearance of 30 to 50 mL/min) the standard dose be halved to one 333 mg tablet three times a day. In patients with severe renal impairment (creatinine clearance <30 mL/min), acamprosate is not recommended (83).

Combination Treatment (Naltrexone and Acamprosate) Since the major effects of naltrexone and acamprosate determined in meta-analyses appear to be different and appear to work by different mechanisms, namely reduction in relapse to heavy drinking in the case of naltrexone, and maintenance of abstinence in the case of acamprosate, it is a reasonable strategy to test the efficacy in alcohol dependence by combining the two medications. Two studies have examined this approach, but demonstrating synergistic effects has been less than straightforward. The first study that demonstrated that a combination of medications might be superior to a single pharmacotherapeutic approach in treating alcohol dependence was conducted in Germany by Kiefer and colleagues (84). The investigators conducted a 12-week RCT of naltrexone 50 mg/day and acamprosate 1998 mg/day, singularly and in combination, in detoxified patients ($N = 160$) with alcohol dependence who also received weekly group therapy (84). The primary outcomes were the time to first drink, time to first relapse to heavy drinking (i.e., for men, ≥ 5 drinks/day and for women, ≥ 4 drinks/day), and CAD. Compared to placebo, all treatment groups, including each medicine alone and in combination, showed significant improvements in time to relapse. However, compared to acamprosate alone, the combination of acamprosate with naltrexone was significantly better in terms of time to relapse, but not better than naltrexone alone.

Feeney and colleagues (85) conducted a 12-week, single-location trial of acamprosate, naltrexone, or the combination in age-, sex-, and alcohol-severity-matched subjects with alcohol dependence ($N = 236$) who were recently detoxified,

but not randomly assigned to groups. There were no significant between-groups differences with regard to CAD, total abstinence or days to relapse, but there were significantly more days to relapse in the combination group compared to the group receiving only acamprosate. In contrast to the findings of additive effects in combining naltrexone and acamprosate, superior to acamprosate alone (84,85), Project COMBINE, a multisite 16-week RCT did not find evidence with either low- or high-intensity behavioral interventions, of additive effects of combining naltrexone 100 mg/day and acamprosate 3 g/day compared to either drug alone (35). In this study, naltrexone was efficacious in reducing the risk of relapse to heavy drinking. However, this outcome was not improved in the group that received intensive, specialist-delivered behavioral therapy (combined behavioral intervention, itself efficacious) in addition to naltrexone. Surprisingly, neither the percent days abstinent, an expected evidence-based outcome for acamprosate, or relapse to heavy drinking were positively impacted by acamprosate as compared to placebo. Acamprosate's lack of efficacy was unexpected in this study and the result has been attributed to the overall level of improvement across treatment groups, the high placebo response rate, and methodological differences compared with the European studies (e.g., European subjects had required premedication abstinence, American subjects had more polysubstance abuse) in which the efficacy of acamprosate has been demonstrated (86).

Investigational or Off-Label Medications for Alcohol Dependence (Not Approved for Treatment of Alcohol Dependence by the U.S. Food and Drug Administration) Many classes of drugs are under active study for the treatment of alcohol dependence. This section focuses on a few of the more promising medications that are active on GABAergic, serotonergic, and dopaminergic systems.

ANTICONVULSANTS AND OTHER GABAERGIC MEDICATIONS

Topiramate

History of the Treatment

As antiseizure medications tend to increase GABAergic activity or reduce glutamatergic activity, initial RCTs of several medications have been conducted in the treatment of alcohol dependence, including divalproex (87), and carbamazepine (88), with modest positive effects. However, topiramate has the most extensive evidence to date for efficacy in randomized, controlled trials.

Pharmacology of the Medication/Treatment

Topiramate's utility in the treatment of alcohol dependence is hypothesized to act to reduce alcohol's reinforcing effects in the central nervous system through binding a nonbenzodiazepine site on GABA_A receptors so as to increase GABAergic activity (89) and also by inhibiting glutamatergic activity through binding and inhibiting activity of corticomesolimbic

AMPA/kainate glutamate receptors that have been upregulated due to chronic alcohol exposure (90).

Efficacy of the Medication/Treatment

Johnson et al. (91) conducted a double-blind 12-week RCT comparing topiramate (titrated up to 300 mg/day as tolerated) and placebo in alcohol-dependent subjects ($N = 150$) receiving outpatient psychosocial support (91). Drinks per day, drinks per drinking day, percentage of heavy-drinking days, and percentage of days abstinent were the primary outcome measures. Compared to those receiving placebo, the topiramate group had a 27.6% lower percentage of heavy-drinking days ($P = 0.0003$), and 26.2% more abstinent days ($P = 0.0003$). Continuing this line of efficacy research, a multisite 14-week double-blind U.S. RCT of topiramate (titrated up to 300 mg/day or maximum tolerated) and placebo was conducted by Johnson et al. in subjects with alcohol dependence ($N = 371$) who received a weekly treatment adherence enhancement therapy (92). Again, topiramate demonstrated a 16.2% mean reduction in the percentage of self-reported heavy-drinking days ($P < 0.001$) compared to placebo, and an 8.44% mean reduction in the rate of self-reported heavy-drinking days over the study interval ($P = 0.002$). Interestingly, there was also an improvement in the self-reported percentage of abstinent days ($P < 0.002$). As a corollary to the self-report measures, plasma gamma glutamyltransferase, a biomarker of alcohol consumption, was significantly reduced in the topiramate group as compared to placebo ($P < 0.001$). On data generated in the same study, another analysis was conducted to determine the effects of topiramate on physical health, obsessional thoughts and compulsions about using alcohol (a measure of craving), and psychosocial well-being (93). Topiramate compared with placebo had a significantly positive impact ($P < .05$) on alcohol-related obsessional thoughts and compulsions, psychosocial well-being, and aspects of quality of life, likely contributing to reducing the risk of relapse. Interestingly, a 12-week double-blind RCT compared topiramate (titrated to 300 mg/day), naltrexone (50 mg/day), and placebo in alcohol-dependent outpatients ($N = 155$) who were 1 week postdetoxification at study entry (94). Although there were no significant differences between naltrexone and topiramate, in time to first relapse, CAD and heavy-drinking weeks, topiramate was superior to placebo, and demonstrated trends toward superiority over naltrexone.

Safety of the Medication/Treatment

Over the approved therapeutic dose range of 200 to 800 mg/day, topiramate follows linear pharmacokinetics. The relative bioavailability is 80% and is not affected by food, with nearly complete oral absorption within 2 hours of administration (95). The drug is not widely metabolized in vivo and is mostly eliminated (70%) unchanged in the urine (95). Johnson et al. (91) reported no serious AEs in their initial RCT, but there were side effects that were reported in the topiramate group more commonly than in the placebo group, respectively, such as dizziness (28.0% vs. 10.7%, $P = 0.007$), paresthesia (57.3% vs. 18.7%, $P < 0.0001$), psychomotor slowing (26.7% vs.

12.0%, $P = 0.023$), memory/concentration impairment (18.7% vs. 5.3%, $P = 0.012$), and weight loss (54.7% vs. 26.7%, $P = 0.001$) (Table 33.3). In examining AEs occurring in greater than 10% of subjects, a similar profile was demonstrated in the multisite RCT as more common with topiramate versus placebo ($P < 0.05$), respectively, including: paresthesia (50.8% vs. 10.6%), altered taste perception (23.0% vs. 4.8%), anorexia (19.7% vs. 6.9%), difficulty concentrating (14.8% vs. 3.2%), dizziness (11.5% vs. 5.3%), and pruritis (10.4% vs. 1.1%) (92). In general, 85% of side effects occur during the period of titration and most of which tend to resolve with continued treatment, but about 20% of those treated in clinical trials drop out due to side effects (92,96). Individual genetic differences may modulate side effects of topiramate. A SNP of the GRIK1 gene coding for the kainate-selective GluR5 glutamate receptor subunit has been recently described in heavy drinkers, in which an allele variant was associated with greater severity of topiramate-induced side effects and also with serum levels of topiramate (97).

With respect to safety advantages of topiramate compared to placebo, measures of liver function (aspartate aminotransferase and alanine aminotransferase) and body mass index were reduced in a clinically small but significant way ($P < 0.001$). In addition compared to placebo, topiramate significantly reduced the mean plasma cholesterol level by 13.30 mg/dL ($P = 0.002$), mean systolic blood pressure by 9.70 mm Hg ($P < 0.001$) and mean diastolic blood pressure by 6.74 mm Hg ($P < .001$), returning blood pressure to the range of prehypertension levels (93).

How the Medication/Treatment Is Optimally Used

Topiramate should be titrated slowly starting at 25 mg/day and increasing at 25 mg/week until the patient reaches the 300 mg/day dose demonstrated effective in clinical trials. The slow titration decreases the frequency of neurocognitive side effects and discontinuation rates as compared to patients taking 50 mg/day and titrated at 50 mg/week, but takes 12 weeks to reach the target dose (98). It is unclear as to whether topiramate in doses less than 300 mg/day is effective in alcohol dependence. Given reports of seizures upon abrupt withdrawal of topiramate in patients without a prior seizure history, it is suggested that topiramate be tapered at the rate of 25% every 4 days for a period of 16 days (98).

Special Considerations

Patients with Impaired Renal Function The product packaging states that patients with moderately impaired kidney function (creatinine clearance 30 to 69 mL/min/1.73 m²) had a 42% decrease in the clearance of topiramate. Since topiramate is mostly excreted unchanged in the urine, it is suggested that for patients with a creatinine clearance below 70 mL/min/1.73 m² and a resulting reduction in clearance of topiramate, 50% of the recommended dose should be given (95).

In postmarketing studies of topiramate, a normal anion gap hyperchloremic metabolic acidosis was a rare dose-related serious AE (95). Because topiramate is a weak carbonic anhydrase inhibitor, the kidneys may leach bicarbonate levels

TABLE 33.3 Non-FDA-approved pharmacotherapies for alcohol dependence

Medication	Prescribing information		Mechanism of action	Common side effects	Warnings/relative contraindications	Drug interactions
	Dose	Comments				
Topiramate (Topamax)	Oral: 300 mg daily (range: 200–800 mg)	1) Need slow titration to 300 mg 2) Typical increment of 25 mg/week <ul style="list-style-type: none"> With moderate renal impairment, reduce dose 50% 3) Monitor patients for low serum bicarbonate	GABA _A receptor activator; AMPA/kainate glutamate receptor inhibitor	<ul style="list-style-type: none"> Dizziness Paresthesia Psychomotor slowing Memory impairment Altered taste perception Pruritis 	<ul style="list-style-type: none"> Renal failure Treatment with carbonic anhydrase inhibitors 	Topiramate concentrations: <ul style="list-style-type: none"> reduced by CYP2C9 inducers (e.g., valproic acid, carbamazepine, phenytoin) increased by 2C9 inhibitors (e.g., delavirdine)
Baclofen (Lioresal; Kemstro) FDA approval: 1994	Oral: 50 mg daily (range: 40–80 mg)	<ul style="list-style-type: none"> No concurrent opioid use; screen for opioids Avoid opioid analgesics Periodic liver function tests recommended 	Stereoselective GABA _B agonist	<ul style="list-style-type: none"> Drowsiness Vertigo Nausea Abdominal pain 	<ul style="list-style-type: none"> Use of CNS depressants Renal failure 	<ul style="list-style-type: none"> Potential synergy combined with any sedating medication

such as can be seen with acetazolamide. Therefore during topiramate treatment, serum bicarbonate levels should be monitored at baseline and over the course of treatment. If a metabolic acidosis develops, of which parasthesias are a common sign, topiramate dose should probably be reduced or discontinued.

Baclofen

History of the Treatment

Baclofen is a potent and stereoselective GABA_B agonist that has been used in clinical practice for the treatment of spasticity and is widely used as a muscle relaxant (99).

Pharmacology of the Medication/Treatment

In animal models, baclofen reduces the alcohol self-administration (100), suppresses acquisition and maintenance of alcohol drinking, relapse-like drinking, and the reinforcing, rewarding, stimulating, and motivational properties of alcohol in rodents (101).

Efficacy of the Medication/Treatment

In humans, 30 mg/day decreases alcohol withdrawal symptoms in alcohol-dependent patients in equivalence to that of diazepam (102). However, it is as yet unclear that baclofen when used in uncomplicated withdrawal has the same efficacy as benzodiazepines in reducing the incidence of seizures or delirium (103). In an open-label pilot study, Flannery and colleagues found significant reductions in drinks per drinking day and heavy-drinking days in alcohol-dependent subjects ($N = 13$) treated over 12 weeks with baclofen 10 mg three times daily with four sessions of motivational interviewing (104). In a 30-day double-blind RCT, Addolorato and colleagues compared 10 mg of baclofen three times daily with placebo in recently abstinent (12 to 24 hours) subjects ($N = 39$) with alcohol dependence and demonstrated significant increases in percentage total abstinence (70% vs. 21%; $P < 0.005$) and CAD (19.6 vs. 6.3 days; $P < 0.005$) (105). In addition, craving, as represented on the Obsessive Compulsive Drinking Scale, as well as on the individual obsessive and compulsive subscales, was significantly and increasingly reduced over the four weekly study timepoints by baclofen compared to placebo.

Safety of the Medication/Treatment

The common AEs associated with baclofen treatment were sleepiness, vertigo, nausea, and abdominal pain, all of which resolved in the first week of treatment. There were no serious AEs and baclofen did not appear to have abuse liability (105). No subjects in the baclofen group in the double-blind RCT discontinued medications as a result, none reported baclofen-induced euphoria, and none demonstrated withdrawal symptoms upon cessation of the study drug. So far, treatment with baclofen appears relatively safe, however, its abuse potential has not been well assessed and abrupt withdrawal has been linked to withdrawal-related delirium that appears not to be dose-related (106). The short-term efficacy of baclofen in the

treatment of alcohol dependence is promising, but further controlled studies with larger numbers of subjects will be needed to make a compelling argument for its safety and appropriateness for general use.

Serotonergic Medications

Serotonin reuptake inhibitors (SRIs) have been demonstrated in animal studies to decrease the consumption of alcohol and enhance serotonergic function in the CNS, and they are used as antidepressants and anxiolytics in clinical treatment (37). Findings from RCTs of SRIs for the treatment of alcohol dependence are inconsistent and meta-analytic procedures on the data suggest that the best use of SRIs may be in treating major depression in patients with co-occurring alcohol dependence (107). One of the major issues with the efficacy of SRIs in the treatment of alcohol dependence appears to hinge on the discovery of a differential therapeutics based upon typology. Kranzler and colleagues found no significant reductions in drinking in an RCT comparing fluoxetine (up to 60 mg/day) to placebo in alcohol-dependent subjects receiving weekly cognitive behavioral therapy (CBT) ($N = 101$) who were not clinically depressed (108). However, discovery of true positive effects may be masked by the inclusion of non- or worse-responders in a clinical study. A secondary analysis of clinical trial data from the same study by alcohol subtype (Type A: earlier onset, more severity of dependence, and greater psychopathology or Type B: later onset, less severity of dependence, and less psychopathology) demonstrated that subjects with Type B alcohol dependence in the fluoxetine treatment group showed significantly worse drinking outcomes than those in the placebo group (109).

In another 14-week RCT of 200 mg sertraline in subjects with alcohol dependence stratified by Type A/B subtype ($N = 100$), the Type A subjects had fewer drinking days and had higher rates of complete abstinence when treated with sertraline compared to placebo (110). At 6 months follow-up after treatment with sertraline, the earlier results demonstrated by Kranzler and colleagues (109) of the negative impact of SRIs in Type B subjects, were extended: Type A alcoholic subjects maintained improved reductions in heavy drinking, whereas Type B alcoholic subjects demonstrated increased heavy drinking (111). In addition, the finding of adverse SRI effects in Type B alcoholics was also demonstrated by Chick and colleagues (112) in an RCT ($N = 493$) of fluvoxamine (up to 300 mg/day) that found in subjects with early onset alcohol problems, there was a higher relapse to heavy drinking than in placebo-treated subjects (\leq age 25). If early-onset, Type B alcoholics are demonstrated to have a higher ratio of impulsivity to cortical control than Type A alcoholics, then SRI's may work to worsen alcohol-related behaviors through reductions in harm-avoidance, which would push an already low balance between action and inhibition further toward action (113).

A different approach to modulating serotonergic function in the treatment of alcohol dependence was undertaken by

Johnson et al. (114) in comparing the efficacy of the 5-HT₃ receptor antagonist ondansetron (an antinausea medication) and placebo, in a 11-week, double-blind, RCT trial of subjects ($N = 271$) with either early- or late-onset alcohol dependence who also received adjunctive CBT. Although there was no significant effect in the overall subject cohort, subjects in the early-onset alcoholism group who received 1, 4, or 16 $\mu\text{g/kg}$ ondansetron twice daily) showed significant reductions compared to placebo in self-reported drinking. Significant reductions in drinking compared with placebo were reported only in the early-onset alcoholism subset, findings that were corroborated by significant reductions in plasma carbohydrate-deficient transferrin. There were no significant differences in outcome with ondansetron or placebo in subjects with late-onset alcoholism. AE rates were similar for the both treatment groups, the most common for ondansetron and placebo, respectively, were headache (3.4% vs. 4.2%), constipation (5.0% vs. 1.4%), tachycardia (0.3% vs. 0%), and rash/pruritis (2.2% vs. 2.8%).

Taken together, these studies suggest that subtyping of patients with alcohol dependence may help resolve conflicting research findings on serotonergic treatment of alcohol dependence, and if validated, may support the use of SRIs and other serotonin-active agents in specially selected subpopulations of patients with alcohol dependence.

Directly Dopamine Active Medications

History of the Treatment

Data from preclinical research have illuminated the role of DA in the positively reinforcing and stimulant-like effects of alcohol, so a reasonable hypothesis is that by blocking DA, one may affect alcohol self-administration in animals, and perhaps drinking in humans. In rats, alcohol consumption induces release of DA from the NAc, the common reward system circuit implicated in the rewarding effects of all drugs of abuse (115). Mesostriatal DA activity is decreased in rodents by chronic alcohol administration (116). In persons with alcohol-dependence, DA and metabolites are decreased with chronic alcohol consumption, which is probably related to the dysphoria that they describe as a motivating factor in relapse (negative reinforcement) (117). As such, DA active medications might play a role in alcohol dependence by modulating hedonic tone.

When alcohol-dependent patients in human laboratory studies were pretreated with the antipsychotic medication haloperidol (a DA antagonist), it reduced craving and consumption of alcohol (118). Haloperidol also decreased the euphorogenic and stimulating effects of alcohol in social drinkers (119). Compared with heavy social drinkers given placebo before an alcohol challenge, those pretreated with 5 mg of the olanzapine (a DA antagonist) had a decreased urge to drink (120).

Whereas DA antagonists have held promise based upon reasonable, neurobiologically based hypotheses, preclinical research, and data from human laboratory studies, in randomized clinical trials for alcohol dependence the results have

mostly been negative. In general, RCTs of both traditional and atypical antipsychotics have not demonstrated positive effects on craving or relapse in patients with alcohol dependence (120–123). However, one RCT of quetiapine 400 mg has demonstrated reductions in days of drinking and heavy drinking, but only in the subset of persons with Type B alcoholism (124).

CONCLUSIONS

Recently, the use of medications to treat alcohol dependence has received increased scrutiny due to its potential impact in improving drinking outcomes as well as enhancing the effectiveness of current behavioral treatment approaches. As our understanding of the underlying neurochemistry and neurobiology has progressed, medications have been developed that target specific neurotransmitter systems involved in the development and maintenance of alcohol dependence. Although there has been increasing progress in the differentiation of efficacious medicines for alcohol dependence, there are still many areas that need further development before we can claim to have constructed an appropriate differential therapeutics. As no pharmacologic intervention in alcohol dependence has yet been shown to have an effect on size warranting its use as a sole treatment, brief but well-rounded behavioral interventions, such as Medical Management (125,126) can add significant motivational support for adherence with pharmacologic treatment and engagement in other recovery-oriented activities (58). Alcohol-dependence medications given adjunctively with psychosocial treatment strategies improve drinking outcomes, yet adoption of these medical treatments in the broader addiction treatment community faces continuing obstacles such as lack of medical personnel, incompatible treatment philosophy, or clinical ignorance of efficacy (2). Pharmacologic interventions that target reductions in drinking without aiming for abstinence may have difficulty gaining clinical traction in the generally abstinence-oriented world of traditional alcoholism recovery programs.

Meta-analytic evidence from multiple clinical trials suggests that of the FDA-approved pharmacotherapies, acamprosate's strongest effects are in achieving and maintaining complete abstinence, while orally administered naltrexone's most robust effects are in decreasing heavy-drinking days. Given the recent finding of nonefficacy of acamprosate in US-based RCTs, and the subsequent analyses which have identified subgroups of responders even in those studies, further work is needed to better elucidate the best candidates for acamprosate treatment. Long-acting injectable naltrexone demonstrates a similar impact as oral naltrexone on heavy drinking, and offers further advantages over oral administration, including low dosing frequency, high intrinsic medication adherence, and reduced first-pass metabolism. These are the medications that should be used first-line. However, even though currently an off-label use of the medication in alcohol-dependent subjects, topiramate clearly fosters reductions in heavy-drinking days. Other medications have a

less-robust evidence base, but there appears to be a signal based on age of onset for the effects of serotonergic medications that warrants further study.

Whereas subacute and maintenance pharmacotherapeutic interventions have been a mainstay of treatment for chronic opioid dependence, it is as yet unclear whether medications are of benefit in the long-term treatment of chronic alcohol dependence. Similarly, other characteristics have yet to be clearly established, such as the optimal dosages and effectiveness of available pharmacotherapies in clinical settings, the optimal psychosocial interventions with each medication, and which subpopulations respond best to which medication.

It is hoped that pharmacotherapies for alcohol dependence may evolve into a more routine and widely used intervention as continuing evidence mounts demonstrating their effects in promoting abstinence and reducing in drinking behavior.

Alternative Pharmacotherapies for Opioid Addiction

Paul J. Fudala ■ Rolley E. Johnson

The development of methadone maintenance by Dole and Nyswander in the mid-1960s (1) ushered in the modern era of pharmacologic treatment for opioid dependence. Previously, except for a brief period of legalized opioid maintenance in several cities of the United States in the early 1900s, abrupt discontinuation of opioids or substitution of decreasing doses of methadone or shorter-acting legally prescribed opioids for patients' drugs of choice were used to "detoxify" opioid-dependent individuals. However, medically supervised withdrawal ("detox") alone is a generally unsuccessful treatment for opioid dependence because relapse typically occurs shortly after an individual completes a course of treatment. Medication-assisted therapy (i.e., opioid replacement therapy) in contrast, however, can enable patients to reduce or stop use of illicit opioids and to stabilize their lives. Still, many opioid-dependent individuals require recurrent or extended courses of treatment.

Since their introduction and approval, mu-opioid agonists such as methadone and the mu-opioid partial agonist buprenorphine have provided treatment options to millions of opioid-dependent individuals worldwide. The mu-opioid agonist methadyl acetate (LAAM) and the opioid antagonist naltrexone have provided for additional treatment options, though with much less of an impact than the former two medications. Efforts to develop new opioid-dependence treatment medications have focused on providing additional alternatives or formulations for those patients who cannot tolerate, do not respond to, or prefer not to take currently available medications. The development of treatment options with less abuse potential, abusability, likelihood for diversion, and risk for unintentional exposure has also been a strong consideration.

Interrupting the powerfully reinforcing effects of opioids and drug-seeking behavior requires a concerted effort by physicians, therapists, and other clinical personnel, as well as by the patients themselves and their families. This is particularly true once an addiction is established as a chronic condition, and will often require multiple interventions. Other chapters in this volume are specifically devoted to a discussion of methadone, buprenorphine, and naltrexone as opioid-dependence treatment agents. This chapter reviews the literature on additional pharmacotherapies which are or have been utilized, as well as some which are actively being investigated for opioid-dependence treatment. These include the opioid agonists LAAM, codeine, dihydrocodeine, morphine, and heroin, and also the nonopioid medications clonidine

and lofexidine. Medications that have been assessed for opioid-dependence treatment but for which only very limited data are available (e.g., gabapentin, venlafaxine, topiramate, AV411) will not be considered here.

NONOPIOID TREATMENT ALTERNATIVES: CLONIDINE AND LOFEXIDINE

The acute opioid-withdrawal syndrome is a time-limited phenomenon, generally of brief duration. Following the abrupt termination of short-acting opioids such as heroin, morphine, or hydromorphone, withdrawal signs and symptoms usually subside by the second or third opioid-free day. Although the opioid-withdrawal syndrome can be extremely uncomfortable for the opioid-dependent individual, in contrast to the syndrome associated with the withdrawal of certain other drugs such as benzodiazepines and alcohol, it does not ordinarily pose a medical risk to the individual. The exception may be, however, in patients already severely compromised where dehydration secondary to vomiting, diarrhea, and sweating could be a significant factor in precipitating a medical crisis. Thus, there is a particular appeal for treating this syndrome symptomatically, especially with medications that do not themselves produce physical dependence. It must be recognized, however, that medically supervised withdrawal from opioids is only one of the initial steps in the treatment process of rehabilitating opioid-dependent individuals if complete and permanent abstinence is the treatment goal.

Clonidine is an α_2 -adrenergic agonist that has been used for the treatment of various disorders including hypertension, autism, attention-deficit hyperactivity disorder, and various types of pain. Clonidine has been shown to be useful in the medically supervised withdrawal of patients from methadone, heroin, and other opioids, as well as preparing individuals for stabilization onto the opioid antagonist naltrexone.

The capacity of clonidine to ameliorate withdrawal-associated effects (e.g., lacrimation and rhinorrhea) is linked to its modulation of noradrenergic hyperactivity in the locus ceruleus (2,3). Additionally, clonidine may affect central serotonergic (4), cholinergic (5), and purinergic systems (6). It seems to be most effective in suppressing certain opioid-withdrawal signs and symptoms, such as restlessness and diaphoresis. However, clonidine is not well accepted by the addicted patient because it does not produce morphine-like

subjective effects or relieve certain types of withdrawal distress, such as anxiety. Sedation and hypotension also limit its utility. No fixed-dosing guidelines are currently available and dosages are generally individualized to each patient based on therapeutic response and side-effect limitations.

Interestingly, clonidine abuse by users of illicit opioids and other drugs has been reported since the early 1980s (7). This abuse may be secondary to a desire to obtain various drug-related effects, such as sedation, euphoria, or hallucinations. Clonidine may also be used to prolong and enhance the effects of heroin or other opioids (8,9). One report described the intentional ingestion of clonidine patches by individuals on a chemical dependency unit who may have done so to obtain psychoactive effects or to alleviate opioid-withdrawal symptoms (10).

Secondary to an effort to identify an agent with less sedating and hypotensive effects than clonidine, a number of other α_2 -adrenergic agonists (lofexidine, guanabenz, guanfacine) have been evaluated for their ability to moderate the opioid-withdrawal syndrome. Of these, lofexidine, a clonidine analogue licensed in the United Kingdom for opioid medical withdrawal treatment, has been the subject of much clinical evaluation. Lofexidine is being studied in the United States and enjoys widespread usage in the United Kingdom as the only α_2 -adrenergic agonist approved there to relieve symptoms in patients undergoing withdrawal from opioids (11). Lofexidine is suggested to be used typically for a period of 7 to 10 days at maximal single doses of 0.8 mg, usually taken three times per day, in dosages ranging up to 2.4 mg/day (12).

Studies conducted in the early 1980s provided initial data indicating that lofexidine could be effective in suppressing some of the signs and symptoms of opioid withdrawal (13–15). More recent trials have provided further evidence for the efficacy of lofexidine. These trials included both open-label and double-blind evaluations, using both inpatient and outpatient populations.

When compared to methadone for the treatment of opioid-withdrawal signs and symptoms in polydrug-abusing opioid-dependent individuals, lofexidine treatment was associated with more severe symptomatology at various time points on and before the 10th (last) day of treatment, but both groups were observed to have a similar course of symptom decline thereafter (16). Both groups also showed similar rates of medical withdrawal treatment completion. In a subsequent open-label study by the same research group (17), the authors found that a 5-day lofexidine treatment regimen may attenuate opioid-withdrawal symptoms more rapidly than a 10-day lofexidine- or methadone-treatment schedule without exacerbating hypotensive side effects.

The combination of lofexidine and methadone has previously been associated with significant hypotension, sedation, and cognitive deficits compared to methadone alone (18). Most recently, the coadministration of lofexidine and methadone was found to induce QTc interval prolongation (19). Study subjects were stabilized on a targeted methadone maintenance dosage of 80 mg/day. After stabilization, subjects received lofexidine initially at a dose of 0.4 mg/day, eventually

escalated to 1.6 mg/day. When maximal ECG responses were considered, statistically significant changes in heart rate (decrease), and PR, QRS, and QTc intervals (increase) were observed with the methadone/lofexidine combination compared to methadone alone. These results were secondary findings from a pilot dose-escalation study evaluating the safety of methadone and lofexidine coadministration referenced above (18).

When lofexidine was compared to clonidine, both treatments were generally found to produce similar therapeutic effects, but lofexidine typically was better tolerated. When lofexidine was compared to clonidine in an outpatient, double-blind trial, both medications produced positive treatment outcomes, but clonidine was associated with more hypotensive effects and required more home visits by medical staff (20). In a double-blind, inpatient study, lofexidine and clonidine were reported to be equally effective in treating the withdrawal syndrome. Clonidine, however, was associated with more hypotension and better treatment retention than was noted for lofexidine (21). In another double-blind, inpatient study using methadone-stabilized opioid-dependent individuals, both lofexidine and clonidine produced a similar suppression of withdrawal symptoms, but lofexidine was associated with less hypotension and fewer adverse events (22).

In an inpatient human laboratory study, oral pretreatment with placebo, lofexidine (0.4, 0.8, and 1.6 mg), and clonidine (0.1 and 0.2 mg) were compared in individuals maintained on 30 mg of methadone who received intramuscular naloxone doses of 0, 0.1, or 0.3 mg (a total of 18 separate experimental sessions). Both lofexidine and clonidine produced dose-related decreases in blood pressure and heart rate, but neither medication mitigated the subject-reported discomfort of precipitated opioid-withdrawal nor autonomic signs of withdrawal (23).

Additional studies using diverse paradigms have also supported the therapeutic effectiveness of lofexidine. For example, a naltrexone–lofexidine combination was associated with a more rapid resolution of the opioid-withdrawal syndrome than was a 7-day lofexidine-only treatment schedule, without substantial increases in withdrawal symptoms or hypotensive side effects (24). When used in a 3-day opioid medical withdrawal procedure with adjunct medications (oxazepam, baclofen, ketoprofen, naloxone, and naltrexone), lofexidine-treated individuals showed significantly lower levels of withdrawal symptoms and fewer mood problems, as well as less sedation and hypotension (25).

When lofexidine was compared to buprenorphine in an open-label study, patients receiving buprenorphine reportedly had less-severe withdrawal symptoms and were more likely to complete medical withdrawal treatment (26). In another open-label evaluation, a noninferiority approach was utilized to compare buprenorphine to lofexidine in 210 randomized individuals undergoing medically supervised withdrawal from heroin. Sixty-five percent of those on buprenorphine and 46% of those on lofexidine completed medical withdrawal, with 46% in the buprenorphine and

36% in the lofexidine group reporting abstinence at 1 month. Interestingly, results from 271 individuals who declined randomization and chose their treatment instead were similar to those obtained from the randomized groups of individuals (27).

Twelve randomized controlled trials comparing buprenorphine to clonidine or lofexidine for modifying the signs and symptoms of opioid dependence in individuals who were primarily opioid dependent were reviewed (28). Findings indicated that buprenorphine was more effective than either clonidine or lofexidine in treating opioid withdrawal as evidenced by reduction in symptoms of opioid withdrawal, and by patients remaining in and completing medical withdrawal treatment.

LAAM: AN OPIOID AGONIST ALTERNATIVE TO METHADONE

LAAM is a derivative of methadone, and similar to methadone, is a synthetic mu-opioid agonist. LAAM was initially developed in the late 1940s by chemists in Germany seeking an analgesic substitute for morphine. The opioid effects produced by LAAM and its active metabolites, along with the potential for administering the parent drug on alternate days or on a three-times-weekly schedule (thus eliminating the need for “take-home” doses), fostered interest in its potential use as an alternative to methadone. For example, a single take-home dose of methadone can eliminate only one clinic visit per week, as methadone must be administered daily. However, a single take-home dose of LAAM could obviate the need for five clinic visits per week, as patients could receive in-clinic doses on Mondays and Wednesdays and a single take-home dose on Fridays.

While it was noted early in the development of LAAM that it could alleviate the signs and symptoms of opioid withdrawal following the termination of morphine administration, it was also observed that giving LAAM on a daily basis could lead to signs indicative of opioid toxicity, such as severe nausea and vomiting and respiratory depression. LAAM had also been shown to produce effects that were qualitatively similar to morphine and methadone. LAAM is converted to two pharmacologically active compounds by *N*-demethylation (*nor*-LAAM and *dinor*-LAAM) in addition to inactive compounds (29–31). The long half-lives of the *nor*-LAAM and *dinor*-LAAM metabolites, 48 and 96 hours, respectively, contribute to the extended duration of activity of LAAM (32).

Numerous studies (33,34) provided evidence for the effectiveness of LAAM as an opioid-dependence treatment agent, and LAAM was approved in the United States in 1993 for the management of opioid dependence. Most of these investigations, whether conducted prior to or following LAAM’s approval in the United States, compared LAAM to methadone, since the latter is considered the standard for opioid-dependence treatment. Outcome measures most often assessed in these studies included the amount of time individuals remained in treatment, patients’ illicit use of opioids and other drugs during the course of treatment, var-

ious elements related to individuals’ social functioning (such as employment history and interactions with legal system), and general medical and psychiatric parameters, including adverse events potentially related to the treatment medication.

A number of factors limited the widespread use of LAAM, including regulatory issues, clinic-staff resistance, and the reluctance by practitioners to consider LAAM as a viable alternative to methadone (35). Most importantly, however, LAAM has been associated with serious cardiac adverse events, including *torsade de pointes* (36,37). Roxane Laboratories, which marketed LAAM, indicated in 2003 that it would no longer make LAAM available for clinical use. Although LAAM is still approved for use by the FDA, it is no longer approved for use in Europe.

OTHER OPIOID AGONISTS: MORPHINE, CODEINE, AND DIHYDROCODEINE

In addition to LAAM discussed above, other opioid agonists including codeine, dihydrocodeine, and morphine have been evaluated for the maintenance treatment of opioid dependence and medically supervised opioid withdrawal. Compared to methadone and buprenorphine, these medications have shorter durations of actions (although sustained-release formulations have been assessed and are used clinically), and may thus be less suitable as maintenance medications. Factors that need to be considered when assessing the viability of these potential treatment agents are cost; medical safety; abusability, abuse liability, and potential for diversion; ease of use; and patient acceptability, among others. None of these medications are approved for the treatment of opioid dependence in the United States. However, it has recently been reported that dihydrocodeine is the second most commonly prescribed opioid-dependence treatment medication (following methadone) by general practitioners in the United Kingdom (38).

In a retrospective investigation from Germany, medical withdrawal treatment outcome differences were assessed in codeine-substituted patients, methadone-substituted patients, and patients injecting heroin illicitly. The treatment regimen utilized methadone in a tapering dosage, and was independent of the opioid substance that patients were using (39). Methadone-substituted (50.4%) and codeine-substituted (45.5%) patients finished medical withdrawal treatment significantly more often than heroin-dependent patients (35.9%).

An open-label study of dihydrocodeine conducted in the United Kingdom assessed dihydrocodeine for the medical withdrawal of methadone-maintained patients (40). All patients initially had their methadone dosages reduced to 10 to 30 mg/day. Dihydrocodeine was then substituted for methadone, initially from 240 mg/day in four divided doses upwards to 600 mg/day over 7 days and then down to 60 mg/day over the next 7 days. Thirteen individuals successfully completed the program, with three of those beginning treatment with naltrexone. One individual relapsed to heroin

use, and six dropped out of the program between days 3 and 11 during the dihydrocodeine treatment phase.

In a 3-year follow-up study in Germany, 199 individuals from a random sample of 297 individuals receiving codeine or dihydrocodeine maintenance treatment for opioid dependence were followed-up with regards to measures such as health, employment, criminal activity, and other outcome assessments (41). Out of the original sample of 297, 65% were still in treatment after 3 years. Over the 3-year period, 4% of the sample (12 patients) had died; 5 of the 12 were drug-related and 5 were AIDS-related. Generally, it was observed that there was improvement in their general physical condition, as well as medical and mental health. There was also a decreasing trend in criminal activity based on measures of conflicts with police, convictions, and imprisonment.

More recently, dihydrocodeine has been compared to buprenorphine and methadone with regards to addiction treatment efficacy (42). In what the authors described as the first likely randomized controlled trial of opioid dependence treatment involving dihydrocodeine, 235 patients were recruited for study participation, with 218 ultimately attending the initial treatment. In this open-label design, 110 patients were randomized to receive methadone and 108 to receive dihydrocodeine. There was no statistically significant difference between the groups for retention in treatment at follow-up, the primary outcome measure, when assessed at 6, 12, or 18 months. At 18 months, 88% of the dihydrocodeine patients remained in treatment compared to 77% on methadone. It was recommended, although not required, that patients remain with their assigned treatment for the duration of the study, or for as long as methadone or dihydrocodeine prescribing continued. Eighteen of the patients that had been randomized to receive dihydrocodeine changed to methadone; three changed from methadone to dihydrocodeine. The authors noted that the change from dihydrocodeine to methadone (which was the standard treatment) was achieved more easily than the converse since many clinicians were unwilling to prescribe dihydrocodeine unless the patient had been randomized to it. There was improvement over time compared to baseline on the various secondary outcome measures (including illicit opioid use, reported crime, and physical health), with no significant differences in these outcomes between groups.

In what was reported to be the first randomized controlled trial to compare buprenorphine and dihydrocodeine for opioid medical withdrawal, an open-label trial recruited 60 individuals who were using illicit opioids (43). Dose-reduction schedules for sublingual buprenorphine and oral dihydrocodeine were at the discretion of the treating physician but could not exceed 15 days. The primary outcome measure was abstinence from illicit opioids (as assessed by a urine sample) at the final study medication prescription. While a significantly higher proportion of individuals randomized to buprenorphine (21%) compared to dihydrocodeine (3%) provided an opioid-negative urine sample, only 23% of individuals overall completed the course of withdrawal medication and provided the required final urine sample.

Various studies have shown positive and encouraging results with regard to the use of slow-release oral morphine for the treatment of opioid dependence, and this medication has been used as an addiction pharmacotherapy in various countries. Formulations for once-daily administration have been developed, which could make the medication suitable for maintenance or medical withdrawal treatment.

Slow-release oral morphine has been evaluated in both comparative and noncomparative studies. In one of the former, 103 of 110 patients completed a 3-week study in Austria designed to assess treatment satisfaction (44). Patients reported significant reductions in somatic complaints, cravings for heroin and cocaine, and withdrawal symptoms compared to baseline. Cocaine consumption as assessed from urine drug screens was also significantly reduced; benzodiazepine consumption remained almost unchanged over the study period.

In another open-label study which assessed the safety and efficacy of slow-release oral morphine for the treatment of heroin dependence in Bulgaria, 19 of 20 patients completed the 6-month treatment protocol (45). Daily maintenance dosages averaged 760 mg, with a range of 440 to 1200 mg. No deaths or serious adverse events were reported. Psychosocial functioning and well-being improved, and a general improvement in patient health was observed. Concomitant use of methadone and other opioids was low, but this was based on self-report and was not verified with objective measures.

Slow-release oral morphine has also been compared to methadone. In an open-label crossover study, 18 methadone-maintenance patients were recruited to receive slow-release oral morphine once daily for approximately 6 weeks; methadone maintenance was resumed following this evaluation period (46). Patient outcomes were assessed during the transition between medications and also after at least 4 weeks on a stable dose of each medication. Three individuals dropped out of the study; two choosing to return to methadone maintenance. The mean initial methadone maintenance dosage was 78 mg (range 25 to 120 mg), while the mean final slow-release oral morphine dosage was 347 mg (range 120 to 570 mg). The transfer from methadone to slow-release oral morphine was not found to be associated with significant changes in the severity of opioid withdrawal across the first 5 days of treatment. The majority of the study patients preferred slow-release oral morphine to methadone.

The opioid agonist medications discussed above have the potential for being useful pharmacotherapies for addiction. However, as noted by Woody with regards to the use of long-acting morphine for opioid dependence treatment (and as can be extended to the development of codeine, dihydrocodeine, and other potential opioid agonist treatments), the medication development pathway would depend on a number of steps (47). These would include securing regulatory approval, getting the medication onto hospital and third-party payer formularies, developing reimbursement policies, and having clinicians use the medication.

HEROIN TREATMENT FOR OPIOID DEPENDENCE—A NEW APPROACH TO ADDRESSING ADDICTION

Following the first studies of heroin maintenance that were conducted in the United Kingdom in the 1970s (48) and the first trial of heroin-assisted treatment in Switzerland in 1994 (49), a number of studies conducted in North America and Europe have assessed the utility of using heroin to treat opioid-dependent individuals who typically were refractory to standard treatment such as methadone.

An excellent overview of some of the randomized controlled trials has recently been provided by Fischer and colleagues (50). Most of the studies involved the use of injected heroin, although utility of oral heroin (both immediate- and sustained-release) and inhaled heroin was also sometimes evaluated. Participants in the studies were typically individuals who did not respond adequately to methadone or other treatments; in some but not all cases, patients also received methadone. Main outcome measures often involved retention in treatment and assessments of illicit opioid and other drug use. Overall, the therapeutic outcomes of the various studies have been generally positive, although evidence of long-term benefit is generally lacking.

As noted by Lintzeris (51), results from randomized controlled trials have generally indicated that treatment with heroin, when compared to methadone treatment, is associated with comparable retention, improved health and functioning, and less self-reported illicit heroin use.

One of the most recently reported studies evaluated injectable heroin ($n = 115$) compared to oral methadone ($n = 111$) in study patients who had not benefited from at least two previous attempts at opioid dependence treatment, including methadone maintenance treatment at a dosage of 60 mg or more per day (52). This study was part of the North American Opiate Medication Initiative and was an open-label, randomized trial conducted in Canada (the cities of Montreal and Vancouver). Heroin was self-administered under supervision in the treatment clinics up to three times daily at a maximum dosage of 1000 mg/day; methadone was dispensed on a daily basis (no maximum dose indicated). The primary outcome measures were retention in addiction treatment at 12 months (or abstinence from opioids) and reduction in illicit drug use or other illegal activities. The results indicated that individuals assigned to heroin treatment were more likely to stay in treatment and reduce use of illegal drugs and engagement in illegal activities than those assigned to methadone. Sixteen of the 115 individuals in the heroin group had a life-threatening overdose or seizure during the study. One death occurred during the study, a methadone group individual who reportedly died from an opioid overdose.

Currently, heroin treatment for opioid dependence is a pharmacotherapeutic option in only a few countries, including the United Kingdom, the Netherlands, and Switzerland, and there are a limited number of individuals receiving such treatment. For example, it has been reported that in the United Kingdom in 2000, only 46 physicians had prescribed

heroin and less than 450 patients were receiving it. In a retrospective review conducted to understand the basis for these low numbers, the criteria by which patients were determined to be eligible for heroin treatment and physicians' stated reasons for prescribing it were examined (53). The results indicated that generally, heroin was considered to be a treatment of last resort for those patients who already had a long history of injecting heroin, or for those who did not previously respond well to other treatments.

SUMMARY

Opioid dependence is a chronic, relapsing medical disorder, often described as a brain disease with behavioral components. It requires comprehensive, multimodal, long-term treatment, as many patients also abuse or are dependent upon other substances. Many also have other medical and psychiatric comorbidity. Various types of pharmacotherapies with different modes of action have been used and continue to be evaluated as treatments for opioid dependence. Because no single medication will be appropriate for every individual, it is important that clinicians have a variety of therapeutic agents available to them. Additionally, pharmacotherapy is not a treatment end in itself; other adjuncts to successful treatment may include psychotherapy, social rehabilitation, vocational training, and others. Intraindividual treatment may also change over time as patients cycle through periods of abstinence and drug use. Rational medication therapy begins with an understanding of not only the disease state generally, but also of the specific dynamics of the addiction process that affect the overall success of treatment.

R.C. Oude Voshaar

INTRODUCTION

Directly after their introduction in the 1960s, the potential of benzodiazepines to induce a state of physical dependence was described in chronic psychiatric patients who abruptly discontinued high-dose benzodiazepine treatment, that is, 300 to 600 mg per day of chlordiazepoxide (1). In the early 1970s, the first reports appeared in the scientific literature of patients who had escalated their benzodiazepine dosage beyond the upper limit of the recommended therapeutic range (2). These reports received little attention. Benzodiazepines were considered safe in clinical practice and only a small number of patients escalated their dosage beyond therapeutic levels. From large pharmacoepidemiologic studies it is estimated that only 1% to 2% of long-term benzodiazepine users escalate their dosage above 40 mg diazepam equivalents per day over the course of several years (3). The first study of physical dependence in normal-dose benzodiazepine usage was by Covi et al. (4), who described a withdrawal syndrome after the discontinuation of 20 weeks of chlordiazepoxide treatment (4). Subsequent studies proved that normal-dose dependence, as manifested by a physical withdrawal syndrome, was a real entity and occurred even if the dosage was tapered-off. About 15% to 25% of long-term (over 12 months) therapeutic dose users develop a definite withdrawal syndrome (5).

Research on the prevalence, characteristics, and treatment of sedative-hypnotic dependence largely relied on definitions of dependence that emphasized the physical aspect of dependence (6). Research in the late 1990s, however, showed that psychological aspects of dependence are important for sedative-hypnotic dependence (7). The first study using DSM-criteria for sedative-hypnotic dependence found past-year prevalence rates of 40% in primary care patients and 52% in psychiatric outpatients who used benzodiazepines at least 3 days a week (8). These figures may be falsely inflated by using DSM-III-R criteria, as the criteria for dependence have been changed in DSM-IV. A recent epidemiologic study reported a past-year prevalence rate of sedative-hypnotic dependence of 2.3% among community-dwelling elderly people, which corresponds to a prevalence rate of about 10% among past-year benzodiazepine users in the population (9).

The abuse and dependence potential of benzodiazepines have stimulated the development of nonbenzodiazepine hypnotics. These drugs, the so-called Z-drugs (zolpidem, zopiclon, zaleplon, and recently, eszopiclon), were supposed to be

devoid of abuse and dependence by having chemical structures different from the benzodiazepines and by binding selectively to alpha1-subunit containing GABA_A-receptors. Although the abuse and dependence potential of these newer drugs are still considered remarkably lower than the classical benzodiazepines, evidence for significant abuse and their dependence potential is growing (10,11).

Today, it still remains controversial whether normal-dose dependence on sedative-hypnotic drugs should be regarded as a clinical problem or the best result for patients with treatment resistant (subthreshold) anxiety disorders and/or insomnia. Nonetheless, the reported prevalence rates of physical dependence associated with long-term benzodiazepine usage are high and vary between 2.2% and 17.6% in the community (12). Half of these long-term users meet DSM-IV criteria for specific disorders, for which the majority have never been treated according to current guidelines (13). Moreover, tapering-off their benzodiazepines does not worsen their psychopathologic symptoms (14,15).

HISTORY OF THE TREATMENT

Increasing knowledge on the dependence liability of sedative-hypnotic drugs as well as problems with stopping benzodiazepines in patients after long-term exposure prompted the development of treatment strategies to discontinue long-term benzodiazepine use. The first benzodiazepine discontinuation studies date from the early 1980s (16,17). Discontinuation strategies applied to long-term benzodiazepine users can be divided into two categories: minimal intervention programs, and systematic discontinuation programs. Minimal interventions are defined as simple intervention applicable to large groups of patients, for example, an advisory letter or a meeting in which long-term users are advised to stop their use. Systematic discontinuation programs are defined as tapering-off programs guided by a physician or psychologist. The main purpose of a systematic discontinuation program is to achieve a state of abstinence without experiencing significant withdrawal symptoms. These treatment programs can be further divided into systematic discontinuation alone or combined with either pharmacotherapy or psychotherapy. Psychotherapy has been added to these programs to achieve higher abstinence rates by either improving patients' coping skills with withdrawal symptoms or treating the underlying psychiatric symptoms. Pharmacotherapy has been added primarily to suppress withdrawal symptoms in order to achieve higher abstinence rates.

MINIMAL INTERVENTION PROGRAMS

Several minimal intervention strategies have been found to be successful in decreasing sedative-hypnotic drug usage in randomized controlled trials (18,19). Most evidence is found for the effect of sending a letter by the primary care physician to patients who have received benzodiazepine prescriptions for at least 3 months (most patients in these studies used benzodiazepines for years) (20). Other minimal intervention strategies that have proven successful include an advisory consultation by the primary care physician followed by either a self-help booklet or the opportunity to receive relaxation therapy and counseling by a nurse practitioner (18). Meta-analysis of these minimal intervention studies revealed that the odds of becoming fully abstinent is two to four times greater when compared to routine medical care or not raising the issue of discontinuation at all (18,19). These effects are robust and independent of the exact methodology of the individual studies, that is, randomization at patient level, randomization at the level of general practices (cluster-randomization), or comparison to a matched historical control group to correct for the Hawthorne effect (i.e., less benzodiazepine prescribed by doctors due to increase in knowledge and awareness caused by participation in a benzodiazepine discontinuation program). Translated to clinical practice, approximately 25% of all long-term benzodiazepine users will completely quit their usage after a minimal intervention strategy and an even larger proportion reduce their daily dosage by more than 50% with such an approach. Over the following 2 years, half of the patients who had quit their usage completely will remain fully abstinent (50).

Minimal interventions have only been evaluated in primary care settings, thereby limiting their generalization to secondary care. Results apply to normal-dose, long-term benzodiazepine users with an average age around 60 years. Determinants of the success of a minimal intervention can be divided into three main categories, that is, usage characteristics including characteristics of the individual drugs, doctor variables, and patient variables. The most important and most consistently reported predictors of being able to discontinue long-term benzodiazepine use by a minimal intervention are a lower daily dosage at baseline and a shorter duration of use. Furthermore, the use of multiple different benzodiazepines is also a pharmacologic factor with a negative impact on outcome independent of dosage and duration of use (21,22). The use of multiple different benzodiazepines probably reflects a more severe or complicated condition, and discontinuation of more than one sedative-hypnotic drug may require closer monitoring and supervision of the patient. Particular pharmacologic differences such as half-life and potency are of little importance in predicting success (21–23).

Many papers note doctor characteristics and their attitudes as important determinants of high benzodiazepine consumption and subsequently disappointing success when applying dose reduction strategies. Several surveys indicate that physicians generally endorse benzodiazepines as an effective treatment for anxiety or insomnia, report quick action,

and strong patient satisfaction (24). Furthermore, the risks associated with the use of benzodiazepines are minimized by doctors and monitoring or restricting renewal of benzodiazepine prescriptions is not regarded an important issue in clinical practice. Finally, many doctors are skeptical about the possibility of successful benzodiazepine discontinuation (24). Interestingly, a multilevel analysis of one of the largest benzodiazepine discontinuation studies showed that in primary care characteristics of physicians contributed marginally to a successful outcome, whereas patient characteristics were of major importance (23). However, little is known about which patient characteristics do influence the outcome of minimal intervention strategies. Age and gender only marginally influence outcome. The attitude about using benzodiazepines and coping strategies for dealing with dependence are probably the most important patient characteristics that influence outcome (25).

SYSTEMATIC DISCONTINUATION PROGRAMS

In contrast to minimal intervention, systematic discontinuation programs have been evaluated in different settings. Numerous discontinuation programs have been described, but the effectiveness of most programs is not substantiated by randomized controlled trials (26). Only two systematic discontinuation strategies have been compared with routine clinical care in a randomized controlled fashion (14,15,27). Both studies were conducted in primary care settings and yielded significantly higher success rates by a gradual dose reduction (GDR) approach compared to routine clinical care. The duration of both taper strategies, however, was quite different. Oude Voshaar et al. (14) evaluated a fixed discontinuation schedule of 25% per week, which resulted in an abstinence rate of 63%, whereas Vicens et al. (27) reduced the dosages with steps between 10% and 25% fortnightly resulting in an abstinence rate of 40%. The optimal duration of a tapering-off schedule remains speculative. A small pilot study with 42 patients found similar success rates when a fixed dosage reduction was compared to abrupt discontinuation (28), whereas extremely high abstinence rates up to 90% have been described in an uncontrolled study of “patient-tailored, symptom-guided benzodiazepine withdrawal” using a withdrawal schedule up to 15 months in a tertiary, specialized care centre (29). The rationale for a slow tapering-off program over months is the hypothesis that it takes time before brain systems regain control of the functions which have been damped down by benzodiazepine usage for years (<http://www.benzo.org.uk/manual/index.htm>). Supporters of “patient-tailored, symptom-guided benzodiazepine withdrawal” further state that “the rate of tapering should never be rigid but should be flexible and controlled by the patient, not the doctor, according to the patient’s individual needs” (<http://www.benzo.org.uk/manual/index.htm>).

Most guidelines and researchers, however, advocate a fixed discontinuation schedule varying from 4 to 8 weeks in duration (14,26,30,31). Within this time period, withdrawal symptoms are generally acceptable for both low- and high-dose

TABLE

35.1

Conversion factors for benzodiazepine agonists in diazepam equivalents^a

Benzodiazepine agonist	Equivalent dosages	Conversion factor to diazepam equivalents
■ Alprazolam	0.5–1 mg	×10–20
■ Bromazepam	5–10 mg	×1–2
■ Brotizolam	0.25 mg	×40
■ Chlordiazepoxide	20–25 mg	×0.4–0.5
■ Clobazam	15–20 mg	×0.5–0.67
■ Clonazepam	0.5–8 mg	×1.25–20
■ Clorazepinezuur	10–15 mg	×0.67–10
■ Diazepam ^a	10 mg	×1
■ Flunitrazepam	1 mg	×10
■ Flurazepam	15–30 mg	×0.33–0.67
■ Ketazolam	15–60 mg	×0.16–0.67
■ Loprazolam	1–2 mg	×5–10
■ Lorazepam	1–2 mg	×5–10
■ Lormetazepam	1–2 mg	×5–10
■ Medazepam	10–20 mg	×0.5–1
■ Midazolam	7.5–10 mg	×1–1.33
■ Nitrazepam	10 mg	×1
■ Nordazepam	10 mg	×1
■ Oxazepam	20–50 mg	×0.2–0.5
■ Prazepam	10–20 mg	×0.5–1
■ Quazepam	20 mg	×0.5
■ Temazepam	20–30 mg	×0.5–0.67
■ Triazolam	0.125–0.5 mg	×20–80
■ Zaleplon ^b	20 mg	×0.5
■ Zolpidem ^b	5–20 mg	×0.5–2
■ Zopiclon ^b	7.5–15 mg	×0.66–1.33
■ Eszopiclon ^b	3 mg	×3.33

^aAn equivalent dosage of diazepam can be calculated by multiplying the dosage of the benzodiazepine with its conversion factor. This has to be done for each benzodiazepine-agonist separately, whereafter the equivalent dosages of diazepam can be summed up.

^bNon-benzodiazepine agonist at the GABA_A-receptor.

benzodiazepine users. A feasible discontinuation schedule for clinical practice is the following (see also 14,30,31). Before tapering-off, benzodiazepine users should be transferred to an equivalent dosage of a long-acting benzodiazepine, for example, diazepam, and stabilized for 2 weeks. For patients taking more than one benzodiazepine, the dosages of the different benzodiazepines should be converted in diazepam equivalents and summed. By transferring all benzodiazepines into one long-acting benzodiazepine, fluctuations of blood levels are minimized, which results in higher discontinuation

rates. Abstinence rates reported by published systematic discontinuation programs show that by transferring to a long-acting benzodiazepines an additional 5% to 10% of the patients will successfully quit (32).

Table 35.1 presents the equivalent dosages for all benzodiazepines. Due to the large pharmacokinetic differences between benzodiazepines, it is impossible to give exact equivalent dosages. This is reflected by the wide range of equivalent dosages reported by different researchers. For that reason, Table 35.1 is based upon different resources and shows the

lower and upper limit of reported equivalents dosages (33; <http://www.benzo.org.uk/manual/index.htm>; 34). Although the preference for a specific long-acting agent is quite arbitrary, diazepam is often chosen due to the availability of 2 mg tablets that can be easily split in two halves of 1 mg each. Prescribing only diazepam 2 mg tablets has at least two advantages. First, the high number of diazepam 2 mg tablets that are often required to be taken before tapering begins confronts the patient with their “high dosage” and enhances their motivation to quit. A second, more pragmatic reason is the opportunity to gradually reduce the daily dosage without switching between tablets of different strengths. During the tapering-off phase, the daily dose of diazepam has to be reduced by 25% each week during weekly visits. Patients and clinicians have the opportunity to divide the last step into two steps of 12.5% for 4 days. The dose reduction period should be concluded 2 weeks after the last reduction step, because withdrawal symptoms rarely exceed a duration of more than 2 weeks.

Some issues need specific attention. First, it is important to collect all supplies of benzodiazepines kept by the patient at home before starting the discontinuation schedule. Benzodiazepine usage by partners or housemates must also be checked, and an agreement must be determined about how the patient and their partner will deal with these benzodiazepine stocks during the withdrawal period. Secondly, every dose reduction step should be accompanied by a consultation with the prescribing physician in order to evaluate withdrawal symptoms, exploring upcoming difficulties and last but not least, to be able to prescribe the exact number of 2 mg tablets of diazepam a patient needs till the next visit (rounding the number of tablets that have to be used each day to the upper whole digit). Patients can be given the opportunity to spread the prescribed daily dosage equally over the day. They do not have any limitations other than a maximum dosage that can be taken a day, but it may be wise to advise to take the largest number of tablets just before sleeping time. Hypnotic drug users should be warned about the possibility of some daytime sedation during the first 2 weeks. A next reduction step can always be postponed if the patient is not able to comply with it, but emphasize that the duration of their complaints (i.e., their withdrawal symptoms) will also be prolonged. In clinical practice, most withdrawal symptoms occur during the second half of the withdrawal phase (35). A complete resolution of withdrawal symptoms depends on the half-life of the agent that is withdrawn. For long-acting agents, all symptoms are generally resolved within 2 weeks, although anecdotal reports have been described of protracted withdrawal symptoms over years (36).

Different instruments can be used to measure benzodiazepine withdrawal symptoms during discontinuation. Two instruments are observer rated, the 34-item Physician Withdrawal Checklist (31) and the Clinical Institute Withdrawal Assessment—Benzodiazepine (CIWA-B) (37). For both instruments, however, data on validity and reliability are limited. The Benzodiazepine Withdrawal Symptom Questionnaire 1 & 2 (BWSQ1&2) have been developed for research purposes and are currently well validated (35,38). The BWSQ1 is a three-

point scale, designed for single administration in epidemiologic research. It measures 20 symptoms (anxiety symptoms are not directly measured) retrospectively over the complete period of benzodiazepine use at times when the dosage was reduced or stopped. The BWSQ2 measures identical symptoms and is intended for repeated measurements during benzodiazepine withdrawal. Perceptual and sensory distortions, loss of appetite, as well as depressed mood play an important role in the BWSQ and a considerable overlap exists between the BWSQ and the CIWA-B questionnaires. A significant increase in scores during diazepam withdrawal differentiates patients who will be unsuccessful in stopping benzodiazepines and those who will be successful in the short term. Moreover, low scores on the BWSQ during the last taper phase predict a lower probability of using benzodiazepines in the following years (35). The BWSQ is therefore a suitable instrument to monitor withdrawal symptoms during treatment.

For interpretation of the scores as well as for motivating patients to continue withdrawal, it is important to acknowledge the difference between rebound symptoms, withdrawal symptoms, and the recurrence of a psychiatric disorder. Rebound is a recurrence of the original complaints of the patient before starting benzodiazepines but of a higher intensity. Withdrawal symptoms are purely related to the discontinuation of the drug and can partly overlap with the original disorder. A clear distinction remains difficult, but there are two specific differences between withdrawal and a relapse of anxiety. The first difference is the length of time between discontinuation of benzodiazepines and the appearance of symptoms, as well as the tendency of the symptoms to improve or worsen over time. True withdrawal symptoms usually develop within a few days after discontinuation, they are most severe directly after discontinuation but continue to lessen until they disappear within 2 weeks (varying on the half-life of the specific agents that was tapered). Relapse of anxiety generally manifests as anxious symptoms that return more than a week after benzodiazepine discontinuation and get progressively worse until treated. The second difference is the symptoms themselves. Several symptoms of withdrawal are not characteristic of anxiety, like sensitivity to light and sound, tinnitus, feelings of “electric shocks,” tremors, myoclonic jerks, perceptual changes, and even seizures in case of high dosages. However, withdrawal symptoms also include many symptoms similar to anxiety, such as agitation, irritability, muscle cramps, fatigue, insomnia, headache, dizziness, and concentration difficulties. Therefore, rebound and withdrawal symptoms should never be a reason to stop tapering-off as a real recurrence of the disorder can only be established after rebound and withdrawal symptoms have been resolved. Withdrawal symptoms after low- and high-dose discontinuation are principally similar, but may differ in intensity. Epileptic seizures are extremely rare during discontinuation of benzodiazepines in therapeutic dosages, even in the case of abrupt discontinuation. In high-dose users, however, rapid discontinuation (within less than 1 week) may result in

epileptic seizures especially in patients using benzodiazepine with a short half-life.

ADDITIONAL THERAPIES FOR SYSTEMATIC DISCONTINUATION PROGRAMS

Pharmacologic Interventions

Nonbenzodiazepine medications have also been examined in combination with systematic discontinuation programs to determine their efficacy and ability to increase success rates (18,19). These drugs have been selected based on their effect on peripheral or central receptors that are supposed to be involved in benzodiazepine withdrawal. Antidepressants and anxiolytic drugs have been examined for their anxiolytic effects. Anticonvulsants and sedative-hypnotic drugs have been examined based on their central GABAergic effects and/or sedative effects. Pro-

pranolol, a beta blocker, has been tested based upon the presence of adrenergically mediated withdrawal symptoms. Flumazenil, a benzodiazepine receptor antagonist, has been tested based upon the hypothesis that it would reset the GABA_A-receptor shift produced by prolonged benzodiazepine usage. Table 35.2 presents an overview of all randomized controlled trials to date.

Meta-analysis of all systematic discontinuation trials evaluating antidepressant drugs revealed a superior effect associated with the addition of an antidepressant. Subgroup analyses showed only significant effects for imipramine and trazodone. Although these results suggest differential effects between antidepressants, these differences are probably chance findings due to small sample sizes of the individual studies. In trials evaluating the addition of antidepressants, these agents are continued after having completed the benzodiazepine discontinuation. Several publications suggest that depressive patients have greater difficulty in stopping benzodiazepine use (39).

TABLE 35.2 Randomized clinical trial evaluating the additive effect of pharmacotherapy to systematic discontinuation alone

Pharmacotherapy	Studies (N)	Patients (N)	Pooled effect estimate odds ratio [95% CI]
<i>Antidepressants</i>			
■ Paroxetine	2	167	1.6 [0.8–3.0]
■ Imipramine	2	75	3.0 [1.2–7.8]
■ Dothiepin	1	87	0.6 [0.3–1.6]
■ Trazodone	2	108	2.6 [1.1–6.4]
<i>Pooled analysis</i>	7	437	1.6 [1.1–2.4]
<i>Anticonvulsants</i>			
■ Carbamazepine	3	99	1.0 [0.4–2.7]
■ Valproate	1	37	4.8 [1.1–20.3]
<i>Pooled analysis</i>	4	136	1.7 [0.8–3.8]
<i>Anti-anxiety agents</i>			
■ Buspirone	5	217	1.1 [0.7–1.9]
■ Progesterone	1	35	0.8 [0.2–3.2]
■ Alpidem	1	25	0.2 [0.0–0.9]
<i>Pooled analysis</i>	7	277	0.9 [0.6–1.4]
<i>Sedatives-hypnotics</i>			
■ Melatonin	2	72	2.5 [1.0–6.4]
■ Hydroxyzine	1	139	1.1 [0.4–2.9]
■ Cyamemazine	1	168	0.4 [0.2–0.8]
<i>Pooled analysis</i>	4	379	0.9 [0.6–1.5]
<i>Other drugs</i>			
■ Propranolol	2	71	0.8 [0.3–1.9]
■ Aspartate	1	144	0.9 [0.4–2.1]
■ Homeogene	1	41	2.0 [0.5–7.5]
■ Sedatif PC	1	46	1.5 [0.5–4.9]
■ Flumazenil	1	40	3.7 [1.0–14.0]

Note: Data from Oude Voshaar et al. (2006) (15,18,45).

This suggests that antidepressants may be successful due to positive effects on the underlying condition for which benzodiazepines were originally prescribed.

Anticonvulsants have not proven successful, with the exception of a large effect for valproate in a small trial. In contrast to what might be expected, non-benzodiazepine anti-anxiety drugs as well as sedative-hypnotic drugs do not have any beneficial effects. Based on stringent rules for evidence-based medicine, that is, meta-analysis of different trials from different research groups, only strong evidence exists for the lack of efficacy for buspirone. The same findings hold for trials of several individual drugs. Propranolol and carbamazepine, however, both attenuate the severity of withdrawal symptoms during a (gradual) dose reduction (16,40). This effect, however, does not translate into higher overall abstinence rates, with the exception for high-dose users (over 20 mg diazepam equivalents) and patients with panic disorder among which carbamazepine might have some effect (40,41).

In most studies, patients receive a maintenance dosage of the additive pharmacotherapy before the start of tapering. Three studies, however, evaluated abrupt substitution of the pharmacotherapy (19). It was found that acute substitution with propranolol or cyamemazine was actually less effective than GDR alone. Furthermore, acute substitution with Homéogène 46 and Sédatif PC was no more effective than abrupt cessation alone.

Psychological Interventions

Eight studies including a total of 499 patients have evaluated the efficacy of psychotherapy to facilitate systematic benzodiazepine discontinuation programs. As shown in Table 35.3,

a pooled effect of these studies clearly shows the effectiveness of this strategy. Although all studies evaluated cognitive-behavioral therapy, the content of the psychotherapy largely varied between studies. This can be explained by differences in the specific patient populations under study. In three studies, patients with an underlying anxiety disorder (panic disorder or generalized anxiety disorder) were treated according to a CBT-protocol for these disorders. This resulted in significantly higher abstinence rates compared to tapering-off benzodiazepine without additive therapy. Similar results were found in studies including only patients with chronic insomnia. The two studies that included a mixed population selected only on the duration of long-term benzodiazepine use (14,15) or severity of benzodiazepine dependence (42) did not find any additional benefit associated with the use of CBT. The CBT in these studies was focused on benzodiazepine dependence and withdrawal, but only marginally on underlying symptoms of anxiety or insomnia.

Conclusion of Additive Therapy

The main conclusion of additive therapy is that pharmacotherapy or CBT is only effective during benzodiazepine tapering-off programs if focused on the underlying problem of the patient. The success rate in the control groups of these studies shows that in cases where an underlying psychiatric problem is present, the success of systematic discontinuation alone significantly decreases. If no depressive disorder, anxiety disorder or insomnia is present, as found in half of all long-term benzodiazepine users (13), systematic discontinuation alone is the preferred treatment.

TABLE 35.3 Gradual dose reduction (GDR) with and without additional cognitive-behavioral therapy

Comparisons	Patients (N)	Effect estimate odds ratio [95% CI]
<i>CBT for anxiety disorders</i>

Overall pooled analysis	499	1.8 [1.3–2.6]

SPECIAL CONSIDERATIONS

Determinants of Successful Outcome

Numerous uncontrolled studies and studies evaluating additional therapies, shows that in general two out of three patients are able to discontinue their benzodiazepine usage successfully by systematic discontinuation (14,15,18,19). Long-term results show that approximately half of the successfully treated patients will remain fully abstinent over the following years. However, patients who were unable to quit completely as well as those patients who relapse, decrease their usage substantially. This is primarily explained by a change of their usage pattern (i.e., intermittent usage of benzodiazepine) and not by a reduction in the average daily dosage used. Psychiatric symptoms generally improve when patients stop using benzodiazepines (31,43). Even in a sample meeting criteria for DSM-IV sedative-hypnotic dependence, reduction of anxiety levels paralleled the reduction of the benzodiazepine dosage (44).

Several factors have been related to successful benzodiazepine discontinuation (for an overview to this topic, see Oude Voshaar et al. (45)). The most reliable predictor for discontinuation is a lower benzodiazepine dosage at the start of tapering-off. No differences have been reported between individual benzodiazepines during gradual discontinuation, although after *abrupt* cessation a shorter elimination half-life resulted in a lower abstinence rate. Demographic variables inconsistently influence taper outcomes. For example, both female and male sex as well as both younger and older ages have been related to successful taper outcome. The high success rates that can be achieved in elderly patients merits some attention, as many physicians are skeptical about the possibility of tapering-off benzodiazepines in elderly patients. A study among nursing home patients found a success rate of 80% (46). A high level of psychopathologic symptoms, especially anxiety and depressive symptoms, as well as the personality traits neuroticism, dependence and vulnerability, resulted in a lower abstinence rate (47). In addition, these personality traits led to the experience of a more severe benzodiazepine withdrawal syndrome upon discontinuation.

Examining all potential predictors together revealed that outcome depends more on nonspecific dependence characteristics, rather than the level of psychopathology, personality traits, or benzodiazepine type (45). Successful discontinuation is associated with a lower benzodiazepine dosage at the start of tapering, the ability of the patient to reduce their dosage already on their own prior to formal treatment, not using alcohol, and a higher degree of compliance with the prescribed benzodiazepine regime during their benzodiazepine treatment. Withdrawal symptoms, especially those experienced during the last half of the withdrawal period, also have an impact on the long-term abstinence (35). In contrast to many other substance use disorders, the treatment of benzodiazepine dependence has been poorly studied within the theoretical context of a psychological model of change. Available but preliminary evidence has yielded counterintuitive results. Patients in the more advanced

stages of change in the transtheoretical model of behavioral change (i.e., preparation, action) were equally successful at achieving abstinence compared to patients in less-advanced stages (i.e., precontemplation, contemplation) (22).

Treatment Setting

The preferred treatment differs per setting. According to the principles of stepped care, minimal intervention should be considered the preferred treatment in primary care. In case a long-term benzodiazepine user is not able to discontinue his or her use with only minimal help, a systematic discontinuation program without any additive treatment should be offered. Patients suffering from a therapeutic dose dependency without clear evidence of an underlying psychiatric condition can be successfully treated in a primary care setting so long as the patient conforms to the guidelines discussed in Section 4.

If an underlying psychiatric condition is present, referral for second-line treatment is preferred. At this moment, it is important to acknowledge different natures of sedative-hypnotic dependence (48). First, there can be unintentional abuse by patients who begin using benzodiazepines to treat an affective disorder or insomnia but end up using them inappropriately. Most often, these patients use benzodiazepines for years while still suffering from underlying psychiatric conditions (13), whereas only a very small proportion will escalate their dosages over the years (3). The majority of evidence on systematic discontinuation of benzodiazepines (as described in Sections 4 and 5) is based on this population. Referral to both addiction and psychiatric clinics are realistic options, with a slight preference for the latter.

The second category is those patients who deliberately abuse benzodiazepines for their pleasant effects, in this paragraph referred to as intentional abusers of benzodiazepines. These patients usually take benzodiazepines in an attempt to get high and often abuse other substances for the same purpose. Multidrug users often take benzodiazepine simultaneously with other drugs to improve the euphoriant effects (especially of methadone), or use benzodiazepines to suppress the distress caused by withdrawal or adverse effects of other drugs like opiates, cocaine, or alcohol. Intentional abuse of benzodiazepines can result in both high-dose benzodiazepine dependence as well as benzodiazepine dependence complicated by a comorbid alcohol dependence and/or an other substance use disorders. A clinic specialized in (benzodiazepine) addiction should be preferred for this population as success rates drop to approximately 15% to 30% (42). Unfortunately, no specific guidelines are available for this important subgroup. Therefore, these patients should be treated according to the general principals of treating substance use disorders. Irrespective of the underlying problems, inpatient treatment seems superior for high-dose users, that is, patients using more than 30 mg diazepam equivalents a day. Other predictors of treatment success in patients with intentional abuse of benzodiazepines are a lower baseline dosage (within the high-dose range) and no previous withdrawal attempts (49). Among intentional abusers of benzodiazepines, patients

with cluster B personality or borderline personality disorder are far less successful in achieving abstinence, suggesting the need of concomitant treatment for these disorders. In contrast, comorbid alcohol dependence and other psychiatric disorders did not influence treatment outcome in patients with intentional abuse of benzodiazepines (49). Despite low success rates in patients with intentional benzodiazepine abuse, those patients able to decrease their benzodiazepine levels significantly regained a much better quality of life at follow-up and experienced less psychopathologic symptoms.

CONCLUSIONS

Whether long-term benzodiazepine use must be discontinued should be considered in the context of diagnosis, current symptoms, side effects, treatment history, and alternative treatment modalities. If one decides to discontinue long-term benzodiazepine treatment, the following guidelines can be given. A first treatment should be started in primary care with a minimal intervention by providing general information to patients and encouraging them to stop the use of benzodiazepines by themselves through a taper. If patients are unable to stop their benzodiazepine use this way, a systematic discontinuation program should be offered to them, since half to two-thirds of the patients can be successfully discontinued. There is some evidence to suggest that patients must be transferred to a long-acting agent and tapered-off a by fixed discontinuation program. Additional treatment should only be given if there is evidence of an underlying psychiatric condition. In that case, patients should be referred to secondary care institutes. Although most evidence supports the use of cognitive-behavioral therapy focused on the underlying condition, available data suggest that antidepressants may also be an option. If these strategies fail, it remains unclear which treatment options should be used. We suggest the following options, depending on local circumstances and patient characteristics. Patients could be offered a symptom-guided taper-off scheme provided in a specialized care setting to prevent significant deterioration or relapse of the underlying disease during or after discontinuation. Patients using high dosages (>30 mg diazepam equivalent) as well as patients with comorbid substance use disorders other than benzodiazepines might be offered inpatient treatment.

INTRODUCTION

Tobacco use is the leading preventable cause of illness and death in the United States and the second most common cause throughout the world (1–3). About 50% of all smokers are estimated to die from medical diseases worsened or caused by their smoking. This amounts to about 450,000 deaths per year in the United States and over 5 million deaths per year worldwide (4). As public awareness of the dangers associated with tobacco use has risen, the percentage of the US population classified as current smokers has declined, from nearly half the population in the mid-20th century to about 20% in 2008 (5). Compared to the general population, people with psychiatric disorders have much higher rates of nicotine dependence; at least 50% of people with posttraumatic stress disorder and depression and 60% of people with schizophrenia, bipolar disorder, and substance use disorders are dependent (6). These individuals also have more difficulty quitting tobacco use and may have other cofactors of poor outcome such as living with another smoker, lack of social support, higher severity of withdrawal symptoms, poor assertiveness skills, and depressed mood (7).

This chapter focuses on the clinical management of nicotine dependence, including ways to increase motivation for “lower motivated to quit” users as well as evidence-based pharmacological and behavioral therapy (BT) approaches for those ready to quit. Clinicians have a good range of evidence-based interventions that they can integrate into their clinical practice to help motivate patients to quit tobacco use (8).

There are many benefits to quitting tobacco use beyond reducing morbidity and mortality (9). One important strategy for motivating patients and their families to quit involves providing personalized feedback about the specific risks and benefits for them in addition to the general information on what they can expect to receive from quitting. For example, those who quit can expect quick improvement of cardiac functioning and reduced respiratory problems such as shortness of breath, cough, and infections such as influenza, pneumonia, and bronchitis. In the longer term, smoking cessation results in an increased life span and reduced morbidity due to decreased risk of coronary heart disease, stroke, dozens of different cancers including lung cancer, vision problems, wound healing, gum disease, peptic ulcers, and more generally, an improved health-related qua-

lity of life. Table 36.1 outlines some of the common health benefits over time. In addition there are many other advantages, including substantial financial savings, improved self-esteem, improved sense of taste and smell, and improved physical features such as whiter teeth, fresher breath, and less premature wrinkling of the skin.

HISTORY OF NICOTINE DEPENDENCE TREATMENT

Tobacco use had historically been seen as a habit or vice. The first tobacco-related Surgeon General’s Report referred to tobacco smoking as a form of “habituation” (10). The first Diagnostic and Statistical Manual of Mental Disorders to classify nicotine dependence and nicotine withdrawal syndrome as disorders was in the DSM III (11). Nicotine is now recognized as the primary addictive ingredient in tobacco and nicotine dependence has many characteristics that are behaviorally and physiologically similar to other addictions (2,3). Specific evidence-based treatments, particularly pharmacological treatments, used by the medical profession for treating nicotine dependence are a relatively recent phenomenon. Community-based interventions developed earlier as the risks started to become apparent; the first formal psychosocial treatment method was developed in the early 1960s with support from the Seventh-day Adventist Church (12). The American Lung Association modeled its own group-treatment program on this early work. In the early 1980s, some smokers began to apply the 12-step principles of Alcoholics Anonymous to smoking cessation. This developed into Nicotine Anonymous (Nic-A), still a valuable resource for those attempting to quit. Evidence-based psychosocial approaches, including cognitive-behavioral treatments, have since been developed and will be reviewed later. The first tobacco cessation medication, nicotine gum, was approved by the Food and Drug Administration (FDA) in 1984, and the next medication to be approved in the United States was the nicotine patch in 1993. The off-label usage of the antidepressant bupropion for nicotine dependence therapy began in the mid 1980s; FDA approval was given in 1996. These initial forays into pharmacotherapy were followed by other nicotine-replacement medications, including the nicotine inhaler, nasal spray, and lozenge. Varenicline (a partial agonist at the nicotinic acetylcholine receptor [nAChR]) was approved for nicotine dependence treatment in 2006. There

TABLE 36.1 When smokers quit—the health benefits over time

20 minutes after quitting: Your heart rate and blood pressure drops. (Mahmud, A, Feely, J. Effect of smoking on arterial stiffness and pulse pressure amplification <i>Hypertension</i> . 2003;41:183.)
12 hours after quitting: The carbon monoxide level in your blood drops to normal. (<i>US Surgeon General's Report</i> , 1988, p. 202)
2 weeks to 3 months after quitting: Your circulation improves and your lung function increases. (<i>US Surgeon General's Report</i> , 1990, pp. 193, 194, 196, 285, 323)
1 to 9 months after quitting: Coughing and shortness of breath decrease; cilia (tiny hair-like structures that move mucus out of the lungs) regain normal function in the lungs, increasing the ability to handle mucus, clean the lungs, and reduce the risk of infection. (<i>US Surgeon General's Report</i> , 1990, pp. 285–287, 304)
1 year after quitting: The excess risk of coronary heart disease is half that of a smoker's. (<i>US Surgeon General's Report</i> , 1990, p. vi)
5 years after quitting: Your stroke risk is reduced to that of a nonsmoker 5 to 15 years after quitting. (<i>US Surgeon General's Report</i> , 1990, p. vi)
10 years after quitting: The lung cancer death rate is about half that of a continuing smoker's. The risk of cancer of the mouth, throat, esophagus, bladder, cervix, and pancreas decrease. (<i>US Surgeon General's Report</i> , 1990, pp. vi, 131, 148, 152, 155, 164, 166)
15 years after quitting: The risk of coronary heart disease is that of a non-smoker's. (<i>US Surgeon General's Report</i> , 1990, p. vi)
Revised:10/26/2007 http://www.cancer.org/docroot/subsite/greatamericans/content/When_Smokers_Quit.asp

are now seven FDA-approved medications, three of which are available over-the-counter (nicotine gum, patch, and lozenge). In addition to clinic-based interventions, internet quit programs and telephone quitlines have greatly enhanced access to psychosocial treatments in the past two decades.

NICOTINE DEPENDENCE PRACTICE GUIDELINES

There are several outstanding practice guidelines available that provide more extensive detail for the clinician and can be used as teaching tools. Each describes how they determined the level of evidence to support the recommendations in the guidelines. Table 36.2 outlines several prominent practice guidelines and relevant websites for them.

Nicotine dependence treatment begins by engaging the patient and assessing his or her readiness to change smoking behavior. Treatment should be tailored to the individual and his or her particular circumstances, motivational level, and other unique factors that influence him or her to use tobacco. This may include helping him or her increase motivation to quit and set a quit date, offering pharmacotherapy and psychosocial treatments, and helping him or her sustain abstinence and prevent relapse.

During the engagement phase, a careful assessment includes identifying the pattern of use and severity of dependence. The Fagerström Test for Nicotine Dependence, which assesses time to first cigarette of the day, the number of cigarettes smoked per day, and other smoking character-

istics, can help to determine severity (13). Biochemical markers of tobacco use include cotinine levels in the blood and CO levels in expired air. Higher cotinine and CO levels are associated with an increased number of cigarettes per day and indicate the likely severity of nicotine withdrawal. For someone who regularly smokes 20 cigarettes per day, expired-air CO levels are typically in the 10 to 30 parts per million (ppm) range and cotinine levels in the 250 to 300 ng/mL range. The CO meter is easy to use and can be a useful motivational tool. The digital read out clearly demonstrates to a smoker the negative effect of smoking on blood oxygen saturation, an effect which is directly related to shortness-of-breath (a common symptom among smokers) and long-term risk of heart disease.

Assessment for history of prior quit attempts should include treatments used, if any, the length of abstinence, and the full context of relapse. If the patient used a medication, the clinician should review the dose and schedule of treatment, including effective use of medication, avoiding missed doses, and proper use, and also any side effects that developed (including determining whether any side effects may have been due to improper use). Prior psychosocial treatments might include group or individual treatment, American Lung Association and other community support groups, acupuncture, hypnosis, or Nic-A. An assessment should also be made of the person's current reasons for quitting, including his other motivation, commitment, and self-efficacy (perceived ability to quit). Another characteristic component of nicotine dependence treatment is helping the patient pick a "quit date" for when s/he will stop using tobacco products.

PHARMACOLOGY OF SMOKED NICOTINE AND MEDICATIONS FOR NICOTINE DEPENDENCE

Pharmacological approaches are an important component of smoking cessation treatment (see Table 36.3), and a brief understanding of the pharmacology of smoked nicotine helps understand nicotine replacement and other medication strategies. The method by which nicotine is administered

determines how quickly it crosses the blood–brain barrier and exerts psychoactive effects. Importantly, the strength of these effects is determined by how rapidly blood levels rise. Smoked tobacco is the most “efficient” method for delivering nicotine. Nicotine that is inhaled through a cigarette reaches the brain in less than 10 seconds and reaches peak arterial levels in 20 seconds (14). The half-life of nicotine is often given as 2 hours; however, it varies considerably from individual to

TABLE 36.3 Available pharmacologic therapies

Medication	Available doses (mg)	Minimum length of treatment	Increased odds of quitting versus placebo
Nasal spray	0.5 per spray	3–6 months	2×
Lozenge	2, 4	12 weeks	2×
Gum	2, 4	8–12 weeks	2×
Inhaler	4 per 80 inhalations	8–12 weeks	2×
Transdermal patch	21, 14, 7	8–12 weeks	2×
Bupropion XR	150	12 weeks	2×
Varenicline	0.5, 1	6 months	2× and 3×

individual, ranging from 1 to 4 hours (15). As a result of the short half-life, and because levels begin to fall only 15 to 20 minutes after a cigarette is smoked, nicotine plasma levels rise and fall rapidly many times throughout the day. As the blood levels fall, smokers experience withdrawal distress and an increased urge to smoke. As the levels rise, withdrawal distress is alleviated and the urge to smoke diminishes. Thus, among dependent smokers, the subjectively felt “need” for nicotine is driven, to a large extent, by negative reinforcement mechanisms which are especially potent due to the rapid rise in nicotine blood levels. Indeed, these considerations are central to understanding why dependence, itself, develops (16).

NICOTINE-BASED MEDICATIONS

There are currently five FDA-approved nicotine-based medications and two FDA-approved non-nicotine-based medications. Other nicotine-based approaches, including the electronic cigarette, or e-cigarette, are under consideration. The neurobiological targets of nicotine replacement therapy (NRT) are the same AChRs that tobacco products target. However, NRT works without exposing people to either the other harmful ingredients of tobacco products or to the extreme peaks and troughs in nicotine blood levels that contribute to and help maintain dependence. As a result, the abuse liability of NRTs is low. Among NRTs, the fastest peak plasma nicotine levels are achieved with the nasal spray (within 5 minutes), compared to the average cigarette in which peak arterial levels can reach 100 ng/mL within about 10 seconds. Therefore, smokers are able to titrate nicotine dose through smoking to keep within a certain peak/trough range that they prefer. Other nicotine replacement medications, including the lozenge, gum, and inhaler are far slower acting, with peak levels reached after about 45 minutes for the lozenge, around 30 minutes for the gum, and around 10 minutes for the inhaler. Peak levels with transdermal nicotine are reached much more slowly, after about 3 to 4 hours. Interestingly, despite the wide range of time-to-peak absorption of nicotine, these products appear to have similar abilities to alleviate withdrawal distress and urges and help individuals remain abstinent in the long term (17). Another important factor to consider is how much nicotine is available for delivery with different products and medications. Of note, a typical cigarette contains about 13 mg of nicotine and the average smoker absorbs about 1 to 2 mg into the body. This information can be helpful, along with cotinine or carbon monoxide levels, in determining doing titration of nicotine replacement medication. Other factors that are used as surrogates for level of nicotine dependence and dosing of medication include time to first cigarette and number of cigarettes per day which are two common measures that are used in studies to determine starting dosage of medications.

NON-NICOTINE-BASED MEDICATIONS

The FDA has approved two non-nicotine-based smoking cessation medications, bupropion and varenicline. The pharmacological actions of bupropion that mediate its effi-

cacy in smoking cessation treatment remain to be clarified. However, there are several hypothesized connections between bupropion and smoking cessation. First, bupropion acts as an antagonist at nACh receptors, many of which are present throughout the mesolimbic system (18). The mesolimbic system mediates reinforcement and addictive liability across the spectrum of drugs of abuse. Second, depletion of dopamine is believed to contribute to symptoms of nicotine withdrawal; animal studies suggest that chronic administration of bupropion increases dopamine concentrations, perhaps through an effect on the dopamine transporter. Third, the effects of bupropion on noradrenergic pathways may also attenuate withdrawal symptoms. Bupropion inhibits firing of noradrenergic neurons in animals and decreases whole-body turnover of norepinephrine in humans. Thus, the efficacy of bupropion in smoking cessation treatment may be due, in part, to its effects on the mesolimbic dopaminergic and possibly noradrenergic systems involved in drug withdrawal (19).

The pharmacological actions of varenicline that mediate its efficacy in smoking cessation treatment are likely a function of its competitive nAChR antagonist properties. Varenicline is also an $\alpha 4\beta 2$ nAChR partial agonist. As a partial agonist, the effect of varenicline on dopamine release is only about 35% to 60% compared to nicotine. Less dopamine activity reduces craving and withdrawal symptoms which also decreases the reinforcing aspects of nicotine (20).

EFFICACY OF THE MEDICATION

There is abundant support for the efficacy of the FDA-approved medications for nicotine dependence (7,21). This brief review draws from two comprehensive meta-analytic reviews of this body of work (21,22). Integrating the guidelines and findings of these reviews into clinical practice does take training and organizational change approaches (23) that will be discussed later in this chapter.

In clinical trials, about 14% of participants receiving placebo achieve long-term smoking abstinence of 6 months. The nicotine patch has been the most extensively investigated of the NRTs, and in meta-analyses, has been found to approximately double the odds that a smoker will achieve long-term abstinence. A similar odds ratio has been reported for the nicotine inhaler, lozenge, and nasal spray. Nicotine gum, used for up to 14 weeks, increased the odds of quitting by 50% compared to placebo. Interestingly, however, the odds of quitting doubled in trials of longer-term gum use.

Among the non-nicotine-based medications, bupropion has been the most extensively studied and meta-analyses show that this medication also approximately doubles the odds of quitting. The odds of quitting with varenicline appear to depend on dosage. The 1-mg dose approximately doubles and the 2-mg dose triples the odds of achieving long-term abstinence. When compared with the nicotine patch, varenicline improves the odds of quitting by 60%. By contrast, the efficacy of other medications is unchanged relative to the nicotine patch. However, it is worth noting that the efficacy of a

new medication tends to erode somewhat over time. Finally, the two second-line medications for smoking cessation, nortriptyline and clonidine, also approximately double the odds of achieving long-term abstinence (21).

A small but growing number of clinical trials have also investigated the efficacy of combinations of smoking cessation medications. Studies of two combinations in particular—patch and gum, patch and nasal spray—have produced the best results. Participants who received one of these combinations were 3.6 times more likely to achieve abstinence compared to placebo (21). A recent study also found strong evidence for the efficacy of the nicotine patch plus the lozenge (24). Recognizing that tobacco dependence is a chronic relapsing disorder, researchers have also begun to investigate the efficacy of long-term medication treatment. As already noted, meta-analyses found greater efficacy of nicotine gum in studies in which the gum was used for more than 14 weeks compared to fewer than 14 weeks. In addition, one study has reported higher quit rates with long-term use of the nicotine patch (24), and the Cochrane analyses did not find a benefit of long-term patch use (22).

EFFICACY OF MEDICATION IN SMOKERS WITH PSYCHIATRIC DISORDERS

Researchers are increasingly turning their attention to investigating the efficacy of smoking cessation treatments in smokers with psychiatric disorders, where rates of smoking are two to four times higher than in the general population. Two randomized medication trials have been conducted with smokers with schizophrenia. George et al. (25) randomly assigned 32 smokers to bupropion or placebo. Quit rates were 47% and 15% at the end of treatment and 22% and 8% at 6-month follow-up in the bupropion and placebo conditions, respectively. Evins et al. (26) randomly assigned 53 smokers to bupropion or placebo. Quit rates were 16% and 0%, respectively, at the end of treatment. Evidence also suggests that smokers on atypical antipsychotics are more likely to achieve abstinence following a quit attempt than those taking typical antipsychotics. One speculation is that atypical antipsychotic-induced decreases in negative symptoms may improve quit rates by reducing the need to use nicotine to achieve these same effects. There is also little evidence that quitting smoking has an adverse effect on the symptoms of schizophrenia. Study samples have been too small in these studies to investigate differences according to smoking status, however.

Studies have also investigated the efficacy of smoking cessation treatments with alcoholics in early recovery. In a meta-analysis of eight clinical trials of concurrent smoking and alcohol treatment, the mean quit rate at follow-up for both intervention and control conditions was 7% (see Table 36.1 in Prochaska et al. (27) for a description of each study). In a more recent clinical trial, Kalman et al. (28) found no evidence for greater efficacy of a high dose (42-mg) versus standard dose of nicotine replacement, although these smokers tend to be highly nicotine dependent. However, in this study,

the likelihood of achieving long-term nicotine abstinence was strongly moderated by length of abstinence from alcohol at time of enrollment in the trial. The smoking abstinence rate among participants with greater than 1 year of alcohol abstinence was 29%, 12% for participants with between 3 and 11 months of abstinence, and 0% among participants with only 2 months of abstinence (see Kalman et al. (29) for a review of this literature). Limited research has shown greater efficacy for combination pharmacotherapy (specifically patch plus gum) among smokers in early recovery.

Importantly, the preponderance of evidence does not indicate that smoking cessation compromises alcohol abstinence. In their meta-analysis, Prochaska et al. (27) found that participants in the concurrent intervention versus alcohol treatment only condition were significantly more likely to be abstinent from alcohol and other drugs. In addition, Kalman et al. (unpublished data) found that few (<10%) of these smokers report that quitting smoking has a negative effect on their ability to cope with urges to drink. Rohsenow et al. (30) found that smoking to cope with urges to drink does not predict relapse to alcohol following a quit attempt. However, in the largest study of tobacco treatment for smokers with comorbid alcohol dependence ($n = 499$), Joseph et al. (31) found that alcohol use outcomes for participants in the concurrent treatment condition were significantly poorer than for participants in the condition in which smoking cessation treatment was provided for 6 months following an alcohol treatment episode (the “delayed” condition). Accordingly, caution dictates that drinking status should be carefully monitored during a smoking quit attempt in this population.

Finally, Hughes (32) reviewed studies investigating the effect of a quit attempt on the emergence of major depression among smokers with a past history of depression. While rates varied widely (from 3% to 24%), within each study, these smokers were more likely to develop major depression following a quit attempt compared to smokers without a past history. Close monitoring of smokers with histories of depression is warranted during smoking cessation treatment. However, clinicians and patients should understand that depressed mood is not uncommon among smokers following a quit attempt and that it often resolves within 1 to 4 weeks. In other words, while careful monitoring of smokers with histories of major depression is advised, negative affect following cessation should not be considered an inevitable precursor to the emergence of a major depressive episode.

FUTURE DIRECTIONS IN PHARMACOTHERAPY

Several medications are currently undergoing evaluation for nicotine dependence. For example, tiagabine, a GABA agonist, diminished craving for cigarettes and increased cognitive performance compared to placebo (33). Preclinical research suggests that medications enhancing GABA decrease the rewarding effects of stimulants, including nicotine. Selegiline, an MAO-B inhibitor, has been shown to decrease craving (34)

and there is preliminary evidence for its efficacy (35). PET studies suggest that MAO-B is reduced in the brains of smokers. After smoking cessation the enzyme activity returns to normal, leading to a drop in the level of dopamine and increases in craving. Selegiline is designed to prevent the effect of smoking cessation on dopamine levels and concomitant craving. Other future directions of medication development include vaccines and other immunologic strategies, including both passive and active immunization against nicotine. Using this model, antibodies would reduce the percentage of nicotine that is able to pass across the blood–brain barrier by binding to it, causing it to become a much larger molecule. As a consequence, less nicotine would reach central nervous system receptors and the rewarding and reinforcing effects of tobacco use would be reduced. The antibody-bound fraction of nicotine would also be protected against quick metabolism and excretion. Together, these effects would prolong the effects of nicotine and reduce the rate of required nicotine intake (36).

Stepped-care is a promising approach to treatment that, unfortunately, has been the subject of very limited investigation. In stepped-care, smokers are transitioned to more intensive treatments when smoking abstinence is not achieved with less intensive treatments. While more research needs to be done to determine the efficacy of stepped-care treatment, practitioners may want to consider such an approach with their patients. For example, a practitioner may advise a patient to use the nicotine patch and subsequently add the lozenge or gum if a lapse occurs. In considering this approach, it is important to note that the transition to the “higher” step should probably occur very quickly after a lapse since the great majority of smokers who lapse do not ultimately achieve abstinence. Finally, the practitioner may want to consider “switching” the patient from a nicotine-based to a non-nicotine-based medication. Again, however, the efficacy of this approach awaits further research.

OPTIMAL USE OF THE MEDICATION, INCLUDING SAFETY CONCERNS

Medications are optimally used by individualizing a prescribed regimen to fit each patient’s unique needs, including the amount of daily tobacco use and severity of nicotine dependence, comorbid psychiatric and medical conditions, concurrently-taken medications, and patient values and preferences. It is particularly important to educate patients about the appropriate use of medications. For example, “chewing” nicotine gum is a “bite and park” technique. A second example is that patients must understand the effect of acidic beverages on the buccal absorption of nicotine from the gum, lozenge, and inhaler. Two common ways to optimize the medications include the concurrent use of two medications for nicotine dependence (such as patch and a short-acting NRT; bupropion and NRT; etc.) and integrating behavioral and/or other psychosocial treatments with medications. The most recent nicotine dependence treatment practice guide-

lines (7,21, see Table 36.2) recommend the integration of nicotine dependence treatment medications with behavioral and supportive psychosocial approaches. The chapter will now discuss each of the seven FDA approved medications in more detail, including available dose strengths, indications for particular doses, suggested amount of treatment time, practical considerations, and safety concerns. Of note, serious side effects from nicotine replacement medications overall are rare. There is a range of opinion as to whether these medications should be used by the pregnant smoker; however it is clear that ongoing smoking is a serious concern for the mother and child.

Nicotine Gum

Nicotine gum is available in doses of 2 and 4 mg. Although the 2-mg gum is recommended for people who smoke fewer than 25 cigarettes per day and the 4-mg gum is recommended for people who smoke 25 or more cigarettes per day, many clinicians will just recommend the 4-mg dose during smoking cessation or forced abstinence situations (such as on an airplane or in a locked medical unit). Smokers should use at least one piece every 1 to 2 hours for the first 6 weeks but not exceed 24 pieces in any 24-hour period. The gum is typically used for 8 to 12 weeks, although as noted earlier, some research has shown that longer duration of use is associated with greater efficacy. As with other NRTs, the gum is effective when it is used to maintain a steady plasma nicotine level. Therefore, while it can also be used to cope with urges as they occur, it is unlikely to be effective when only used ad libitum.

Nicotine gum releases nicotine from an ion-exchange resin. The gum should be chewed slowly until a peppery taste is achieved (usually after two or three “chews”) and then placed between the teeth and cheek for a few minutes. The process is then repeated until the taste dissipates (after about 30 minutes). The nicotine released has a medicinal effect only when it is absorbed through the oral mucous membranes. It should not be swallowed because absorption depends on the pH of the medium and nicotine cannot be absorbed in a highly acidic medium. For this same reason, acidic beverages (e.g., coffee, soft drinks) should not be used for 30 minutes before or 30 minutes after gum use. Finally, nicotine gum is not recommended for patients with temporomandibular joint problems, dental problems, and dentures.

Side effects and adverse effects of nicotine gum can include local irritation in the mouth, tongue, and throat, mouth ulcers, hiccups, jaw ache, gastrointestinal symptoms (flatulence, indigestion, and nausea), anorexia, and palpitations. Chewing the gum too fast can cause lightheadedness, dizziness, hiccups, nausea, vomiting, or insomnia. Another frequently occurring side effect of chewing nicotine gum is the apparent constriction of the muscles of the throat. As nicotine constricts the blood vessels in the gums, use of nicotine gum for a longer period of time can lead to gum diseases, owing to inadequate blood flow. Heartburn can occur as a side effect of

nicotine gum use if the nicotine containing saliva is swallowed rather than absorbed buccally.

Nicotine Toxicity

Nicotine toxicity, while rare, can occur if the individual continues the usual smoking patterns while also using NRT. Although concurrent use can occur with any type of NRT product with tobacco products, clinicians have been most careful when prescribing the NRT patch since this is a long-acting product. In most cases, individuals who start NRT patch might slip and also use a few cigarettes while trying to quit. This does not mean that the NRT should be discontinued; however, the clinician should work with the patient in an attempt to determine the ongoing triggers and whether some short-acting NRT (gum, lozenge, spray, or inhaler) might be added to the NRT patch or if there are some BT strategies that could be helpful to manage ongoing cravings. Tobacco users try to avoid nicotine intoxication symptoms when smoking or using other forms of tobacco. Symptoms of nicotine overdose include chest pain, irregular heartbeat, nausea, vomiting, along with severe dizziness, blurring of vision, and seizures.

Nicotine Lozenge

The nicotine lozenge is available in 2 and 4-mg dosages. The 2-mg lozenge is recommended for tobacco users who are less heavily addicted (e.g., smoke their first cigarette of the day more than 30 minutes after waking in the morning). The 4-mg dose is recommended for more heavily addicted users. Suggested dosing is at least nine lozenges per day during the first 6 weeks of treatment, with one lozenge every 1 to 2 hours. The lozenges should be used for up to 12 weeks with a dose taper to one lozenge every 2 to 4 hours starting in week 7 and further tapering to one lozenge every 4 to 8 hours in weeks 10 to 12. Usage should not exceed 20 lozenges per day. As with the gum and inhaler, nicotine absorption occurs through the oral mucous membranes and users should be instructed to avoid acidic food and drink for 30 minutes before and after use.

Side effects and adverse effects of the nicotine lozenge can include irritation of the teeth, gums and throat, indigestion, diarrhea or constipation, flatulence, insomnia, hiccups, headache, and coughing. The lozenges should be sucked slowly and gently, and not chewed or swallowed, as this may cause heartburn or indigestion. Nicotine toxicity may occur if not used as directed.

Nicotine Patch

Nicotine patches are available in 21, 14, and 7-mg dosages. A typical nicotine dependence treatment regimen can be 8 to 12 weeks, and one method starts the patient on a 21-mg patch for 1 month, followed by 2 weeks of the 14-mg dose and 2 weeks with a 7-mg dose. Some clinicians just prescribe the 21-mg dose for the full 8 to 12 weeks and do not taper to

lower mg dose patches. The nicotine patch allows nicotine to be slowly absorbed through the skin. At the start of each day, the patient should place the patch on a relatively hairless, clean location (typically between the neck and waist), rotating the location every day to avoid local skin irritation. The patch may be removed at night if the patient experiences disruption of normal sleep. The nicotine patch provides continuous release of nicotine. Peak nicotine levels are reached after 4 to 6 hours and then gradually decline over the course of the rest of the day, dropping to very low but detectable levels during the night. The 21-mg patch provides the user with about 16-mg of nicotine over a 24-hour period. The transdermal patch does not allow for self-titration of dose, like the other NRT products (gum, spray, inhaler, and lozenge) which can be taken to help quell momentary craving or withdrawal distress.

Side effects and adverse effects of the nicotine patch can include local skin reactions or erythema (25%), itching, burning, or tingling when the patch is applied. This usually goes away within an hour, and is a result of nicotine coming in contact with the skin. Some patients complain of vivid and sometimes unpleasant dreams and/or insomnia with overnight patch use; this is more frequent with the 24-hour patch and one remedy is to remove the patch while sleeping.

Nicotine Nasal Spray

The nicotine nasal spray contains aerosolized nicotine that is delivered to the nostril. Each spray contains 0.5 mg of nicotine. One dose consists of two sprays of 0.5 mg each, one to each nostril (1-mg of nicotine total). Each bottle contains enough nicotine for roughly 50 doses. Initial treatment should be 1 to 2 doses every hour, increasing as needed for relief of withdrawal symptoms. Minimum recommended dosage is eight doses per day. Usage should not exceed 40 doses per day. Recommended duration of therapy with the nasal spray is 3 to 6 months. Nicotine from the nasal spray is absorbed through nasal mucous membranes, resulting in more rapid absorption than NRTs absorbed through oral mucous membranes or transdermally. Therefore, the nasal spray may be appropriate for smokers who respond strongly to the “hit” of nicotine that cigarettes provide. Patients should avoid sniffing, swallowing, or inhaling through the nose while administering doses, as this may increase irritation. The spray is best administered with the head tilted backwards slightly.

Side effects and adverse effects of the nicotine nasal spray can include local airway irritation (i.e., coughing, rhinorrhea, lacrimation, nasal irritation), though tolerance to these appears to develop relatively quickly. Systemic effects include nausea, headache, dizziness, tachycardia, and sweating (37). The spray replicates the repeated administration of nicotine seen in smokers, potentially resulting in reinforcing peaks. As such, an initial concern regarding the spray was the potential for abuse due to the relatively rapid time course to peak blood level, although cases of abuse have been rare.

Nicotine Inhaler

The nicotine inhaler consists of a perforated cartridge filled with 10-mg of nicotine and an additive to reduce irritation from inhaled nicotine. A draw from the inhaler is similar to the average draw from a cigarette and produces about 0.1 μmol of nicotine at room temperature, with nicotine delivery decreasing sharply below 40°F. Similar to other NRTs, the recommended time on the medication is about 12 weeks and this might be extended based on individual situation and need for tapering off. The inhaler must be “puffed” and, therefore, imitates the upper airway stimulation experienced while smoking, though absorption is in fact primarily through the oropharyngeal mucosa. As such, acidic foods such as coffee and soft drinks should be avoided for half an hour before and after use. Efficacy of the inhaler is optimized by frequent use. Users should consume at least six cartridges per day. Each cartridge delivers a 4-mg dose of nicotine over 80 inhalations.

Side effects and adverse effects of the nicotine inhaler are similar to those of the spray and can include local irritation, cough, headache, nausea, dyspepsia. Local irritation in mouth and throat was reported by 40% of patients using the inhaler as compared to 18% of patients on placebo. Coughing (32% active vs. 12% placebo) and rhinitis (23% active vs. 16% placebo) were also higher for those using the inhaler.

Bupropion SR (Zyban, Wellbutrin)

This is a heterocyclic, atypical antidepressant that blocks the reuptake of both dopamine and norepinephrine. It is a strong antagonist to the $\alpha_3\beta_2$ nicotinic receptor and weaker antagonist to the $\alpha_4\beta_2$ and α_7 nicotinic receptors (38). Treatment for nicotine dependence with bupropion SR should begin about 1 to 2 weeks before the patient's quit date. The PDR recommends a dose of 150-mg should be taken each morning for 3 days, followed by a dose of 150-mg twice daily for the remainder of the treatment. From clinical experience, some patients benefit from a longer time period (1 week) before the dose is increased to 300 mg per day. Dosage should not exceed 300 mg daily. Similar to other nicotine dependence treatments, the PDR recommends 12 weeks for treatment; however, individual situations may suggest using the medication for a longer time period.

Bupropion SR's efficacy in nicotine dependence treatment is not due to its antidepressant properties, although it has been found helpful in patients with a prior history of depression. Of note, NRT has also been shown to be effective in helping people with a prior history of depression. If insomnia occurs with bupropion SR, taking the second daily dose earlier in the evening may be helpful. Alcohol should be used moderately while taking bupropion SR, and patients should be evaluated for alcohol dependence or any other substance use disorders. Bupropion SR is contraindicated in patients with a history of seizures or eating disorders, and patients who have used an MAO inhibitor in the past 14 days.

Side effects and adverse effects of bupropion are more limited with this medication in smoking cessation studies compared to studies of depressed patients, although the reason for this is not understood. Some of the common side effects include dry mouth, insomnia, nausea, and skin rashes. Less frequently, use of bupropion is also associated with hostility, agitation, depressed mood, suicidal thoughts and behavior, and attempted suicide. As a result of these concerns, the FDA requires a black-box warning about these possible adverse effects and recommends that the provider monitor any changes in patient mood or behavior while the patient is taking bupropion. This warning about neuropsychiatric problems is also present for varenicline. Finally, as noted, bupropion should not be used for patients who have an eating disorder or who have a history of seizures.

Varenicline (Chantix)

This is a partial agonist of the $\alpha_4\beta_2$ subtype of the nAChR and a full agonist at α_7 neuronal nicotinic receptors (39). Typical nicotine dependence treatment with varenicline involves an initial upward titration of dose. The patient should be instructed to take varenicline on a full stomach, starting at 0.5 mg once daily for the first 3 days followed by 0.5 mg twice daily for 4 days. The patient then takes 1 mg twice daily for 3 months. The patient should be instructed to cease smoking on day 8 of the treatment, when the dosage increases to 1 mg twice daily. Varenicline is approved for up to 6 months. If insomnia becomes an issue, the second pill of the day should be taken at supper instead of bedtime. Dosage of varenicline in patients with significant kidney disease (creatinine clearance ≤ 30 mL/min) or who are currently on dialysis should be reduced.

Side effects and adverse effects of varenicline can include constipation, flatulence, headache, increased appetite, nausea, vomiting, vivid, strange or unusual dreams, insomnia, taste changes (20). These were the most common adverse events, occurring at twice the rate as with placebo or in more than 5% of subjects. Less frequently, use of varenicline is also associated with hostility, agitation, depressed mood, suicidal thoughts and behavior, and attempted suicide. As a result of these concerns, the FDA requires a black-box warning about these possible adverse effects and recommends that the provider monitor any changes in patient mood or behavior while the patient is taking varenicline.

PSYCHOSOCIAL TREATMENT

Psychosocial treatments are an important component of nicotine dependence treatment. Unfortunately, psychosocial treatments are underutilized and most often not a component of treatment. Treatment is most likely to be medication only. There are many reasons for this, including poor reimbursement, lack of provider training in the techniques, and emphasis on medications due to direct to consumer advertising. All the treatment guidelines recommend the use of psychosocial treatment, and some individuals do not want a medication,

preferring to use BT or some other type of psychosocial treatment.

The core psychosocial treatments for nicotine dependence are similar to other substance use disorders, including Cognitive Behavioral Therapy (CBT) (relapse prevention), Motivational Enhancement Therapy/Motivational Interviewing (MET/MI), and 12-step facilitation (7). CBT and MET have been adapted and evaluated specifically for nicotine dependence, both as brief interventions in primary care and more intensive interventions in smoking cessation clinics. Internet- and telephone-based interventions are also broadly available and effective. In general, psychosocial treatments aid in smoking cessation by increasing patient awareness of the risks of tobacco use and the benefits of quitting; increasing motivation to quit, and engage in treatment; providing support for changes in behaviors and activities that will help sustain abstinence over time; encouraging use of medications. Of note, there is a need for more research on treatment that is tailored to specific risk factors such as different psychiatric disorders, motivational levels, and severity of dependence. A comprehensive evaluation and reevaluation if treatment is not working can help with improving treatment outcomes and delivering patient-centered care (40).

Assessing motivation to quit smoking is important. The transtheoretical model describes five stages of motivational readiness to change a behavior: precontemplation, contemplation, preparation, action, and maintenance stages (41). Patients not interested in quitting or who are not willing to readily engage in a discussion about quitting are in the precontemplation stage. Patients willing to discuss the pros and cons of quitting, however, who are not willing to quit for many months are in the contemplation stage. Those who are planning to quit in the next month are in the preparation stage. Those ready to make a quit attempt are in the action stage, and those successfully abstinent for at least 3 to 6 months are in the maintenance stage (41). There are outstanding resources available that provide detail on specific approaches for these different motivational levels. For this chapter, the focus will be on two broad categories into which clinical programs often divide their treatments: those for lower motivated patients (patients in the precontemplation or contemplation stages of change) and those for more highly motivated patients (patients in the preparation or action stages of change).

Lower Motivated Patients

Many patients are lower motivated and do not initially want to stop using tobacco products. Different strategies can be used to help motivate these individuals, including MET, brief personalized feedback interventions, reducing barriers to accessing treatment, connecting to support groups or Healthy Living/Wellness oriented groups, educating their family members, and recommending they speak to others who have quit. Some strategies to help patients prepare for quitting include suggesting they monitor their own tobacco

use, which may lead to recognition of how much and in what situations patients are smoking, discussion about the benefits of quitting and risks of continued use, and assessing who could provide support and who or what might be the barriers to change.

MET strategies try to help the individual increase their motivation and commitment to quit. The approach gives the clinician a framework of maintaining empathy, optimism, and a nonconfrontational style in the context of lower motivation and lack of agreement on a goal of abstinence. MET works very well with Prochaska and DiClemente's stages of change model which recommends modifying the strategies based on the patient's readiness for change (42). When patients appear to have no internal motivation to quit, a confrontational style predictably elicits patient resistance and nonengagement in treatment. By "joining up" with patients and meeting them at their stage of change, clinicians are more likely to be able to develop realistic goals with the patient. These might be limited to increasing awareness about risks and benefits, providing knowledge about treatment options, and understanding the particular motivators for and barriers to change. As motivation increases patients may feel more comfortable setting a goal to reduce or eliminate cigarette use only in a specific place (like in the car or home) versus complete abstinence. Brief personal feedback interventions by a physician or other medical staff can increase the likelihood of treatment success two- to tenfold (43,44). Personalized feedback that has been shown to help increase motivation includes giving feedback on the patient's cost of cigarettes for 1 year (cost per day = packs × costs per pack × 365 days), carbon monoxide score (if you have a CO meter), and information on the relationship of the patient's own specific health concerns (cardiac, pulmonary, impotence, wrinkles, wound healing, etc). Other helpful feedback includes discussing the interaction of a patient's medications with tobacco metabolism, and the negative effect on low-density lipids from smoking.

Higher Motivated Patients

The general approach to the motivated client is to initially engage with them by doing a comprehensive assessment, give them information on treatment options, confirm the motivation to quit, learn about potential barriers and strengths, and set a quit date. Helping them quit includes preparing for the quit date, selecting the medication option that they prefer, enlisting supportive friends or family, and engaging in some type of psychosocial treatment (individual, group, internet, Quitline). This phase includes learning about cues and triggers and anticipatory guidance on how to manage these, learning about nicotine withdrawal and the appropriate use of medications to manage the symptoms, and psychosocial strategies to help manage cravings, withdrawal symptoms, and triggers to use. CBT and BT in general are appropriate treatment options for most dependence issues including nicotine dependence. BT

involves the identification of affective, cognitive, and environmental cues that trigger tobacco use behavior. Awareness of these trigger cues is helpful in planning intervention strategies to prevent relapse upon their presentation. BT strategies often normalize the role of abstinence lapses during the progress of treatment (“slips”) such that “falling off the wagon” is not viewed as an irreparable failure. Discussion of management techniques for withdrawal symptoms, such as sleep disturbance and irritability, can be useful and can allow individuals to learn techniques from others when performed in a group setting. This can also occur as part of a separate relapse prevention coping skills training. Stress management and relaxation training are often used as secondary interventions to buttress behavioral methods. Stimulus control strategies involve the removal or alteration of cues that have been strongly associated with tobacco use, for example, avoiding certain situations that are likely to increase craving. Problems with the group format include low compliance, lack of availability of groups, and a general reluctance to participate on the part of some patients. Problems with the individual format include higher cost and the need for more counselors per population (45).

Despite little controlled research examining psychosocial intervention with spouses and significant others or families, social support for individuals who are attempting to quit using tobacco appears to enhance treatment success. Immediate family and social circles can be involved in treatment via education about supportive roles and behaviors. Concerned others can be engaged as well, providing assessment information or helping to enhance patient motivation. Conjoint sessions with family members may help with motivation, education, and sustaining changes. This may also address a barrier if a family member is a tobacco user.

Hypnosis, acupuncture, and laser therapy are approaches that some individuals believe have been beneficial in their efforts to stop using tobacco. The empirical evidence does not support use of these therapies, though poor study methodology makes a definite conclusion impossible to make (40,46,47). Hypnosis claims to reduce or even ameliorate the desire to use tobacco or to help solidify a commitment to quit. Acupuncture is a traditional Chinese therapy that aims to reduce the withdrawal symptoms associated with tobacco cessation through the insertion of needles into specific areas of the body. Laser therapy purports to operate under the same mechanisms of action as acupuncture using low-level lasers instead of traditional needles.

Many areas now have meetings of Nic-A groups that are structured similarly to Alcoholics Anonymous groups. These groups are based on the 12-step approach to recovery. Nic-A is a relatively new organization and does not therefore have the extensive network that other 12-step programs have developed over time. No formal controlled studies looking at the benefits obtained by attending Nic-A have been conducted. Written self-help materials such as

those distributed within Nic-A can play a vital role in patient education, especially regarding the negative health effects of tobacco, the benefits of quitting, and the nature of the addiction. Self-help literature, internet resources, and Nic-A can be efficiently incorporated into formal treatments as well as brief interventions, individual and group treatments.

SPECIAL CONSIDERATIONS

There is no one ideal treatment method for nicotine dependence. Special management issues exist for a number of populations and individual circumstances. Treatment of nicotine dependence in psychiatric populations requires particular attention. Individuals presenting as nicotine dependent with a co-occurring mental illness, another addiction, or all three are more likely to require modifications to traditional nicotine dependence treatment. One critical issue in treatment planning is the actual timing of treatment. There is literature supporting concurrent treatment and also supporting the delay of nicotine dependence treatment until the other issues are stabilized. Successful nicotine cessation in persons with active alcohol dependence is less likely than in individuals recovering from alcohol dependence, though some treatment programs have addressed both simultaneously with success. NRT appears to be especially helpful among smokers with co-occurring mental illness and addiction. Appropriate treatment of the mental illness or other addiction is integral to successful co-treatment, including appropriate medication and therapy methodologies. Individuals presenting with a co-occurring disorder often benefit from an initial motivational enhancement approach that bolsters their sense of self-efficacy and readiness to change (43). Adding BT may help to confront the social and other skill deficits that are often at hand among persons suffering from these co-occurring problems (48). Successful treatment for nicotine dependence has been shown in several studies to be positively associated with recovery from alcohol dependence (48–50). However one notable study, inconsistent with the majority of related literature, suggested that despite reaching a greater number of patients by offering tobacco and alcohol dependence treatment at the same time, concurrent treatment may have an adverse effect on alcohol abstinence when compared to the delay of nicotine dependence treatment (31).

ADDRESSING TOBACCO THROUGH ORGANIZATIONAL CHANGE

The better integration of nicotine dependence treatment into routine clinical practice requires system changes as well as training and education of staff and physicians. All the evidence-based practice guidelines also include information on doing system change. The Addressing Tobacco Through Organizational Change (ATTOC) model has been

used in all types of clinical settings, including inpatient, outpatient, community-based outreach, mental health, addiction, general medical, emergency room settings, etc. (23). The ATTOC model helps an agency/practice to develop specific patient, staff, and environmental goals that will help assure improved patient care, staff recovery, staff training, new policy development, communication, and environmental restrictions or campus tobacco-free initiatives. Staff training is not enough for changing the culture of clinical practice to integrate nicotine dependence treatment. Table 36.4 provides a list of internet sites that can be helpful for patients and staff education.

CONCLUSIONS

Nicotine dependence treatment is efficacious and cost-effective. Blending medications and psychosocial treatments improves clinical outcomes, as does the use of multiple medications for the more severely dependent. There are specific strategies for patients with different levels of motivation; using motivation-based treatment approaches may help patients create more realistic goals in which they are more invested. In addition to individual and group counseling approaches, the use of internet sites and telephone quitlines

allow for greater access to help for many. Nic-A is another free resource; however this network is much smaller than that of Alcoholics Anonymous or other 12-step Fellowship groups.

Self-Help Programs Focused on Substance Use: Active Ingredients and Outcomes

Rudolf H. Moos ■ Christine Timko

Self-help groups (SHGs), often called mutual help or support groups, are an important component of the system of care for individuals with substance use disorders (SUDs). SHGs are composed of individuals who share a common problem, such as a SUD, and who meet regularly to exchange support and information about how to manage and overcome that problem and lead more meaningful lives; in general, these groups do not have professionally trained leaders. SUD patients have high rates of posttreatment relapse and additional episodes of specialized care; participation in SHGs tends to improve the likelihood of achieving and maintaining remission and to reduce the need for further professional care. SHGs offer a safe, structured setting in which members can express their feelings, improve their communication and interpersonal skills, clarify the reasons for their substance abuse, learn self-control, and identify new activities and life goals. Thus, several professional organizations, including the American Psychiatric Association and the American Society of Addiction Medicine, recommend referrals to SHGs as an adjunct to the treatment of patients with SUDs.

SUBSTANCE USE FOCUSED SELF-HELP PROGRAMS

Twelve-Step Self-Help Programs

The most prevalent substance use focused self-help programs, including Alcoholics Anonymous (AA), Narcotics Anonymous (NA), and Cocaine Anonymous (CA), follow traditional 12-step principles. AA is a fellowship whose primary purpose is to help individuals with alcohol-related problems maintain sobriety. It is structured around the 12 steps (e.g., admission of powerlessness over alcohol, belief in a higher power) and 12 traditions (e.g., an emphasis on common welfare and recognition that personal recovery depends on AA unity). Other key aspects of AA involve open and closed-group meetings, sponsorship, and literature that describes AA, shares AA tenets, and provides guidance to recovering individuals. AA estimates that there are about 1.2 million members and 52,000 groups in the United States and more than 2 million members and 105,000 groups worldwide (see www.aa.org).

NA is a fellowship of recovering individuals with drug use problems. NA grew out of AA and is similar to AA in that it provides a structured support network in which members share information about overcoming addiction and living productive, drug-free lives through adherence to the 12 steps and 12 traditions. NA encourages complete abstinence from all drugs, including alcohol, but, consistent with AA, accepts the use of prescribed medications for psychiatric and medical disorders. NA has about 44,000 weekly meetings in more than 120 countries worldwide (see www.na.org).

CA is a fellowship open to individuals who want to stop using cocaine, including “crack” cocaine and other mind-altering substances. CA’s program of recovery was adapted from AA and, like AA, uses the 12-step recovery method. There are an estimated 30,000 members and more than 2,000 groups (see www.ca.org).

Traditional 12-step SHGs may have some limitations for individuals who have both substance use and psychiatric disorders, in part because they may be less able to bond with other members who do not share experiences associated with psychiatric problems. Double Trouble in Recovery (DTR) is a 12-step fellowship adapted from the 12-step method of AA; it is designed to meet the unique needs of dually diagnosed individuals. It has amended step 1 and step 12 of the 12-steps to include mental disorders so that, for example, step 1 is “We admitted we were powerless over mental disorders and substance abuse—that our lives had become unmanageable.” In addition, it specifically addresses the problems and benefits associated with psychiatric medications (see www.doubletroubleinrecovery.org).

Alternative Self-Help Programs

Many individuals do not believe in 12-step principles or traditions and find it hard to accept the idea of submitting themselves to a Higher Power. This fact has led to the growth of several self-help programs that are not based on the 12 steps, including SMART Recovery, Secular Organizations for Sobriety (SOS), LifeRing, and Women for Sobriety (WFS). (see Chapter 38 for further details on these alternative self-help programs.)

Self-Management and Recovery Training (SMART Recovery) espouses a rational treatment orientation and focuses on teaching individuals new coping skills and more logical ways of thinking and acting. It emphasizes practical methods of changing maladaptive behavior rather than a 12-step or spiritual approach. SMART's four-point program includes: (1) building and maintaining motivation to abstain, (2) learning how to cope with urges, (3) managing thoughts, feelings, and behavior, and (4) balancing momentary and enduring satisfactions (see www.smartrecovery.org).

SOS provides support for individuals who seek to achieve and maintain sobriety, a forum to express thoughts and feelings about recovery, and a nonreligious or secular approach that does not depend on the 12 steps or traditions. Members are expected to acknowledge their addiction and take personal responsibility for achieving and maintaining sobriety. Members tend to be well-educated individuals who have been in professional treatment; many members also attend AA (see www.secularsobriety.org).

LifeRing is another secular alternative to AA and NA. It is similar to AA/NA in that it is oriented toward abstinence; however, it is based on the belief that the positive social reinforcement of the group, rather than a Higher Power, can support individuals in their quest to lead a clean and sober life. Members are encouraged to rely on the group process to guide them toward the development of an individualized path to recovery. In addition to regular in-person group meetings, LifeRing sponsors internet-based chat rooms, a recovery focused message board, and specialized email forums (see www.unhooked.com).

Many women attend and benefit from AA or NA, but some women are alienated by the emphasis on powerlessness, humility, and surrender and/or express discomfort with face-to-face self-disclosure in group meetings populated mostly by men. These issues led to the development of WFS, which shares AA's focus on meditation and spirituality, but espouses the idea that sobriety depends on taking personal responsibility for one's behavior rather than on a Higher Power. WFS provides an alternative for women who prefer an emphasis on improving self-esteem, independence, and personal responsibility, and who wish to explore personal issues in groups with other women (see www.womenforsobriety.org).

SELF-HELP GROUPS AND SUBSTANCE USE AND QUALITY OF LIFE OUTCOMES

The majority of research on substance use focused SHGs has been conducted on 12-step groups. In general, the findings show that individuals with SUDs who regularly attend and become involved in 12-step groups tend to experience better substance use and quality of life outcomes than individuals who do not participate in these groups.

Self-Help Groups and Substance Use Outcomes

Project MATCH (Matching Alcoholism Treatments to Client Heterogeneity) was a large clinical trial that compared the outcome of 12-step facilitation, cognitive-behavioral, and

motivational enhancement treatment for patients with alcohol use disorders. Patients who attended AA more often in each 3-month interval after treatment were more likely to maintain abstinence from alcohol in that interval. In addition, more frequent AA attendance in the first 3 months after treatment was related to a higher likelihood of abstinence and fewer alcohol-related consequences in the subsequent 3 months; these findings held for patients in each of the three types of treatment (1).

Comparable findings have been obtained in several other studies. For example, alcohol-dependent individuals who participated in SHGs in the first and second years after intensive outpatient treatment were more likely to be abstinent in the second and third years, respectively; attendance at two or more meetings per week was associated with less severe relapses (2). Outpatients with SUDs who attended more 12-step SHG meetings in the prior 6 months were more likely to be abstinent at both 6-month and 5-year follow-ups (3).

Individuals who attend SHGs over a longer interval are more likely to maintain abstinence than are individuals who stop attending. Patients who participated in a minimum of six meetings in the prior 6 months had better substance use outcomes at 6- and 30-month follow-ups; in addition, this level of attendance prior to the 6-month follow-up was associated with better 30-month outcomes. Individuals who discontinued attendance or attended intermittently had substance use levels that were similar to those of individuals who reported no regular attendance (4).

In a prospective study of individuals with alcohol use disorders, a longer duration of attendance in AA in the first year after help-seeking was associated with a higher likelihood of 1-, 8-, and 16-year abstinence and freedom from drinking problems (Fig. 37.1). Moreover, after controlling for the duration of AA attendance in year 1, the duration of attendance in years 2 to 3 and 4 to 8 was related to a higher likelihood of 16-year abstinence (5).

These findings hold for participation in NA and for SUD patients with different diagnoses. According to Witbrodt and Kaskutas (6), individuals who attended more 12-step group meetings in the first 6 months after seeking treatment were more likely to be abstinent at a 6-month follow-up; those who

Figure 37.1. Alcohol-related outcomes at 16 years by duration of participation (number of weeks) in AA in the first year ($N = 461$).

attended more meetings in the subsequent 6 months were more likely to be abstinent at a 12-month follow-up. Comparable findings were obtained for patients with alcohol use disorder diagnoses only, patients with drug use disorder diagnoses only, and patients with both drug and alcohol use disorder diagnoses.

Attendance is an important indicator of participation, but it may not adequately reflect the depth of an individual's involvement in a SHG, as shown by such indices as number of steps completed, acceptance of 12-step ideology, and self-identification as a group member. In this respect, patients with cocaine use disorders who regularly engaged in 12-step activities but attended meetings inconsistently had better drug use outcomes than patients who attended consistently but did not regularly engage in 12-step activities (7). Moreover, independent from their level of 12-step group attendance, patients who believed more strongly in 12-step ideology were more likely to be abstinent independent of their level of 12-step group attendance (8).

Maintaining attendance without significant involvement may indicate reluctance to fully accept 12-step group ideology and the goal of abstinence. Individuals who attend SHGs but are unable to embrace key aspects of the program are less likely to benefit from it. Thus, optional SHG attendance may be more closely associated with better substance use outcomes than is SHG attendance that is expected as part of a treatment program, perhaps because voluntary participation reflects more motivation for change than does expected or coerced participation (9).

Self-Help Groups and Quality of Life Outcomes

SHGs also appear to promote positive quality of life outcomes, as indicated by more personal and social resources and better social functioning. With respect to personal resources, participation in SHGs has been associated with increases in self-efficacy for abstinence, and decreases in distress, depression, and psychiatric symptoms. According to Suire and Bothwell (10), individuals who worked all 12 steps had more self-esteem and social confidence and were more optimistic and trusting than were individuals who had not worked all 12 steps. In addition, some studies have shown an association between participation in SHGs and higher levels of spirituality and perceived meaning of life.

Affiliation with 12-step SHGs tends to promote more reliance on approach coping and less on avoidance coping. In this vein, compared to patients who had no continuing care after residential treatment, at a 1-year follow-up patients who attended 12-step SHGs tended to rely more on coping responses aimed toward reducing substance use, such as stimulus control (e.g., removing reminders of drinking from home), counterconditioning (e.g., engaging in physical activity instead of drinking), self-reevaluation (noting that dependency on substances reduces self-esteem), and reinforcement management (rewarding themselves for trying to stop drinking) (11). In addition, a longer duration of AA attendance has been linked to more reliance on approach and less on avoidance coping at both 1-year and 8-year follow-ups (12).

There also is a relatively robust relationship between SHG involvement and better social support and functioning. For example, individuals with alcohol use disorders who attend more AA meetings, and those who attend AA longer, tend to report more support from friends (12). Similarly, individuals with drug use disorders who attended NA once a week or more had more friends and social resources than their peers who did not attend NA or attended infrequently (13).

In a review of this area, Groh and colleagues (14) concluded that more involvement in AA was associated with larger friendship networks, primarily due to acquiring an AA sponsor and the development of new 12-step friends. Involvement in AA was also linked to more support for abstinence from friends and to higher quality friendships and more general support. The strength of affiliation among AA members may be comparable to or even stronger than that for close friends and family members.

LINKAGES BETWEEN SELF-HELP GROUPS AND TREATMENT

Many individuals participate in both SUD treatment and SHGs; in general, these two sources of help tend to bolster involvement in each other and contribute to better substance use outcomes.

PARTICIPATION IN SELF-HELP GROUPS AND TREATMENT

Compared with individuals who initially entered only AA, individuals who entered both treatment and AA participated in AA as much or more in the subsequent 15 years. Individuals who stayed in treatment longer in the first year after initiating help-seeking subsequently showed more sustained participation in AA. More extended treatment later in individuals' help-seeking careers was not associated with later participation in AA, which suggests that treatment providers' referrals to AA have more influence in the context of an initial treatment episode (15).

There also is a more specific link in that, compared to patients who participate in treatment not oriented toward 12-step principles, patients who participate in 12-step facilitation treatment, which introduces patients to 12-step philosophy and encourages them to join a group and get a sponsor, are more likely to affiliate with 12-step SHGs. These patients are more likely to attend meetings, talk to a sponsor, read 12-step literature, incorporate the steps into their daily life, and talk to friends in 12-step groups (1,16). Similarly, patients with cocaine use disorders who receive individual drug counseling based on 12-step philosophy are more likely to attend and participate in SHGs than are comparable patients who receive supportive-expressive or cognitive treatment.

In Project MATCH, patients who developed a stronger alliance in treatment were more likely to attend AA during and after treatment (1). More generally, a supportive and spiritually oriented treatment environment can enhance participation in 12-step activities. In this vein, patients in more supportive

treatment environments increased 12-step involvement during treatment; that is, they were more likely to acquire a sponsor and 12-step friends and to read 12-step literature. Moreover, when patients who had a high risk of dropping out of SHGs after treatment were treated in a more supportive environment, their risk of dropout declined (17).

These findings suggest that participation in treatment tends to strengthen SHG affiliation, which may bolster the effects of treatment. A supportive treatment milieu and strong treatment alliance may enhance patients' motivation for recovery and strengthen the impact of counselors' recommendations to maintain affiliation with SHGs. Moreover, treatment that emphasizes the value of SHGs in recovery encourages more SHG involvement than treatment that does not have this emphasis.

TREATMENT, SELF-HELP GROUPS, AND SUBSTANCE USE OUTCOMES

Participation in treatment and participation in SHGs have independent effects on substance use outcomes that tend to augment each other. In the long-term study of individuals with alcohol use disorders described earlier, individuals who participated in both treatment and AA were more likely to be remitted at both 1- and 16-year follow-ups than were individuals who received only treatment in the first year (15). Similarly, among clients with drug use disorders, longer episodes of treatment and weekly or more frequent SHG attendance have been independently associated with 6-month abstinence. Moreover, in a nationwide sample, alcohol-dependent individuals who participated in 12-step SHGs in addition to treatment were more than twice as likely to achieve an abstinent recovery as were individuals who obtained formal treatment alone (18).

The orientation of treatment can also influence the outcome of SHG participation: According to Humphreys and colleagues (16), as the treatment emphasis on 12-step approaches increased, the positive relationship of SHG participation to better substance use outcomes became stronger. More specifically, there was a stronger relationship between 12-step SHG participation and better substance use outcomes among patients from 12-step treatment programs than among patients from cognitive-behavioral or eclectic programs.

Essentially comparable findings were obtained in the NIDA Collaborative Cocaine Treatment study. Patients in individual drug counseling that emphasized 12-step principles changed more in 12-step beliefs and behaviors than did patients in supportive-expressive therapy and cognitive therapy, which placed less emphasis on 12-step ideology. These patients also experienced better substance use outcomes; changes in patients' 12-step beliefs and behaviors explained or mediated part of this effect (19).

Participation in SHGs may even compensate for the lack of services provided in treatment. In a study of dually diagnosed patients in residential programs, more attendance at 12-step SHGs was associated with better discharge and 1-year substance use and psychiatric outcomes. The benefits of 12-step SHG attendance depended on the intensity of services provided during treatment. More 12-step SHG attendance during treatment was

associated with better alcohol and drug outcomes at discharge only among patients treated in low-service-intensity programs; more attendance after treatment was associated with better psychiatric and family/social functioning at 1 year only among patients receiving low-service-intensity care (20).

SELF-HELP GROUPS AND HEALTH CARE UTILIZATION AND COSTS

Involvement in SHGs can reduce the use and costs of health care. Compared to individuals who initially obtained professional outpatient care, individuals who entered AA had less income and education and experienced more adverse consequences of drinking at baseline, suggesting somewhat worse prognoses. Nevertheless, individuals who initially sought help from AA had alcohol-related and psychosocial outcomes comparable to those who initially obtained outpatient treatment, and they had 45% lower alcohol-related health care costs over a 3-year period.

By increasing their patients' reliance on SHGs, professional treatment programs that emphasize 12-step approaches may lower subsequent health care costs. In this vein, compared with patients treated in cognitive-behavioral programs, patients treated in 12-step programs were more involved in SHGs at both 1- and 2-year follow-ups after discharge from acute treatment. In contrast, patients treated in cognitive-behavioral programs received more inpatient and outpatient care after discharge, resulting in 64% higher 1-year and 30% higher 2-year annual health care costs. Patients treated in 12-step programs also had higher rates of abstinence at both 1-year and 2-year follow-ups (21).

PERSONAL FACTORS, PARTICIPATION, AND SELF-HELP GROUP OUTCOMES

In a search to identify individuals who may be especially well-suited for participation in SHGs, researchers have examined a range of personal factors, including severity and impairment related to substance use, and disease model beliefs and religious/spiritual orientation. In addition, some studies have considered the suitability of SHGs for individuals with substance use and psychiatric disorders, women, youth, and members of racial and ethnic minority groups.

SEVERITY AND IMPAIRMENT

Individuals who are heavier substance users, have more substance-related problems, and are more dependent on substances are more likely to affiliate with SHGs. More impaired clients also are more likely to continue SHG attendance and less likely to drop out after treatment than less impaired clients are.

Compared to individuals with less severe substance use problems, those with more severe problems may benefit more from SHG involvement. Morgenstern and colleagues (22) found that patients with more severe substance use and psychosocial problems who had high levels of SHG affiliation had better 6-month substance use outcomes; outcomes were

poor when group affiliation was low. For patients who had less severe problems, levels of SHG affiliation were not related to outcomes. Individuals with more severe problems may benefit more from the support and structure of SHGs because it helps to alleviate their distress and increase their self-control and interpersonal and coping skills.

Consistent with these ideas, 12-step SHG attendance appears to be more effective for individuals who have relapsed than for those who have maintained interim recovery status. In this regard, for patients who resumed drinking at a 1-year follow-up after residential treatment, those who attended 12-step SHGs after relapse were more likely to be abstinent at 4- to 5-year follow-ups than were those who did not attend these groups. However, among patients who were abstinent at the 1-year follow-up, those who attended SHGs were no more likely to remain abstinent at 4- to 5-year follow-ups than were those who did not attend these groups (23). These findings suggest that 12-step SHGs may be more effective at initiating than maintaining abstinence.

DISEASE MODEL BELIEFS AND RELIGIOUS/SPIRITUAL ORIENTATION

Individuals whose beliefs are more consonant with a 12-step orientation are more likely to affiliate with 12-step SHGs. More specifically, patients who believe in the disease model of substance use, and have an abstinence goal and an alcoholic or addict identity tend to become more involved in SHGs and are less likely to drop out (17). Patients with both SUDs and posttraumatic stress disorders (PTSD) whose beliefs matched 12-step philosophy participated more in SHG activities; more participation was associated with less distress for these patients but with more distress for patients whose beliefs did not match 12-step principles as well (24).

Because of the emphasis on spirituality in 12-step SHGs, there has been speculation that less religious or spiritually inclined individuals may participate and benefit less from these groups. In fact, individuals with stronger religious beliefs are more likely to attend and become involved in 12-step SHGs and are less likely to drop out. In a 3-year study that examined the role of religiosity in AA, more spiritually oriented individuals attended more meetings than secular individuals did; in addition, secular and religiously uncommitted individuals had a sharper decline in AA involvement than spiritual and religious individuals did. These findings suggest that 12-step SHGs are somewhat less engaging for more secular individuals (25). Nevertheless, when they become involved in SHGs, less religious individuals appear to derive as much or more benefit from them as more religious individuals do.

Acceptance-based responding, or awareness of internal experiences that enable an individual to respond adaptively to stressors such as craving, may explain part of the effect of spirituality/religiosity on enhanced 12-step SHG involvement. In this vein, individuals who are higher on spirituality/religiosity tend to increase more in acceptance-based responding. In turn, acceptance-based responding has been linked to increased 12-step SHG involvement (26).

INDIVIDUALS WITH SUBSTANCE USE AND PSYCHIATRIC DISORDERS

A high proportion of patients with SUDs have co-occurring psychiatric disorders. In general, except for individuals with psychotic disorders, dually diagnosed individuals appear to attend and benefit from substance-use-focused 12-step SHGs as much as do individuals with only SUDs. A study of patients discharged from hospital-based residential treatment showed that dually diagnosed patients attended a comparable number of 12-step SHG meetings in the 3 months before 1-, 2-, and 5-year follow-ups as did patients with only SUDs. SHG attendance was similarly associated with a higher likelihood of 5-year remission for both groups of patients (27).

A few studies have focused on individuals with specific psychiatric disorders. Patients with SUDs and PTSD participated as much in 12-step SHGs after treatment as did patients with only SUDs. The dually diagnosed patients who participated more in SHGs were more likely to be abstinent and experienced less distress; they also were more likely to maintain stable remission (28). Some aspects of 12-step SHGs, such as their spiritual emphasis and provision of support, may be especially helpful to trauma survivors by lessening their sense of shame and hopelessness and providing an enhanced sense of purpose in life.

The situation may be different for individuals who have SUDs and co-occurring major depression. Compared to patients with only SUDs, those who also had major depression were less likely to become involved in 12-step SHGs after treatment. At a 2-year follow-up, the association between SHG involvement and abstinence was stronger for patients who had only SUDs than for patients who also had major depression. Depressed individuals may have interpersonal problems that make it harder to develop friendships and to acquire and relate to a sponsor; thus, they may need more support and guidance to become involved in and benefit from 12-step SHGs (29).

Some dually diagnosed individuals may do especially well in dual-focused 12-step SHGs, such as DTR. In fact, individuals who experience more severe consequences of drug use and more psychiatric symptoms are more likely to maintain attendance in DTR, which is associated with better adherence to medication regimens. With respect to outcomes, individuals who affiliate more strongly with DTR are less likely to continue to use substances and tend to improve more in self-efficacy for recovery, leisure time activities, feelings of well-being, and social relationships (30).

Women

Women with alcohol or drug use disorders are at least as likely as are men to attend SHGs and continue to participate in them. Participation in SHGs is also associated with as good or better outcomes for women as for men. In a comparison of women and men with alcohol use disorders, women were more likely than men to attend AA and went to more AA meetings in the first year after initiating help-seeking. More extended participation in AA was associated with a higher likelihood of remission for both women and men; however,

the positive association between a longer duration of AA attendance and stable remission was stronger for women (31).

Compared to men, women may be more in tune with 12-step philosophy, which involves acceptance of powerlessness over the abused substance and dependence on a higher power to attain sobriety. Women with SUDs often report low self-esteem, an external locus of control, stable attributions for failure, and frequent substance use when feeling powerless or inadequate. These personal characteristics are congruent with 12-step ideology, which expects individuals with substance use problems to admit past wrongdoing, acknowledge inability to control substance use, and trust a higher power to achieve recovery.

Youth

Many adolescents attend SHGs after treatment and those who do tend to experience better substance use outcomes. In a study that followed adolescents for 8 years, Kelly and colleagues (32) found that AA/NA attendance in the first 6 months and 12 months posttreatment was associated with a higher likelihood of abstinence at each subsequent follow-up. Attendance at just one meeting per week was associated with better outcomes and attendance at three or more meetings per week was associated with complete abstinence.

More broadly, adolescents who have more severe alcohol and drug problems and are more motivated for abstinence are more likely to attend 12-step SHGs. Adolescents often attribute their relapses to social situations and the pressure to use substances. Therefore, they may benefit from contact with a sponsor who can be a role model, structure that helps them avoid high-risk situations, participation in substance-free social events, and the opportunity to try out a new lifestyle (33).

However, adolescents' attendance tends to decline over time, in part due to boredom and lack of perceived fit with the group. There also are important barriers to SHG participation for adolescents, including less severe substance use problems and less motivation for abstinence, practical problems arranging transportation to and from meetings, discomfort with the emphasis on spirituality, and issues that are quite different than those of older members, many of whom are concerned with marital and employment problems that are less relevant to adolescents.

MEMBERS OF RACIAL AND ETHNIC MINORITY GROUPS

Compared to Caucasians, African Americans may be more likely to attend SHGs, increase their affiliation during treatment, identify as AA members, experience a spiritual awakening in AA, and do service at AA meetings; in addition, they appear to be less likely to drop out of SHGs after treatment. Certain characteristics of 12-step SHGs may especially appeal to African American patients, including the fact that meetings are widely available and open to anyone, are free of charge, and have a strong social and spiritual component.

In order to meet their unique recovery needs, African Americans appear to integrate cultural factors and a unique language and perspective in the process of affiliation with AA. According to Durant (34), African Americans are more likely

to associate their problems with racism and economic disadvantage than with alcohol abuse; they are less likely to accept the disease concept of alcoholism. Nevertheless, they respond to modeling and support from mentors and sponsors, modify the moral aspects of AA to meet their spiritual needs, and adapt the AA world view to better fit their racial and cultural background.

Compared to non-Hispanic white individuals, Hispanic individuals may be less likely to attend AA after treatment, perhaps because they tend to turn to their existing family and community support system. For example, In Project MATCH, Hispanic individuals attended AA less often after 12-step treatment than non-Hispanic white patients did. Nevertheless, as judged by self-identification as an AA member, having an AA sponsor, experiencing a spiritual awakening, and celebrating an AA birthday, they were as committed to AA as were non-Hispanic whites. Moreover, attendance at AA tends to be associated with decreased alcohol consumption among Hispanic individuals, just as it is among non-Hispanic whites (35).

Twelve-step SHGs have been criticized as less well-suited for American Indian groups because they entail the disclosure of personal problems, emphasize Western religious beliefs, and have a philosophy of powerlessness over alcohol that runs counter to the mores of many tribes on self-reliance and stoicism. Although self-help cannot be universally appropriate for all American Indian tribes, due to the tribes' cultural diversity, it can be appropriate for some. Native American modifications of SHGs incorporate elements of the medicine wheel, purification sweat, and sacred pipe as healing devices. The 12 steps have been blended with the medicine wheel in the Wellbriety Movement, a culture-specific recovery approach for Native Americans.

ACTIVE INGREDIENTS OF SELF-HELP GROUPS

The effectiveness of SHGs in curtailing substance use is based largely on four key ingredients: (1) abstinence-specific and general support that emphasizes the value of identification with abstinence-oriented role models and strong bonds with family, friends, work, and religion; (2) the goal direction and structure of a consistent belief system that espouses a substance-free lifestyle; (3) involvement in rewarding activities that do not involve substance use, including helping others overcome substance use problems; and (4) an emphasis on bolstering members' self-efficacy and coping skills (36).

These critical factors appear to be common change factors that underlie long-term recovery from substance abuse. In support of this idea, a survey of SHGs, including traditional 12-step groups, SMART Recovery, SOS, and WFS, showed that active involvement in a support group was associated with a higher likelihood of long-term remission irrespective of the particular group to which the individual belonged (37).

ABSTINENCE-SPECIFIC AND GENERAL SUPPORT

SHGs are an important source of abstinence-specific and general support, and may be especially effective in counteracting the influence of substance users in a social network. SHGs

provide modeling of substance use refusal skills, ideas about how to avoid relapse-inducing situations, practical advice for staying sober, and helpful hints about how to address everyday life problems. Individuals who continue to attend AA more regularly after treatment are more likely to have social network members who support cutting down or quitting substance use than are individuals who attend AA less regularly. In fact, the increase in friends' abstinence-oriented and general support explains part of the positive influence of SHG involvement on remission (3,38).

Individuals who have fewer heavy drinkers in their social network, more people who encourage reduction in drinking, and more AA-based support for reducing drinking, are more likely to initiate and maintain abstinence. In addition, the number of AA-based social network members who support reduced drinking tends to explain part of AA's effect on abstinence. Involvement in AA also may protect individuals from the potential negative influence of a "wet" social network.

GOAL DIRECTION AND STRUCTURE

SHGs provide a context of goal direction and structure in the form of a shared ideology that enhances individuals' immersion into the group. The shared ideology, which is reinforced by explaining group beliefs in understandable terms, specifying changes needed to maintain sobriety, and providing the 12 steps as a guide for change, helps members negotiate the recovery process. AA norms appear to result in more personal and intimate self-disclosures, and less conflict, in AA groups than in non-AA support groups.

There also is a system of taking turns in AA that exemplifies its egalitarian nature and low levels of conflict. In this vein, members acknowledge and identify with previous speakers' contributions and do not openly confront or challenge them, thereby communicating acceptance, maintaining solidarity, and reducing the potential for disagreement. AA members tell life stories aligned with AA principles, which supports the development of shared identities characterized by dependence on AA and relevance to the 12 steps (39).

The emphasis on spirituality is a key aspect of the goal direction in 12-step SHGs. In this sense, AA can be seen as a spiritual recovery movement that rewards compliance with its norms by engaging individuals in a social system that promotes new meaning in their lives. According to Zemore (40), increases in patients' 12-step involvement from baseline to a 1-year follow-up predicted a higher likelihood of abstinence at follow-up. This relationship was partially explained by an increase in religious practices and spirituality, indicating that spiritual change may contribute to recovery within the context of SHG involvement.

REWARDING ACTIVITIES

Another active ingredient of SHGs involves their role in engaging members in rewarding substance-free social pursuits. Members who are more involved in group meetings and related activities, such as doing service and becoming a sponsor, are

more likely to achieve and maintain abstinence. Involvement in community groups predicted 1-year abstinence among drug-dependent individuals independent of attendance at AA/NA and being a sponsor. Adolescents may also benefit from the substance-free and sober social events and activities and avoidance of high-risk social situations associated with SHGs. By helping their members become more socially integrated, SHGs increase the likelihood of sustained abstinence.

SHGs also provide members an opportunity to help other individuals in need through service at meetings and other pro-social and altruistic behaviors. Recovering individuals who become sponsors or are otherwise engaged in helping other alcoholic individuals are less likely to relapse and tend to experience fewer depressive symptoms. Similarly, compared to DTR members who were less involved in sharing at meetings and helping other members, those who were more involved in these activities were more likely to remain abstinent (30). The type of helping that occurs in SHGs, which includes personal contact with peers who have similar problems, may be especially beneficial in that it enhances the helper's social status, social bonding, and sense of purpose (41).

SELF-EFFICACY AND COPING SKILLS

Affiliation with AA tends to be associated with increases in members' motivation for abstinence and self-efficacy to avoid drinking. Findings from Project MATCH showed that self-efficacy predicted a higher likelihood of abstinence and explained part of the association between participation in AA and abstinence. In addition, AA attendance at 6 months posttreatment predicted self-efficacy at 9 months, which predicted abstinence at 15 months. Self-efficacy to avoid drinking explained part of the effect of AA attendance on abstinence for both less severe (Type A) and more severe (Type B) alcoholic individuals (42).

A study that assessed patients in 12-step treatment during treatment and at 1- and 6-month follow-ups focused on several common change factors, including commitment to abstinence, self-efficacy, and active cognitive and behavioral coping. More affiliation with AA in the month after treatment was associated with increases in these change factors and with better 1- and 6-month substance use outcomes. These common change factors appeared to explain all of the effect of AA affiliation on 6-month substance use outcomes (43).

As noted earlier, individuals who are more involved in 12-step groups tend to rely more on approach and less on avoidance coping. According to Humphreys and coworkers (38), approach coping responses explained part of the effect of involvement in SHGs on the reduction of substance use. Affiliation with SHGs also promotes more reliance on coping skills directed toward reducing substance use. The active ingredients of SHGs that foster improvement in coping skills likely include modeling of substance use refusal skills, ideas about how to manage relapse-inducing situations, and practical advice for coping with craving.

These effective ingredients of SHGs reflect four critical factors that aid long-term recovery of SUDs: (1) forming

bonds and obtaining social support from new relationships and role models, such as a new spouse/partner, friend, or sponsor; (2) supervision or monitoring, such as by a sponsor or spouse/partner, and the provision of positive consequences for continued remission; (3) involvement in rewarding activities that do not involve substance use, such as a program of exercise, spiritual or religious pursuits, or social and service activities that include helping other people; and (4) affiliation with a group that provides a sustained source of hope and self-confidence.

FACILITATING PARTICIPATION IN SELF-HELP GROUPS

In general, individuals participate much longer and more intensively in SHGs than they do in treatment. Many individuals with SUDs depend more on SHGs than on treatment as their dominant resource, probably because SHG meetings are accessible and free, entry is easy, and rewarding long-term social networks are likely to develop. However, there are many obstacles to participation, including lack of motivation and perceived need for help, and dropout rates may approach 75% in 12 months. Accordingly, treatment providers need to strengthen their efforts to help patients engage in these groups.

Relatively few patients begin SHG attendance after treatment; thus, participation should be initiated during treatment to maximize the likelihood that it will persist after treatment. Some useful ways for treatment staff to strengthen the SHG referral process include providing an introduction to a sponsor or recovery guide, addressing potential barriers such as lack of transportation and child care services, and maintaining contact to enhance continuing attendance. For example, when counselors educate patients about 12-step concepts during treatment and provide access to meetings and well-functioning role models who are in recovery, patients tend to find 12-step SHGs more palatable and to increase their involvement in 12-step activities.

12-STEP AND SOCIAL NETWORK TREATMENT

Treatment oriented toward 12-step principles increases the likelihood that an individual will participate and affiliate with 12-step SHGs. More specifically, 12-step facilitation treatment effectively promotes participation in 12-step SHGs among both alcohol- and drug-dependent clients (44). Adaptations of 12-step treatment have been developed for patients with substance use problems seen in nonspecialty care settings (45) and for patients with substance use and other psychiatric disorders. An adaptation for dual diagnosis patients that includes medication compliance and social skills, on-site DTR groups, and case managers who help patients find and attend meetings, appears to be successful in increasing 12-step SHG participation (46).

A socially focused treatment that tries to shape a patient's social network to reinforce sobriety in part by emphasizing the importance of AA can also increase participation in AA.

According to Litt and colleagues (47), network support treatment successfully enhanced patients' involvement in AA, increased the proportion of abstinent individuals in patients' social networks, and strengthened the extent to which the social network encouraged abstinence. For individuals who are disinclined to engage fully in treatment, intensive case management may be another way to enhance participation in treatment and in SHGs.

BRIEFER INTERVENTIONS

There also are brief interventions, such as motivational interviews, that appear to help get patients engaged in SHGs. Clients who receive motivational enhancement interventions are more likely to participate in 12-step SHG meetings than do clients in usual care. However, Kahler and colleagues (48) found that a 1-hour motivational enhancement intervention was more effective than a 5-minute brief advice condition, but only for patients with relatively little prior self-help participation. Motivational enhancement involves discussing both the perceived costs and benefits of 12-step SHG involvement and, in so doing, may engender an increase in ambivalence for some patients who are strongly committed to attending AA/NA.

Timko and DeBenedetti (49) designed a three-session intensive referral condition for patients entering outpatient SUD treatment. Counselors gave patients a schedule of SHG meetings, encouraged patients to join a group, work the first steps, and obtain a sponsor; arranged AA/NA members to escort patients to meetings, made contracts with patients to attend meetings, and followed-up by checking with patients about whether they had attended meetings and obtained a sponsor. Compared to patients in a standard referral condition, patients in the intensive referral condition were more likely to attend 12-step SHG meetings, read 12-step literature, provide service during a meeting, consider themselves to be a 12-step group member, celebrate a 12-step birthday, and have a sponsor.

Similarly, in a study of adolescent SUD programs, clinicians from sites at which clients had high SHG attendance rates were more likely to have used active strategies to connect youth with SHGs. These clinicians monitored clients' meeting attendance, prescreened sponsors, and taught clients how to find an appropriate sponsor. They also often worked with local members of AA or NA to conduct meetings at the treatment site; members helped clients find sponsors, arranged transportation to meetings, and linked adolescents to sober social activities within the recovery community (50).

CONCLUSIONS

A high priority for future research is to specify the characteristics of individuals who are most likely to benefit from SHGs and to consider the benefits and barriers to joining SHGs and beliefs associated with participation. We also need more information about the optimal duration and frequency of

participation for individuals who vary in the severity of their disorder and level of personal and social resources. Other issues to address include identifying personal and contextual predictors of dropout and of the duration of participation, and developing an integrative model of the role of SHGs and other life context factors as joint influences in the course of relapse and remission.

Most generally, the finding that a longer duration of participation in SHGs predicts better substance use outcomes indicates that SHGs are most beneficial when they become an ongoing supportive aspect of individuals' lives. Extended 12-step group engagement may initiate and maintain the personal and social changes needed to solidify stable remission, especially abstinence-specific and general support, goal direction and structure, involvement in rewarding substance-free activities, and enhanced self-efficacy and coping skills. SHGs represent an important part of the array of effective interventions that can change the enduring aspects of individuals' life contexts and increase the likelihood of a long-term course of recovery.

Key Points

1. Sustained attendance at SHGs is associated with a higher likelihood of abstinence and better substance use outcomes.
2. Involvement in SHGs may accrue benefits over and above those of attendance itself.
3. Delay in participation and dropout from SHGs foreshadows poorer substance use outcomes.
4. Participation in SHGs can substitute for, bolster, and help to explain the benefits of treatment; it can also reduce health care utilization and costs.
5. Less religious individuals appear to benefit from SHGs as much as do individuals who are more religious.
6. In general, expect for individuals with psychotic disorders, individuals with both substance use and psychiatric disorders appear to attend and benefit from substance-use-focused 12-step SHGs as much as do individuals with only SUDs.
7. Women with alcohol or drug use disorders are at least as likely as are men to attend SHGs and to benefit from them.
8. Many adolescents with SUDs attend SHGs after treatment and those who do tend to experience better substance use outcomes.
9. SHGs contribute to better substance use outcomes by providing support, goal direction and structure; exposure to abstinent role models, rewarding substance-free activities, and a focus for building self-confidence and coping skills.

Arthur T. Horvath

INTRODUCTION

This chapter overviews five support groups for addictive behavior. These groups are in many aspects fundamentally different from and hence alternatives to 12-step groups such as Alcoholics Anonymous (AA; which is discussed in Chapter 37). In order of longevity these groups are Women for Sobriety (WFS), Secular Organizations for Sobriety/Save Our Selves (SOS), Moderation Management (MM), SMART Recovery (SMART), and LifeRing Secular Recovery (LifeRing). They appear to comprise, as of 2009, the complete list of widely available non-12-step and nonreligious addiction support groups. This chapter is oriented toward providing information that would help professionals and their patients identify whether alternatives in general, and which alternatives in particular, might be helpful for a particular patient.

Groups not covered in this chapter are those with a religious orientation (e.g., Overcomers Outreach; Overcomers in Christ; the Calix Society; Jewish Alcoholics, Chemically Dependent Persons, and Significant Others), those which offer only a small number of meetings (e.g., Men for Sobriety), and Rational Recovery (RR), which as of January 2000, no longer offers support groups.

HISTORY OF ALTERNATIVE SUPPORT GROUPS

The modern alternatives to 12-step groups are relatively young and unknown. AA, the original 12-step group, began in 1935. The oldest of the alternatives, WFS, began in 1976. Despite the continued predominance of 12-step groups in the United States, the alternatives appear slowly to be gaining recognition. Where available, they have become valuable options for professionals and their patients to consider in treatment planning.

Although these alternatives arose in response to the perceived mismatch between some individuals and 12-step groups, the alternatives nevertheless have significant similarities with 12-step groups. All 12-step and alternative groups are without substantial empirical support of effectiveness. All offer 60- to 90-minute meetings at no charge but request donations. All are essentially self-supporting, primarily through member donations and the sale of recovery materials (including newsletters, books, workbooks, audio- and videotapes, and software, some of which may be produced by lay individuals or professionals not directly affiliated with the organization). All have recommended reading lists. All have an extensive

official and/or unofficial Internet presence. This presence evolves as Internet communication evolves, and currently includes online meetings (text and/or voice), listserves, message boards, blogs, and chat rooms. All (except MM) are abstinence-oriented. All (except SMART and LifeRing) were founded by an individual who had a new perspective about recovery from addictive behavior. All are nonprofit corporations.

Nevertheless, the programmatic and organizational differences between these alternatives and 12-step groups are substantial and numerous. None emphasize reliance on a “higher power” for recovery. On the other hand, none are opposed to religious or spiritual beliefs in their members. None offer formal sponsorship of new members by experienced members. All are supportive, both in principle and in practice, of appropriate professional treatment for addictive behavior. None expect members to attend for life, but rather to attend for as long as (or whenever) it is helpful. Typical attendance during the period of active involvement is one to three meetings per week, but there are few guidelines about frequency of attendance (vs. AA’s “90 meetings in 90 days”). All apparently appeal primarily to higher-functioning individuals (although this may be an artifact of the effort often required to locate these alternatives). All are accepting, both in principle and in practice, of individuals with neurotic (but not necessarily psychotic) comorbidity, and all encourage professional treatment of these conditions. All are flexible in the application of their program principles to the individual case. All are supportive of 12-step groups for individuals who benefit from them. All suggest that some individuals may be impeded in their recovery by 12-step groups, or benefit more from alternative groups, or both. All are very small (in comparison to AA’s more than approximately 100,000 meetings worldwide). All operate on very limited budgets. All appear to be evolving more rapidly than 12-step groups.

The differences between 12-step groups and alternatives with respect to meetings and meeting leaders are also substantial and numerous. All groups typically devote major portions of their meetings to discussion (“cross talk”). None have speaker meetings (although their leaders may give separate public presentations). All have, or prefer to have, small meetings (approximately 6 to 12 members), to allow ample opportunity for individual participation. All have meeting formats, but tolerate (or even encourage) significant variation based on local custom or preference. None have extensive meeting rituals. All are led by a facilitator who guides the discussion. The facilitator is typically a peer, and a member of the group’s

recovery program (but a significant minority of facilitators in some alternatives are behavioral health professionals). Because of the responsibility involved in being a facilitator, all appear to experience difficulty finding facilitators. Because of the lack of a lifetime membership requirement, all experience difficulty retaining facilitators. All aspire to international availability, as qualified facilitators can be identified.

The five alternatives differ from one another primarily on their view of addiction as a disease. WFS takes a disease approach. SOS and LifeRing leave this issue up to the individual, but emphasize physiologic aspects of addiction more than psychological ones. MM views addictive behavior as a learned maladaptive behavior, not a disease. SMART originally also viewed addiction as a learned maladaptive behavior, but in 2008 changed to accepting belief in addiction as a disease (or not) as a personal belief of the participant.

Contact information for each organization is included in Box 38.1, which also includes the American Self-Help Clearinghouse. This clearinghouse maintains a searchable database of over 1100 national, international, model, and online support groups, some of them for addictive behavior, and a database of local support group clearinghouses. These databases can be used to locate specialized support groups for various faiths, occupations, and addictive behaviors.

DESCRIPTION OF EACH ALTERNATIVE SUPPORT GROUP

Women for Sobriety

History

WFS was founded in 1976 by Jean Kirkpatrick, PhD, to address the unique problems of women alcoholics. She sug-

gested that these problems include self-value, self-worth, guilt, and humiliation. Kirkpatrick's own experience was that AA was only partially helpful to her as a woman alcoholic.

Despite professional treatment and AA attendance, Kirkpatrick had a 30-year drinking history, including hospital and mental hospital admissions, hit-and-run accidents (during blackouts), and jail time. She had recurring episodes of depression and attempted suicide several times. She nevertheless earned a doctorate in sociology from the University of Pennsylvania by age 50. She died in June 2000, at the age of 77.

Kirkpatrick's AA experience was one that she believes is typical for women. The recounting of the harm caused by drinking seemed to be good for men in AA and reminded them of their reasons not to relapse. For her, however, recounting painful and often humiliating past drinking experiences seemed to make even more difficult the task of accepting herself and gaining mastery of her life. Additionally, AA did not address how societal views of women (vs. men) alcoholics posed additional challenges for recovering women.

Program

WFS has two primary publications (1,2). The WFS newsletter is *Sobering Thoughts*. WFS is intended for women alcoholics (including those who also have prescription medication problems). Kirkpatrick suggested that for some women AA may be more effective at achieving initial sobriety, because initially a woman may be overwhelmed by the complexity of the WFS program. After several months of abstinence, however, most women are believed to be ready to appreciate the idea that women need a different approach to recovery.

Kirkpatrick was ultimately able to stop drinking in her early 50s by relying on the philosophies of the Unity Church,

Box 38.2 The WFS “New Life” acceptance program

Level I: Accepting alcoholism as a physical disease.

“I have a life-threatening (drinking) problem that once had me.”

Level II: Discarding negative thoughts, putting guilt behind, and practicing new ways of viewing and solving problems.

“Negative thoughts destroy only myself.”

“Problems bother me only to the degree I permit them to.”

“The past is gone forever.”

Level III: Creating and practicing a new self-image.

“I am what I think.”

“I am a competent woman and have much to give life.”

Level IV: Using new attitudes to enforce new behavior patterns.

“Happiness is a habit I will develop.”

“Life can be ordinary or it can be great.”

“Enthusiasm is my daily exercise.”

Level V: Improving relationships as a result of our feelings about self.

“Love can change the course of my world.”

“All love given returns.”

Level VI: Recognizing life’s priorities: emotional and spiritual growth, self-responsibility.

“The fundamental object of life is emotional and spiritual growth.”

“I am responsible for myself and my actions.”

From Kirkpatrick J. *WFS “New Life” Acceptance Program* [brochure]. Quakertown, PA: Women for Sobriety, 1993, with permission. Copyright Jean Kirkpatrick, 1993.

Emerson, and Thoreau. Several years after achieving sobriety, she formulated the principles of WFS, based in part on these philosophies. She also included in WFS cognitive-behavioral change techniques, and an emphasis on health promotion and peer support.

WFS views alcoholism as a physical disease that a woman can grow beyond by learning new self-enhancing behavior via:

1. Positive reinforcement (approval and encouragement)
2. Cognitive strategies (positive thinking)
3. Letting the body help (relaxation techniques, meditation, diet, and physical exercise)
4. Dynamic group involvement.

Box 38.2 presents the WFS “New Life” Acceptance Program.

Meeting Format

WFS meetings are led by a Certified Moderator. Certification is based on having at least 1 year of continuous sobriety, reading *Turnabout* (1), subscribing to the WFS newsletter, and passing a written test about WFS principles and their application in meetings. WFS instituted certification to assure that moderators with a history of AA attendance understood the differences between WFS and AA principles and meeting formats.

Meetings are open to all women alcoholics. Newcomers are given a packet of introductory information. Meetings begin with a reading of the Statement of Purpose, followed by introductions (“Hello, my name is Jean, and I’m a competent woman”). Most of the meeting is devoted to discussion of member’s concerns, and how the “New Life” Acceptance Program (see Box 38.2) can be applied to them. Following discussion each member is asked to describe something positive she has accomplished in the past week.

The meeting closes with the members standing, holding hands, and saying: “We are capable and competent, caring

and compassionate, always willing to help another, bonded together in overcoming our addictions.”

Secular Organizations for Sobriety/Save Our Selves

History

Secular Organizations for Sobriety/Save Our Selves (SOS) was established in 1985 by Jim Christopher, in Hollywood, CA. Christopher had been sober since 1978, initially using AA. He separated from AA early in his recovery, because he wanted an approach that was based on personal responsibility rather than reliance on a higher power. In 1985, he wrote “Sobriety without Superstition” for *Free Inquiry*, a leading U.S. secular humanist journal. Because of the strong positive response to the article he founded SOS.

Program

SOS has two primary publications (3,4), and publishes the *SOS International Newsletter*. Originally intended for alcoholics, SOS has been extended to the full range of addictive behavior (both substance and activity addictions), and in some cases to family members as well. SOS is for individuals who desire recovery but are uncomfortable with the spiritual content of 12-step groups and would prefer a personal responsibility approach. Specialized groups for family members, youth, or youth in dysfunctional families are also allowed. The only requirements of an SOS meeting are that it be secular and promote total abstinence.

SOS views the cycle of addiction as having three elements: physiologic need for the substance, the learned habit of using and all the associations to using, and the denial of both the need and the habit. Over time the addiction becomes the highest priority, and it begins to destroy the rest of life. However, the cycle of addiction can be replaced by the cycle of

Box 38.3 Suggested guidelines for sobriety of SOS

1. To break the cycle of denial and achieve sobriety, we first acknowledge that we are alcoholics or addicts.
2. We reaffirm this truth daily and accept without reservation the fact that, as clean and sober individuals, we cannot and do not drink or use, no matter what.
3. Since drinking or using is not an option for us, we take whatever steps are necessary to continue our Sobriety Priority lifelong.
4. A quality of life—“the good life”—can be achieved. However, life is also filled with uncertainties. Therefore, we do not drink or use regardless of feelings, circumstances, or conflicts.
5. We share in confidence with each other our thoughts and feelings as sober, clean individuals.
6. Sobriety is our priority, and we are each responsible for our lives and our sobriety.

sobriety: acknowledgement of the addiction, acceptance of the disease or habit, and making sobriety the highest priority in life (the “Sobriety Priority”). The Sobriety Priority is a cognitive strategy to be applied daily, to weaken associations to using, and to allow new associations to develop. SOS accepts that participants may use a wide variety of techniques or approaches in recovery. SOS emphasizes that it concerns itself only with helping participants accomplish the Sobriety Priority, and not with transforming the rest of life. With sobriety secured, participants are in a much better position to grow as individuals, but this remains a personal matter. Box 38.3 reproduces the Suggested Guidelines for Sobriety.

Meeting Format

The suggested meeting format includes an opening statement summarizing the purpose of the meeting, announcements (e.g., the availability of new literature), anniversaries (of sobriety), the reading of the Suggested Guidelines for Sobriety, and introductions of all present. The meeting proper is next (“This meeting is now open. We ask that you try to keep your sharing to a reasonable length of time so that everyone can participate.”). The closing includes passing the hat, and a ritual (“Let’s close by giving ourselves a hand for being here to support and celebrate each other’s sobriety.”)

The members of each SOS group are allowed to create a meeting structure that meets their needs. Most SOS meetings have an active exchange of information, experiences, and ideas.

Moderation Management

History

MM was founded in 1993 by Audrey Kishline to support individuals who desire to moderate their alcohol consumption. Her own experience had been that it was difficult to obtain support for this goal.

During her 20s, Kishline’s drinking increased to the level of a moderate problem. She eventually sought treatment. Ultimately, this treatment included two inpatient stays, an after-care program, and consultation with at least 30 alcoholism treatment professionals, all of whom diagnosed her as “alcoholic.” She also attended AA regularly for several years, attending hundreds of meetings. Her initial reaction to treat-

ment was that her drinking became more severe. She suggested that at least in part this increase was a self-fulfilling prophecy based on what she had learned about alcoholism as a disease over which she was powerless. She also suggested that over several years she gradually matured out of her drinking problem, as she became more involved in the responsibilities and activities of life (e.g., marriage, children, homemaking, college courses, hobbies, and friends). As this maturing occurred, her beliefs about herself also evolved. Rather than believing herself to have a disease, she chose to abstain because of the kind of life she wanted to lead.

Several years prior to writing her 1994 book (5), Kishline chose to return to moderate drinking. She asserted that she was misdiagnosed initially, and that moderation of her alcohol consumption had been overlooked as an option for her. She founded MM in the hope that the moderation option would not be overlooked for others in similar situations.

Kishline had a drunk driving crash on March 25, 2000, in which she killed two passengers in an oncoming car. A fact left out of many media reports was that at the time of the crash Kishline had stopped attending MM and had been attending AA for about 2 months. It would not appear to be reasonable to blame either AA or MM for her behavior.

Program

MM originally had one primary publication (5), but switched to another (6). MM is intended for individuals who fit the description “problem drinker” rather than “alcoholic.” There are two fundamental requirements for membership: a willingness to accept responsibility for one’s own behavior and a desire to moderate (or stop) drinking. MM is not aimed at individuals who have experienced significant withdrawal symptoms from alcohol, who have medical conditions exacerbated by alcohol (e.g., heart disease, diabetes, gastrointestinal problems, and so on), or who are experiencing other relevant conditions including pregnancy or desired pregnancy, a behavioral health disorder, being on medications that interact negatively with alcohol, or being in personal crisis. Lastly, MM is not designed for individuals who are already abstaining successfully after a history of severe dependence.

MM recommends that as early as possible in their MM involvement members abstain for 30 days, during which time they examine how drinking has affected their lives, write

down their life priorities, consider the quantity, frequency, and circumstances of their past drinking, and learn the moderation guidelines MM suggests. Members might also complete the Drinker's Checkup, a free interactive program available on the MM website, or the Short Alcohol Dependence Data Questionnaire (SADD) (7), also available on the MM website. On the SADD scores from 1 to 9 suggest low dependence on alcohol, 10 to 19 medium dependence, and 20 or higher (maximum score 45) high dependence. Individuals who score below 16 are considered good candidates for MM. Those who score between 16 and 19 are encouraged to obtain professional assessment before attending a moderation program. Individuals who score 20 and above are encouraged to pursue abstinence. Even individuals with low scores are not discouraged from pursuing abstinence, but are offered the alternative of MM as a means to abstain.

MM hopes to reach problem drinkers early in their problem drinking career by offering an approach that appeals to common sense and does not require excessive effort (relative to the intensity of the problem). MM is therefore partly a prevention program (see Section 8). If an individual is not successful following MM's moderation guidelines, the individual is encouraged to pursue abstinence.

MM views drinking problems as arising from bad habits, rather than being the manifestations of a disease. MM is based on empirically supported cognitive-behavioral moderation training (see Chapter 44). Box 38.4 reprints the nine steps of MM. MM suggests that 6 to 18 months of once-weekly attendance is usually needed for successful completion of its program.

MM understands moderate drinking to be (for men) no more than 4 standard drinks per day, no more than 4 drinking days per week, and no more than 14 standard drinks per week. A standard drink is the amount of alcohol in a 12-ounce bottle of beer, a 5-ounce glass of wine, or a 1.5-ounce shot of liquor, all of which, because of differing concentrations, have approximately equal amounts of pure alcohol. For women, moderate drinking is understood to be no more than 3 standard drinks per day, no more than 4 drinking days per week, and no more than 9 standard drinks per week. Both sexes are encouraged not to drink and drive, or to drink in situations where the drinker or others might be endangered.

Meeting Format

Meetings are led by a moderator, and begin with the reading of an opening statement describing the purpose of MM, followed by a reading of the nine steps (see Box 38.4) and ground rules for members. Visitors (the meetings are open) and newcomers are invited to introduce themselves. Anyone who recently completed the recommended initial 30 days of abstinence is acknowledged.

The first working section of the meeting is devoted to giving every member the opportunity to update the group on the member's activities since the member's last meeting. Feedback by others may be offered. The next working section is general discussion. If no one has a topic to discuss, the moderator suggests one, which would typically be one of the ideas or techniques covered in the MM book. The meeting ends with the reading of a closing statement.

Smart Recovery

History

SMART (Self-Management and Recovery Training) incorporated as a nonprofit organization in 1992 under the name Rational Recovery Self-Help Network. The organization entered into an agreement with Jack Trimpey, the founder and owner of Rational Recovery Systems, to use the name Rational Recovery and to operate Rational Recovery support groups. The board of directors, of which Trimpey was a member, had evolved from an informal group of advisors, mostly mental health professionals, that Trimpey had assembled for an initial meeting in 1991. Trimpey took the leading role in establishing and incorporating the organization.

Beginning about 1993 there was increasing disagreement between Trimpey and the organization about how the organization would be managed, and the nature of its program. These developments culminated in 1994 with the mutual agreement between Trimpey and the organization to separate. This separation was accomplished by changing the organization's name. Individual support groups made their own decisions about which affiliation to maintain. As of 2000, RR groups have ceased altogether.

Box 38.4 The nine steps of MM

1. Attend meetings and learn about the program of MM.
2. Abstain from alcoholic beverages for 30 days and complete steps three through six at this time.
3. Examine how drinking has affected your life.
4. Write down your priorities.
5. Take a look at how much, how often, and under what circumstances you used to drink.
6. Learn the MM guidelines and limits for moderate drinking.
7. Set moderate drinking limits and start weekly "small steps" toward positive lifestyle changes.
8. Review your progress at meetings and update your goals.
9. After achieving your goal of moderation, attend MM meetings any time you feel the need for support, or would like to help newcomers.

From Kishline A. *Moderate Drinking: The Moderation Management Guide for People Who Want to Reduce Their Drinking*. New York, NY: Crown; 1995, with permission. Copyright Audrey Kishline, 1994.

Box 38.5 SMART Recovery purposes and methods

1. We help individuals gain independence from addictive behavior.
2. We teach how to:
 - Enhance and maintain motivation to abstain
 - Cope with urges
 - Manage thoughts, feelings, and behavior
 - Balance momentary and enduring satisfactions.
3. Our efforts are based on scientific knowledge, and evolve as scientific knowledge evolves.
4. Individuals who have gained independence from addictive behavior are invited to stay involved with us, enhance their gains, and help others.

Reprinted with permission of SMART Recovery. Copyright SMART Recovery, 1996.

Program

SMART has two primary publications (8,9) and extensive training materials for meeting facilitators. The SMART newsletter is *SMART Recovery: News and View*. There is a specialized application for SMART in correctional facilities, the InsideOut program (10), which was developed on a grant from the National Institute on Drug Abuse. The InsideOut program includes a facilitator manual and videotape, participant workbook, and male and female participant videotapes. SMART is intended for individuals who desire to abstain from any addictive behavior (substance or activity), or who are considering abstinence. SMART assumes that there are degrees of addictive behavior, and that all individuals to some degree experience it. Individuals for whom the negative consequences of addictive behavior have become substantial are the ones likely to be considering or desiring abstinence.

The SMART program is consistent with a cognitive-behavioral perspective, which does not require a belief in addiction as a disease. However, just as participants are free to have any conception (or not) of a higher power, they are similarly free to have any understanding of addiction as a disease. Box 38.5 reprints the SMART purposes and methods statement.

There are four primary goals for an individual in the SMART program: motivational maintenance and enhancement, effective urge coping, rational thinking (leading to effective emotional and behavioral management), and lifestyle balance. In service of these goals, many cognitive-behavioral and other psychological techniques are taught. With respect to changing addictive behavior itself, the program draws from established references of the cognitive-behavioral approach (11). Self-help literature on addictive behavior (12–14), as well as cognitive-behavioral self-help literature on a broad range of topics, including mood management, assertiveness training, relationships, effective communication, and stress management, is also recommended (15), and techniques derived from this literature are incorporated into the SMART program. Consistent with SMART's previous affiliation with RR, as well as its cognitive-behavioral orientation, Rational Emotive Behavior Therapy (REBT) techniques and terms (16) are a prominent but not an essential aspect of the SMART program.

Meeting Format

Meetings are open unless closed by local custom. Meetings begin with an opening statement by the facilitator. The statement describes the four primary goals of the SMART program, and outlines the meeting to follow. Participants check in and establish an agenda for who will be the primary focuses of the discussion. The major portion of the meeting follows, consisting of discussion guided by the facilitator on the four primary goals of the SMART program, and the Tools SMART continues to evolve to accomplish these goals, as they apply to the individual situations discussed. One of the principal approaches is to consider “activating events” volunteered by the members. Activating events can include urges, life circumstance changes, thoughts, social interactions, or other experiences that lead or potentially lead to undesired emotions or behavior, including addictive behavior. Activating events are typically analyzed using Ellis' ABCDE method (16). The Disputation step, in which irrational ideas are disputed, can draw upon the entire range of scientific knowledge about addictive behavior. After passing the hat for donations, the formal meeting concludes with a check out, possibly to include each participant proposing a personal homework project, which would put into action the ideas or techniques from the meeting that have been significant for that participant.

LifeRing Secular Recovery

History

LifeRing Secular Recovery (LifeRing) began as the Northern California set of SOS meetings. In 1999, a federal court ruling prohibited SOS from using that name in Northern California. Representatives of the Northern California meetings, on May 23, 1999, adopted the name LifeRing Secular Recovery. During 2000, LifeRing emerged as an organization independent of SOS. A constitutional congress ratified bylaws on February 17, 2001. Some former SOS meetings from outside of Northern California are now affiliated with LifeRing.

Program

LifeRing has two primary publications (17,18). One LifeRing motto is “empower your sober self.” LifeRing views the addicted individual as a person in conflict between an “addict self” and “sober selves.” Recovery is the process of reinforcing

and building connections between the sober selves until they merge into a resilient and predominating sober self. Each participant is encouraged to develop a Personal Recovery Program.

LifeRing uses the “Three-S” philosophy of Sobriety, Secularity, and Self-Help. Sobriety is understood as complete abstinence from alcohol and other drugs. Another LifeRing motto is “we do not drink or use, no matter what.” LifeRing welcomes participants of any religious belief or none. Religious or spiritual beliefs are not part of the LifeRing program (Secularity), which focuses on enhancing human effort to overcome addiction. LifeRing meetings focus on reinforcing the participant’s striving to maintain sobriety. Individual motivation and effort are understood as the foundations of change of change (Self-Help).

The LifeRing program suggests that there are as many ways to get sober as there are individuals. No one approach will work for all. A successful recovery plan probably involves some learning by experimentation. Therefore, the LifeRing publications emphasize a wide range of tools, including changing one’s self-image, understanding the effects of substances, eating well, exercising, and recalling the bad effects of one’s use, etc.

Meeting Format

Box 38.6 reprints the suggested opening statement for meetings. Meeting facilitators are termed convenors. Convenors are normally required to have 6 months of recovery. Meetings typically focus on answering the question “how was your week?” Convenors aim to foster a discussion that is informal, supportive, and conversational. The discussion focuses on the challenges to recovery the participants have faced in the previous week, and the ones they expect to face in the upcoming week.

EVIDENCE OF EFFICACY

With respect to experimental evidence of efficacy, alternatives and 12-step groups are similar. Although the 12-step literature is substantially larger, neither has definitive evidence of efficacy. However, the ultimate justification of a support group will not be established by an efficacy study. Millions have attended 12-step groups despite their lack of evidence of efficacy. Although alternatives have lower attendance, they continue to exist, in one instance for more than 30 years. Support groups exist because recovering individuals choose to attend them.

An unfortunate aspect of alternatives is the failure of many professionals to educate patients about their existence. Evidence is emerging about how many professionals exhibit this failing (19), despite numerous calls for both professionals and nonprofessionals to adopt a broader perspective on recovery (20–22).

The majority of the evidence about alternatives addresses the issues of who might differentially benefit from one support group versus another, and who attends these groups. Penn (23) found comparable outcomes for participants in a 12-step or SMART-oriented day-treatment program for the addicted mentally ill. The investigators needed to make the 12-step arm of the study more client-centered (as SMART already is), in order to reduce the subject dropout rate. Atkins (24) found that although participation in any support group is related to good recovery outcomes, subjects whose individual beliefs better matched the support group had greater levels of participation and better outcomes. Nonreligious subjects were less likely to participate in 12-step groups. Religious respondents were less likely to participate in SOS. Religiosity had little impact on SMART Recovery participation.

Box 38.6 LifeRing opening statement for meetings

Opening statement

This is a regular open meeting of LifeRing Secular Recovery. LifeRing is a self-help support group for all people who want to get and stay clean and sober. We feel that in order to remain in recovery, we have to make sobriety the top priority in our lives. By sobriety, we mean complete abstinence from alcohol and other addictive drugs. Out of respect for people of all faiths and none, we conduct our meetings in a secular way, which means that, during this hour we do not use prayer or talk about religion. We rely in our recovery on our own efforts and on the help of the group members and other friends. Everything that we share at this meeting is completely confidential and stays in this room. If you are under the influence of alcohol or drugs now, we ask that you maintain silence at this meeting. You may speak with members afterward.

The meeting format is flexible. We generally begin by checking in and talking about the highlights and heartaches of our past week in recovery, and what we plan to do to stay clean and sober in the coming week. We encourage cross talk throughout the meeting. By cross talk we mean questions and positive, supportive feedback. Positive experiences from your own recovery are welcome. Please allow enough time for everyone to participate by limiting your speaking time if necessary. If this is your first time at this meeting of LifeRing—Welcome. Please introduce yourself by your first name. If you would like, tell us how long you have been in recovery and then tell us about your past week and your coming week in recovery. If you would like to know more about the LifeRing approach, we have LifeRing books and handouts available here. Thank you.

Reprinted with permission of LifeRing Secular Recovery.

As to who is attending WFS and why, Kaskutas (25–28) studied women who attended WFS only, or both WFS and AA. Their responses support the suggestion that women may need a different approach to recovery. Women who attended only WFS reported that they did not feel that they fit in at AA, that AA was too negative, that they disliked the “drunkalogues” and the focus on the past, and that AA is better suited to men’s needs than to women’s needs. Women attended WFS for support and nurturance, for a safe environment, for discussion about women’s issues, and for the emphasis on positives and self-esteem. Attending WFS for 1 year was associated with an increase in self-esteem. For women who attended both WFS and AA, insurance against relapse and AA’s availability were frequently cited reasons to attend AA. Respondents were primarily white, educated, middle aged, and middle or upper class. Most had also participated in individual psychotherapy. Kaskutas and colleagues (29,30) have begun to consider how recoveries in both WFS and 12-step groups can be understood from the broader perspectives of world views and spiritual activities. It seems likely that studying WFS participants—and eventually participants in the entire range of alternative support groups—will greatly expand our understanding of the diversity of recovery.

SOS participants are predominantly white, educated, and nontheistic (31). Most have had negative experiences with AA. Connors and Derman (32) found similar demographics, but less negative experience with AA. Both surveys found that SOS involvement was associated with sobriety.

MM participants are white, middle-class, and well-educated. They appreciate the nondisease approach to recovery, and find the emphasis on choice and self-control a better match for their values (33). MM tends to attract more women and younger participants (34). There are mixed findings about level of physical dependence on alcohol (34–36). Individuals who inquire about MM then actually attend MM have more serious alcohol problems than those who simply inquire (35). Perhaps as MM has become better known it has attracted more women and individuals with higher levels of alcohol problems (36).

SMART Recovery participants have a significantly higher level of internal locus of control than do AA members (37). LifeRing presents the results of a membership survey on its website. The membership is comparable to the other alternatives.

HOW ALTERNATIVE SUPPORT GROUPS ARE OPTIMALLY USED?

If an individual has no experience with addictive behavior support groups, sampling all that are available would seem most sensible. Further research may provide guidance regarding the initial matching of individuals to addictive behavior support groups. However, given the general paucity of *treatment* matching findings, we might expect to discover that it is difficult to predict which individuals will do better in which support groups. The wisest course of action in practice, until clear findings suggest otherwise, would appear to

be encouraging patients to sample the available support groups and make their own choices.

If an individual has no strong preferences, 12-step groups would seem more desirable than the alternatives simply because of their availability and size (which increase the likelihood that suitable models of success would be identified). If alternatives are preferred, and more than one is reasonably proximate and not inappropriate for one’s gender (WFS) or goal (MM), on what basis might one be selected over another? Although the information provided here may be helpful, probably the best test of compatibility is the individual’s reaction to each available meeting. Because the quality of these meetings is quite dependent on the style and ability of the facilitator, it seems likely that the group environment the facilitator engenders may be a larger factor in the desirability of an individual meeting than the organization’s official program or meeting format. Consequently, where more than one alternative is available, an individual might attend selected meetings of each. Just as there is presumably a high degree of variability in the helpfulness of 12-step sponsors, there is presumably a high degree of variability in the helpfulness of the individual meetings of alternative support groups.

Excellent advice has been offered on how to integrate mental health treatment with 12-step attendance (20). This advice is needed because of the apparent contradictions between these two perspectives. There appear to be far fewer of such contradictions for the individual attending an alternative. Similarly, because alternatives, like mental health treatment, tend to emphasize self-empowerment, and 12-step groups tend to emphasize powerlessness, contradictions are also likely to arise if the individual attends both alternative and 12-step groups and/or treatment. However, many individuals are able to look past these contradictions and experience benefits from both approaches. Some, for instance, appreciate the social support of 12-step groups (which are also more available), but rely on alternatives for their primary orientation to recovery.

If no suitable group is available, an option for the motivated individual, depending on the desired affiliation, would be to start one’s own group. Given that teaching a subject is often the best way to learn it, this option has much to recommend it. The objection that those in early recovery should be guided by those in long-term recovery overlooks the fact that recoveries without this guidance occur routinely (38,39). If attending or starting a group is not an option, the literature of one or more of these alternatives may by itself be helpful. As previously noted, all the alternatives have extensive Internet presences, which may be of benefit to those who can access them.

SPECIAL CONSIDERATIONS

Not included in this chapter are estimates of the number of groups each organization offers. None of these organizations has a substantial administrative staff. The careful monitoring of currently active meetings is necessarily a low priority, given the challenges faced in disseminating information about the

existence of these organizations. The order of magnitude for the number of each organization's meetings is "hundreds," whereas for AA the order of magnitude is "tens of thousands." Of more significance to the provider or patient is whether there are meetings in the patient's locality.

However, all of these organizations are making increasing use of the communication options the Internet continues to develop. Therefore, the absence of local meetings appears to be a decreasing impediment to active involvement in these organizations for individuals willing to go online. Although meetings-per-week is an obvious metric in the face-to-face world, we need to await the development of widely recognized metrics in the virtual world in order to assess the relative sizes of the online communities each of these organizations is sponsoring. A noteworthy aspect of these virtual communities is that, with the use of screen names, the anonymity in recovery that AA suggested as valuable is now a realistic option.

Serious ethical and legal issues may arise when an individual, for considered and responsible reasons, chooses to pursue an alternative approach to recovery, but a treatment provider or third party insists on 12-step group attendance and/or 12-step-oriented treatment. It would appear to be unethical to insist that an individual use a 12-step approach to recovery if the individual wishes to pursue another approach. However, insistence on a 12-step recovery approach continues to be widespread (19).

If the third party is the government, then a series of U.S. Federal Circuit Court decisions that began in 1996 is relevant. These five decisions (2nd, 3rd, 7th, 8th, and 9th Circuit) have held that government-required 12-step attendance violates the establishment clause of the U.S. Constitution's First Amendment (40). Although the distinction between a religious and spiritual approach is widely made in the 12-step community (with 12-step groups being considered of the latter type), these decisions have held that 12-step groups are religious enough that a citizen cannot be ordered by the government to attend one. The U.S. Supreme Court has already declined to hear an appeal of the decision in the 2nd Circuit. It appears likely that further decisions around this precedent will be in lower courts, perhaps for the purpose of awarding damages. Given the frequency with which judges, probation, and parole officers order individuals in the criminal justice system to "attend AA," the ramifications of these decisions, for alternative support groups in particular and the addiction treatment community in general, are just beginning to be recognized.

CONCLUSIONS

A fundamental conclusion about alternative support groups is that they could be highly valuable resources for many individuals, but awareness of their existence is slight and growing very slowly. This conclusion gives rise to a number of questions. Will enough individuals attend alternatives so that one or more may come to exist as equal members of the recovery community, and not merely as "alternatives?" Will widespread awareness of the existence of alternatives increase the number

of individuals involved in support groups (or recovery or treatment) or will they draw their participants only from those who otherwise would have attended 12-step groups? How much time will be needed before there is widespread awareness of these recovery resources? What are the root causes of the slow growth of awareness about alternatives, and what can be done to address these causes? If awareness continues to grow too slowly, would some form of affirmative action be appropriate, and who would sponsor this affirmative action?

William B. O'Brien ■ J. Gabriel Piedrahita ■ Francisco (Sebastian) P. Bacatan, Jr.

In the presence of fellow therapeutic community residents and guests, a beautiful and confident young lady, a proud Daytop graduate, stood at the podium and related her tragic life journey. Her name was Sheila. This is her story (1):

Sheila's mother was 22 years old, attractive, and naïve. She met a dashing foreign importer from Germany in an eastside restaurant in New York City where she worked as a waitress. They struck up a friendship immediately, which soon developed into a serious relationship. She soon found herself pregnant, the information which she revealed to him on the eve of his return to his homeland. He explained that he had a wife and family back home, that he cared for her and that he would be back to the U.S.

Sheila's mother, now deserted, experienced the loneliness and abandonment that all women in like situations feel, but in addition, she feared her parents' reaction. As the pregnancy progressed, she stayed closer to her apartment in the east Bronx, NY, and away from her parents. The baby (Sheila) was born at New York Lincoln Hospital. No one else was there with this young mother; no one was to know of the birth. Once discharged with her baby, Sheila's mother moved among her Bronx neighbors, all strangers, in her quest to find someone who wanted a baby. Sheila's mother gave her baby away. She, then, returned to her work at the restaurant. The crisis had passed. So did Sheila, into the hands of strangers.

After a few weeks, the grandparents, worried sick over the sudden absence of their daughter, Sheila's mom, traveled from their upstate home in Utica, NY, to her Bronx apartment to ease their fears. They did not find Sheila's mom. She was at work at the restaurant. However, before they left the apartment building, the superintendent's wife informed them of the baby and their daughter's successful efforts to give the child away. Though struggling with the good feelings of a grandchild against the backdrop of a daughter-in-panic giving her child away, they decided to go to the restaurant and confront their daughter. That resulted in an hysterical scene, from which they drew bits and pieces of information: yes, she had a baby girl; not sure of the father; the baby is with an unknown couple not far from her apartment; she cannot recall the street and apartment.

It took the grandparents six weeks to find the couple and their granddaughter, which they swiftly claimed, bringing her with them on their return to Utica, NY. The grandfather, however, had somewhat of a drinking problem, creating not a few heated arguments, leaving Sheila a very uncertain, emotionally damaged girl. Very soon, Sheila became frightened by the grandparents' constant fighting and grandpa's drinking.

At age 9, Sheila's mother reappeared for the first time at the grandparents' home to claim her daughter since she learned that her welfare allotment could be increased. Sheila was, at

first, reluctant to go but eventually was assured by her mother that she loved and wanted her.

Sheila returned to live with her mother from her 9th to 15th year. When she arrived on Daytop's doorstep, Sheila was a devastated young girl using drugs to block out her mom's drinking, her mother's many boyfriends' abuse and sexual advances. By age 15, she had 4 pregnancies, 3 abortions, and a baby boy, all by her mother's boyfriends.

She soon found the Daytop therapeutic community much more than a port in the storm. She grew to trust, to give and receive true love, to respect herself and no longer to feel worthless and cheap. Even her appearance changed from a disheveled young girl to an attractive, sparkling young lady. In Daytop's long journey, few found in Daytop a truer home more than tragic Sheila.

This is one of the sad tales of young people who come to the therapeutic community, wounded, experiencing loneliness and helplessness; who receive assistance in redirecting their lives; and who go through the experience of brokenness, witnessing the death of a loved one, a separation or divorce of one's parents, neglect and companion difficulties, failure in school, domestic violence, sexual abuse, unwanted pregnancies, and abortion. This catalogue of crises and problems seems endless. They speak of poverty, boredom, and broken homes. They describe excitement and comradeship provided by their gangs. One common denominator ran through all these unfortunate stories: drugs.

WHAT IS A THERAPEUTIC COMMUNITY?

The therapeutic community is a drug-free, self-help program, a highly structured, family-like environment where positive peer interaction assumes center stage (2–8). The therapeutic community is different from other drug treatment approaches, mainly in its use of the community as the key agent of change (3,6,9). This approach is referred to as “the community method” (2). The therapeutic community believes that drug abuse is not in itself a disease but merely a manifestation of underlying problems that the addicted need to overcome with the encouraging support of a caring community. The therapeutic community impresses upon the drug abusers that “only you can do it, but you cannot do it alone” (6).

RELIGIOUS ROOTS OF THE THERAPEUTIC COMMUNITY

The root of the term “religion” is the Latin term “ligare,” from which our terms “ligament” and “ligature” arise. Thus, re-ligion means, literally, a reconnection, reunion, reconciliation” (10).

The concept and dynamics of the modern-day therapeutic community can be traced deeply into the past, even as far back as the early intertestamentary communities (11–13). Glaser (11) established the connection between the modern-day therapeutic communities with the early biblical communities and concluded that the therapeutic community has strong religious roots. In the 1947 discovery of the Dead Sea Scrolls, there is a description of Qumran, a community that flourished roughly around 200 BC to AD 50 (14). Some scholars observed that the problems experienced by the members of the Qumran community are somewhat akin to those experienced by the residents of today's therapeutic communities (11; see also 12,13,15).

Glaser (11) indicated one can readily recognize that the problems reflected in the “Rule of the Community” of Qumran were dealt with in a similar way as they are in the modern-day therapeutic community: conforming one's spirit and actions to the dictates of the community. This was accomplished in the Qumran community through mutual criticism, while in the therapeutic community it is achieved through the process of the encounter group. The resemblance between these two (mutual criticism and group encounter) is reflected in this brief excerpt found in the Dead Sea Scrolls:

They shall rebuke one another in truth, humility, and charity. Let no man [*sic*] address his companion in anger, or ill-temper, or obduracy, or envy prompted by the spirit of wickedness. Let him not hate him (because of the wickedness of his uncircumcised heart), but let him rebuke him on the very same day lest he incur guilt because of him. Furthermore, let no man [*sic*] accuse his companion before the congregation without having first admonished him in the presence of witnesses (11).

According to De Leon (2), Glaser (11), and Rom-Rymer (15), another similarity between the Qumran community and the present-day therapeutic community is their strong adherence to the rules and norms of the community. The Dead Sea Scrolls' “Manual of Discipline” has a rule that reads: “You shall reprove your neighbor, lest you bear sin because of him” (16). The Qumran community had a deep awareness of the close involvement they had with each other. If one saw another commit sin and did nothing about it, that person is as guilty of that sin as the person who had committed it (16). In the therapeutic community, members, likewise, have this same awareness of co-responsibility and involvement through the practice of responsible concern by being one's “brother's/sister's keeper.”

Roots in Early Christian Church

Although the link between the Qumran community and Jesus's early community is yet to be established, it is widely assumed that the “beliefs of the inter-testamentary community and those of the Synoptic Gospels stemmed from the same historical period and, perhaps, the same sources” (11). Both communities were intent upon the task of reconnecting themselves to God and neighbor through “full, unreserved,

open confession of fault followed by appropriate restitution or penance” (13). These are central features of the present-day therapeutic community. O. Hobart Mowrer, a noted research psychologist at the University of Illinois, had done extensive research into the linkages between the present-day therapeutic community and the early Christian formulation (11,15,17). He pointed out that early Christianity was essentially a small group movement that celebrated fellowship or “koinonia.” Koinonia is the anglicization of a Greek word (*κοινωνία*) that connotes fellowship, sharing in common, communion, a People of God, and rooted and grounded in love (18). The first mention of koinonia in scriptures is Acts 2:42: “They devoted themselves to the apostles' teaching and to fellowship, to the breaking of bread and to prayer.” Fellowship is a central ingredient of Christian life. Believers in Christ are to come together in love, faith, mutual support, and encouragement. There were no churches or cathedrals, but rather small groups of people meeting in homes (13), most likely in the homes of prominent members of the community (19). It is this element of koinonia that maintains the sense of unity and communion among the diverse Christian groups and their leaders (19,20).

Mowrer (10) explained that it is here, in these small communities, that we find the ancient practice of “exomologesis.” Exomologesis is a Greek word meaning “confession,” joined with publicly manifested repentance (21). The practice of exomologesis perdures in the present-day therapeutic community (17). It demands complete openness about one's life, both past and present, followed by crucial behavioral change, with the avowed support and encouragement from other members of the community (17). Central to the process was the demonstration of public contrition before the entire congregation. Further, “spiritual reinstatement” was achieved by the imposition of a public penance commensurate with the offense (22), pleas for forgiveness along with plans for restitution. The closing phase is celebrated with warm fellowship (koinonia). Mowrer (10) described this process in the early Christian community as a healing experience.

A small-groups movement in which alienated, sinful, “neurotic persons” confessed before their peers while accepting the penance imposed under the guidance of the particular “congregation” (or house church) to which they belonged. From all indications, this ... experience was [found to be] “highly therapeutic” while this early version of Christianity survived and prospered ... because it was redemptive and rehabilitative in an intensely practical [as well as in] psychologically and socially important ways (10).

Scholarly research into the primitive Christian Church of the first four centuries indicates that many of the practices of the first Christian community were conducted with similar intent as that of the present-day therapeutic community (15). It was with the arrival of Constantine the Great (AD 325), ruler of the Roman Empire (12), that the practice of exomologesis began to gradually disappear in favor of a private, “auricular” confession solely to a priest (10), until it was completely abandoned in the 13th century at the Lateran Council in 1215 (23).

The Protestant Reformation in the 16th century (12,20) decided to eliminate the “middle man,” that is, the priest confessor, but as Mowrer (12) argues, the move failed to reestablish exomologesis, the practice of openness, mutual support, and admonition in a small group as practiced in the early church.

However, centuries later, the original healing practice of exomologesis found its way back into self-help groups, namely, the Oxford Group, People of the Way, and Alcoholics Anonymous (11; see also 3,12,13,15), but, most particularly, into the modern therapeutic communities. Exomologesis becomes, then, a characteristic of the therapeutic community to build a “common unity” of purpose and interests toward self-knowledge and growth (koinonia). The healing dimension of this koinonia comes from an aligned relationship that overrides each person’s distorted perception of self and its interactions and fulfills the human yearning for belonging and relevance. Koinonia connotes not only being together but also doing together in a frank, close relationship that overcomes brokenness and divisiveness and so promoting wholeness with self, others, and the environment. Koinonia empowers and renews its members to interact in a beneficial multilevel relationship.

MULTIDIMENSIONAL APPROACH TO HEALING

The basic premise of the therapeutic community is that the person (substance abuse client) “enjoys” a disorder that affects all aspects of his or her life (3). It is a disorder of the whole person (3,4,6,7,24–26). Individual attitudes and behaviors, emotional management, and one’s personal values, all these are slated for change. Such a multidimensional goal can be negotiated in a communal setting. Throughout the years, the therapeutic community has enhanced substance abuse treatment, intervention, prevention, and educational services for both adolescents and adults. It has emphasized a holistic approach to healing, using interdisciplinary staff, proven paraprofessionals, as well as family members to provide a wide variety of services to accommodate the need portfolios of adolescents as well as of adults (29). It utilizes multiple approaches in responding to the changing needs of its clients.

“The distinctive feature of the therapeutic community is . . . that the community itself . . . is the primary teacher and is the primary healer,” proclaims De Leon (24). He notes further that as teacher, the community is capable of transmitting skills; as healer, the community is capable of mediating the variety of life experiences, which become healing experiences. Since the disorder in question involves the whole person, the multidimensional goal of changing the individual can be managed in a 24-hour, 7-day a week context for purposes of lasting learning and healing. Individual change moves forward through the intervention of peer challenge and role modeling across the therapeutic environment. In the therapeutic community, one discovers an interesting composite made up of the environment, the systems, and the structure, which, taken together, are capable of achieving healing along with educational dividends (2). In the therapeutic community,

“the disorder of the whole person means that change is multidimensional.” “Individual change is viewed along several dimensions of behavior, perceptions, and experiences” (2), and, for purposes of facilitating change, multiple interventions are open to the community.

The therapeutic community also recognizes the need to engage other agencies, utilizing a cross-reference system, embracing different approaches in an effort to provide a holistic, healthy structure for substance abuse clients in recovery. The Daytop therapeutic community, for example, invites speakers from other agencies to facilitate educational seminars, such as Planned Parenthood, Teen Challenge, and others. It encourages residents to attend weekly Alcoholics Anonymous meetings. The Daytop therapeutic community participates in the Youth Assistance Program (YAP), where young residents visit the local correctional facilities. This is a program where the inmates of the facility provide their own insights into the problems of youth today as seen through the prism of their personal experiences (1). It is vital that in addressing the problems, substance abuse clients must utilize multilevel approaches while building partnerships with sister agencies in the community. In dealing with the substance abuse clients, one needs to consider an approach that is centered upon the partnership of family, school, and community forces. There is a strong need to address the interrelatedness of the differing systems of the larger community in order to have an effective treatment program. According to the African saying that “it takes a whole village to raise a child,” correspondingly “it takes a whole community to raise an integrated person.” In the therapeutic community, there is strong emphasis upon the need for rebuilding a sense of community, or village, in which everyone reasserts his or her shared responsibility in the process of nurturing the substance abuse clients.

HEALING THROUGH A CARING FAMILY ENVIRONMENT

Family is vital in the life of substance abuse clients. It is the setting where the valuable aspects of self-esteem, self-acceptance, and sense of responsibility are nurtured. Although ideally the family is where these should be in play, the fact is that there are many substance abuse clients who do not enjoy stable and healthy families. These clients are numbered “among the damaged” because their families have been severely wounded and stand clearly in need of healing. It is impossible to learn these tasks when one lacks a healthy, functioning family setting (27). It is true that “the therapeutic community can never [fully] replace the functional family, [but] it is a temporary place enjoying the support with the natural family” (28). In this case, the therapeutic community is a place where the family can also relearn and refashion itself.

The therapeutic community recognizes the importance of healing not only for the wounded clients in treatment but for the families as well (27). Here the community provides a safe harbor of care, nurture, and emotional support for troubled clients and their families. In the Daytop therapeutic

community, there is a special focus on the family through its Family Association Programs for purposes of identifying imbalances while empowering parents to recalibrate their lives by embracing new values. In Daytop there is a saying: “We try to heal the soul of the family!” (27) By “soul,” Daytop does not refer to one’s inner force or beliefs, but rather one’s entire self. The therapeutic community has given evidence of some success due to its efforts in soul-caring by providing the quintessential nourishing family environment, which, more often than not, has been found wanting in the original familiar situation. The English word “care” comes from the Latin word “cura,” which connotes, among other things, attention and healing. This consideration stands at the portals of the therapeutic community, a formula for living that encourages individuals and families to embrace one’s soul-life as the inner core of their being (27). The process of healing (care of self and one’s soul) is not accomplished in isolation but, rather, in the collective journey traveled through family with each member supporting the other.

Herein lies the root of the therapeutic community outreach to families of substance abuse clients, which serves to heal relationships between members within the family unit. It aspires to increase the solidarity of the family while promoting its own well-being. The therapeutic community family outreach opens up avenues for confronting tensions, conflicts, and consequent maladjustments in the vast sea of family tensions through efforts of reorganization and reintegration. The therapeutic community offers innovative approaches for understanding the soul-life of the family unit as well as the blueprints for organizing families in support of each other. This approach in promoting the well-being of the family is an example of family systems theory. It represents a holistic approach, which positions every part of family life in terms of the “family as a whole.” The dynamics of family system theory in the therapeutic community is reflected in this story (1):

A 14-year-old boy from Long Island, NY came to Daytop because of his alcohol and drug problems. The Daytop director evaluated the family situation and discovered that the father had a serious drinking problem. He confronted the parents with the challenge that, if they seriously desired to help their son, the father needed to deal with his problem immediately. There was a special urgency, as the director advised, for both parents to join the Family Association. The director later reported that the father had stopped drinking, joined AA, and both parents became active members in the association. The entire family now is engaged in weekly family therapy as part of the son’s treatment program.

HEALING THROUGH CARING PEERS

On the occasion of her visits to one of the therapeutic communities, Brieland (29) recorded the experience of a young resident: “I went on drugs because I wanted to belong. I wanted to have friends. However, they weren’t friends, were they? A friend wouldn’t give you something that he knew would harm you? However, I have true friends here, real friends” (29).

True friendships and positive peer role models serve as primary agents of change in the therapeutic community. De Leon (2) asserts that the strength of the community in the context of healing and change (psychological and social learning) “relates to the number and quality of its peers serving as role models.” The therapeutic community requires a multiplicity of role models (roommates, older and younger residents, as well as senior and junior staff) to maintain the integrity of the community while ensuring the promotion of individual growth and healthy relationships.

William Glasser, who is recognized as “the father of reality therapy,” contends that human beings have some basic needs that must be satisfied in order to exist in a reasonably satisfying life (30). The first is the need for a relationship of mutual respect and affection with at least one other person. Bassin (30) further asserts that Glasser’s concept of love goes beyond any romantic and sexual connotation. Essentially, it relates to the vital ingredients of concern, acceptance, and respect. A second universal need indicated by Glasser is the feeling of self-worth, which is produced to a greater degree by the love of a responsible person and the return of that love (30). Glasser argues that when one is unable to fulfill the needs for love and worth, one experiences pain, loneliness, and discomfort. The therapeutic community fulfills these two basic needs, particularly by providing a caring setting where residents feel nurtured and supported, physically and psychologically safe, as well as understood and accepted by others. It is a place that fulfills the essential need to be connected and to belong. The therapeutic community is set apart from other approaches due to the strategic use of healthy peer relationships to facilitate change and growth (2,3).

HEALING THROUGH CARING MENTORS

In the therapeutic community, members are expected to serve as role models for purposes of “maintaining the integrity of the community as well as of ensuring the wide acceptance of social learning” (2). A greater investment of responsibility is expected from staff and senior members of the community who serve as “caring mentors” for newer members. Staff and senior residents act as guides in assisting others in their recovery (3). The credentials of therapeutic community mentors are their own experiences in self-help recovery. When new members walk through the doors of a therapeutic community residence, they are not met by doctors, professors, or priests. Someone equally wounded greets them. That someone has been where the new members now find themselves at entry, and that someone has successfully traveled the path toward recovery. These therapeutic community mentors serve as caring guides for new members through the processes of self-discovery and change. They ensure that new members of the community receive exposure to a range of growth experiences through positive interactions with others. To serve as caring mentors in the lives of younger residents is a paramount responsibility of staff and senior residents.

St. Thomas Aquinas stressed: *Nemo dat quod non habet*, “You cannot give what you do not have.” In the therapeutic

community, every staff and senior members must model the expected behaviors and values demanded by this idealistic community. Each member is reminded of the significance of the axiom “talk the talk and walk the walk,” in the process of effectively guiding other members of the community toward growth and change. Palmer (31) argues, “we teach who we are.” According to him, “selfhood” of the significant adult remains a key factor in the formation of the young. To make a difference in their lives, one needs to bear the identity and authenticity of an integrated person. Such integrity springs from the inner persona of the adult. He argues further that the courage to teach reveals a primordial demand to first probe the “heart’s longing to be connected with the largeness of life, a longing that animates both love and work” (31). Likewise, these are the underlying tenets of the therapeutic community: in changing oneself, we change others; in helping others, we help ourselves. The common struggles in life are the backdrop for one’s connectedness with others as well as one’s commitment to help.

HEALING THROUGH HONESTY AND RESPONSIBLE CONCERN

O. Hobart Mowrer maintains that the practice of honesty, responsible love, and concern is intrinsically therapeutic (29). The therapeutic community provides honesty with a new dimension: radical self-disclosure and transparency. It is here where one discovers healing and wholeness. When a resident feels “nurtured, supported, and safe as well as accepted by others,” he or she is more likely to participate in the community and risk the challenge to change (2). The “tough love and rugged honesty” of the therapeutic community is always within the context of a caring and nurturing setting, which Winnicott refers to as a “holding environment” (32). Carl Rogers, the “father of client-centered therapy,” explained that the healing outcome from the environment of the therapeutic community springs from the encounter process that is at the heart of that caring environment (29). “Shame, fear, anger, guilt, confusion, despair, and aloneness” (2) are some of the early pains experienced by members of the community, and these are “associated with circumstantial stress, pressures, and psychological injuries” of the past, as well as from isolation. However, the therapeutic community offers an environment that fosters nurturing and caring, along with physical and psychological safety as well as social relatedness. As Abraham Maslow (33) indicated in his commentary on his visit in 1965 to Daytop Staten Island, “in order to be open and trusting, one must first create a safe environment where the participant is able to experience a true sense of belonging and of being respected as a person.” Even though within and without the therapeutic community—setting, past traumas have a way of resurfacing and haunting, in a safe setting, such as the caring family of the therapeutic community, confronting these traumas and resolving them constitute a liberating experience.

When there is genuine dialogue between people, each person is seen, understood, and acknowledged by the other (34). What emerges from this is a meeting between people at a

deeper level. When someone speaks candidly to another person, with defenses discarded, they are placing a call upon that person to respond to them at a profound level. They are calling out for that person to recognize them at their particular stage of struggling to exist in their everyday lives. When someone calls out in this way, it is impossible not to respond. Tucker (34) claims: “a meeting between you and that person suddenly takes place. . . . Once one has responded, one has taken responsibility for another.”

HEALING THROUGH RESPONSIBILITY

In exploring the meaning of responsibility, Bratter (35) argues that the English word “response” appears to be less proactive than the French term “repondre,” or the German “antworten.” He explains that the German term “verantwortung” appears more comprehensive. It suggests answering for one’s actions. “Ability” connotes being able to accomplish a task that coincides with the therapeutic community’s overall definition of “responsibility” (35). He defines the word “responsibility” where the emphasis is placed on the person’s ability to respond to external challenges with reasonable judgment. Bratter (35) cited Patterson to emphasize this point:

The meaning of life is not found in questioning the purpose of existence. It arises from the response which man [*sic*] makes to life, to situations, and to tasks with which life confronts him. Although there are biological, psychological, and sociological factors influencing man’s [*sic*] response, there remains the element of choice. He cannot always control the conditions by which he is confronted, but he can control his responses to them. Man [*sic*] is thus responsible for his responses, his choices, [and] his actions.

In the therapeutic community, the residents and staff are immersed in dialogue on how to be responsible through the continual, candid feedback of the group. This is the goal of psychotherapy, according to Bratter (35), to help the individual assume responsibility for self, in the sense of recognizing the active, responsible force in one’s life; being capable of making decisions; and assuming consequences. Along with this acceptance, the recognition of responsibility toward others follows upon a readiness to discover the obligations arising from the values one holds, whether they relate to one’s children, parents, friends, employees, colleagues, the community, or one’s country (35). Each person is responsible for the other. Daytop’s Millbrook Center in Upstate New York has become a mecca for visitors. In the *Capsule Anecdotes—Daytop Stories*, it shares the memorable visit of one of the recent guests to that center:

Very young adolescents with youthful enthusiasm and ever-present smiles greet the visitor. Following swiftly behind is the offer to provide a guided tour of the premises and the program content. Guests become intrigued by this lovely, smiling youngster and wonder whether s/he actually had been an addict. “Just as sweet as my own children,” the guests are overheard to say. However, something unique tends to distinguish this youngster from most kids. A youthful but clear sense of responsibility. They reach out to assist the visitors up the steps.

They hold the door. They offer them a glass of water and so on. Actually, in the course of these visitor tours, in which this particular visitor was fortunate to participate, one was so impressed with this incident. “An incident suddenly drew our young tour guide away from us to the side of a young girl crying. She had just received word that her mother was rushed to the hospital after an auto accident. Begging our forbearance for a few minutes, our guide sat down with the trembling, sobbing “sister,” holding her hand and sharing her tears. Once he saw that another resident arrived on the scene to continue concern for the grieving “sister,” he apologized to us and continued his tour as if nothing happened. So much gentle responsibility wrapped in a 15-year-old boy. “We were so impressed!” the guest declared (1).

In the therapeutic community, responsibility is regarded as an essential part of a mutually dependent relationship between the individual and the society. Being part of the community means taking on the full responsibilities of membership while accepting the consequences when these responsibilities do not bear fruit. One cannot be satisfied with a passive, noncontributing membership style. On the contrary, one must be aware of his or her role in accepting full responsibility in the larger community. “Accountability and responsibility are integral tools for interrupting self-defeating lifestyles” (36) while facilitating the recovery process in the community.

The therapeutic community encourages its members to care for and support each other. “I am my brother’s/sister’s keeper,” the Christian principle holds, while in the therapeutic community, it reaches further, “in helping my brothers/sisters, I, also, help myself!” Helping each other includes helping peers to struggle (37). Helping others becomes a key component in the process of helping oneself. It echoes what Mowrer frequently insisted upon: “The best way to help yourself is to help others” (29).

HEALING THROUGH ONE’S WOUNDEDNESS

The dynamics of the therapeutic community encourages and empowers individuals to embark upon a journey into self-knowledge and personal growth. Recognizing the difficulties on the path to gathering a candid picture of oneself, just as the eye cannot reflect upon itself, the therapeutic community itself serves as a complete reflection of a member’s potential. At the same time, it surfaces patterns of denial, hypocrisy, manipulation, and self-deception where they exist. Harris (18) states, “we do not have a sense of our own [selves] unless other people mirror it back to us.” Such a process opens up an avenue to accept in oneself uncertainties, inadequacies, helplessness, as well as instances of lack of control. This is what Kurtz and Ketcham (38), in *The Spirituality of Imperfection*, describe as the discovery that “something is awry; that there is, after all, something ‘wrong’ with us.” Entering the therapeutic community in itself is a cry for help. The experience becomes a form of grasping at one’s limitations, maladaptive behaviors, fears, and negative attitudes. In another sense, the community becomes a holding environment

that provides the individual with a safe place to accept imperfection, to develop a vision of life, and to implement a curative way of living in which those imperfections can be constructively addressed (38).

In this journey of declaring ownership for one’s limitations and wounds, the recognition of one’s own weaknesses fosters the development of compassion. The member gradually discovers that both the weaknesses and the destructive behavior of others are not really far from one’s own behavioral performance. One can also be convinced early on that the craving for love expressed by others resides also deep in one’s own heart. Such a glimpse of compassion serves to support the caring environment that permeates all activities in the community. A Daytop staff member shared a glimpse of his early experience as a staff member, working with the adolescents at Daytop Millbrook (1). He approached the director one day with this observation, “I cannot understand why these kids were on drugs!” The director, an ex-addict, looked at him and said, “If you cannot understand why these kids are here, you will never be able to move them. You will never be able to touch their lives and you will never be able to help them.” He refers to this episode as the beginning of his personal journey. It was the beginning of an inventory of his own imperfections or “woundedness” to be better equipped to compassionately accompany the young people in Daytop. He concluded: “Even professional people working in the therapeutic community cannot position themselves to assist the young people at Daytop unless they first recognize in themselves a certain ‘woundedness’. This recognition stands at the gates of the therapeutic community!” (1).

There is a general assumption that the more perfect one appears, the more one will be loved (35). Actually, the reverse is more often true. The more willing one is to admit human weakness, the more lovable he or she becomes (35). Kurtz and Ketcham (38) likewise claim that one’s woundedness, helplessness, and powerlessness are essential to the fabric of being human. They moreover declare: “To deny our errors is to deny ourselves.” In the therapeutic community, the more willing we are to admit human weakness and failure, the more effective we become in guiding and healing others. The more willing we are to be in touch with our limitations, the more understanding we become with others. The more we are in touch with our woundedness, the more we are able to express compassion (1). “Acknowledging the solidarity of shared humanness remains a fundamental requirement for effectively helping and counseling the wounded,” Albers (36) further points out. The struggle to be oneself and to acknowledge one’s humanity among others is, indeed, a struggle, but “when there is a real commitment, there is community” (34).

THERAPEUTIC COMMUNITY: THE WOUNDED HEALER

The therapeutic community was born out of the crying need of a suffering and an anguished group of social outcasts “who forged an instrument for change that came to be known as the ‘therapeutic community’” (39). The therapeutic community

founders soon discovered that peer group influence was extremely effective in bringing on change and in learning how to live again. Through peers, wounded people were able to relate deeply and emotionally on the basis of shared experience, a common ground of woundedness, and on this premise they moved forward in an historic effort to assist each other to reclaim their lives via mutual support and peer modeling.

The therapeutic community actualizes the paradox of the wounded healer. Its members can be described as the “twice-born” mentioned in *The Varieties of Religious Experience* of William James (40): “The “twice-born” have known tragedy, failure, and defeat and they have named them as such; but they also have a new sense of possibility of somehow rising above such experience ... It is only in the embracing of our torn self, only in the acceptance that there is nothing “wrong” with feeling “torn,” that we can hope for whatever healing is available and can, thus, become as “whole” as possible. Our own brokenness allows us to become whole” (38).

The community represents a living paradox that embraces the human condition as “both/and” (both a wounded warrior and a healer; both a saint and a sinner) rather than “either/or” (either a wounded warrior or a healer; either a saint or a sinner). The healing experience of the therapeutic community transcends its own boundaries. Nouwen (41) points out that to a “wounded healer,” a compassionate person, nothing human is alien: “compassion breaks through the boundaries of language and national boundaries, rich and poor, educated and illiterate ... this compassion pulls people into the larger sphere where they can see that every human face is the face of a neighbor. There is the necessity to recognize the suffering of his time in his own heart and make that recognition the starting point of his service.” He claims that the “willingness to see one’s own limitations and ‘woundedness’ as rising from the depth of the human condition” remains a potent source of healing (41). The therapeutic community staffs and facilitators need to recognize their own woundedness to be able to heal the wounds of others.

CONCLUSION: THE THERAPEUTIC COMMUNITY, A HEALING KOINONIA

The central inquiry of this chapter is to discuss the healing components of the therapeutic community as a koinonia (community). It proposes that the therapeutic community, as koinonia, offers an effective healing approach in dealing with wounded substance abuse clients. For people who do not fall into this labeled “wounded” category, it serves to confirm and strengthen positive traits of character. The therapeutic community rebuilds a person’s self-esteem, self-image, self-respect, and self-dignity. It restores a sense of hospitality to self and to others. The therapeutic community assumes a certain maturity through responsible concern for peers.

The therapeutic community affirms the fundamental values common to all religions, but particularly to the Christian faith. It stands as a model for the holistic and multidimensional treatment approach in addressing the needs of the

substance abuse client as a whole person. The therapeutic community is a paradigm for comprehensive treatment programs that incorporates partnership with families, schools, and other community forces in a common effort to promote a healthy and caring environment for their clients. It offers other helping agencies a pattern for building small communities through caring peer relationships, which facilitate change and growth through honesty, responsible concern, and responsibility. The therapeutic community recognizes the necessity of being in touch with one’s vulnerability, one’s “woundedness,” and this provides helping professionals and educators with a framework for ministering more effectively to wounded substance abuse people. The journey of fashioning and refashioning peoples’ lives remains the crowning moment of the community effort. The therapeutic community is in many ways a *koinonia* where the “wounded” are healed through the embrace of an *agape* and caring community. As a young Daytop graduate declared, “The therapeutic community is truly an Easter place!”

Marc Galanter ■ Helen Dermatis

Psychotherapy for people dependent on alcohol and other drugs presents unique problems for the office-based practitioner. Among these are the ever-present vulnerability to relapse to substance use and high dropout rates. In order to address this problem, we can consider how engaging the input of people close to an addicted person can help in achieving a stable abstinence and deal with the vulnerability to dropout from treatment. To understand this option, it is first important to understand that certain conditioned drug-seeking behaviors may be extinguished if appropriate aversive stimuli are interposed after triggers to drug use are presented.

A drug user can become entangled in an interlocking web of self-perpetuating reinforcers that contribute to the persistence of drug abuse, despite compromising consequences, and the user's imperviousness to a traditional, psychodynamic psychotherapeutic approach does not necessarily take such conditioning factors into account. This is because neither the user nor the therapist is typically aware of their existence due to the unconscious nature of the conditioned response of drug seeking. The therapist's attempt to alter the course of the stimulus-response sequence is therefore often not viable, even with the aid of a willing patient, as neither party is necessarily aware that a conditioned sequence is taking place.

Sufficient exploration, however, can reveal the relevant stimuli and their effect through conditioned sequences of drug-seeking behavior. I initially described a technique for guided recall of relevant conditioned stimuli in a psychotherapeutic context, whereby the alcoholic or addict may become aware of the sequence of circumstances that can precipitate relapse (1). Once this is done, the patient's own distress at the course of the addictive process, generated by the patient's own motivation for escaping the addictive pattern, may be mobilized. This motivational distress then serves as an aversive stimulus. The implicit assumption behind this therapeutic approach is that the patient in question wants to alter his or her pattern of drug use and that the recognition of a particular stimulus as a conditioned component of addiction will then allow the patient, in effect, to initiate the extinction process. If a patient is committed to achieving abstinence from an addictive drug such as alcohol or cocaine but is in jeopardy of occasional slips, this cognitive labeling can facilitate consolidation of an abstinent adaptation.

As we shall see, the input of people close to the patient can help to reveal triggers to drugs use that may not have been apparent to the patient. Such an approach is less valuable in the context of (a) a lack of motivation for abstinence, (b) fragile

social supports, or (c) compulsive substance abuse unmanageable by the patient in the patient's usual social settings. Hospitalization or replacement therapy (e.g., methadone or buprenorphine) may be necessary in such cases, because ambulatory stabilization through psychotherapeutic support is often not feasible, even with the support of family and close peers. On the other hand, for willing patients, or ones whom family and friends have convinced to cooperate, the network approach can be most valuable.

THE NETWORK THERAPY TECHNIQUE

This approach can be useful in addressing a broad range of addicted patients characterized by the following clinical hallmarks of addictive illness. When they initiate consumption of their addictive agent, be it alcohol, cocaine, opiates, or depressant drugs, they frequently cannot limit that consumption to a reasonable and predictable level; this phenomenon has been termed *loss of control* by clinicians who treat persons dependent on alcohol or drugs (2). Second, they have consistently demonstrated relapse to the agent of abuse; that is, they have attempted to stop using the drug for varying periods of time but have returned to it, despite a specific intent to avoid it.

This treatment approach is not necessary for those abusers who can learn to set limits on their use of alcohol or drugs; their abuse may be treated as a behavioral symptom in a more traditional psychotherapeutic fashion. Nor is it directed at those patients for whom the addictive pattern is most unmanageable, such as addicted people with unusual destabilizing circumstances such as homelessness, severe character pathology, or psychosis. These patients may need special supportive care such as inpatient detoxification or long-term residential treatment.

Key Elements

Three key elements are introduced into the Network Therapy technique. The first is a cognitive-behavioral approach to relapse prevention, which has been considered valuable in addiction treatment (3,4). Emphasis in this approach is placed on triggers to relapse and behavioral techniques for avoiding them, in preference to exploring underlying psychodynamic issues.

Second, support of the patient's natural social network is engaged in treatment. Peer support in Alcoholics Anonymous (AA) has long been shown to be an effective vehicle for

promoting abstinence, and the idea of the therapist's intervening with family and friends in starting treatment was employed in one of the early ambulatory techniques specific to addiction (5). The involvement of spouses (6) has since been shown to be effective in enhancing the outcome of professional therapy.

Third, the orchestration of resources to provide community reinforcement suggests a more robust treatment intervention by providing a support for drug-free rehabilitation (7). In this relation, Khantzian pointed to the "primary care therapist" as one who functions in direct coordinating and monitoring roles in order to combine psychotherapeutic and self-help elements (8). It is this overall management role over circumstances outside as well as inside the office session that is presented to trainees, in order to maximize the effectiveness of the intervention.

CBT and Social Support

Cognitive–Behavioral Therapy This format for treatment has been shown to be effective for a wide variety of substance use disorders, including alcohol (9), marijuana (10), and cocaine dependence (11). It is premised on the original findings by Wikler (12) on conditioning models of drug seeking in heroin-addicted subjects.

The CBT approach is goal oriented and focuses on current circumstances in the patient's life. In Network Therapy, reference in both individual and conjoint sessions can be made to salient past experiences. CBT sessions are typically structured, so, for example, patients begin each network session with a recounting of recent events directly relevant to their addiction and recovery. This is followed by active participation and interaction of therapist, patient, and network members in response to the patient's report. CBT emphasizes psychoeducation in the context of relapse prevention, so that circumstances, thoughts, and interpersonal situations that have historically precipitated substance use are identified and the patient (and network members as well) are taught to anticipate where such triggers can precipitate substance use.

The process of guided recall, noted previously, is particularly important because it allows the therapist both individual sessions with the patient alone and network sessions—in conjunction with network members along with the patient—to guide the patient to recognize a sequence of conditioned stimuli (triggers) that play a role in drug seeking. Such triggers may not initially be apparent to the patient or network members, but with encouragement and prompting, they can emerge over the course of an exploration of the circumstances that have led, either in the past or in a recent "slip," to substance use.

Social Support This issue has been studied in a variety of data sets in relation to the recovery from substance use disorders. For example, in the federal Project MATCH, three modalities—twelve-step facilitation, motivational enhancement, and cognitive–behavioral approaches—were compared. In a secondary analysis of findings from this multisite study, it was found (13) that certain aspects of social support were most

predictive of abstinence outcomes. Two social network characteristics that had a positive effect on outcome were the size of the supportive social network in the person's life and the number of members who were abstainers (or recovering alcoholics). I have found that nonproblem drinking participants are important to a long-term clinical outcome. As a matter of fact, a large number of network members, when their participation is effectively maintained over time, can counter a variety of circumstances that may undermine a patient's abstinence. Additionally, they can provide varied aspects of support relative to the patient's experience in recovery. And indeed, they should be free of substance-related problems. Of interest in this context, it has been reported that men are more typically encouraged by their wives to seek help, whereas women are more often encouraged by mothers, siblings, and children (14).

Community Reinforcement Family involvement in substance abuse treatment has long been shown to be effective in improving outcome, and there are numerous approaches that make use of social network involvement in treatment, including Behavioral Couples Therapy (15), Marital Therapy (16), and the Community Reinforcement Approach (17,18).

More specifically, a Community Reinforcement and Family Training (CRAFT) program includes many aspects of treatment that were employed in Network Therapy. The CRAFT approach was developed to encourage drinkers to enter therapy and reduce drinking, in part by eliciting support of concerned others, as well as to enhance satisfaction with life among members of the patient's social network who were concerned about his or her drinking. As in Network Therapy, the CRAFT program includes a functional analysis of the patient's substance use, that is to say, understanding the substance use with respect to its antecedents and consequences. Like Network Therapy, it also serves to minimize reciprocal blaming and defensiveness among the concerned significant others and to promote a patient's sobriety-oriented activities.

In one large trial in which concerned significant others were randomized to one of three conditions, a comparison was made between Al-Anon-facilitated therapy, an approach similar to the Johnson Institute interventions, and the CRAFT model (25). In that study, the CRAFT intervention was found to be more effective in engaging treatment-refusing, alcoholic subjects. Similar positive findings were obtained in studies on CRAFT with illicit drug users (19,20). On the other hand, in another study, concerned significant others were successfully trained to apply a modified Johnson Intervention technique in the absence of a therapist, and this approach was found to be successful in itself (21).

Initial Encounter: Starting a Social Network

So how does one go about developing Network Therapy? The patient should be asked to bring his or her spouse or a close friend to the first session. Alcoholic patients often dislike certain things they hear when they first come for treatment and

may deny or rationalize, even if they have voluntarily sought help. Because of their denial of the problem, a significant other is essential to both history taking and implementing a viable treatment plan. A close relative or spouse can often cut through the denial in a way that an unfamiliar therapist cannot and can therefore be invaluable in setting a standard of realism in dealing with the addiction.

Some patients make clear that they wish to come to the initial session on their own. This is often associated with their desire to preserve the option of continued substance abuse and is born out of the fear that an alliance will be established independent of them to prevent this. Although a delay may be tolerated for a session or two, it should be stated unambiguously at the outset that effective treatment can be undertaken only on the basis of a therapeutic alliance built around the addiction issue that includes the support of significant others and that it is expected that a network of close friends and/or relatives will be brought in within a session or two at the most.

The weight of clinical experience supports the view that abstinence is the most practical goal to propose to the addicted person for his or her rehabilitation (22,23). For abstinence to be expected, however, the therapist should assure the provision of necessary social supports for the patient. Let us consider how a long-term support network is initiated for this purpose, beginning with availability of the therapist, significant others, and a self-help group.

In the first place, the therapist should be available for consultation on the phone and should indicate to the patient that he or she wants to be called if problems arise. This makes the therapist's commitment clear and sets the tone for a "team effort." It begins to undercut one reason for relapse, the patient's sense of being on his or her own if unable to manage the situation. The astute therapist, however, will assure that he or she does not spend excessive time on the telephone or in emergency sessions. The patient will therefore develop a support network that can handle the majority of problems involved in day-to-day assistance. This generally will leave the therapist to respond only to occasional questions of interpreting the terms of the understanding among himself or herself, the patient, and support network members. If there is a question about the ability of the patient and network to manage the period between the initial sessions, the first few scheduled sessions may be arranged at intervals of only 1 to 3 days. In any case, frequent appointments should be scheduled at the outset if a pharmacologic detoxification with benzodiazepines is indicated, so that the patient need never manage more than a few days' medication at a time.

What is most essential, however, is that the network be forged into a working group to provide necessary support for the patient between the initial sessions. Membership ranges from one to several persons close to the patient. Larger networks have been used by Speck (24) in treating schizophrenic patients. Contacts between network members at this stage typically include telephone calls (at the therapist's or patient's initiative), dinner arrangements, and social encounters and should be preplanned to a fair extent during the joint session. These encounters are most often undertaken at the time when

alcohol or drug use is likely to occur. In planning together, however, it should be made clear to network members that relatively little unusual effort will be required for the long term and that after the patient is stabilized, their participation will amount to little more than attendance at infrequent meetings with the patient and therapist. This is reassuring to those network members who are unable to make a major time commitment to the patient as well as to those patients who do not want to be placed in a dependent position.

Defining the Network's Membership

Once the patient has come for an appointment, establishing a network is a task undertaken with active collaboration of patient and therapist. The two, aided by those parties who join the network initially, must search for the right balance of members. The therapist must carefully promote the choice of appropriate network members, however, just as the platoon leader selects those who will go into combat. The network will be crucial in determining the balance of the therapy. This process is not without problems, and the therapist must think in a strategic fashion of the interactions that may take place among network members. The following case illustrates the nature of their task.

A 25-year-old graduate student had been abusing cocaine since high school, in part drawing from funds from his affluent family, who lived in a remote city. At two points in the process of establishing his support network, the reactions of his live-in girlfriend, who worked with us from the outset, were particularly important. Both he and she agreed to bring in his 19-year-old sister, a freshman at a nearby college. He then mentioned a "friend" of his, apparently a woman whom he had found attractive, even though there was no history of an overt romantic involvement. The expression on his girlfriend's face suggested that she did not like this idea, although she offered no rationale for excluding this potential rival. However, the idea of having to rely for assistance solely on two women who might see each other as competitors was unappealing. The therapist therefore finessed the idea of the "friend," and both she and the patient moved on to evaluating the patient's uncle, whom he initially preferred to exclude, despite the fact that his girlfriend thought him appropriate. It later turned out (as expected) that the uncle was perceived as a potentially disapproving representative of the parental generation. The therapist encouraged the patient to accept the uncle as a network member nonetheless, so as to round out the range of relationships within the group, and did spell out my rationale for his inclusion. The uncle did turn out to be caring and supportive, particularly after he was helped to understand the nature of the addictive process.

Defining the Network's Task

As conceived here, the therapist's relationship to the network is like that of a task-oriented team leader, rather than that of a family therapist oriented toward insight. The network is

established to implement a straightforward task, that of aiding the therapist in sustaining the patient's abstinence. It must be directed with the same clarity of purpose that a task force is directed in any effective organization. Competing and alternative goals must be suppressed, or at least prevented from interfering with the primary task.

Unlike family members involved in traditional family therapy, network members are not led to expect symptom relief for themselves or self-realization. This prevents the development of competing goals for the network's meetings. It also assures the members protection from having their own motives scrutinized and thereby supports their continuing involvement without the threat of an assault on their psychological defenses. Because network members have—kindly—volunteered to participate, their motives must not be impugned. Their constructive behavior should be commended. It is useful to acknowledge appreciation for the contribution they are making to the therapy. There is always a counterproductive tendency on their part to minimize the value of their contribution. The network must, therefore, be structured as an effective working group with high morale. This is not always easy.

A 45-year-old single woman served as an executive in a large family-held business—except when her alcohol problem led her into protracted binges. Her father, brother, and sister were prepared to banish her from the business but decided first to seek consultation. Because they had initiated the contact, they were included in the initial network and indeed were very helpful in stabilizing the patient. Unfortunately, however, the father was a domineering figure who intruded in all aspects of the business, evoking angry outbursts from his children. The children typically reacted with petulance, provoking him in return. The situation came to a head when both of the patient's siblings angrily petitioned me to exclude the father from the network, 2 months into the treatment. This presented a problem because the father's control over the business made his involvement important to securing the patient's compliance. The patient's relapse was still a real possibility. This potentially coercive role, however, was an issue that the group could not easily deal with. The therapist decided to support the father's membership in the group, pointing out the constructive role he had played in getting the therapy started. It seemed necessary to support the earnestness of his concern for his daughter, rather than the children's dismay at their father's (very real) obstinacy. It was clear to the therapist that the father could not deal with a situation in which he was not accorded sufficient respect and that there was no real place in this network for addressing the father's character pathology directly. The hubbub did, in fact, quiet down with time. The children became less provocative themselves, as the group responded to my pleas for civil behavior.

The Use of Alcoholics Anonymous

Use of self-help modalities is desirable whenever possible. For the alcoholic, certainly, participation in AA is strongly encouraged. Groups such as Narcotics Anonymous, Pills Anony-

mous, and Cocaine Anonymous are modeled after AA and play a similarly useful role for drug abusers. One approach is to tell the patient that he or she is expected to attend at least two AA meetings a week for at least 1 month, so as to become familiar with the program. If after a month the patient is quite reluctant to continue, and other aspects of the treatment are going well, the patient's nonparticipation may have to be accepted.

Some patients are more easily convinced to attend AA meetings; others may be less compliant. The therapist should mobilize the support network as appropriate, so as to continue pressure for the patient's involvement with AA for a reasonable trial. It may take a considerable period of time, but ultimately a patient may experience something of a conversion, wherein the patient adopts the group ethos and expresses a deep commitment to abstinence, a measure of commitment rarely observed in patients who undergo psychotherapy alone. When this occurs, the therapist may assume a more passive role in monitoring the patient's abstinence and keep an eye on the patient's ongoing involvement in AA.

Use of Pharmacotherapy in the Network Format

For the alcoholic, disulfiram may be of marginal use in assuring abstinence when used in a traditional counseling context (25), but becomes much more valuable when carefully integrated into work with the patient and network, particularly when the drug is taken under observation. A similar circumstance applies to the use of oral naltrexone for stabilizing abstinence in an opioid-dependent person. In the case of alcohol, it is a good idea to use the initial telephone contact to engage the patient's agreement to abstain from alcohol for the day immediately prior to the first session. The therapist then has the option of prescribing or administering disulfiram at that time. For a patient who is earnest about seeking assistance for alcoholism, this is often not difficult, if some time is spent on the phone making plans to avoid a drinking context during that period. If it is not feasible to undertake this on the phone, it may be addressed in the first session. Such planning with the patient almost always involves organizing time with significant others and therefore serves as a basis for developing the patient's support network.

The administration of disulfiram under observation is a treatment option that is easily adapted to work with social networks. A patient who takes disulfiram cannot drink; a patient who agrees to be observed by a responsible party while taking disulfiram will not miss his or her dose without the observer's knowledge. This may take a measure of persuasion and, above all, the therapist's commitment that such an approach can be reasonable and helpful.

Disulfiram typically is initiated with a dose of 500 mg, and then reduced to 250 mg daily. It is taken every morning, when the urge to drink is generally least. Particulars of administration in the context of treatment has been described (26).

As noted previously, individual therapists traditionally have seen the addicted person as a patient with poor prognosis. This is largely because in the context of traditional

psychotherapy, there are no behavioral controls to prevent the recurrence of drug use, and resources are not available for behavioral intervention if a recurrence takes place—which may occur. A system of impediments to the emergence of relapse, resting heavily on the actual or symbolic role of the network, must therefore be established. The therapist must have assistance in addressing any minor episode of drinking so that this ever-present problem does not lead to an unmanageable relapse or an unsuccessful termination of therapy.

How can the support network be used to deal with recurrences of alcohol use, when in fact, the patient's prior association with these same persons did not prevent him or her from drinking? The following example illustrates how this may be done when social resources are limited. In this case, a specific format was defined with the network to monitor a patient's compliance with a disulfiram regimen.

A 33-year-old public relations executive had moved to New York from a remote city 3 years before coming to treatment. She had no long-standing close relationships in the city, a circumstance not uncommon for a single alcoholic in a setting removed from her origins. She presented with a 10-year history of heavy drinking that had increased in severity since her arrival, no doubt associated with her social isolation. Although she consumed a bottle of wine each night and additional hard liquor, she was able to get to work regularly. Six months before the outset of treatment, she attended AA meetings for 2 weeks and had been abstinent during that time. She had then relapsed, though, and became disillusioned about the possibility of maintaining abstinence. At the outset of treatment, it was necessary to reassure her that prior relapse was in large part a function of not having established sufficient outside supports (including more sound relationships within AA) and of having seen herself as failed after only one slip. However, there was basis for real concern as to whether she would do any better now, if the same formula was reinstated in the absence of sufficient, reliable supports, which she did not seem to have. Together the therapist and she came up with the idea of bringing in an old friend whom she saw occasionally and whom she felt she could trust. They made the following arrangement with her friend. The patient came to sessions twice a week. She would see her friend once each weekend. On each of these thrice-weekly occasions, she would be observed taking disulfiram, so that even if she missed a daily dose in between, it would not be possible for her to resume drinking on a regular basis, undetected. The interpersonal support inherent in this arrangement, bolstered by conjoint meetings with her and her friend, also allowed her to return to AA with a sense of confidence in her ability to maintain abstinence.

Format for Medication Observation by the Network

1. Take the medication every morning in front of a network member.
2. Take the pill so that that person can observe you swallowing them.
3. The observer writes down the time of day the pills were taken on a list prepared by the therapist.
4. The observer brings the list in to the therapist's office at each network session.
5. The observer leaves a message on the therapist's answering machine on any day in which the patient had not taken the pills in a way that ingestion was not clearly observed.

Meeting Arrangements

At the outset of therapy, it is important to see the patient with the group on a weekly basis for at least the first month. Unstable circumstances demand more frequent contacts with the network. Sessions can be tapered off to biweekly and then to monthly intervals after a time.

To sustain the continuing commitment of the group, particularly that between the therapist and the network members, network sessions should be held every 3 months or so for the duration of the individual therapy. Once the patient has stabilized, the meetings tend less to address day-to-day issues. They may begin with the patient's recounting of the drug situation. Reflections on the patient's progress and goals, or sometimes on relations among the network members, then may be discussed. In any case, it is essential that network members contact the therapist if they are concerned about the patient's possible use of alcohol or drugs and that the therapist contact the network members if the therapist becomes concerned about a potential relapse.

Adapting Individual Therapy to the Network Treatment

As noted previously, network sessions are scheduled on a weekly basis at the outset of treatment. This is likely to compromise the number of individual contacts. Indeed, if sessions are held once a week, the patient may not be seen individually for a period of time. The patient may perceive this as a deprivation unless the individual therapy is presented as an opportunity for further growth predicated on achieving stable abstinence assured through work with the network.

When the individual therapy does begin, the traditional objectives of therapy must be arranged so as to accommodate the goals of the substance abuse treatment. For insight-oriented therapy, clarification of unconscious motivations is a primary objective; for supportive therapy, the bolstering of established constructive defenses is primary. In the therapeutic context that is described here, however, the following objectives are given precedence.

Of primary importance is the need to address exposure to substances of abuse or to cues that might precipitate alcohol or drug use (27). Both patient and therapist should be sensitive to this matter and explore these situations as they arise. Second, a stable social context in an appropriate social environment—one conducive to abstinence with minimal disruption of life circumstances—should be supported. Considerations of minor disruptions in place of residence, friends, or job need not be a primary issue for the patient with

character disorder or neurosis, but they cannot go untended here. For a considerable period of time, the substance abuser is highly vulnerable to exacerbations of the addictive illness and in some respects must be viewed with the considerable caution with which one treats the recently compensated psychotic.

Finally, after these priorities have been attended to, psychological conflicts that the patient must resolve, relative to his or her own growth, are considered. As the therapy continues, these come to assume a more prominent role. In the earlier phases, they are likely to reflect directly issues associated with previous drug use. Later, however, as the issue of addiction becomes less compelling from day to day, the context of the treatment increasingly will come to resemble the traditional psychotherapeutic context. Given the optimism generated by an initial victory over the addictive process, the patient will be in an excellent position to move forward in therapy with a positive view of his or her future.

A LONGER COURSE

The following case description illustrates how a network was engaged in treating a patient in long-term care for his addictive problem.

A 22-year-old man left a message on the therapist's answering machine asking if he could make an appointment. When called back, he said he wanted help to address his heroin habit. He said, "I gotta get clean." In response to a few questions, he described himself as a 30-year-old, single artist who clearly had aspirations to achieve wider recognition. He had been using heroin intranasally on and off for 3 years, but for the past 6 months was "sniffing" large doses at least twice a day.

At the initial encounter, given concern about his reliability, the therapist asked to engage collateral support for the patient. He asked if they could both speak on the phone with a friend or a close family member of his who could be a resource for him until the next session. Although he was somewhat wary, he agreed to their calling a cousin with whom he had a close relationship and who had repeatedly expressed concern over his drug use. The three agreed that the cousin would meet him for dinner right before the next scheduled session, and come with him to that appointment.

The patient appeared with his cousin 4 days later. He was somewhat tremulous, and reported that he and a friend, also addicted to heroin, had decided to detoxify themselves abruptly with some naltrexone that his friend had acquired. They supported each other, suffering miserably over the intervening days.

This patient was a good candidate for Network Therapy: his continuous dependence on heroin had been less than a year in duration, and this was less than appropriate for maintenance on buprenorphine or methadone. It would be desirable to avoid his dependency for the long term on an opioid if that could be avoided—and he did not want that option anyway. His network was constituted of three people: his cousin, a close friend, and an uncle 20 years his senior,

whom he viewed as a mentor and friend. For the first 3 weeks, individual and network sessions were alternated each week. Over the subsequent weeks, the frequency of network meetings was decreased relative to the therapist's sense of the patient's stability in treatment. After 6 months the network members came to a session only once every month or two.

A second component of the treatment was to provide protection from relapse by having the patient take oral naltrexone, an opioid antagonist, which blocks the effect of an agonist, heroin or otherwise, such as hydrocodone. It was arranged that he would take two 50-mg pills twice weekly (Monday and Wednesday), and three on a third occasion (Friday). He would do this in front of his cousin, who lived only one block away from him. This naltrexone regimen was continued over the course of the ensuing 10 months, and after that on the patient's own recognizance.

At the outset of treatment, the therapist had stipulated that the patient was not to use marijuana, alcohol, or other drugs, explaining to him and the network how any of these could lead to a relapse. He was also expected to give a urine sample for toxicology at random times in order to assure abstinence from drugs. The patient did indeed say at one point in the treatment that he felt supported in avoiding marijuana by virtue of the fact that he did not want to have a positive urine toxicology.

The therapist had often discussed with the patient his vulnerability to alcoholism given his family history. Alcohol was a blight on his family, as his father always drank heavily every evening, making him very uncomfortable during his occasional visits to home. After 3 months in treatment, however, the patient said that he had "never bargained for not drinking at all" and that he didn't quite see himself as abstinent from alcohol for the long term. As the therapist and he discussed this, they agreed that it was best that he stay abstinent for at least a year, and toward the end of that time his options could be discussed. The issue was also discussed with the network members, who were wary of the patient embarking on something other than total abstinence, but the therapist pointed out that a test of drinking was "better during treatment than afterwards." This was discussed at some length, and the patient implemented a diary of his drinking, limited to no more than two beers a day and no wine or hard liquor.

At one point during the subsequent treatment, tragedy befell the family, as the patient's younger brother, who also drank abusively, had an auto accident while drunk and was gravely injured. After this, the patient had continued to keep his drinking diary, but a month after his brother's accident, he decided that he was better off remaining abstinent, and decided to do so. He did indeed maintain abstinence over a year of subsequent ongoing psychotherapy for general adaptive issues, and reported being abstinent 3 years after that.

RESEARCH ON NETWORK THERAPY

Network Therapy is included under the American Psychiatric Association (APA) Practice Guidelines (28) for substance use disorders as an approach to facilitating adherence to a

treatment plan. The Substance Abuse and Mental Health Services Administration (SAMHSA) includes a description of Network Therapy in its National Registry of Evidence-Based Program and Practices (29), and Network Therapy is listed in one of its Treatment Improvement Protocols (TIP) as Substance Abuse Treatment and Family Therapy (30). To date, five studies have demonstrated its effectiveness in treatment and training. Each addressed the technique's validation from a different perspective: a trial in office management, studies of its effectiveness in the training of psychiatric residents and of counselors who work with cocaine-addicted persons, an evaluation of acceptance of the network approach in an Internet technology transfer course, and a trial evaluating the impact of Network Therapy relative to medication management in heroin-addicted persons inducted on to buprenorphine. In addition, Network Therapy components that have been adapted and combined with other psychosocial treatments to treat patients with opioid or alcohol dependence are described below.

An Office-Based Clinical Trial

A chart review was conducted on a series of 60 substance-dependent patients, with follow-up appointments scheduled through the period of treatment and up to 1 year thereafter (31). For 27 patients, the primary drug of dependence was alcohol; for 23, it was cocaine; for 6, it was opiates; for 3, it was marijuana; and for 1, it was nicotine. In all but eight of the patients, networks were fully established. Of the 60 patients, 46 experienced full improvement (i.e., abstinence for at least 6 months) or major improvement (i.e., a marked decline in drug use to nonproblematic levels). The study demonstrated the viability of establishing networks and applying them in the practitioner's treatment setting. It also served as a basis for the ensuing developmental research supported by the National Institute on Drug Abuse.

Treatment by Psychiatry Residents

We developed and implemented a Network Therapy training sequence in the New York University Psychiatric Residency Program and then evaluated the clinical outcome of a group of cocaine-dependent patients treated by the residents. The psychiatric residency was chosen because of the growing importance of clinical training in the management of addiction in outpatient care in residency programs, in line with the standards set for specialty certification.

A training manual was prepared on the network technique, defining the specifics of the treatment in a manner allowing for uniformity in practice. It was developed for use as a training tool and then as a guide for the residents during the treatment phase. Network Therapy tape segments drawn from a library of 130 videotaped sessions were used to illustrate typical therapy situations. A Network Therapy rating scale was developed to assess the technique's application, with items emphasizing key aspects of treatment (32). The scale was evaluated for its reliability in distinguishing between two contrasting addiction

therapies, Network Therapy and systemic family therapy, both presented to faculty and residents on videotape. The internal consistency of responses for each of the techniques was high for both the faculty and the resident samples, and both groups consistently distinguished the two modalities. The scale was then used by clinical supervisors as a didactic aid for training and to monitor therapist adherence to the study treatment manual.

We trained third-year psychiatry residents to apply the Network Therapy approach, with an emphasis placed on distinctions in technique between the treatment of addiction and of other major mental illness or personality disorder. The residents then worked with a sample of 47 cocaine-addicted patients. Once treatment was initiated, 77% of the subjects did establish a network, that is, bring in at least one member for a network session. In fact, 1.47 collaterals on average attended any given network session, across all the subjects and sessions. This is notable, because compliance after initial screening was not necessarily assured. Almost all of those who completed a 24-week regimen (15 of 17) produced urines negative for cocaine in their last three toxicologies. On the other hand, only a minority of those who attended the first week but who did not complete the sequence (4 of 18) met this outcome criterion (33). The residents, inexperienced in drug treatment, achieved results similar to those reported for experienced professionals (34,35). These comparisons supported the feasibility of successful training of psychiatry residents naive to addiction treatment and the efficacy of the treatment in their hands.

To better understand the role of therapeutic alliance in Network Therapy, Glazer et al. (36) reviewed videotaped network sessions on 21 out of the 47 cocaine-addicted patients and rated them on level of patient-therapist alliance using the PENN Helping Alliance Rating Scale and the Working Alliance Inventory. The tapes that were selected to be rated were those that represented the participants' first videotaped Network Therapy session. Results showed a significant positive correlation between therapeutic alliance and outcomes as measured by the percentage of cocaine-free urine toxicology screens and by eight consecutive cocaine-free urines.

Treatment by Addiction Counselors

This study was conducted in a community-based addictions treatment clinic, and the Network Therapy training sequence was essentially the same as the one applied to the psychiatry residents (37). A cohort of 10 cocaine-dependent patients received treatment at the community program with a format that included Network Therapy, along with the clinic's usual package of modalities, and an additional 20 cocaine-dependent patients received treatment as usual and served as control subjects. The Network Therapy was found to enhance the outcome of the experimental patients. Of 107 urinalyses conducted on the Network Therapy patients, 88% were negative, but only 66% of the 82 urine samples from the control subjects were negative, a significantly lower proportion. The mean retention in treatment

was 13.9 weeks for the network patients, reflecting a trend toward greater retention than the 10.7 weeks for control subjects.

The results of this study supported the feasibility of transferring the network technology into community-based settings with the potential for enhancing outcomes. Addiction counselors working in a typical outpatient rehabilitation setting were able to learn and then incorporate Network Therapy into their largely twelve-step-oriented treatment regimens without undue difficulty and with improved outcome.

Use of the Internet

We studied ways in which psychiatrists and other professionals could be offered training by a distance-learning method using the Internet, a medium that offers the advantage of not being fixed in either time or location. An advertisement was placed in *Psychiatric News*, the newspaper of the APA, offering an Internet course combining Network Therapy with the use of naltrexone for the treatment of alcoholism.

The sequence of material presented on the Internet was divided into three didactic “sessions,” followed by a set of questions, with a hypertext link to download relevant references and a certificate of completion. The course took about 2 hours for the student to complete. Our assessment was based on 679 sequential counts, representing 240 unique respondents who went beyond the introductory web page (38). Of these respondents, 154 were psychiatrists, who responded positively to the course. A majority responded “a good deal” or “very much” (a score of 3 or 4 on a four-point scale) to the following statements: “It helped me understand the management of alcoholism treatment” (56%), “It helped me learn to use family or friends in network treatment for alcoholism” (75%), and “It improved my ability to use naltrexone in treating alcoholism” (64%). The four studies described in this section support the use of Network Therapy as an effective treatment for addictive disorders. They are especially encouraging given the relative ease with which different types of clinicians were engaged and trained in the network approach. Because the approach combines a number of well-established clinical techniques that can be adapted to delivery in typical clinical settings, it is apparently suitable for use by general clinicians and addiction specialists.

Network Therapy in Buprenorphine Maintenance

Galanter et al. (39) evaluated the impact of Network Therapy relative to a control condition (medical management, MM) among 66 patients who were inducted on to buprenorphine for 16 weeks and then tapered to zero dose. Network Therapy resulted in a greater percentage of opioid-free urines than did MM (65% vs. 45%). By the end of treatment, Network Therapy patients were more likely to experience a positive outcome relative to secondary heroin use (50% vs. 23%). The use of Network Therapy in office practice may enhance the effectiveness of eliminating secondary heroin use during buprenorphine maintenance.

ADAPTATIONS OF NETWORK THERAPY TREATMENT

Rothenberg et al. (40) adapted Network Therapy and combined it with relapse prevention and a voucher reinforcement system in the treatment of opioid-dependent patients who were enrolled in a 6-month course of treatment with naltrexone referred to as behavioral naltrexone therapy (BNT). The Network Therapy component involved one significant other who could monitor adherence to naltrexone. In addition to the patient receiving vouchers for each day of abstinence and each pill taken, the network member was reinforced with a voucher for each pill recorded as monitored. The primary treatment outcome was retention in treatment. Patients who used methadone at baseline did more poorly than those using only heroin, as demonstrated in the retention rates: 39% vs. 65% and 0% vs. 31%, respectively, at 1 month and 6 months.

Copello et al. (41) combined elements of Network Therapy with social aspects of the community reinforcement approach and relapse prevention referred to as social behavior and network therapy (SBNT) in the treatment of persons with alcohol drinking problems. A number of social skills training strategies are incorporated into the treatment, especially those involving social competence in relation to the development of positive social support for change in alcohol use. Every individual involved in treatment is considered a client in his or her own right, and the person with alcohol problems is referred to as the focal client. The core element of the approach is mobilizing the support of the network even though this may involve network sessions that are conducted in the absence of the focal client. In their initial feasibility study with 33 clients, there were two cases in which sessions were held with network members in the absence of the focal client, and in both cases re-engagement of the focal client in treatment was achieved. Out of the 33 clients enrolled in the study, 23 formed a network with the mean number of network members equal to 1.82 and the mean number of network sessions equal to 5.24. In a multisite, randomized controlled trial of 742 clients with alcohol problems, the UKATT research team (42) compared SBNT to motivational enhancement therapy (MET). Both treatment groups exhibited similar reductions in alcohol consumption and alcohol-related problems and improvement in mental functioning over a 12-month period.

Additional studies involving the UKATT study sample were conducted assessing (a) cost-effectiveness (43), (b) client-treatment matching effects (44), and (c) clients' perceptions of change in alcohol drinking behaviors (45). The UKATT team evaluated the cost-effectiveness of SBNT relative to MET. SBNT resulted in a fivefold cost savings in health, social, and criminal justice service expenditures and was similar to cost-effectiveness estimates obtained for MET. The UKATT research team (44) tested a priori hypotheses concerning client-treatment matching effects similar to those tested in Project MATCH. The findings were consistent with Project MATCH in that no hypothesized matching effects were significant. Orford et al. (45) interviewed a subset of

clients ($n = 397$) who participated in this trial to assess their views concerning whether any positive changes in drinking behavior had occurred and to what they attributed those changes. At 3 months after randomization to treatment, SBNT clients made more social attributions (e.g., involvement of others in supporting behavior change) and MET clients made more motivational attributions (e.g., awareness of the consequences of drinking).

Copello et al. (46) adapted SBNT for persons presenting with drug problems. Of 31 clients enrolled in the study, 23 received SBNT and had outcomes data available at 3-month follow-up. Reductions in the amount of heroin used per day and increases in family cohesion and family satisfaction were documented. Open-ended interviews with clients, network members, and therapists were conducted in a qualitative investigation of respondents' perceptions of SBNT (47). Major themes that emerged from the analysis of interview responses included the value of SBNT in (a) increasing network support for reducing drug use, (b) promoting open and honest communication between clients and network members about drug use, and (c) increasing network members' understanding of drugs and the focal person's behavior. Williamson et al. (47) suggest that these features of SBNT may be more prominent when the problem is one of illicit drug use than when the problem involves alcohol use.

PRINCIPLES OF NETWORK TREATMENT

Start a Network as Soon as Possible

1. It is important to see the alcohol or drug abuser promptly, because the window of opportunity for openness to treatment is generally brief. A week's delay can result in a person's reverting back to drunkenness or losing motivation.
2. If the person is married, engage the spouse early on, preferably at the time of the first phone call. Point out that addiction is a family problem. For most drugs, you can enlist the spouse in assuring that the patient arrives at your office with a day's sobriety.
3. In the initial interview, frame the exchange so that a good case is built for the grave consequences of the patient's addiction, and do this before the patient can introduce his or her system of denial. That way you are not putting the spouse or other network members in the awkward position of having to contradict a close relation.
4. Then make clear that the patient needs to be abstinent, starting now. (A tapered detoxification may be necessary sometimes, as with depressant pills.)
5. When seeing an alcoholic patient for the first time, start the patient on disulfiram treatment as soon as possible, in the office if you can. Have the patient continue taking disulfiram under observation of a network member.
6. Start arranging for a network to be assembled at the first session, generally involving one of the patient's family or close friends.
7. From the very first meeting you should consider how to ensure sobriety till the next meeting, and plan that with the

network. Initially, their immediate company, a plan for daily AA attendance, and planned activities may all be necessary.

Manage the Network with Care

1. Include people who are close to the patient, have a long-standing relationship with the patient, and are trusted. Avoid members with substance problems, because they will let you down when you need their unbiased support. Avoid superiors and subordinates at work, because they have an overriding relationship with the patient independent of friendship.
2. Get a balanced group. Avoid a network composed solely of the parental generation, or of younger people, or of people of the opposite sex. Sometimes a nascent network selects itself for a consultation if the patient is reluctant to address his or her own problem. Such a group will later supportively engage the patient in the network, with your careful guidance.
3. Make sure that the mood of meetings is trusting and free of recrimination. Avoid letting the patient or the network members feel guilty or angry in meetings. Explain issues of conflict in terms of the problems presented by addiction; do not get into personality conflicts.
4. The tone should be directive. That is to say, give explicit instructions to support and ensure abstinence. A feeling of teamwork should be promoted, with no psychologizing or impugning members' motives.
5. Meet as frequently as necessary to ensure abstinence, perhaps once a week for a month, every other week for the next few months, and every month or two by the end of a year.
6. The network should have no agenda other than to support the patient's abstinence. But as abstinence is stabilized, the network can help the patient plan for a new drug-free adaptation. It is not there to work on family relations or help other members with their problems, although it may do this indirectly.

Keep the Network's Agenda Focused

1. *Maintaining abstinence.* The patient and the network members should report at the outset of each session any exposure of the patient to alcohol and drugs. The patient and network members should be instructed on the nature of relapse and plan with the therapist how to sustain abstinence. Cues to conditioned drug seeking should be examined.
2. *Supporting the network's integrity.* Everyone has a role in this. The patient is expected to make sure that network members keep their meeting appointments and stay involved with the treatment. The therapist sets meeting times and summons the network for any emergency, such as relapse; the therapist does whatever is necessary to secure stability of the membership if the patient is having trouble doing so. Network members' responsibility is to attend network sessions, although they may be asked to undertake other supportive activity with the patient.

3. *Securing future behavior.* The therapist should combine any and all modalities necessary to ensure the patient's stability, such as a stable, drug-free residence; the avoidance of substance-abusing friends; attendance at twelve-step meetings; medications such as disulfiram or blocking agents; observed urinalysis; and ancillary psychiatric care. Written agreements may be handy, such as a mutually acceptable contingency contract with penalties for violation of understandings.

Make Use of Alcoholics Anonymous and Other Self-Help Groups

1. Patients should be expected to go to meetings of AA or related groups at least two to three times, with follow-up discussion in therapy.
2. If patients have reservations about these meetings, try to help them understand how to deal with those reservations. Issues such as social anxiety should be explored if they make a patient reluctant to participate. Generally, resistance to AA can be related to other areas of inhibition in a person's life, as well as to the denial of addiction.
3. As with other spiritual involvements, do not probe the patients' motivation or commitment to AA once engaged. Allow them to work out things on their own, but be prepared to listen.

Joan E. Zweben

INTRODUCTION

This chapter describes the elements of individual therapy from the perspective of therapists working in the community as well as those working in addiction treatment programs. It gives an overview of the treatment tasks for therapists who are not specialists in the addiction field but are aware of the roles of alcohol and other drug use in undermining their patients' progress in other areas. It also reviews the tasks of the therapist or counselor who works within a structured addiction treatment program.

A great deal of addiction treatment is conducted in groups, and the relative expense of individual sessions can lead to downplaying their value. However, such sessions can play a key role in promoting the engagement and retention that is associated with positive substance abuse treatment outcomes. It is imperative that the therapists have familiarity with the stages and tasks of recovery and have the ability to tailor interventions accordingly. Individual therapy with a clinician familiar with addiction and recovery can make a significant contribution to the patient's quality of life at all stages.

No single definition allows us to distinguish between therapists and counselors, but historically the terms have been used to indicate level of training and scope of practice. Therapists, by custom and by law in many states, have advanced degrees in psychiatry, psychology, or social work and corresponding state licenses to practice autonomously. Counselors working in substance abuse treatment programs may or may not have credentials, and usually have circumscribed roles that include case management, exploring current obstacles to recovery efforts and teaching of early recovery skills. They may conduct individual sessions, depending upon particular organizational licenses and state laws.

Noncredentialed counselors were integrated into treatment teams on inpatient units in the 1950s, when the Minnesota model was developed at Hazelden (1), and when it became apparent that the mental health model that defined alcohol problems as a symptom of an underlying disorder was not producing good results. Counselors in 12-step recovery were brought in to create a new model that treated alcoholism as an independent disorder that must be addressed as such. Therapeutic communities (TCs), developed and expanded in the 1960s, also relied predominantly on noncredentialed staff in recovery (2–4). Some of these clinicians and managers were hired into the private sector programs and brought important perspectives on the importance of affiliating with a culture that supports recovery.

Some of these counselors have little training, except what they receive onsite, but many states require some form of credentialing, usually certification, and such programs can be quite demanding. Some require 200 to 300 hours of course work, plus supervised field placement experience. Many of the counselors are quite gifted and their street skills have made them keen observers of human behavior. In the last decade, the U.S. federal Center for Substance Abuse Treatment (CSAT) put extensive efforts into defining the competencies required for counselors in addiction treatment settings (5). They address the following issues:

- What professional standards should guide substance abuse treatment counselors?
- What is an appropriate scope of practice for the field?
- Which competencies are associated with positive outcomes?
- What knowledge, skills, and attitudes (KSAs) should all substance abuse treatment professionals have in common?

This effort by CSAT has provided a framework for curriculum development to the credentialing bodies, and also a structure for the selection, onsite training, and evaluation of counselors in the workplace.

CSAT also offers a *Directory of Addiction Study Programs (DASP)* (<http://nattc.org/dasp/main.asp>), a comprehensive list of institutions offering a certificate, associate, bachelor, master, and/or doctoral program in substance use disorders treatment. Included in this directory are institutions offering a concentration, specialty or minor in the addiction field.

THERAPISTS AND COUNSELORS WITHIN A SPECIALTY TREATMENT PROGRAM

Individual therapists and counselors have a variety of roles, depending on whether they are in specialty programs or private practice, and whether they are licensed or not. Both counselors and therapists in specialty programs may be utilized to do a comprehensive assessment, but whether this includes a precise evaluation of a mental disorder that coexists with the addictive disorder depends on whether the clinician has the training and appropriate license to do so. Although it can be difficult to get an accurate diagnosis, uncontaminated by substance-induced symptoms, it is nonetheless important to make a provisional diagnosis or a sufficiently clear description of symptoms to allow for treatment planning. This diagnosis can be revised as further information emerges.

Entry into a specialty program is often precipitated by a crisis and this is often best managed in individual sessions. It is tempting for family members and outside therapists to breathe a sigh of relief once the patient is admitted to a residential or inpatient program, but engaging family members and outpatient therapists at this stage gives an excellent opportunity to promote their involvement in the treatment episode (6,7) and in the patient's long-term recovery. Even a single meeting with family members permits the therapist to work more effectively with the patient toward good resolution of the current crisis. Some desirable outcomes of the crisis intervention are relief from stress and fear, enhancing the patient's confidence in the utility of professional help, harnessing the opportunities in the crisis, and increasing awareness that the alcohol and other drug use is only one element that needs to be addressed.

Structured programs rely heavily on group interventions, and these have some distinct advantages (8). Indeed, some staff may take the position that individual sessions undermine group participation. However, individual sessions have strategic value in promoting engagement, particularly for patients who are not yet comfortable disclosing important issues in a group format. It is important that therapists repeatedly encourage patients to bring important issues to the group as soon as they surface, and fears of further disclosure can be addressed.

Licensed therapists usually have strong clinical skills to bring to this effort. Individual sessions offer more time to explore issues related to motivation, work on ambivalence about abstinence, discuss incidents where behavioral strategies appeared to break down, and focus on the interplay between alcohol and other drug use and other psychiatric disorders that may be present. Although all of this can be done in the group setting, time constraints can preclude the kind of thorough discussion that improves results.

Therapists in Independent Practice

Finding a Therapist with Adequate Proficiency

The task of finding a therapist who is competent to assess and treat substance abuse issues is more complicated than one might assume. Unfortunately, academic degrees and professional licenses may not accurately represent specific skills to address substance abuse. Graduate or medical schools do not necessarily integrate thorough training in the assessment and treatment of addictive disorders into their core curricula, nor are their supervisors always prepared to address these issues in clinical training settings. Indeed, the older and more "seasoned" the clinical supervisor, the less the likelihood that he or she has had formal training in addressing substance abuse. Some seek it out, but many assume their basic training will serve them with only modest modifications and underestimate the importance of specialized knowledge. Licensed professionals have been known to be too wedded to their theoretical models, or their temperament may hamper their ability to revise their practices in the light of emerging evidence.

The claim that "I have been seeing alcohol and drug users for many years" does not settle questions of competence. Therapists become comfortable with the practices they have developed over time and are not usually in a position to study their dropouts. Many patients report minimizing or concealing their alcohol and other drug use for years, whereas their therapists focus on psychodynamic issues. When such issues become apparent, some therapists assume that a referral to 12-step programs or other forms of self-help is adequate to address the addiction. In the absence of specific knowledge about conducting a drug and alcohol assessment, they are ill equipped to determine if this will be enough.

The issue of the therapist or counselor's recovery status has been debated for decades. Many patients indicate that having a therapist in recovery increases their confidence that they will be understood and be given helpful guidance. However, some recovering people, like some licensed professionals, can be quite rigid and may find sophisticated ways to blame the patient if the treatment is not working. Although this issue has not been extensively studied, there are currently no data that support the notion that recovery status leads to greater or lesser effectiveness. The same is true for licenses and credentials. It is likely that in the end, therapist variables will be shown to have a major influence on substance abuse treatment outcome, as it has in psychotherapy itself (9). In the psychotherapy literature, therapist variables (the quality of the relationship, therapist effects such as positive regard) account for 18% of the variance, and the specific treatment method accounts for 5% to 8% (9).

In selecting good therapists for referral, it is helpful to consider

- Evidence of basic knowledge, through course work or continuing education activities
- Recent updates in training
- Good relationship skills, as reflected in patient and colleague feedback and patient satisfaction surveys.

Finding a Specialty Program

Therapists in the community are in a prime position to intervene early on developing problems with alcohol and other drugs, and if they are proficient, they may save the patient decades of self-destructive behavior. However, the patient may reach a point where more structure is needed than a private practitioner can provide and referral to a specialty program is in order. Patients rarely welcome such a recommendation. Indeed, it can take months or even years to prepare a psychotherapy patient to enter a specialty program, as these patients often do not recognize the significance of their alcohol and other drug use in their distress. A rapidly changing landscape in which programs open, close, or are acquired by different corporate entities makes it difficult to know which programs are sound. General considerations when choosing a program should include

- Whether the program has a current license from the Commission on Accreditation of Rehabilitation Facilities (CARF) or the Joint Commission (aka the Joint Commission on the

Accreditation of Health Care Organizations) or another certifying entity recognized by the state where the program is located.

- If not part of a local medical center, whether the program has a close relationship or current referral agreement with local primary and specialty care, including detoxification if needed.
- If the program involves family members in therapy and recovery planning. This means that geographical considerations should usually take precedence over prestige, unless financial resources permit participation no matter what the location.
- If the program uses evidence-based practices and explains them clearly to family members.
- If the program either provides or has access to medications, including psychotropic medications and medications used to treat addiction (such as buprenorphine or methadone). The program should not discriminate against patients needing specific types of medications. It is especially important that programs do not discourage patients needing opioid agonists or partial agonists from utilizing such medication as part of a comprehensive program of recovery.
- If the program is willing to maintain a collaborative relationship with the therapist in the community and include the therapist when possible in recovery planning meetings.

It is very important to assess financial resources and plan for a long-term recovery process. In private sector programs, what is offered as data on outcomes often originates from the marketing department and the average patient or family member is not equipped to evaluate the data they are shown. Interestingly, public sector programs are under more pressure to utilize evidence-based practices and document outcomes, and are often subject to third-party scrutiny. High prestige programs are often touted as the most desirable and some families mortgage their retirement in order to send their loved one for a month or more. The key question is what resources will be needed for the long term? What services will need to be continuous? For example, a patient with complex medical and psychiatric problems will possibly need a team that includes several physician specialists and a therapist, one of whom must agree to coordinate the care over the long term. The choice of inpatient or residential treatment should rest on whether the patient will get the needed services there, and what is offered in the brochure may not correspond to what is readily available once the patient enters the program. Inpatient/residential treatment may be an excellent way to sort out the patient's different problems, but the long-term structure and treatment plan will determine success. Unfortunately, the patient who has regular crises can elevate the anxiety of family members and even the therapist, resulting in magical expectations for specialty treatment. Not all essential activities need to be provided by professionals. There is a growing emphasis on a recovery-management approach that provides long-term supports and recognizes multiple pathways to healing (10). This paradigm shift requires relinquishing a crisis-oriented, acute care model that focuses on isolated treatment episodes

in favor of a broader perspective in which professional treatment plays an important but not exclusive role.

Possible Conflicts between Therapists and Addiction Specialists

Smooth working relationships take time to develop, and many exist between addiction specialists and therapists in the community. It is helpful for the addiction specialist to recognize that time spent educating other professionals about treating addictive disorders has a multiplier effect, in that many other patients will benefit. Stigma is alive and potent; many therapists still have a stereotyped view of individuals with alcohol and other drug problems, especially about their prognosis. However, with training, therapists can become quite proficient at handling mild to moderate substance abuse problems and in preparing patients for specialty treatment if it will be needed. This puts them in a prime position to do prevention and early intervention, a valuable service to their patients.

Although it is increasingly common to find graduate programs providing education and supervision about the treatment of addictive disorders, older, seasoned therapists are the least likely to have received such training except for brief intensive workshops, often required for initial licensure or license renewal. Therapists who have been in practice for several decades may enjoy excellent reputations as clinicians, but may not appreciate their own limitations in addressing alcohol- and drug-using behavior. Since therapists do not systematically follow their dropouts, they can become comfortable with their way of handling these issues without knowing true outcomes.

Conflicts are also possible between some traditional models of psychotherapy and principles of addiction treatment. For example, insight-oriented psychodynamic therapy places great value on insight into root causes as a primary source of behavior change, whereas addiction treatment stresses the importance of structure and systematic transmission of specific skills to change drug-using behavior. Addiction specialists are more likely to be directive, particularly in early recovery, whereas psychodynamic therapists have more varied styles. These differences can be managed with good communication. Community therapists have an enormous contribution to make in early identification and intervention and to improve quality of life for the recovering patient.

Another major source of tension between psychotherapists and addiction specialists can also be the failure to understand the importance of self-help group participation. This is addressed later in this chapter.

Strengths and Limits of Office-based Therapy

There are distinct advantages to office-based therapy, and challenging disadvantages. Social stigma and the possibility of severe negative consequences to admitting substance use cause many individuals to avoid or delay seeking help for extended periods of time, especially in group settings. An office setting affords far greater reassurance of privacy and confidentiality. It is a far less threatening point of entry into treatment, and for those already in psychotherapy, there is an excellent opportunity to avoid the full-blown consequences

of a substance use disorder through identification and early intervention by a therapist who is already trusted. There is greater possibility of flexible, individualized care. Most addiction treatment programs rely heavily on group interventions, for very good reasons. They often do a comprehensive assessment but are limited in their ability to offer individualized treatment. They also may be rigid in their rules, making it difficult to deal with patients who are ambivalent about their goals, or promote premature discharge of patients who are unable to achieve abstinence quickly or who relapse after doing well. Patients may also resist self-help group participation, the cornerstone of most addiction treatment programs. This resistance may often be more effectively dealt with in an individual therapy modality. A more complete discussion of patients who can benefit from office-based treatment can be found elsewhere (8).

Office-based treatment may have significant limitations, especially for the practitioner who does not have strong connections to other resources, including specialty addiction treatment programs. It is important for the therapist to identify an addiction medicine specialist to identify, evaluate, and treat addiction-related medical conditions. Early psychosocial treatment typically requires multiple visits each week, and patients may not be able to afford this, or their insurance may not cover anything but licensed addiction treatment programs. Individuals whose alcohol or other drug use is severely out of control usually require the firm structure of an inpatient, residential, or intensive outpatient specialty program to be launched into a successful recovery process. This is especially true if the patient is a suicide risk, or at risk of harming others. Therapists may be unwilling or unable to provide drug and alcohol testing in the office, and unable to find a monitoring program in the community. This undercuts his or her ability to have an objective marker of progress. It is highly desirable for therapists working with individuals to have an addiction recovery group available, either in his or her practice or in the community. This may be difficult to achieve. In short, the solo practitioner must assemble a variety of the resources normally found within structured programs to be prepared to meet the needs of the addicted patient.

In summary, the therapist in the community is in an ideal position to do early intervention, provide assistance to those with mild-to-moderate problems, and prepare patients to enter a specialty treatment program if that becomes appropriate. They can make an invaluable contribution to the quality of recovery, particularly if they develop an understanding of what it takes and are sensitive to relapse warning signs.

History of the Treatment

Individual psychotherapists have long attempted to address alcohol and other drug use within their preferred models. Leon Wurmser (11,12) represented a classic psychoanalytic view and recommended that the therapist provide and maintain an attitude of warmth, kindness, and flexibility in contrast to a more authoritarian approach adopted by many addiction treatment programs. He described substance

abusers as having severe pathology due to childhood trauma, which must be addressed for treatment to be effective.

Edward Khantzian emphasized the user's vulnerabilities in self-regulation and self. He viewed drug use as self-medication in which individuals seek the specific actions or effects of each class of drugs in order to relieve or change a range of painful affect states (13–15). He thought that modified dynamic group therapy was an excellent way to address patients' difficulties in understanding and regulating feelings, self-esteem, relationships, and self-care. Henry Krystal introduced the concept of alexithymia, describing substance abusers' difficulty with recognizing, naming, tolerating, and verbalizing emotions (16). He viewed this as emanating from early failure to individuate from the mother and was not optimistic about the potential of psychotherapy to remedy these deficits. The early theorists relied on resolution of the underlying problems to address the substance abuse.

Stephanie Brown is perhaps the first person to write comprehensively about addressing alcoholism in the context of psychodynamic psychotherapy, from a perspective more focused on the addictive behavior itself (17–19). Her first book was published at a time when it was very unlikely that the patient's alcoholism would be recognized and appropriately addressed by physicians, psychologists, and other helping professionals. At that time, many recovering individuals felt mistrust of professionals, feeling they had been discouraged from pursuing abstinence and their entry into recovery had been delayed, sometimes by decades, by a well-meaning professional. Alcoholics Anonymous (AA) was viewed with condescension by many professionals. Her book, rich with clinical examples, described the recovery process in developmental stages: drinking, transition, early and ongoing recovery, and described the therapist's tasks at each stage. Recovery was more than the absence of drinking; it was a complex developmental process with many permutations. Her discussion of the potential partnership between AA and psychotherapy went beyond encouraging a positive attitude on the part of professionals and outlined a model for how the therapist could enhance the synergy. Because she skillfully integrated the perspective of a psychodynamic therapist with that of a recovering person, this book was greatly appreciated by psychotherapists in the community. Since her methodology was qualitative and observational, her work has not been widely recognized by researchers. Evidence from controlled trials is discussed later in this chapter.

Unique Features of the Treatment Approach

Setting Goals: Harm Reduction versus Abstinence

The issue of harm reduction versus abstinence as a treatment goal can be a significant aspect of the therapeutic encounter in individual psychotherapy for a patient with a substance use disorder, and the therapist should be familiar with these concepts and their own stance on this feature of treatment. Harm reduction is a public health strategy intended to reduce the impact of particular behaviors on individuals, families, and communities. Abstinence is on one end of the continuum of

harm reduction and controversy exists about the merits of intermediate goals.

The controversy over harm reduction versus abstinence goals has existed for at least a decade, with some polarization still evident but also a blending of practices over time. There is a research literature supporting a variety of benefits from both interventions, but to date there is no controlled trial comparing the results of random assignment to programs with each goal. We know that abstinence-oriented treatment produces a small percentage (possibly 20%) of continuous, unbroken abstinence over a period of many years. Nonetheless, it yields significant benefits of reduction of alcohol and other drug use, reduction of drug-associated crime, improvement in family, medical (including psychiatric) status, and family functioning. We do not know if harm reduction treatment programs (as opposed to specific harm reduction interventions) produce comparable benefits. They may well do so, but they have not been rigorously studied in the same way. A more extensive discussion of harm reduction approaches by some of its main proponents can be found elsewhere (20,21).

In this author's view, harm reduction can be seen as a continuum on which total abstinence produces the most extensive and stable gains, but behavior changes short of that still produce meaningful benefits. Many, perhaps most, patients enter treatment with a deep desire to practice controlled use, but those who seek treatment in specialty settings have typically spent much of their lives trying to do so, with serious negative consequences. Those who achieve abstinence for extended periods of time, with occasional slips or short relapses, can often maintain their gains. We know that abstinence-oriented programs, despite their imperfections, produce substantial harm reduction. We do not know if harm reduction programs produce equivalent harm reduction. These important studies still need to be conducted.

Patients seen in private practice may be possible candidates to choose their own harm reduction goals. These should be consistent with health guidelines on consumption, for example, limits on alcohol (www.niaaa.nih.gov/FAQs). There are no sure methods for selecting who will do well with a harm reduction approach, but a short personal history of substance use, no family history of problematic substance use, and no physical dependence on the substance are commonly used criteria. Disqualifiers include pregnancy, medical and psychiatric conditions exacerbated by use, and hazardous interactions with prescribed medications. In the case of illicit drugs, the risks of procuring, possessing, and using the substances are a consideration. Therapist neutrality should be carefully communicated so that the therapist is not seen as endorsing these behaviors.

Therapists who are not substance abuse specialists need to familiarize themselves with immediate and delayed negative effects of alcohol and other drugs (covered in detail in this book) the patient is taking in order to be able to identify and discuss negative consequences. The majority of addiction specialists are convinced by their observations that once a person has crossed the boundary into uncontrolled use, he or she is unlikely to be able to return to controlled use of their

primary drug of abuse *and* all other intoxicants. The clinician can acknowledge that the patient will select his or her own goals despite our recommendations, but we can avoid suggesting that one goal is as good as another and can emphasize that abstinence offers the widest margin of safety and the best foundation for progress.

Therapists can use harm reduction as an engagement strategy, collaborating with the patient on a treatment contract that acknowledges that if the patient cannot stay within limits, abstinence becomes the goal. This provides a structure for the patient to discover time-worn principles for himself or herself if these are relevant. It allows the therapist to keep the alliance with the patient in focus while giving forthright feedback on the patient's decision making. It is important to avoid a power struggle over abstinence goals, but it is equally important to give clear recommendations. Patients can be asked to make specific commitments to a goal, and then keep notes of their experiences. Many patients decide the struggle to maintain controlled use is exhausting and total abstinence is actually a relief.

Careful documentation is especially important when the therapist supports harm reduction goals, as liability issues can be significant if the patient causes harm to others in the course of active alcohol and other drug use.

Engagement

Motivational Enhancement

Counselors trained in substance abuse treatment settings are more likely to have been exposed to systematic motivational interviewing and enhancement techniques, due to extensive training efforts over the last 15 years. These techniques, described in detail in Treatment Improvement Protocol #35 (22) (available at no charge from the National Clearinghouse for Alcohol and Drug Information, <http://ncadi.samhsa.gov/>), are reviewed in Chapter 46 of this book. It is a set of principles geared to the individual's stage of change. These stages include

- Precontemplation, in which the patient is unaware or underaware that alcohol and other drug use is a problem.
- Contemplation, in which the patient is aware that there is a problem, but highly ambivalent and not yet committed to action.
- Preparation, in which the patient is feeling more positive about taking action, or making small steps.
- Action, in which the patient is taking visible steps toward quitting.
- Maintenance, in which the patient is focusing on maintaining gains, including mastering relapse prevention strategies.

Clinicians within specialty programs may assume that the patient who has been admitted is in the Action stage and may underestimate the ambivalence that is still lurking. Patients themselves downplay it for fear of disappointing their caregivers and peers. Others, under coercion, may be biding their time until they are once again free to drink and use. Individual

sessions can provide a place where there is adequate time to elicit ambivalence and perhaps actual plans to use, and address them more thoroughly.

There are a number of psychodynamic reasons for continued substance use that may be useful to address. Fear of failure can increase resistance to making an abstinence commitment. The patient, wishing to avoid another discouraging experience, does not commit wholeheartedly to the effort. Closely related to this is a feeling of hopelessness or fear of the unknown. If the patient has a significant other who drinks and/or uses, the thought of abstinence and recovery can bring appropriate fears that the relationship might not survive. If domestic violence has been part of the relationship, vulnerability may be further enhanced. An addiction pattern in the family of origin can be another psychological obstacle. Despite the pain caused by the addiction, patients may feel on some level that drinking and using are how one belongs in this family, and abstinence will effectively make them an orphan. Patient may feel survival guilt in relation to family members or other significant persons. This self-reproach for leaving others behind may be another contributor to fears, particularly if the patient has previously had some successful time in recovery. Many of these feelings and beliefs may not be conscious, or may only be partially conscious, and can benefit from careful exploration that usually does not occur in groups because of time constraints. In the early abstinence stage, the goal of this exploration is to identify specific obstacles that often mystify the patient. Most arrive in treatment when they are suffering significant negative consequences and often do not understand their own resistance in the face of overwhelming evidence that alcohol and other drugs are having a destructive influence in their lives. The therapist should make clear that it is not necessary to resolve complex emotional issues in order to change drug-using behavior. Labeling the key issues can allow them to move on. Work on resolution takes place later on a foundation of abstinence.

The conviction that drinking and using are a form of self-medication is another prevalent reason to resist an abstinence commitment. Patients often have plausible reasons for their beliefs and it is unwise to discount their position. An educational posture is likely to be the most productive. Most patients focus on the initial effect of the drug, and do not adequately weigh the longer-term effects, even when they know what these are. For example, many cite the euphoria and feelings of relaxation that accompany the first drink of the day as a reason why they are sure that it helps them manage stress. Even though they usually “know” that alcohol is a central nervous system depressant, they do not connect drinking with their worsening depression over time. The therapist can alert them to the difficulties of focusing on a drug’s immediate reward and ask them to notice and discuss the unfolding consequences. Journal-keeping is an excellent way to do this, but careful inquiry can also bring insight about the longer-term consequences. The therapist should be prepared to identify specifics related to the patient’s drug(s) of choice:

Susan had begun using methamphetamine in her 20s when she began feeling overwhelmed caring for her three

children and noticed she was becoming more and more depressed. Methamphetamine energized her and made her feel able to manage her increasingly complicated life. Over time, however, her depression and desperation worsened and she began using more and more of the drug just to get through her day. She sought psychiatric help, but she went through a series of antidepressants and reported that “they didn’t work.” Upon inquiry, she was able to identify turning points in the escalation of her use, and consider the possibility that her self-medication strategy was in fact resulting in longer and deeper episodes of depression, and counteracting any benefits of the medications.

Preparing the Patient for Specialty Treatment if Needed

Patients do not greet the recommendation to specialty treatment with enthusiasm for a variety of reasons. Many resent the pressure to give up their drugs and do not yet have strong enough incentives to undertake the task. Many communities do not have an appropriate program. For example, working patients often seek an intensive outpatient program with evening sessions, but residential treatment is the only option. The patient may lack insurance coverage or other financial resources for payment. Some large public sector programs offer specific programs for higher functioning patients who can pay and these are typically less expensive than other high-profile programs that advertise extensively. However, they may provide excellent treatment, particularly since their funding requires attention to evidence-based practices.

It must be acknowledged that addiction treatment programs vary widely in quality and patient resistance may be justified in terms of local lore or professional reputation. The clinician must assess whether the potential benefits of the program outweigh its shortcomings. A safe environment with a firm structure alone is an enormous benefit that may outweigh other objections. Patients may insist that they can only benefit from a program tailored to their preferences (e.g., no 12-step elements), which either does not exist or is otherwise unavailable. The clinician can adopt a “take what you need and leave the rest” stance when encouraging a more realistic approach. It may also be useful to take the position that “it is necessary that you want a better life for yourself so badly that you are willing to do a lot of things you do not like.” In any case, the therapeutic alliance is the clinician’s strongest asset and if the patient needs specialty treatment, it is likely that a crisis will eventually present itself as the catalyst for action.

It should be noted that recovery is a long-term process that may or may not require continuing professional treatment, so families must manage their resources with this long-term view. It is common for therapists and family members to be anxious and exhausted coping with the alcoholic or drug user, and reach for residential/inpatient treatment as the only acceptable solution. Skillful advertising promotes the idea that high-end treatment can be the “cure” for addiction and families can spend hard earned savings to provide this level of service. It is important that an addiction specialist makes a careful assessment to determine which actual services will meet the needs of the patient.

Connecting Presenting Problems with Alcohol and Other Drug Use

Many patients do not connect their alcohol and other drug use with the troubles that propel them to seek therapy, so the therapist must help them make that link. This requires familiarity with the different drugs of abuse, not only their short-term effects but also the longer-term consequences that unfold days or weeks after the episode of use, or after the patient has gone from occasional to regular use. The therapist should not attempt to “prove” that the patient’s problems are the result of drinking and/or using, but should make the connection and encourage the patient to think about it, including keeping a journal to promote closer observation. For example, the woman described above (Susan) who used methamphetamine to energize her to cope with her three children may not connect her worsening depression with her stimulant use. The husband whose wife is frustrated over his “not being there” may not acknowledge the role of marijuana in their marital difficulties. In addition to the detailed descriptions of drug effects contained in this volume, clinicians should keep a recent reference book at hand, such as the well-known guide by Marc Schuckit (23) to confirm the links between alcohol and other drug use and specific psychiatric symptoms. Alcohol and other drugs are great imitators of or contributors to conditions that therapists see regularly. These include low self-esteem, interpersonal conflict, sexual problems, difficulties in following through at home or work, “boredom” in relationships or at work, and a host of other complaints.

Setting Goals

Patients entering a specialty addiction treatment program usually do so with the expectation that they accept abstinence as a goal. However, it is important to make room for an ongoing discussion of ambivalence, which is always present to some degree. For some patients, a wavering commitment to abstinence surfaces once they feel better and begin to convince themselves that they “can handle it now.” Others harbor fantasies of controlled use from the outset. Some treatment programs convey the impression that ambivalence is somehow a sign of failure or lack of commitment to recovery and thus discourage disclosure. It is important to convey that ambivalence is normal and open discussion can provide insight and encouragement. This is an excellent opportunity to reinforce the idea that cravings or feelings do not have to be acted upon.

A variety of programs, especially those designed for the severely mentally ill and those addressing HIV/AIDS, provide low-threshold admission in which the goal is to engage the patient and focus on whatever goals are acceptable to reduce harm to self and others. In these programs, setting specific goals that are realistic, incremental, and achievable is important. Early successes increase motivation and engagement, and some patients eventually find themselves committing to total abstinence even when they had no intention of doing so when they entered the program.

Regardless of program orientation, some risk factors require immediate attention. Imminent danger to self and/or

others must be addressed immediately. Vigorous intervention is required for patients who are suicidal, homicidal, psychotic, or at risk for serious violence at home or elsewhere. Other dangers include driving while intoxicated, having unprotected sex with strangers, or patterns of self-mutilation. Patients may also need a medically managed withdrawal. Drugs such as cocaine, methamphetamine, or marijuana can be discontinued immediately without medical consequences. Alcohol may require a medicated withdrawal; this should be assessed by a physician before stopping abruptly. Benzodiazepines and other sedative–hypnotics require physician assessment and management for withdrawal. Withdrawal from opiates is not in itself life-threatening, but the stress of withdrawal can be dangerous to patients with other medical conditions, such as heart disease. A full discussion of management of withdrawal can be found in relevant chapters in this book.

Patients may also enter treatment at risk for serious and possibly irreversible psychosocial consequences if substance use continues. These include the loss of a job, breakup of an important relationship, loss of professional licensure, loss of child custody and/or visitation, and incarceration. Patients with these kinds of dilemmas may cooperate with recommendations for early treatment goals or they may refuse to accept recommendations. In the latter case, it is possible that skilled motivational enhancement interventions that maximize the patient’s legitimate choices at each point may prove successful in enlisting cooperation. It is important for the therapist to take an appropriately active stance while avoiding fruitless overcontrolling behavior that reflects a power struggle rather than firm guidance.

Establishing Abstinence: Stabilization Phase

Mastering the Behaviors of Abstinence

Cognitive–behavioral and contingency management strategies have been extensively researched and can be employed as a component of psychotherapy to assist patients to establish and maintain abstinence (see Chapters 44, 45, and 47). Early recovery skills include the ability to anticipate and manage cravings and urges. As stated in the popular video series, *Beat the Street*, “Avoid if you can; cope if you must.” Assertiveness is often a problem, and a variety of approaches teach patients how to assert themselves without being apologetic, how to refuse alcohol and other drugs, how to extract themselves from compelling but dangerous situations, and how to establish a protective structure that will facilitate progress. It is important to identify family members and others who can be relied upon to provide support in the recovery process. Often, it takes effort to reconnect with such people, or develop new relationships, and the therapist can provide an arena to discuss difficulties and make a plan to address them.

It is useful to distinguish between alcohol and other drug use that occurs in the early stages of recovery from that which occurs after abstinence has been relatively stable for an extended period of time. The first reflects a failure to establish stable abstinence, whereas a relapse after a sustained period of time often requires a different approach. In both cases, it

is useful to start with an examination of ambivalence about recovery, as a shift in motivation must be addressed first. It is common to find counselors or therapists turning toward their array of techniques, offering them, looking for new ones, and becoming frustrated when the patient does not follow through or comes back with a report that “it didn’t work.” Return of ambivalence is often the basis for lapses or relapses on the part of the patient. A lapse is a relatively circumscribed episode of use that does not involve a major deterioration in functioning. A relapse is a continuation of use over a period of time and often involves a regression to patterns characteristic of the worse period of active use. In the latter, recovery is no longer a priority, behavior reverts to old survival skills (such as lying to avoid accountability), and the patient returns to old people, places, and things. To the extent that the relapse involves such serious regression, the therapist must in effect start over to help the patient re-establish abstinence. However, it is also important to “do the detective work” on how and when decisions were made that made alcohol and other drug use inevitable. Unresolved grief over the loss of an important relationship may be a factor, or job problems or family illness may precipitate or contribute to the relapse. It is very common for patients to describe feeling bored or overconfident at time abstinent progresses, or feeling they do not need to continue activities such as 12-step program attendance that were important to recovery.

Identifying and Addressing Co-occurring Disorders

Although there is general consensus that psychotherapy should focus on discontinuing drug use before addressing other issues (24), in practice this may not work. Patients may insist that their traumatic experiences haunt them and they cannot be expected to give up their alcohol and other drug use until they make some progress toward putting their feelings to rest. Women in domestic violence situations who seek treatment in substance abuse settings may not be able to focus on their substance abuse until they receive some help for the threats from their relationship. Brown and colleagues (25) offer a Steps of Change Model that proposes that substance-abusing women seeking help may have a hierarchy of readiness, based on the urgency of their issues. Those in battering relationships may be ready to make changes in their exposure to violence before they are fully receptive to substance abuse treatment. The clinician who offers meaningful help is in a good position to engage the patient about the substance use. Treatment priorities should not be determined by rigid formulas, but the therapist can work within a recovery-oriented framework and address topics consistent with where the patient is in the recovery process. Thus, specific content can be discussed at any time, but the goals can shift from engagement, to stabilization (symptom management), to mastery.

Trauma issues are frequently cited as a reason why patients cannot make an abstinence commitment. They express fear that their symptoms will become unmanageable and refuse to proceed further until these issues are “resolved.” They can be reminded that establishing safety is the first step to

resolving trauma issues and they cannot be safe if they continue to drink and use. The therapist must give adequate attention to preparing the patient for the possibility of an upsurge of symptoms by making a careful assessment of the patient’s resources and enhancing coping skills for that troubled time. Seeking Safety (26) is an empirically validated, manualized treatment for stabilization of such patients in early recovery. It offers a wealth of strategies to strengthen patient-coping skills and is well regarded by clinicians and patients alike.

Family and Social Issues

Couples and family issues are addressed elsewhere in this volume. Suffice it to say that the patient will benefit from family interventions designed to coach others about how to support the recovery process. Dislocations in family functioning are also best dealt with in a coordinated fashion, with goals related to what the patient can handle at each stage of recovery. Although Alanon can be invaluable to family members, its emphasis on disengagement may conflict with the need to develop and strengthen the social supports that are needed in recovery. The therapist’s goal is to address inappropriate forms of enmeshment and facilitate health and social connections.

Facilitating the Use of Self-Help Programs

One of the most important tasks of the therapist is to facilitate the use of the self-help system. These programs fill a variety of needs that cannot be met by professional treatment alone: a community that supports the recovery process, a wide range of role models, structured activities to fill the gaps left by the absence of alcohol and other drug use, and a process for personal development that has no financial barriers. It is not interchangeable with professional therapy or substance abuse treatment, but complements and augments its effects.

There are now a variety of self-help groups (e.g., LifeRing, SMART Recovery; see Chapter 38), but the 12-step system is the largest in the world, with a great variety of groups in most urban environments and some resources in rural communities (see Chapter 37). At high risk times, such as holidays, there are often meetings at all hours of the day and night, providing a safety structure unmatched by anything except residential treatment. High-profile celebrities have made the public aware that meetings are attended by members of all social classes. A patient who is truly working the steps is often an excellent therapy participant, in that he or she is “open, honest, and willing,” that is, committed to the kind of self-examination that therapy requires.

A variety of studies support the view that 12-step participation (usually AA) is beneficial and promotes long-term sobriety (27–31). Supportive interventions such as arranging for someone to take a newcomer to a meeting facilitate attendance (32), but attendance in itself is not enough. Recent research indicates that an intensive intervention to promote participation did increase involvement and was in turn associated with improved outcomes for both alcohol and other drug use (33). This finding held even for patients with

considerable previous 12-step program experience and formal treatment. There is only a moderate correlation between attendance and involvement, the latter being more related to positive outcomes (34). Earlier studies distinguished between attendance and involvement, the latter being measured by such things as finding and working with a sponsor, chairing meetings, working the steps, and doing service (35–37). These studies also supported the view that involvement was related to positive outcomes.

Opinions about the value of particular research methods can skew the debate on AA effectiveness. The prestigious *Cochrane Reviews* analyzed eight experimental trials involving 3417 people and concluded that none of the studies unequivocally demonstrated the effectiveness of AA or 12-step facilitation (TSF) approaches for reducing alcohol dependence or associated problems (38). On July 25, 2006, the *New York Times* reported “review sees no advantage in 12-step programs.” Unfortunately, this type of headline fails to acknowledge the limitations of the *Cochrane Reviews*. In general, their exclusive focus on experimental studies dismisses a large body of relevant research, particularly important with respect to 12-step programs because patients cannot be randomized to AA or no AA. It is not possible to control whether they attend or not. The randomized studies that do exist are based on more indirect methods. Kaskutas, principal investigator in some of the studies, has offered critiques of this specific review (39), citing serious errors in how the studies are described and classified. For example, she notes the conflating of the manualized TSF intervention, used in professional treatment settings, with the 12-step self-help group. She also notes that experimental evidence is only one of six criteria for establishing causation, and the evidence from other types of studies is compelling (39).

On a more clinical note, it is important for the therapist to facilitate engagement in a self-help program, particularly in the early stages of recovery. If the patient is in a structured program, this task is made easier in that participation to attend self-help meetings is usually encouraged or required, and attending with peers who feel just as anxious reduces some obstacles. The therapist in private practice or in a nonspecialty organizational setting may have a more difficult task. Some therapists “require” attendance at meetings as a way to address addictive behavior. For the patient, this approach underestimates the complexity of acknowledging that drinking and/or using is a problem and that behavior needs to change. Just attending a meeting can be very charged and there are many reasons for patients to resist. In addition, self-help meetings do not address all aspects of the problem; hence, therapists need to develop proficiency at handling some of the clinical issues.

Common resistances to participation in 12-step meetings includes a generalized discomfort with strangers, or about being the outsider in a group where everyone knows one another; fears of being swallowed up by a “cult”; distaste for the rituals, especially the opening statement “I am an alcoholic/addict”; and awkwardness about “that religious stuff.” The therapist can encourage examination of these issues, while

conveying the expectation that at some point the patient will give meetings a fair try. Eliciting the patient’s picture about what meetings are like can provide an opportunity to correct misconceptions or to encourage the patient to compare what they fear or imagine with what meetings are actually like. It is productive to explore the charged issues, as these are usually reflective of broader problem areas. It is very important to give the patient permission to be ambivalent and to air negative feelings with the therapist. It may be useful to ask the patient to report first on what they disliked and then on what they learned. Negative feelings about meetings in no way preclude reaping benefits. “Take what you need and leave the rest” is an AA slogan that allows many to continue to attend. However, the therapist should monitor engagement and ask regularly about what would foster greater involvement. It is enormously useful for the therapist to provide a place for patients to talk about what is happening on a regular basis. A more extensive discussion on the intersection between self-help groups and psychotherapy can be found elsewhere (8,17).

One of the best ways to become more effective in facilitating the use of the self-help system is for the therapist to attend a variety of meetings that might be appropriate to his or her patient population. Since the 12-step system is the largest in the world, it is important to familiarize oneself with those meetings in the community. Alternative groups are also available, but they are typically fewer in number and hence less able to offer a firm support system. If the therapist is not in recovery, it is important to look for an “open meeting” in the 12-step system. It is particularly useful to note: (a) what you think, feel, and do prior to attending the meeting, while there, and afterwards; (b) what you observe about the group process; and (c) what are the strengths and limits of this group process compared to a therapy group. The self-help system and psychotherapy complement each other and it is important to understand the similarities and differences. Some therapists are uncomfortable with the “no-cross talk” rule, because they think the person sharing needs support they do not get. However, speakers are usually approached by others immediately after the meeting, and it has been proposed that social support is one of the main effective elements offered by the 12-step system (40,41).

Patients on psychotropic medication and those with severe mental illness should be coached and supported in meeting selection and attendance. Some meetings are more tolerant of medication and/or eccentric behavior, and it is helpful to have some starting suggestions. The AA literature (42) states very clearly that medication prescribed by a physician familiar with addiction is compatible with recovery and not the business of other AA members. Nonetheless, some meeting participants express their opinions freely and may bring pressure to bear on the patient to discontinue medication. This is particularly problematic when coming from a sponsor. Therapists should familiarize themselves with the AA pamphlet on medication and provide copies in the office. Role-plays on the handling of intrusive peers can be beneficial. Those with cognitive impairments can benefit from

coaching about how to behave in meetings. The therapist can review the opening rituals, go over what happens in the meetings, and remind the patient that meetings are not a place to share delusions. The 12-step structure at its best is welcoming and stable but not overly intrusive. This will vary among meetings, but those working with mental health patients can identify appropriate meetings from the recommendations of other patients.

Difficulties with a sponsor are more complicated and the therapist must remain respectful of the sponsor relationship while challenging a sponsor's inappropriate positions. Patients often cite their relationship to their sponsor as one of the most important elements in their recovery. However, patients may select sponsors who are very rigid and controlling, often re-enacting unhealthy relationship themes from childhood. The therapist can point out that a sponsor is not given a permanent appointment. People have different sponsors at different times in recovery, depending on what they need at the time. Here again, the patient may need specific help to extricate himself or herself from a negative situation.

Ongoing Recovery Issues

While individual psychotherapy can be useful in the early stages of substance abuse treatment, it also has great potential to improve the quality of recovery by addressing issues that remain after a period of extended abstinence. Patients usually need to improve their ability to identify, modulate, tolerate, and appropriately express their feelings. They need to learn to manage their feelings without being self-destructive. In collaboration with a skilled therapist, they need to learn to distinguish between strong but appropriate feelings, feelings that represent a pathologic condition such as major depression (that may need medication), and ones that may be detrimental to their psychological health. Recovering people may be intolerant of affects, but they may also be too reluctant to seek psychotropic medications, as “using a pill to feel better” is understandably a charged issue. The appropriate use of medications is not only important for a satisfying recovery, but also it can play a key role in preventing relapse as well.

Interpersonal issues are usually an important focus in ongoing recovery, as key relationships have usually been distorted by alcohol and other drug use. The selection of a mate while drinking and using usually raises issues about the durability of the relationship once abstinence is stable. During the using phase, the more intact partner or spouse often takes over key functions, such as parenting and management of finances. Recovery often brings dissatisfactions with power imbalances in relationships, which need to be carefully renegotiated on a realistic timetable. Even changes for the better raised anxiety levels and the therapist can be an important anchor as well as guide through the turmoil. Other common issues include separation and individuation, self-esteem, and issues related to childhood trauma or other sources of post-traumatic stress disorder (PTSD).

A wide range of psychotherapies can be beneficial during extended abstinence, but it is crucial that the therapist have

an appreciation of relapse potential once the patient begins to explore anxiety-provoking material. It is particularly easy to underestimate vulnerability in patients who are articulate and high functioning. Patients typically do not want to disappoint their therapists by announcing that relapse has occurred. Therapists should work with the patient to make a list of relapse warning signs for that individual and should inquire periodically about fantasies or cravings about drugs, or “exceptions” such as a drink here and there. Carelessness about attire, getting inadequate sleep, and loss of a previously regular exercise schedule can also be indications of a relapse state of mind or an actual relapse.

Research-based Principles and Interventions

The last decade has seen increasing emphasis on integrating evidence-based practices into addiction treatment programs. Private practitioners may be insulated from these expectations, unless their managed care payers impose requirements. In this case, there may be a “pick from this list” approach that constrains the ability to do individualized treatment planning or an arduous appeals process that discourages initiative. In the course of this discussion, it is important to keep in mind that evidence-based *principles* are as important as specific interventions found that showed efficacy in clinical trials (43). Examples of key elements of principles that guide funders include

- There is a strong correlation between retention in treatment and positive outcomes. Thus, we need to engage and retain patients, not discharge them for manifesting their substance-using behaviors.
- Services that are sufficiently comprehensive and continuous over time produce better outcomes. This includes attending to practical issues such as housing and transportation.
- Medications are compatible with recovery and improve outcomes when appropriately used.
- Addictive disorders behave like other chronic disorders and need to be addressed in a chronic care model, not an acute care model.
- Harm reduction approaches yield benefits in terms of public health and safety.

Controlled Trials

The first systematic investigations of psychotherapy in the treatment of addiction were conducted by George Woody and colleagues (44,45) who examined the role of psychotherapy for a male veteran population in a methadone maintenance program. Patients received individual drug counseling, supportive-expressive therapy, or cognitive-behavioral therapy plus drug counseling. The patients receiving psychotherapy improved considerably more than those who received drug counseling alone, with no differences found between types of therapy. The addition of psychotherapy was most important for patients with a high level of psychiatric symptoms.

This random assignment controlled trial legitimated the use of psychotherapy in addiction treatment, although financial constraints have always limited its use.

More recently, Project MATCH (46) demonstrated that individual therapy sessions of cognitive-behavioral coping skills therapy, motivational enhancement therapy, or TSF therapy all produced reductions in drinking outcomes from baseline to 1 year after treatment. These psychosocial treatments were well defined and manuals have been made available by both the National Institute on Alcohol Abuse and Alcoholism (NIAAA) (47,48) and the CSAT (49). It is important to remember that this study was conducted under highly controlled conditions, with far more resources than community-based programs enjoy. Fidelity checks are required in treatment trials to assure that the treatment is conducted with consistency across settings. It is in effect a form of clinical supervision, using a trained professional to review and rate audio or videotapes. Many funders of community treatment will not pay for clinical supervision. Nonetheless, it is possible that the manuals will be helpful to practitioners and training supervisors in community settings.

Specific evidence-based interventions that have been widely disseminated include motivational enhancement therapy, cognitive-behavioral therapy, contingency management (50), community reinforcement approaches, Seeking Safety (for PTSD and substance abuse), and certain family therapies. These have shown positive results in efficacy trials and vary in the extent to which effectiveness trials, which demonstrate that they work in the community, have been conducted. In any case, it is widely acknowledged that they may need to be adapted to be responsive to cultural variations. However, not enough is known about what critical elements must be maintained to preserve their potency. Practitioners are advised to familiarize themselves with these approaches, as they offer valuable tools to assist patients at different points in the recovery process. A more extensive review of research-based interventions can be found in Rounsaville et al. (51).

Meta-analysis

Unfortunately, there are no meta-analyses of psychotherapy for the treatment of substance use disorders. This reflects the relative lack of well-controlled studies of psychotherapy for substance abuse treatment. Inasmuch as the majority of patients seen in specialty settings for substance use disorders have at least one other co-occurring mental disorder, it is important to integrate effective treatments for those disorders when possible. While insufficient work has been done on the main combinations of substance use disorders and other disorders, a variety of interventions have been studied and found beneficial (52).

A recent meta-analysis (53) notes that short-term treatments are insufficient for many patients with complex disorders and examines the effectiveness of long-term psychodynamic psychotherapy (LTPP) on this challenging group of patients. The analysis included studies of patients with personality disorders, eating disorders, depressive and anxiety disorders, and combinations of these disorders (but did not

include patients with substance use disorders). For many of the patients, the disorders were chronic, that is, lasting more than 1 year. There were 23 studies, involving 1053 patients (none on psychotropic medication), in this meta-analysis. Both RCTs ($n = 11$) and carefully designed observational studies ($n = 12$) were included. The comparative analyses showed significantly better outcomes in overall effectiveness, target problems, and personality functioning than shorter forms of therapy. Within-group effect sizes were large (0.78–1.98) and stable, even across complex mental disorders. It is important to note that substance use disorders were not a part of this meta-analysis, and it is likely that a good working knowledge of addiction and recovery is essential for producing good outcomes in LTPP.

Therapeutic Alliance

Perhaps the earliest recognition of the importance of the therapeutic alliance was documented in a classic study of the usefulness of psychotherapy for opiate-dependent patients, which influenced subsequent psychosocial studies (54). Researchers and clinicians have since confirmed that some counselors or therapists achieve better outcomes (55–57) and emphasis is shifting to include examination of common factors in addition to specific interventions. Therapeutic alliance is also related to treatment dropout (58,59). Unfortunately, there has not been sufficient in-depth examination of this variable. How can programs select for clinicians with greater capability of forming an alliance? To what extent can this be taught? How can therapists be trained to deal with conflicts or ruptures in the alliance? What teaching or supervision methods are most effective? Is it better to focus on the clinician's ability to form and maintain an alliance, or on methods of obtaining fidelity to a manual? Although these are not mutually exclusive, the current emphasis on implementing specific evidence-based interventions will likely require hard choices in an era of diminishing resources.

CONCLUSIONS

Individual therapy has been studied because it allows for better control in trials on specific interventions, such as motivational enhancement or cognitive-behavioral therapy, but far too little is known about its optimal use in addiction treatment and recovery. Since it is relatively expensive to provide, it is important to understand when it is essential, desirable, unnecessary, or even contraindicated in a specialty program. Patients often report that having individual attention allows them to settle into treatment and make a sustained commitment, but it is not possible at this time to disentangle the relative contributions of different activities. For therapists working in private practice in the community, it is crucial to appreciate what must be done to effectively address alcohol and other drug use within the ongoing therapeutic relationship. It is also important to know how to prepare a patient for specialty treatment if needed. Interventions have been developed that show efficacy in controlled trials, but these are rarely used by private practitioners in the community.

Manuals exist for treatments with a strong evidence base, but little work has been done on how to disseminate them among private practitioners and train such clinicians in their use. Inasmuch as most patients with alcohol and other drug problems do not seek help in specialty settings, it is important to understand how best to strengthen the ability of community practitioners to address this issue.

Arnold M. Washton

INTRODUCTION

The history of group therapy adapted specifically for treating substance use disorders (SUDs) is not easily traced, but over the past several decades group therapy has evolved into the most prevalent form of substance abuse treatment in the United States. Group therapies are used for treating all types of SUDs (including those involving the use of alcohol, cocaine, opioids, sedatives, marijuana, and various combinations of these and other substances) and for individuals suffering from co-occurring psychiatric and addictive disorders. A broad spectrum of group therapy models (e.g., cognitive/behavioral, psychoeducational, motivational, interpersonal, 12-step, psychodynamic) are utilized by substance abuse treatment programs and practitioners operating from differing theoretical orientations. Most group-based interventions for SUDs incorporate a variety of therapeutic strategies and techniques consistent with recent trends toward integrative rather than monolithic approaches (1).

For purposes of this chapter, group therapy is defined as treatment delivered to a preselected cohort of addicted individuals in the context of regularly scheduled group therapy sessions led by a professionally trained group leader—typically an addition therapist, counselor, or other mental health professional with relevant training and experience. Considering that this is only one chapter in a comprehensive textbook, the present discussion of group-based interventions for addiction is unavoidably limited. More extensive coverage of this topic can be found in other publications (2–5).

The topics addressed in this chapter are (a) efficacy of group therapy for addiction, (b) advantages and limitations of group approaches, (c) differences between group therapy and self-help groups, (d) patient selection factors, (e) groups designed for different stages of recovery, and (f) group management considerations.

EFFICACY

Although group therapy has emerged as the most popular treatment modality for SUDs, empirical evidence of its clinical efficacy is sparse. Most studies have compared the effectiveness of different models of group therapy, but only a handful have compared group to individual therapy and results are inconsistent.

Bowers and al-Redha (6) found that alcohol-dependent patients who received couples therapy in a group format

showed greater reductions in alcohol consumption at 6-month follow-up than patients who received couples therapy individually. In addition, there was some indication that couples treated in the group format reported more improved marital adjustment and higher ratings of relationship satisfaction than couples treated individually.

Schmitz et al. (7) compared outpatient delivery of the same 12-session cocaine relapse prevention (RP) program in group versus individual therapy formats. Although the proportion of patients producing cocaine-free urine samples at the end of treatment did not differ between formats, group RP patients reported using cocaine on significantly fewer days during treatment and experienced fewer cocaine-related problems than did individual RP patients. Follow-up data collected at 12 and 24 weeks posttreatment revealed no significant differences between formats regarding cocaine use or any other outcome measures, leading the authors to conclude that the efficacy of RP interventions is not strongly influenced by delivery format. Similarly, Graham et al. (8) found no significant differences in outcome regarding substance use between individual and group delivery of a structured RP approach. Only one psychosocial outcome measure (social support from friends at 12-month follow-up) showed a significant difference that favored the group format.

Weiss et al. (9) found that in patients struggling with concurrent bipolar and SUDs, integrated group therapy designed to address both disorders was more effective than group drug counseling alone in reducing both drug use and psychiatric symptoms. Rosenblum et al. (10) reported that substance abusers in a soup kitchen who received motivationally enhanced group counseling were significantly more likely than others who received concrete services only (i.e., information, referral, advocacy) to show reduced drinking and increased participation in some type of substance abuse intervention (e.g., formal treatment and/or 12-step groups) during the follow-up period. A study by Crits-Christoph et al. (11) comparing the effectiveness of four psychosocial treatments for cocaine-dependent outpatients indicated that patients receiving a combination of group drug counseling plus individual drug counseling were more likely to show decreased drug use over time than patients who received group drug counseling only or group drug counseling plus individual psychotherapy.

An extensive study by Panas et al. (12) involving 7815 patients from 63 publicly funded outpatient substance abuse treatment programs has provided perhaps the strongest

empirical evidence to date of the efficacy of group approaches. This study found that type of treatment, defined as proportion of group to individual therapy, was strongly and positively associated with various treatment performance measures including completion of treatment and achievement of treatment goals.

Although the above studies provide some empirical support for the effectiveness of group-based treatment interventions, more extensive research in this area is sorely needed. Acknowledging this pressing need, Morgan-Lopez and Fals-Stewart (13) describe various methodologic and other obstacles that have tended to stifle substance abuse group therapy research. In addition to problems inherent in evaluating and measuring group process, these obstacles include data analytic complexities caused by group member interactions, changing group membership over time, and limited control over treatment delivery ingredients.

Despite the absence of a solid empirical base for utilizing group therapy as the treatment of first choice for addiction, the current popularity of group interventions appears to be based largely on its historically long-standing use as the mainstay of addiction treatment programs in the United States, its cost-effectiveness, and on the apparent goodness of fit between certain clinical needs/characteristics of addicted individuals and the combination of therapeutic forces that group therapy uniquely provides.

ADVANTAGES OF GROUP THERAPY

From an economic standpoint, group therapy is more cost-effective to deliver than individual therapy, making it increasingly attractive in current efforts to reduce health care costs. Due to limited resources, most treatment programs, especially those supported by public funds, are unable to make individual therapy routinely available to their patients. As compared to individual therapy, group therapy allows a larger number of patients to be treated by fewer clinicians on a given workday. Importantly, group therapy enjoys a high rate of patient acceptance and desirability among individuals seeking treatment for SUDs. In fact, patients seeking addiction treatment often prefer group to individual treatment.

One of the most striking therapeutic benefits of group-based interventions for SUDs is readily apparent to clinicians who routinely provide this type of treatment. Namely, that groups often have a unique ability to empower clients to change even after individual therapy and/or other interventions have failed. When people struggling with a common adversity join together in pursuit of a common goal, a variety of potent forces are mobilized that motivate and inspire them to overcome the adversity. This same phenomenon is evident, for example, in how people cope with the aftermath of natural disasters and other severely traumatic or life-threatening situations.

Group therapy incorporates a unique combination of therapeutic forces not available in other forms of treatment (3,5). Groups provide therapeutic opportunities for (a) mutual identification and reduced feelings of isolation and shame; (b) peer

acceptance, support, and role modeling; (c) confrontation and realistic feedback; (d) peer pressure, social support, structure, and accountability for making positive changes; (e) acquisition of new coping skills; (f) exchange of factual information; and (g) instillation of optimism and hope. The gathering together of people who share a common problem often creates a bond between them, stemming from a sense of mutual identification and an expectation of being intuitively understood. This is critically important in counteracting the intense feelings of isolation, shame, and guilt that addicted individuals often experience. The social stigma of addiction and profound humiliation of having lost control over one's behavior makes rapid acceptance into a peer group all the more important for newcomers. The group instills optimism and hope by giving newcomers a chance to make contact with others who are succeeding in making positive changes and by instantly supplying newcomers with a positive support network committed to the pursuit of common goals. Groups often enhance treatment retention as a by-product of the bonding that develops between group members. Groups provide a forum for developing better coping abilities and avoiding common pitfalls in recovery. Because groups typically place high value on self-disclosure, active participation, compliance with group norms (e.g., abstinence, punctuality, attendance, honesty), a spirit of cooperation among group members, and facing rather than avoiding problems, it is difficult for resistant or noninteractive patients to "hide out" in small groups because all members are expected to routinely participate in group discussions.

LIMITATIONS OF GROUP THERAPY

Given the numerous advantages of group therapy, what might be some of its limitations and when might individual therapy be preferable? First, unlike individual therapy where patients enjoy total privacy and confidentiality, group therapy inevitably requires patients to disclose their identity and personal problems to strangers. This can be a problem especially for patients who live in small communities where the chances of encountering people who might know them can be substantial. While maintaining strict confidentiality regarding group members' identities and the content of sessions is a cardinal rule of group therapy, there is no way to control what group members might say or do outside of group sessions. Despite increasing public enlightenment about addiction as a widespread disorder affecting people from all walks of life, unwanted disclosure of information about an individual's alcohol or drug problem still holds the potential to damage careers, reputations, and relationships.

A second limitation of group therapy is that the content and pace of the treatment is determined by the group as a whole and not by the needs of any one individual. Inevitably there are times when group therapy is out of step with the needs of some members while appropriately addressing the needs of others. This limitation is most evident in open membership groups where new members are admitted throughout the life of the group as others leave. Each time newcomers enter an

ongoing group, the continuity of treatment is interrupted as attention shifts back to newcomer issues. By contrast, individual therapy allows the therapist to address patient's issues as they arise and to spend as much time within a session or as many sessions as necessary to deal with these issues.

A third limitation of groups is that typically only a small portion of the therapy time is devoted to the needs of any one individual. This is offset to some extent by the benefits that group members may derive indirectly from participating in discussions that focus on the issues of other members. Nonetheless, individual therapy devotes 100% of the therapy time to the needs of one person, which may be more likely to engender change or perhaps do so more rapidly.

A fourth limitation is that group therapy may not be suitable or appropriate for all addicted individuals. While many, if not most, can benefit from group therapy and prefer it to other forms of treatment, others are simply not good candidates for group treatment. Patients with severe borderline personality disorders often find the intense interpersonal interaction and scrutiny in group sessions intolerably stressful. Similarly, patients who are avoidant, shy, or schizoid may be unable to participate actively in group discussions or form meaningful connections with other group members. Apart from psychiatric impairment, some patients simply do not want to be in group therapy for whatever reasons and flatly refuse to participate, preferring individual therapy instead. Although further exploration of this unreceptive stance may help to allay certain commonly held fears and misconceptions about group therapy (e.g., expectations of harsh confrontation by peers), some patients remain adamant about not wanting group therapy and it is important for clinicians to respect these patients' wishes.

GROUP THERAPY VERSUS SELF-HELP GROUPS

Group therapy and self-help groups such as Alcoholics Anonymous (AA) are not good substitutes for one another. Each forum provides a unique form of help and, ideally, they should be seen as synergistic rather than competing activities. Self-help groups have many advantages, but the in-depth attention given to psychological and personal issues that take place in professionally led recovery groups is simply not available in self-help meetings. Many individuals are not comfortable revealing personal details of their lives in the public forum of a self-help meeting and are more inclined to do so in the smaller, more intimate setting of a group therapy session. In group sessions, members are strongly encouraged to give objective feedback to one another, whereas in self-help meetings giving feedback (known as "cross talk") is not permitted. These are not criticisms of self-help groups, which contain their own unique blend of therapeutic forces, but fundamental differences between these two very different forms of help for people struggling with the problem of addiction. Unlike group therapy, self-help meetings are characterized by peer rather than professional leadership, an absence of screening or exclusion criteria, unlimited size of membership, widespread availability,

and an absence of time limits on the length of participation which may extend over a participant's lifetime.

PATIENT SELECTION FACTORS

A formal selection process is required to ensure that patients are placed in groups best suited to meet their needs. Ideally, screening of potential group members should be conducted by the clinician who leads the group. No matter how rigorous the selection process may be, it is sometimes impossible to ensure that the composition of patients placed in a group is ideal for conducting the group's therapeutic work. The goal of patient selection should be to achieve a reasonable degree of homogeneity and heterogeneity among group members (3). It is important that all group members find a basis for identifying with one or more of the other members because admitting a newcomer into the group who shares few characteristics with other members may create problems for that individual and for the group as a whole. At the same time, diversity enhances the richness of the group experience. Group members can differ in age, gender, race, socioeconomic status, educational level, and other variables as long as one member is not the lone "outlier" (3). Generally, newcomers will fare better when there are at least one or two other group members with whom they can readily identify. Individuals who are different from all other group members in one or more important respects (e.g., one woman among a group of men, one gay person among heterosexuals, one seriously impaired person among highly functional people) are likely to feel out of place in the group, not participate actively in group discussions, and/or drop out prematurely.

Group membership should not be limited only to patients who have the same primary drug of choice, considering that the addictive disorder, not the drug use itself, is the focus of treatment. Heterogeneity in this regard can help group members realize that different substances often lead to the same constellation of problems and that changes required to deal effectively with these problems are very similar, regardless of a person's substance(s) of choice. When a newcomer happens to be the only person in a group with a particular drug of choice, identification and bonding with other group members can be compromised. For example, a lone cocaine user may feel out of place in a group where alcohol is the substance of choice of all other members. It is important to help such patients identify as soon as possible the similarities between addictions to different types of substances and encourage them to identify with these similarities rather than the differences in order to feel part of the group and derive maximum therapeutic benefit from being there. Despite similarities, however, the group should not ignore some of the unique problems associated with the use of different types of substances such as residual cognitive impairments following chronic alcohol use, lingering withdrawal symptoms of depression and insomnia following cessation of opioid use, and sexual acting-out behaviors often associated with cocaine and methamphetamine use. Addressing substance-specific issues straightforwardly, proactively, and whenever they arise can

help to promote group cohesiveness and induct patients with different substances of choice into the group.

In addition to the above, other important patient selection factors include the patient's desired treatment goals, motivation or reasons for entering the group, and stage of readiness for change. Individuals committed to the goal of total abstinence from all psychoactive substances usually do not mix well in groups with those who choose nonabstinence goals such as harm reduction, moderation, or partial abstinence (i.e., abstinence from the most problematic substance, but not others). Those pursuing a goal of total abstinence from all psychoactive substances often feel irritated and unsafe in groups where others are not committed to the same goal and may feel that the presence of these group members not only adversely affects their own motivation to refrain from all substance use, but also distracts the group from its primary mission of supporting abstinence. Similarly, those not choosing total abstinence are likely to feel criticized and out of place in a group where all other members are committed to abstinence. Thus, patients with incompatible or opposing goals are not likely to work well together in groups and their seemingly irreconcilable differences can consume too much of the group's time and thwart the therapeutic work. Traditionally, substance abuse treatment groups have restricted membership to patients who are committed to total abstinence or at least willing to comply with an abstinence requirement during their tenure in the group. Recognizing that many patients who seek help for SUDs are not ready or willing to accept total abstinence as their goal, harm reduction and moderation groups have emerged as alternatives for these patients, whether or not abstinence is their ultimate goal (14,15).

Similarly, mixing mandated and nonmandated patients can be problematic. Group members mandated into treatment under threat of serious consequences (e.g., loss of personal freedom, job, driver's license, professional licensure) are frequently mistrustful and reticent to participate openly and actively in group discussions. Their presence in a group frequently disrupts group cohesiveness and inhibits the participation of voluntary members who may respond negatively to others who are perceived as being in the group only to avoid severe consequences. This is not necessarily an insurmountable problem, if properly addressed, but doing so can consume an inordinate amount of group time and requires a great deal of intervention by the group leader to manage this difficult and often contentious issue. Nonetheless, even with the group leader's best efforts, there is no guarantee that this issue will be resolved to the satisfaction of all group members and some of the nonmandated patients may end up leaving the group prematurely, feeling that it is simply not the best place for them to get the help they need.

GROUPS FOR DIFFERENT STAGES OF RECOVERY

Phase-Specific Groups

Work on the application of the stages of change model (16) to group therapy indicates that substance abuse treatment groups function best when all members are in a similar stage

of change (15,17). Ideally, groups should be composed of individuals either in the early stages of precontemplation, contemplation, and preparation or those in the latter stages of action and maintenance. The types of therapeutic interventions that work best in the treatment of addiction often depend on what phase of recovery or stage of change the person is in. Individuals grappling with addiction typically progress through a series of phases as they move from active use toward sustained abstinence and recovery. Accordingly, many treatment programs offer phase-specific groups that focus on the tasks and goals most relevant to each stage. This may include motivation enhancement or pretreatment induction groups for those who need preparatory work before making an abstinence commitment or participating in a formal treatment program, early abstinence groups for those in the process of breaking free of alcohol/drug use, and RP or continuing care groups for those in the middle and later stages of recovery. This stratification of groups offers a number of clinical advantages: (a) it focuses the group work on the specific problems, tasks, and goals relevant to each phase; (b) it provides predefined progress markers that give group members a sense of personal accomplishment as they complete one phase and move on to the next; (c) it makes it easier for individuals to identify and relate to stage-specific issues being addressed in the group and to bond with other group members who are dealing with similar issues; and (d) it facilitates patient placement into a group best suited to meet his or her needs at each stage of the recovery process. The rationale for stratification is based on the assumption that matching treatment interventions to meet the specific needs of patients as they progress through different stages of recovery is likely to enhance clinical outcomes. There is a natural progression from an initial focus on breaking free of substance use, to securing abstinence, to preventing relapse, and eventually to addressing a variety of psychological issues. The dividing lines between different stages are somewhat arbitrary and the rate of progression through each stage varies from person to person.

Mixed-Phase Groups

Despite the numerous advantages of phase-specific groups, there are also drawbacks. One significant disadvantage is that the group composition may change too frequently and become disruptive as members move from one phase to the next. Another limitation is that private practitioners or small treatment programs may not have sufficient caseloads or manpower to reliably maintain different groups for patients in each phase of treatment and thus mixed-phase groups may be the only feasible alternative. In a mixed-phase model, participants stay in a group as long as needed to achieve their treatment goals and/or as long as their participation in the group remains productive. Individuals struggling with addiction move through the change process at such different rates that it is not possible to specify in advance how long it will take for a given group member to achieve his or her treatment goals. As compared to phase-specific groups, mixed groups

contain a broader array of patients at different phases of recovery: some in the early phases, others farther along in the process, and still others somewhere in between. All have an opportunity to interact with one another in a group setting and derive mutual benefits from doing so. A potential drawback, however, is that inevitably there will be times when the group membership becomes skewed as, for example, when a majority of members is in the early phases of recovery. When this happens the smaller number of more advanced members may become disenchanted or bored with the types of issues that consume the group's time.

Early Recovery Groups

Early recovery groups focus on issues most relevant to the beginning stages of treatment: helping members to establish initial abstinence, stabilize their overall functioning, acknowledge and accept their addiction problem, work through initial ambivalence and reluctance about giving up alcohol/drug use, establish a social support network, become bonded to other members and integrated into the group, overcome early relapses and other setbacks without dropping out, deal effectively with both immediate and delayed consequences of their addiction, and begin the process of identifying and changing some of the dysfunctional self-defeating cognitions, emotions, and behaviors intertwined with their addiction. This is an ideal wish list and certainly not every group member will achieve all of these goals during their tenure in the group. In the absence of financial constraints that limit length of stay, tenure in a group varies according to how quickly patients progress toward achieving their goals, ranging usually from several months to as much as a year, if circumstances permit.

Newcomers struggling to establish or maintain initial abstinence usually need specific guidance and support from other group members on early recovery issues such as (a) discarding all drug supplies and paraphernalia, (b) avoiding contact with dealers, users, parties, bars, and other high-risk situations, (c) learning how to recognize self-sabotaging behaviors and other "setups" for drug/alcohol use, and (d) learning how to manage urges and cravings. Once initial abstinence is established, the focus predictably shifts to stabilization of the individual's functioning. Often, a profound sense of disappointment emerges in the newly abstinent patient soon after the patient realizes that life is still fraught with problems despite having given up alcohol/drugs. This realization may lead the patient to seriously question whether the struggle of staying abstinent is really worthwhile, especially if and when delayed consequences of prior substance use such as financial, legal, and relationship problems begin to surface while the patient is actually doing well. Support and advice from established group members who have "been there" can be extremely helpful at this point to counteract the newcomer's tendency to impulsively self-medicate their resentment, anxiety, and fear.

The issues discussed in early recovery groups are largely patient-driven so that members' problems, crises, and issues can be effectively dealt with as they arise. The leader often plays a very active, and at times directive, role in guiding the

group discussion by keeping it focused on relevant issues, encouraging participation of all members and ensuring that members provide helpful therapeutic feedback to one another without lecturing, advice-giving, hostile confrontation, and other unhelpful behaviors. At times, the group leader may suggest that a certain topic or issue be addressed in the group based on important themes that have emerged in recent group sessions. Where appropriate, the leader may take a portion of the session to review group rules or guidelines such as those regarding how group members can give good feedback to one another, especially when there is an influx of new members. In early recovery groups, members are actively encouraged to maintain contact with one another outside the group. This stands in marked contrast to traditional (psychodynamic) group psychotherapy where outside contact between group members is viewed as undesirable "contamination" that must be avoided.

Relapse Prevention and Continuing Care Groups

The essential tasks and goals of RP and continuing care groups are to help patients' strengthen their commitment to abstinence, work through residual ambivalence about giving up alcohol and drugs, and both learn and practice RP strategies. Although RP is the primary focus of this phase, the group should not focus exclusively on substance use but on a wider range of issues in greater depth. These issues may include the recovery tasks of repairing damaged relationships, forming new ones, working toward resolving the lingering impact of developmental and trauma issues, enhancing self-esteem, and creating a reasonably satisfying lifestyle that is free of alcohol and other drugs. Relapses that occur after abstinence has been firmly established and practiced for at least several months are frequently caused not so much by environmental triggers (which is more typical during the early phases) as by failure of the patient to cope adequately with negative emotions generated by interpersonal conflicts and other types of life problems and stressors. Research on the relapse process indicates that the most common precipitants of relapse are negative mood states, interpersonal conflict, and social pressures to use alcohol/drugs (18). Among the many topics addressed in this phase of treatment are how to identify negative feelings; how to manage anger; how to avoid impulsive decision-making; how to relax and have fun without drugs; how to give and receive constructive criticism; how to be assertive without being aggressive; and how to deal with problems in interpersonal relationships.

In addition to providing coping skills training, it is equally important to sensitize patients to relapse warning signs so that appropriate measures can be taken to "short-circuit" what is often a progressive backsliding in attitudes and behaviors. Explaining the relapse dynamic (1,19) as a progressive identifiable process that is set in motion long before returning to substance use empowers group members to interrupt what otherwise might be an insidious slide toward relapse, which they are unable to recognize while it is happening. Moreover, group members must be alerted to the possibility that flare-

ups can occur many months (or even years) after stopping alcohol and drug use.

RP groups should also address psychological issues that go beyond the basic cognitive and behavioral factors that promote a return to substance use. This involves exploring in detail the inner emotional life of each group member and interpersonal problems that repeatedly give rise to the compulsive desire to “self-medicate” (20). Patients with long, destructive histories of substance use often lack the ability to identify, manage, tolerate, and appropriately express feelings. The ultimate goal here is not merely the acquisition of self-knowledge and insight but fundamental change in the individual’s characteristically maladaptive patterns of thinking, feeling, behaving, and interacting. For example, learning how to tolerate unpleasant feelings instead of impulsively obliterating them with chemicals is an essential part of group treatment at this stage. At an appropriate time the group should also address members’ long-standing, deep-seated problems that may stem from parental alcoholism, physical/sexual abuse, or other developmental and life traumas. Coordination between individual and group therapy is especially vital here. Moreover, whenever such sensitive highly charged issues are being discussed, the group leader must be especially mindful of the possibility that group members may be at increased risk of relapse. Even when in-depth exploration of difficult issues appears to be well-tolerated, patients should always be alerted to the possibility of relapse as an attempt to avoid painful issues.

GROUP MANAGEMENT CONSIDERATIONS

Leadership Roles and Responsibilities

The group leader serves a variety of essential functions. These include (a) establishing and enforcing group rules in a caring, consistent, nonpunitive manner to protect the group’s integrity and progress; (b) screening, preparing, and orienting potential newcomers to ensure suitability and proper placement in the group; (c) keeping group discussions on track and focused on important issues to maximize the therapeutic benefit for all group members; (d) emphasizing, promoting, and maintaining a caring, nonjudgmental, therapeutic climate in the group that both counteracts self-defeating attitudes and promotes self-awareness, expression of feelings, honest self-disclosure, and adaptive alternatives to drug use; (e) managing problem members who are disruptive to the group in a timely and consistent manner to protect the membership and integrity of the group; and (f) educating patients about selected aspects of alcohol/drug use, addiction, recovery, and related issues.

Effective leadership of an addiction recovery group demands that the leader adopt a certain posture in the group that differs significantly from that of traditional psychodynamically oriented psychotherapy groups, particularly in the early stages of recovery. In traditional groups, the therapist gently guides and focuses the attention of group members on matters pertaining to group process, group dynamics, and the complicated interpersonal interaction among group members. With the exception of carefully timed comments, the therapist may re-

main quiet and nondirective in the customary mode of psychodynamic psychotherapy. By contrast, in early abstinence groups the therapist must work actively to keep the group focused on concrete here-and-now issues that pertain directly to addiction-related issues. The therapist plays a very active and directive leadership role that includes questioning, confronting, advising, and educating group members on relevant issues. The therapist keeps the group task-oriented and reality-based, and serves as the major catalyst for group discussion. Addressing substance-related issues is always the number one priority of the group, and the therapist must be sure always to keep the group focused on this task.

It is not the group leader’s role to direct or control the group discussion, but rather to facilitate a process whereby members learn how to interact with one another in an increasingly open, honest, empathetic manner that promotes positive change. When a group is working properly, the leader functions as a coach or guide, staying in the background while the group takes responsibility for the therapeutic work. When the group is not working properly, the leader is doing a lot of talking and/or spending a lot of time exhorting members to participate more actively in group discussions. Well-functioning groups require deliberate and persistent intervention by the group leader to return maximum responsibility for what goes on in sessions to the group’s members, consistent with the psychotherapeutic principle of analyzing resistance before dealing with content (3,19). It is much more important to help group members recognize their passivity than it is to try to drag them into doing the therapeutic work. As compared to early recovery groups, where the group leader plays a much more active role, later stage groups should be helped to focus increasingly on group process and become reliably self-correcting when the discussion strays offtrack or becomes unproductive.

Preparing New Members for Group Entry

Preparing new patients for group entry involves not only orienting them to basic group ground rules, but also establishing realistic goals and expectations. Before admitting new patients to a group, the group leader should ideally meet individually with each prospective newcomer for at least one or two sessions to assess motivation, clarify myths and misconceptions about group therapy, and address resistances to group participation. Prospective members should also be informed about how the group works, how to give useful feedback, and how to refrain from unhelpful group behaviors (3,19). Before newcomers attend a first group meeting they should agree in writing to adhere to the group ground rules.

Managing Peer Confrontation and Feedback

Peer confrontation can be extremely effective in helping group members achieve a more realistic assessment of their maladaptive attitudes and behaviors. But heavy-handed, excessive, and poorly timed confrontation can be countertherapeutic and damaging. Some patients enter groups

with the mistaken idea that humiliation and aggressive confrontation are the ways to force resistant group members to face reality. Sometimes harsh confrontations are rationalized as attempts to be “truly honest” with members who are seen as “resistant” or not conforming to group expectations and norms. Group members typically have less tolerance for negative attitudes and obfuscations than do group leaders, especially when these attitudes are reminiscent of their own problems. Likely targets for attack are members who repeatedly relapse, those who are experienced as defiant, superficial, or insincere, and those who minimize their problem and make little attempt to bond with other members. The group leader should not allow unpopular, frustrating, resistant, or severely troubled group members to be verbally scapegoated and bludgeoned by their peers, even when the content of what is being said is entirely accurate. Harsh or excessive confrontation must not be used as a means to push unpopular or troubled members out of the group and discourage them from coming back. It is often the style rather than content of peer confrontation that determines its impact on the recipient. The main goal of confrontation is to make the person more receptive to change without eliciting defensiveness or destructive acting-out behavior.

Managing Common Problems

Among the most common problems that arise in group therapy are the following: chronic lateness and absenteeism, hostility and other disruptive behaviors, lack of active participation, superficial presentations, proselytizing and hiding behind AA, and playing cotherapist. Because of space limitations, these problems are touched on only briefly here. More in-depth discussion of these issues can be found elsewhere (3,19).

Lateness and Absenteeism

An atmosphere of consistency and predictability is essential for group therapy to be effective. Because most patients have histories of irresponsible behavior during active addiction, when this type of behavior arises in the group it should not be ignored. A pattern of repeated lateness and/or absenteeism adversely affects group morale and cohesion. It is almost always a sign of ambivalence about being in the group and should be addressed as such.

Hostility and Other Disruptive Behaviors

Sometimes the content of what a member says in a group session is less important than the way he or she says it. The group leader must attend the session continuously to affect body language, voice intonation, and overall communication style of group members. Some members are chronically antagonistic, argumentative, and sarcastic. They repeatedly devalue the group, complain about how poorly it is run, point out minor inconsistencies, and reject advice or suggestions offered by other group members or the group leader. The group leader should not ignore these types of negative behaviors. An

appropriate intervention by the group leader might be to say, “I wonder if anyone else is experiencing Tom’s remarks as hostile and devaluing? Can someone offer him feedback about how he’s coming across and how it is affecting the atmosphere in the group?” The group leader should guide the ensuing discussion to make sure that group members do not use this as an opportunity to assault and demean the problem group member for “bad” behavior, but rather help him to see the self-defeating nature of his actions as well as the negative impact of his behavior on the entire group.

Silence and Lack of Participation

Some group members sit quietly on the sidelines as observers of the group discussion, glad to have the focus of attention not be on them. Silent members may secretly harbor feelings of ambivalence, resentment, and annoyance about being in treatment, and doubt whether they need to be in the group at all. Some members are just shy and need gentle coaxing and encouragement from the group to open up. An example of how to address a silent group member might be as follows: “I’ve noticed that Dale has not participated at all during the past two or three group sessions. Maybe the group can try to find out what’s holding her back and perhaps encourage or make it easier for her to join in the discussion?”

Superficial Presentations

Terse or superficial presentations that focus on facts rather than feelings and reveal little or nothing about the presenter are another forms of patient resistance to the group’s therapeutic work. In these situations, the group leader can intervene by saying something like, “I’ve noticed that when Jason talks about himself his statements are very brief and factual. They tell us very little about what’s on his mind or what he is actually feeling. I’m wondering if others share my observations and concerns.” Similarly, some group members present lengthy stories recounting external events and circumstances full of irrelevant details and devoid of emotional content. This is often indicative of a member who is just going through the emotions of being in treatment to satisfy a spouse, employer, or mandate. The group leader might intervene by saying, “Jeff, you’ve just given the group a very long and detailed account of the events of last week, but we heard very little about how you were feeling these past few days on the heels of your recent relapse. I’m wondering if other group members are getting the type of information from you that they would need to give you meaningful feedback. I notice that some group members look bored and uninterested. How are you all feeling right now?”

Proselytizing and Hiding Behind AA

This is one of the most difficult problems to address in group therapy for addiction (13,20). In almost every recovery group there are likely to be some members solidly linked into AA or other 12-step programs who insist with unwavering conviction that AA is the one and only pathway to successful recovery. They may be openly intolerant of other

members who do not embrace AA and take it as their mission to proselytize the benefits of AA in the hopes of converting nonbelievers. Additionally, they may complain that there is not enough “recovery talk” in the group and that the format of group sessions does not sufficiently parallel that of an AA meeting. These individuals will often polarize the group into opposing factions: those who embrace AA enthusiastically and wholeheartedly versus those who are more tempered in their posture toward AA or reject it completely. If this polarization is not addressed, it will ultimately destroy group cohesion, create an unsafe climate in the group, divert valuable attention from other important issues, and stall the group’s therapeutic work. (It is important for group leaders to acknowledge that although AA can be extremely helpful to people struggling with addiction, many are not receptive at first to the 12-step program and should be coaxed rather than coerced into giving AA a try. Moreover, there is a general consensus among addiction treatment professionals that no single method of recovery is best for everyone with an addiction problem.) A potentially helpful intervention may include saying something like, “Well group, we could probably debate the pros and cons of AA here for many sessions and still not reach agreement among everyone in the room. I think it would be more useful to talk about how group members feel that there is a serious split among you on this issue and how it is affecting what we do here in the group.”

Playing Cotherapist

Some group members play the role of therapist’s helper that serves (unconsciously) as a diversion or smokescreen for dealing with their own issues. They often try to perform certain of the group leader’s functions such as keeping the group discussion on track, confronting other members on inappropriate behaviors, and reinforcing group norms. Because their input is often very helpful to the group it is easy for other members and sometimes the group leader to overlook the fact that the self-appointed “cotherapist” spends so much time being a helper that his or her own issues are rarely, if ever, addressed. An appropriate intervention might include saying something like, “Robert, you’ve been extremely helpful to other group members and it’s very clear that everyone here values your input. But I’m wondering if the group can take some time to get to know you a little better and try to help you identify what you want to work on here.”

Responding to a Group Member’s Substance Use

When a group member reports that he or she has used alcohol/drugs since the last group session, the group must give first priority to addressing this issue. In doing so, the group leader should role model a direct, compassionate, nonpunitive response. The group leader’s task is to help the group utilize the discussion of a member’s use as an opportunity to learn something useful. Suggested guidelines for dealing with a group member’s recent alcohol/drug use are as follows: (a) Ask the individual to give the group a detailed account of

the sequence of feelings, events, and circumstances that led up to the use. (b) Invite others to ask the patient about early warning signs, self-sabotage, and other factors that may have preceded the actual substance use. (c) Ask others to share any suggestions or feedback they can offer the patient about the use and how to prevent it from happening again. Also ask them to share their feelings about the episode, reminding them to avoid any tendency they may have to scapegoat the patient or to act out feelings of anger and frustration with negative comments. (d) With the patient’s active participation, ask the group to develop a list of suggested strategies and behavioral changes to guard against the possibility of further substance use.

Although most group members respond supportively to a fellow member’s substance use, there is an unspecified limit as to how many times this will happen. When a group member shows little evidence of using previous suggestions about how to prevent further use, other members may start to become intolerant and feel that this individual may be jeopardizing the integrity of the group. Peer confrontation can become very intense when dealing with relapse issues and the group leader must guard vigilantly against the group’s tendency to scapegoat or ostracize the struggling member.

SUMMARY

This chapter discusses the efficacy, advantages, and limitations of group therapy as well as various practical considerations involved in group formation and leadership. Group therapy has evolved over several decades into the treatment of choice for addiction. Stage-specific groups that address the changing needs of patients as they move through different phases of recovery help to enhance patient-treatment matching and clinical outcomes. Although clinically effective, group therapy is not the best or only treatment option for every individual with an addiction problem. Group therapy should not be used as a stand-alone treatment but ideally as just one component of a more comprehensive multimodality treatment approach. Group leaders serve many important and complex functions including deciding which patients to bring together in a group, keeping group discussions focused on relevant topics, and handling various types of problems that arise during group sessions. In addition to its therapeutic benefits for patients, groups provide a valuable source of personal and professional growth, even for the most seasoned clinician.

Family/Couples Approaches to Treatment Engagement and Therapy

William Fals-Stewart ■ Wendy K. K. Lam

INTRODUCTION

Historically, alcoholism and drug addiction have been viewed by the majority of treatment providers and researchers, as well as by the public at large, as problems of the “individual.” In turn, intervention approaches focused largely or exclusively on the diagnosed individual. During the last four decades, this conceptualization has slowly given way to a greater awareness of family members’ crucial roles in the etiology and maintenance of, not to mention the long-term recovery from, various kinds of addictive behaviors. Consequently, treatment providers and researchers alike have placed greater emphasis on understanding drinking and drug use from a family systemic perspective and, in turn, on exploring how consideration of partner and family dynamics may be understood and used to address individuals’ substance abuse.

As it turns out, the preponderance of available evidence reveals that marital and family therapy approaches are among the most efficacious in terms of prevention, change initiation, and treatment of substance use disorders. Indeed, some have argued that these intervention approaches are the most effective methods for treating alcoholism and drug abuse, principally because of the substantial improvements seen across a very broad range of outcomes (e.g., substance use reduction, improved child functioning, reduced domestic violence).

In this chapter, we will (a) present a brief history of couple- and family-based perspectives and treatment approaches; (b) describe the unique features of these treatment approaches that differentiate them from other models; (c) discuss the various partner- and family-involved approaches for substance use that focus on treatment engagement and active therapeutic models, and review the available evidence of efficacy for these approaches; (d) present optimal implementation techniques used by the most efficacious couple- and family-based approaches; and (e) identify special considerations that clinicians and researchers alike may be likely to encounter when conducting couples- and family-based treatment with substance-abusing couples. Lastly, the chapter will conclude with an exploration of possible future directions with respect to partner- and family-involved therapies with substance-abusing patients.

HISTORY OF FAMILY- AND COUPLES-BASED APPROACHES FOR SUBSTANCE ABUSE TREATMENT

The traditional framework from which substance use disorders are viewed is succinctly captured in the commonly stated axiom among treatment providers, “Alcoholism and drug abuse are individual problems best treated on an individual basis.” It is a long-standing clinical philosophy that had held sway in the substance abuse treatment community for much of the last half century and had a very powerful influence on the treatment of alcoholism and other drug use disorders (1). By the early 1970s, there was an acknowledgement among many providers that the focus on the individual was necessary, but not sufficient, since it did not adequately consider the contextual factors that served to support patients’ continued use or relapse. Despite the very dominant individual-focused paradigm, the family and home environments were simply too important to ignore. This shift toward consideration of the family when treating addictive behavior was legitimized in a special report given to the U.S. Congress in the early 1970s by the National Institute on Alcohol Abuse and Alcoholism; that body described couple and family therapy as “one of the most outstanding current advances in the area of psychotherapy of alcoholism” and recommended funding of controlled studies to test the effectiveness of these promising methods (2).

Since that time, the call to examine family-based treatment approaches for substance abuse has been answered by many different research groups, initially with small-scale studies and, as evidence of effectiveness accumulated, followed by large-scale randomized clinical trials. Results of this programmatic line of research yielded findings that were both consistent and highly positive; compared to individual-based therapies, partner- and family-involved interventions were more efficacious in terms of substance use reductions, improvements in patients’ psychosocial adjustment, and amelioration of serious family problems, such as domestic violence and children’s maladjustment (3,4). As a result, an increasing number of treatment providers and the programs in which they work began intervening with the family as a way to reduce or eliminate abusive drinking or drug use by one or more of its members. In the last decade, the Joint Commission on Accreditation of Health Care Organizations standards for accrediting substance abuse

treatment programs in the United States required that an adult family member who lives with an identified substance-abusing patient be included at least in the initial assessment (5). Thus, in the last 50 years, some involvement of the family in the treatment of substance abuse moved from being viewed in most circles as inappropriate all the way to a component of competent standard practice.

FAMILY TREATMENT FOR SUBSTANCE MISUSE: UNIQUE AND DEFINING FEATURES

Definitions: Marriage and Family

When considering what makes partner- or family-focused interventions for alcoholism and drug abuse unique, a deceptively simple answer is that these treatments focus on or otherwise involve intimate partners or other family members. Although certainly true, how does one define terms like “marriage” and “family”? In many important respects, what defines these terms has been and very much remains in a state of flux. To gain appreciation of this, one needs to only reference headlines or watch the news about the heated debates among those who favor or are opposed to same-sex marriage. How our society and our culture, as well as other societies and cultures, define and operationalize these terms is among the great sociopolitical debates of our generation. Simply stated, there is no encompassing definition of *family* or *marriage*; this has always been the case. Different societal norms and attitudes influence definitions of such cultural constructions, and because cultures and beliefs change over time, the definition of what is meant by marriage and family changes in concert.

However, at least for the purpose of operationalizing these terms to identify an “intervention unit,” it nonetheless seems possible to distill certain qualities and characterizations of these institutions that are somewhat consistent under a variety of circumstances and conditions. In the most inclusive sense, family or marriage (or at least an intimate relationship—marriage carries legal elements as well as sociocultural ones) implies an enduring involvement on an emotional level with other people. For practical purposes, family can be defined according to the individual’s closest emotional connections, of which marriage is a subset. In other words, the individual constructs who is his or her family or his or her partner(s), which is not to be confused, of course, with those persons the individual “likes.” Thus, our definition moves beyond the pure genetic, biologic, or legal definitions, but also encompasses emotional and behavioral connections defined by the individual who identifies “partner” and “family.” As a practical consideration, it is common for providers to identify a romantic partner as one with whom the patient has married or lived with for at least a year. For individuals who work with broader family systems, such systems are often partially defined by those with whom the patient currently lives (e.g., married partner and children) or lived with while growing up (e.g., family of origin members, such as parents and siblings). From this perspective, we see the family can take many different forms, including, but not limited to,

(a) a traditional nuclear family in which members are cohabiting in household (where either one or both parents are working); (b) a household or family headed by a single parent; (c) a “blended” family resulting from divorce, separation, and remarriage; (d) a same-sex couple with or without custodial children; (e) a multigenerational household including grandparents, parents, and children; and even (f) long-term cohabiting partners who are not romantically linked but define themselves as a family (6). Depending on the need of the patient, any of these can ultimately become the familial unit of intervention.

The Interplay between Substance Use and Marital/Family Maladjustment

Compared to traditional individual-focused interventions for alcoholism and drug abuse, family-based approaches try to understand these disorders from a systems perspective. People are not islands. They interact with others in their social and environmental network; they influence those networks and those networks influence them. Although there are certainly many social networks (e.g., work, school, and church), the family is very often the most proximal, influential, and powerful. Proponents of family-based intervention approaches universally hold that the power of the family can be used to help bring about healthful behavioral change.

The interconnection between substance use and familial distress appears to be marked by what can be best described as “reciprocal causality.” Certain commonly observed characteristics and behaviors of alcoholics and drug abusers (e.g., denial of problems, checking out of interactions and general cognitive distortion of information) are not conducive to positive family environments. In turn, these characteristics contribute high relationship and family distress, which makes for an environment that serves to promote (inadvertently or otherwise) continued use or relapse (7). Thus, as shown in Figure 43.1, the link between substance use and

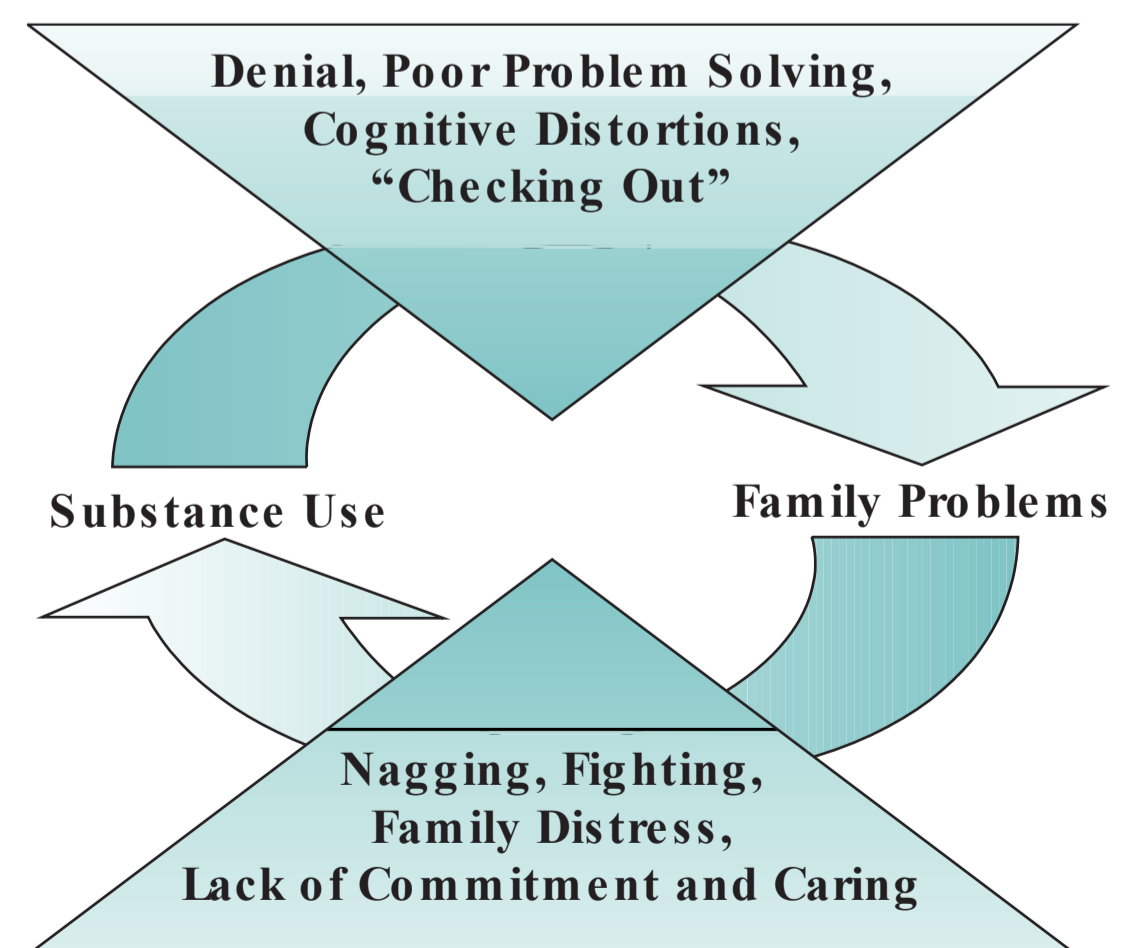

Figure 43.1. “Vicious cycle” between substance abuse and family problems.

relationship problems is not unidirectional, with one consistently causing the other, but rather each can serve as a precursor to the other, creating a “vicious cycle” from which couples that include a partner who abuses drugs or alcohol often have difficulty escaping (8).

There are several family environment antecedent conditions and reinforcing consequences of substance use. Couples, marital, and family problems (e.g., poor communication and problem-solving, arguing, and financial stressors) often serve as precursors to excessive drinking or drug use, and unfortunately, resulting family interactions can inadvertently help to facilitate continued drinking or drug use once these behaviors have developed. For example, substance abuse often provides more subtle adaptive consequences for the family members, such as facilitating the expression of emotion and affection (e.g., caretaking when a parent or partner is suffering from a hangover). Finally, even when recovery from the alcohol or drug problem has begun, marital and family conflicts can, and very often do, precipitate relapses.

Lastly, the family is an extremely important molding influence for children, with deleterious effects on children’s emotional and behavioral functioning well-established in both the scientific and the lay press. As part of the family of the substance-abusing patient, children in the home become caught in the dynamics of the “vicious cycle” created by substance abuse within the family (8,9). Distress within the couple spills over into their parenting and the family environment to impact children (10); sometimes, in turn, children’s distress may feed back into the family’s functioning. For example, alcoholic parents are less likely than nonalcoholic parents to monitor what their children are doing, which can lead to affiliation of their adolescent children with drug-using peers (11), creating another source of family conflict. Parental substance abuse thus often has direct and serious physical, emotional, behavioral, and economic consequences on parenting and children. Moreover, the ancillary short- and long-term negative influences created within the family are often no less destructive. Exposure to violence, interparental conflict, and stress, which are comparatively high in families with an alcoholic or drug-using family member, compromises children’s functioning, and may increase their likelihood of becoming substance users in adolescence (12). Although researchers and providers tend to think of the deleterious effects of parenting and parental substance misuse on children (which are indisputable), it is also clear that stress in the family that can be created by children helps to provide a family context conducive to continued use or relapse.

Foundational Frameworks of Couple/Family-Focused Treatments for Substance Abuse

The strong interrelationship between substance use and family interaction supports the use of interventions that address both substance misuse and family functioning. Approaches to relationship- and family-focused treatments for substance abuse take many different forms, but most are founded largely or exclusively on one of three foundational frameworks (13,14).

The best known of these and the most widely used is the *family disease approach*, which views alcoholism and other drug abuse as an illness experienced by the family, suffered not only by the substance user but also by family members.

Interventions founded on this perspective, such as Al-Anon and related approaches, focus on the patient and his or her detachment from family members during the recovery process. Family members are taught there is nothing they can do to stop the substance user besides stop enabling behaviors, and instead are encouraged to focus on their own recovery. As such, any family member involvement in treatment, if it occurs, is conducted in parallel to that of the substance-abusing individual, rather than as an integrated part of the patients’ treatment. In many ways, although interactions are considered, this framework remains most closely tied to individual-based conceptualizations of substance use, which place the primary responsibility of change within the individual patient.

The *family systems approach* applies the principles of general systems theory to families, with particular attention paid to ways in which families maintain a dynamic balance between substance use and family functioning and whose interactional behavior is organized around alcohol or drug use. From this perspective, the family system provides a context that enables excessive drinking and/or drug use. Alcoholism and other addictive disorders are diseases that flourish in and are enabled by family systems. Family members react to the identified patient with particular behavioral patterns. They may enable the substance misuse to continue by shielding the patient from the negative consequences of his or her actions. Such behaviors are referred to as *codependence*. In this way, the person with the drug or alcohol use problem is said to suffer from the *disease of addiction*, whereas the family members suffer from the *disease of codependence*.

In a general sense, treatment evolving from a family systems perspective aims at identifying the function that substance use within the family serves, and then restructuring interaction patterns associated with drinking or drug use to make that maladaptive behavior unnecessary in the maintenance of the family system functioning. Structural (15) and strategic (16) theory and therapy methods fall within this broader systems framework.

The *behavioral model* assumes that family interactions serve to reinforce alcohol- and drug-using behavior. The goal of couple and family therapy from this perspective is to eliminate reinforcement for substance use by the family, which is often unintentional, and to promote reinforcement of behavior conducive to abstinence.

Family-based behavioral models are the foundation for the most commonly used interventions with alcoholic and drug-abusing couples. From this perspective, three general reinforcement patterns are typically observed in couples with a substance-abusing partner: (a) reinforcement for substance-using behavior in the form of attention or caretaking, (b) shielding the substance user from experiencing negative consequences related to his or her drinking or drug use, and (c) punishing substance use behavior. Behaviorally oriented

treatment focuses on changing spousal and other family members' interactions that serve as stimuli for abusive substance use or that trigger relapse. More adaptive and reinforcing interaction antecedents, such as improving communication and problem-solving abilities and strengthening coping skills, are developed in ways that reinforce sobriety.

EFFICACY OF COUPLES- AND FAMILY-INVOLVED APPROACHES

During the last several decades, many different couples-based and family therapy approaches have been developed (or at least modified) to engage and treat substance-abusing patients; a large and growing body of research evidence supports their effectiveness. Because of the multiple forms of family-based approaches that have been used to address substance abuse, and the wide array of outcomes explored by both treatment providers and investigators, it is well beyond the scope of this chapter to discuss them all. Among the most frequently referenced in the research and clinical literatures include (a) community reinforcement and family training, (b) behavioral couple therapy (BCT), (c) solution-focused couple therapy (SFCT), (d) brief strategic family therapy, (e) multisystemic family therapy, and (f) multidimensional family therapy. In some cases, some of these are minor variations of each other, although many would argue that some of the nuanced differences may have a great influence on treatment response and outcomes for a given patient and his or her family.

For reasons that are more pragmatic than conceptual or theoretic, family-involved therapeutic interventions for alcoholism and substance abuse have been categorized as either *partner-focused approaches* (that include intimate partners as part of the intervention) or *family approaches* (that address larger family systems that may or may not include the dyadic system). Of course, in practice and research, this distinction often becomes blurry; for example, some partner-involved therapies for substance abuse have also incorporated substantial elements of parent training to improve children's adjustment (17,18). Nonetheless, such distinctions between couples- and family-involved therapies offer some organizational structure to any discussion of such treatment methods and how they may be used to engage or treat substance-abusing individuals within these families.

Partner- and Family-Involved Approaches to Engagement

Treatments developed to help substance-using individuals to recognize problem behavior and seek help to change have involved both partners and other family members. The Community Reinforcement Approach (CRA) is based on an assumption that by shifting patterns of reinforcement and contingencies across environmental influences and events, an individual substance abuser's behavior can change. Within this broad community framework, the family is one of many critical environmental influences of interest (19). Given the

importance of family, CRA was modified to focus on the family. The resulting *Community Reinforcement and Family Training* [CRAFT; (20)] aims to teach family members (most often spouses of substance abusers) how to (a) encourage the substance abuser to evaluate whether or not drinking or drug use is problematic, (b) support sobriety, (c) seek out and encourage treatment for substance abuse, and (d) participate in that treatment in a way that is most beneficial.

A more coercive approach, the *Johnson Institute Intervention*, commonly referred to as an "Intervention," involves training family and significant others to confront an alcohol or drug abuser, request that he or she seek treatment, and impose consequences for not seeking help (21). The goal of this program is treatment engagement by the substance abuser. The approach is controversial (on practical and ethical bases), and there is limited evidence of effectiveness with the widely diverse population of individuals with alcohol use disorders (22).

Unilateral family therapy (UFT) is used to help family members develop or strengthen coping skills, to enhance healthful family functioning, and to help create a family environment that is conducive to sobriety or at least reduced drinking and drug use. UFT outlines a series of graded steps that families can use prior to initiating any sort of confrontation with the substance abuser to recognize his or her problem and seek formal treatment. Although research is limited, in a small-scale trial, participation in UFT was associated with significantly greater likelihood that individuals with drinking problems would enter treatment or reduce their drinking (23).

It is also important to mention certain related approaches that, rather than focus on initiating change, emphasize self-healing. For example, Dittrich (24) has developed a *group program for wives of treatment-resistant substance abusers*. Following the family disease framework, this treatment is designed to help partners cope with their own emotional distress rather than trying to motivate the substance-abusing partner to seek help or otherwise change. This particular approach borrows heavily from Al-Anon, the most commonly used source of support for family members of substance abusers, which advocates family members detach from the substance abusers in a loving way, accept they are powerless to control the substance abuser, and seek support from other Al-Anon members.

Results of randomized clinical trials have compared some of these approaches in terms of their efficacy in engaging patients in treatment. One investigation compared the CRAFT, Al-Anon, and Johnson Institute Intervention approaches for effectiveness in getting individuals with drinking problems into formal treatment. The highest overall treatment rate for the alcoholic family members was associated with the CRAFT therapy (64%). The majority of families in the Johnson Institute condition chose not to complete the intervention; in fact, 70% failed to follow up with the critical confrontation session. Because Al-Anon is not designed to facilitate entry into treatment, it is not surprising that this was not a common outcome (25).

Couple-Based Approaches to Treatment

The majority of couple- and family-involved approaches to substance abuse have focused on efforts to treat the substance abuser to attain and adjust to sobriety, and to maintain these gains. Two commonly referenced couple approaches, BCT and SFCT, dominate the research and practice areas of couple therapy, respectively.

BCT (3) has, to date, the strongest empirical support for its effectiveness (26). When using BCT with a married or cohabiting alcoholic or drug-abusing patient, a therapist treats the partners together and works to build support from within the dyadic system for abstinence. In a global sense, emphasis is placed on increasing reinforcement with the dyadic system for abstinence. To accomplish that goal, BCT seeks to strengthen the relationship by improving partners' communication and having partners participate in relationship enhancement exercises (e.g., participating in mutually shared rewarding activities, and observing and recognizing caring behaviors). As the relationship strengthens, partners are taught skills and engage in exercises to positively reinforce aspects of sober living.

Empirical support for the effectiveness of BCT with alcoholic and drug-abusing couples is extensive. Multiple studies have compared drinking and relationship outcomes for alcoholic patients and their partners treated with BCT to various forms of therapy that involve only the individual patient (e.g., individual counseling sessions and group therapy). Results of these investigations have been very consistent, revealing a pattern of less frequent drinking, fewer alcohol-related problems, happier relationships, and lower risk of marital separation for alcoholic patients who received BCT than for patients who receive only individual-based treatment (27).

Although the research on the effects of BCT for married or cohabiting patients that abuse drugs other than alcohol is more recent, the outcomes have been no less impressive than those obtained for alcoholic couples. Compared to individual treatment for the substance-abusing partner only, BCT for drug-abusing men and their non-substance-abusing female partners resulted in fewer days of drug use, fewer drug-related arrests and hospitalizations, a longer time to relapse after treatment completion, and more positive relationship adjustment (28). Although BCT studies with alcoholic and drug-abusing patients have recruited samples that consisted largely or exclusively of married or cohabiting male patients and their non-substance-abusing female partners, preliminary investigations with married or cohabiting female patients and their non-substance-abusing male partners have yielded positive results similar to those for substance-abusing men (29,30). Interestingly, the use of BCT with alcohol- and drug-abusing couples also has important effects on other aspects of family functioning that are not primary targets of the intervention, including improvements in custodial children's emotional and behavioral adjustment (even though the children did not participate in BCT nor was parenting an emphasis of the intervention) (31) and reductions in domestic violence (32).

SFCT (33) primarily emphasizes solutions to the presenting issue or concern, rather than the origins of the problem. Simply stated, SFCT is a strengths-based, solution-focused brief therapy approach to couple distress and substance use. The basic conceptualization of relationship problems in SFCT is that distressed couples (a) are locked into a negative mindset, (b) are stuck in problem talk, (c) have inherent strengths but are not seeing or utilizing them, and (d) are not noticing the exceptions to when the problem occurs. In SFCT, problem talk is completely discouraged; the goal of the therapist is to help the couple identify and coconstruct active solutions to the problem, often found in the exceptions (i.e., those times when the problem does not occur), and identify small achievable goals that may enhance optimism for further behavioral change. The therapy is brief, sometimes lasting only one to two sessions, and rarely more than ten. Few empirical outcome evaluations of the use of solution-focused therapies with substance-abusing populations have been conducted, although it appears that treatment providers believe it to be effective and commonly use this approach with these patients (34). Empirical evaluations, however, are needed to determine the accuracy of the provider beliefs.

Family Approaches to Treatment

As noted, no one family-involved intervention has come to dominate family therapy for alcoholism and drug addiction. Upon reflection, this is not a surprise; as opposed to partner-involved therapy (which inherently narrows the intervention unit to intimate partners), family therapy has a much larger field of family types and, relatedly, family issues that it is called upon to address. The bulk of the controlled clinical research trials that include a family component in substance abuse treatment examine adults with partners in couple-based approaches. However, it is also important to consider the role of family and significant others in the treatment of adolescents who struggle with alcohol problems. Thus, in addition to the models listed above, three other approaches that have been developed for use primarily with substance-abusing adolescents and their families are reviewed: (a) brief strategic family therapy (BSFT), (b) multidimensional family therapy (MDFT), and (c) multisystemic family therapy (MST). Each of these approaches integrates structural (13) and strategic (14) theory and principles within a family systems perspective, and although highly intensive, has developed a strong base of empirical support.

In BSFT (35), substance-abusing behavior is seen to develop in response to unsuccessful attempts at dealing with developmental challenges. Rigid family structures are also believed to contribute to the development of adolescent substance abuse. The therapist attempts to intervene in the system through the parents by changing parenting practices, improving the parent-adolescent relationship, and teaching conflict resolution skills. A series of randomized trials has demonstrated empirical support for BSFT at engaging and treating substance-using adolescents and their families, including Hispanic youth and families; a multisite effectiveness trial is currently under way (36).

MDFT (37) views adolescent substance abuse as a result of multiple interacting factors, which may include failure to meet developmental challenges as well as other forms of abuse or trauma. The primary goals of treatment are to improve adolescent, parental, and overall family functioning, which in turn will impact the substance-abusing and other problematic behaviors. MDFT is a very flexible approach; the treatment length is determined by the treatment provider, setting, and family and may include a combination of individual and family sessions. MDFT begins with a thorough multisystem assessment of both developmental ecologic risk and protective factors. This information is then used to create an MDFT case conceptualization, which identifies the strengths and weaknesses in the adolescent's multiple systems and becomes the basis of treatment. MDFT has demonstrated strong efficacy in reducing substance use and delinquency with juvenile justice-involved adolescents (38).

MST (39) is based on Bronfenbrenner's social ecologic model of behavior, seeking to understand the substance-abusing behavior within a broader, real-world context. MST assumes that substance abuse is influenced by variables from multiple systems, targeting change in other areas (e.g., arrests, out-of-home placements, and mental health) as well as substance use. Thus, one of the goals of treatment is to assess the strengths and needs of each system and their relationship to the presenting problem. Family members play a large role in determining treatments goals. MST focuses on the present and targets a broad set of specific and well-defined problems through the use of daily and weekly assignments. The MST therapist is responsible for addressing and overcoming any barriers that may result during the course of treatment.

With its broad, ecologic, and family focus, MST was not originally designed to target substance use specifically. As such, initial studies examining substance-related outcomes of MST among violent and chronic juvenile offenders showed long-term effects on substance use-related outcomes through adulthood (e.g., drug-related arrests or convictions) (40), though less consistently valid substance use reductions (41). Recent pilot and larger trials that integrate MST with other contingency management strategies aimed specifically at reducing substance use suggest promising effects on both self-report and biologic substance use reductions (42).

OPTIMAL IMPLEMENTATION OF FAMILY-BASED TREATMENT

There is considerable debate among providers about how to implement family-based treatments as part of an overall package to address alcoholism and substance abuse. It is sometimes asserted among some providers that participation in family treatment should not occur until the identified patient has been sober for at least a year. There are at least three problems with that recommendation: (a) given that so many patients who received treatment in substance abuse treatment settings relapse during the year after leaving treatment, only

a limited number of patients would actually be sober for a year and be eligible for family-involved treatment; (b) if patients remains sober for a year, they often will not meet the necessary diagnostic criteria for a substance abuse treatment program to be able to provide services (in many states, a current diagnosis of a substance use disorder is required for admission); and (c) there is no empirical support that delaying family treatment enhances efficacy.

Optimally, it is important to include a family member or members in the intervention package as early as possible. In our experience, family members often bring a different perspective than the patient on the family and its role in the etiology and maintenance of the patient's drinking and drug use behavior. They can also give providers a sense of whether or not the family will be functionally supportive of the patient's efforts to maintain a sober lifestyle, as well as how much focus will need to be placed on the family as treatment unfolds. As a general rule of thumb, the best time to implement family-focused treatment for substance abuse is as soon as possible. An early assessment can inform providers about the possible role of the family in the patient's treatment.

Lastly, in an ideal situation, there should be family therapy providers who do "family work" with patients, which is provided as a complement to individual-focused treatments by yet another provider. Such staffing allows for certain therapeutic boundaries to exist between partner- and family-focused therapy sessions and individual-focused sessions. In reality, many programs do not have the resources to enjoy the luxury of having separate providers for family therapy. Nonetheless, it is often out of necessity that a single provider serves as the individual counselor and the family counselor. In our experience, one person can effectively serve as the individual counselor and the family counselor. When that is the only way that family therapy can be provided, it is important to establish confidentiality boundaries between what is discussed in family therapy versus what is discussed in individual therapy. Typically, the contents of the individual sessions are kept confidential from the family therapy sessions (3).

SPECIAL CONSIDERATIONS

There are several clinically significant considerations in implementing effective family intervention with substance abusers that may challenge its use. One that is commonly encountered among couples and families with a substance-abusing member is violence. In situations where the risk of types of violence that are severe (i.e., aggression that has the potential to result in serious injury or is life threatening), the immediate intervention goal is safety; in these situations, partner and family therapy is contraindicated (43). For some families, there may, in fact, be legal restrictions (i.e., restraining orders or no contact orders) that preclude conjoint family sessions.

Another factor to consider is whether more than one actively substance abusing family member is present—particularly if these individuals have formed a drinking or

drug use partnership of some type. Sometimes referred to as “double-trouble couples,” these family systems may support continued use versus abstinence (44). Research on family-based approaches for these situations is lacking, and it is often recommended that individual therapy be used prior to engaging family members in these circumstances.

Another critical consideration is the existence of high levels of blame and rumination from family members (usually the partner) toward the substance-abusing individual. There may also exist important practical barriers to partner or family intervention; these include (a) geographic distances among family members or among family members and the treatment provider; (b) family members who are divorced, incarcerated, or otherwise separated; (c) coordination of family members’ and treatment providers’ schedules; and (d) securing reimbursement for services delivered to multiple individuals in the context of formal treatment.

FUTURE DIRECTIONS AND CONCLUSIONS

Although there is an increasing awareness of the efficacy of partner- and family-involved approaches to alcoholism and drug abuse, there are several important gaps in the research literature and in general practice that reflect the next generation of research in this area. More specifically, the following five areas seem most pressing: (a) disseminating evidence-based marital and family treatments to community-based treatment programs, (b) applying these approaches with specific populations, (c) examining mechanism of action, (d) exploring the use of partner- and family-involved approaches as part of a stepped care model, and (e) addressing the behavioral and emotional needs of non-substance-abusing partners.

Dissemination

Although marital and family approaches for substance abuse have very strong research support, they are not widely used in community-based alcoholism and drug abuse treatment settings. For example, Fals-Stewart and Birchler (45) conducted a national survey of 398 randomly selected U.S. substance abuse treatment programs and found fewer than 10% of the programs used any form of partner-involved therapy. Despite its proven efficacy, BCT in particular was viewed as too costly to deliver and requiring too many sessions. Investigators and treatment providers will need to work in concert to identify barriers and ways to overcome them, so these very powerful methods can reach patients in need of them.

Specific Populations

Although the body of empirical literature supporting the use of marital and family therapy for substance abuse is substantial, it is critical to also recognize its limitations. Among these are the types of families that are typically the subject of such studies, which usually include largely white, male substance-abusing patients. Studies on the efficacy of marital and family therapy approaches for women with substance use disorders are far less

common, although available evidence does suggest that they are efficacious (30). Even fewer studies have examined partner- and family-involved interventions with same-sex couples, although a very recent trial yielded encouraging results (46).

Relatedly, it is also important to recognize that BCT trials have focused on couples in which only one partner has a drug or alcohol problem. Dual-using partners, or “double-trouble” couples, represent a very unique challenge. In our experience, women who are married to or are in relationships with substance-abusing men have particularly bad outcomes compared to women in relationships with men who do not use alcohol or other drugs. This comes as no surprise, given that women in double-trouble couples fail to get support for abstinence in their homes. Methods to engage both partners and promote mutual abstinence (e.g., contingency management for both partners and motivational interviewing) are worthy next steps to address the needs of these patients.

A great deal of research has been conducted related to both family therapy and culture and ethnicity, but very little of this has appeared in the family therapy literature on substance abuse. This represents what is likely the most important gap in the extant empirical literature to date. Observations with over 1500 substance-abusing couples in randomized clinical trials suggest that BCT may have benefits across some, but not all, racial/ethnic groups. Understanding the degree to which the “vicious cycle” of substance use affects families in universal ways and can thus be treated similarly, as well as the degree to which other cultural and ethnic factors must be considered to achieve benefits for diverse families, will be critical for the research and practice fields to address.

Lastly, despite all efforts to engage partners and families, there are patients whose partners or family members will simply not be involved in treatment. There can be any number of reasons for this; a patient may simply refuse, the family members may refuse, or scheduling between participants and providers becomes impossible. These patients represent a clearly definable population in their own right. An intriguing option is to engage in family therapy by working only with the patient to promote family change. Such an approach eschews the multiple barriers that clinicians often face when trying to engage and treat larger family systems. As paradoxical as they may first appear, one-person couple therapy and one-person family therapy have shown promise in preliminary pilot-sized trials (47,48). However, more comprehensive efficacy trials are needed to explore observed positive effects in these one-person family interventions compared to standard individual and partner- and family-involved treatments.

Mechanisms of Action

We now have confidence that many treatments are effective, some more than others, but despite the successful efforts of substance abuse treatment researchers to conduct rigorous clinical trials and spell out in treatment manuals what the treatments consist of, little research has formally investigated what the active ingredients of these treatments are. In other words, what are the mechanisms of action that make

certain partner- and family-involved approaches curative? If these factors can be identified, then these approaches can be modified to maximize efficiency and effectiveness of treatment.

Partner- and Family-Involved Treatment in the Context of Stepped Care

Since partner- and family-involved therapies have been shown to be efficacious across a number of different formats [e.g., abbreviated formats (49), multifamily, and one-person couples treatment], some of these interventions may be good candidates for a stepped care approach (50), moving from least to most intensive as treatment response dictates. As an example, married or cohabiting patients entering treatment can enter a therapy group, without the participation of their partners, which focuses on relationship issues. Patients for whom it is clinically indicated can then move to a multicouple group format that would include their partners. Couples who require more conjoint treatment can participate in a planned abbreviated couple therapy; if that is insufficient, then patients and their partners can participate in the standard form of couple therapy, which is the most intensive, requiring the most time and greatest commitment by both providers and partners.

Partners as Patients

In our experience, partners of substance-abusing patients have a host of emotional and behavioral problems. These range from increased risk for infection from sexually transmitted diseases, victimization from intimate partner violence, and increased levels of psychological depression. Intervention models, such as BCT, lean heavily on the non-substance-abusing partners to support and promote abstinence. It is quite plausible that if the emotional and behavioral needs of these partners are not adequately addressed, they will have fewer resources to bring to partner-involved intervention approaches, leading to overall poorer treatment response and outcomes for the substance-abusing patient and the couples more broadly. An important next step in this overall programmatic line of research is to examine the moderating effects of the psychological adjustment of non-substance-abusing partners on treatment response and outcome and, if such factors moderate effects, design interventions that address the unique needs of these partners.

CONCLUSION

As has been well documented in the scientific and lay press, the emotional, economic, and societal toll of alcoholism and drug abuse is incalculable. The effects of substance use disorders affect not only the patients but also those around them; in fact, those emotionally closest to the substance-abusing patient often suffer the most. Partner- and family-involved approaches have had such well-documented success because such methods view outcomes across multiple dimensions of functioning that go well beyond the frequency of substance

use toward outcomes like child and family adjustment, family violence, relationship quality, and so forth. By seeking to foster family environments conducive to abstinence, marital and family approaches have great potential to help maintain long-term and even multigenerational healthful change.

INTRODUCTION AND OVERVIEW

Cognitive behavioral treatments are among the most well-defined and rigorously studied psychotherapeutic interventions for substance use disorders. While this chapter focuses almost primarily on cognitive behavioral therapy (CBT), it should be noted that CBT shares several features with several other empirically supported behavioral approaches reviewed in this volume. First, cognitive, behavioral, and motivational therapies are applicable across a broad range of substance use disorders. That is, well-controlled trials have supported their efficacy across alcohol, stimulant, marijuana, and opioid-dependent populations. Second, these approaches were developed from well-founded theoretical traditions with established theories and principles of human behavior. Third, these approaches are highly flexible and can be implemented in a wide range of clinical modalities and settings. Moreover, they are compatible with a variety of pharmacotherapies and, in many cases, foster compliance and enhance the effects of pharmacotherapies including methadone, naltrexone, and disulfiram. Finally, these approaches are relatively brief/short-term and highly focused approaches that emphasize rapid, targeted change in substance use and related problems. In this manner, they are very compatible in a health care environment that is increasingly influenced by managed care, best clinical practice models, and professional accountability.

At the most simple level, CBT attempts to help individual patients recognize, avoid, and cope. That is, recognize the situations in which they are most likely to use drugs or alcohol, avoid those situations when possible or appropriate, and learn to cope more effectively with a range of problems and problematic behaviors associated with substance use. CBT has two critical components and defining features: First, a thorough functional analysis of the role alcohol and illicit drugs play in the individual's life. For each instance of substance use the patient experiences during treatment, the therapist and patient will identify the patient's thoughts, feelings, and circumstances before the substance use, as well as the patient's thoughts, feelings, and circumstances after the episode of substance use. Early in treatment, the functional analysis plays a critical role in helping the patient and therapist assess the determinants, or high-risk situations, that are likely to lead to substance use, as well as shed light on some of the reasons the individual may be using drugs or alcohol. The second critical component of CBT is skills training.

In CBT, this consists of a highly individualized training program that helps substance users change old habits associated with their drug use and learn or relearn more adaptive skills and responses.

HISTORY

Cognitive behavioral treatments have their roots in classical behavioral theory and the pioneering work of Pavlov, Watson, Skinner, and Bandura (1,2). Pavlov's work on classical conditioning demonstrated that a previously neutral stimulus could elicit a conditioned response after being paired repeatedly with an unconditioned stimulus. Furthermore, repeated exposure to the conditioned stimulus without the unconditioned stimulus would eventually lead to extinction of the conditioned response. The power of classical conditioning was demonstrated in drug abuse by Wikler (3) who confirmed that opioid addicts exhibited conditioned withdrawal symptoms upon exposure to drug paraphernalia. Today, classical conditioning theory is the basis of several behavioral approaches to substance use treatment, such as cue exposure and stimulus avoidance as an early component of many addiction counseling approaches.

Second, Skinner's work on operant conditioning demonstrated that behaviors that are positively reinforced are likely to be exhibited more frequently. The field of behavioral pharmacology, which has convincingly demonstrated the reinforcing properties of abused substances in both humans and animals, is grounded in operant conditioning theory and principles. Behavior therapies assume that drug use and related behaviors are learned through their association with the positively reinforcing properties of the drugs themselves as well as their secondary association with other environmental stimuli. CBT attempts to disrupt this learned association between drug-related cues or stimuli and drug craving or use by understanding and changing these behavior patterns. A wide range of behavioral interventions, including those that seek to provide alternate reinforcers to drugs use or reduce reinforcing aspects of abused substances, also are based on operant conditioning theory.

CBTs conceive substance use disorders as complex, multidetermined problems, with a number of influences playing a role in the development or perpetuation of the disorder. These may include family history and genetic factors; the presence of comorbid psychopathology; personality traits such as sensation seeking or impulsivity; and a host of

environmental factors, including substance drug availability and lack of countervailing influences and rewards. Though CBTs primarily emphasize the reinforcing properties of substances as central to the acquisition and maintenance of substance abuse and dependence, these etiologic influences are seen as heightening risk or vulnerability to the development of substance use problems. For example, some individuals may find substances unusually highly rewarding secondary to genetic vulnerability, comorbid depression, a high need for sensation seeking, the modeling of family and friends who use substances, or environments devoid of alternative reinforcers.

CBTs also reflect the pioneering work of Ellis and Beck that emphasizes the importance of the person's thoughts and feelings as determinants of behavior. CBT evolved in part from dissatisfaction with the extreme positions of radical behaviorism (e.g., emphasis on overt behaviors) and classical psychoanalysis (emphasis on unconscious conflicts or representations). CBT emphasizes how the individual perceives and interprets life events as important determinants of behavior (4). A person's conscious thoughts, feelings, and expectancies mediate an individual's response to the environment. CBT also seeks to help patients become aware of maladaptive cognitions and then learn to challenge and change them.

Just as CBT assumes that many individuals essentially "learn" to become substance users over time, through complex interplays of modeling, classical conditioning, or operant conditioning, each of these principles is invoked in CBT to help the patient stop using drugs and alcohol. For example, modeling is used to help the patient learn new behaviors (e.g., how to refuse an offer of drugs, how to break off or limit a relationship with a drug-using associate) by having the patient participate in role plays with the therapist during the treatment. That is, the patient learns to respond in new, unfamiliar ways by first watching the therapist model those new strategies and then practicing those strategies within the supportive context of the therapy hour.

Operant conditioning concepts are used several ways in CBT. First, through a detailed examination of the antecedents and consequences of substance use, the therapist attempts to develop an understanding of the reasons the patient may be more likely to use in a given situation and to understand the role that drugs or alcohol play in their life. This "functional analysis" of substance use is used to identify the high-risk situations in which the patient is likely to use drugs and thus to provide the basis for learning more effective coping behaviors in those situations. Second, the therapist attempts to help the patient develop meaningful alternate reinforcers to drug use; that is, other activities and involvements (relationships, work, hobbies) that serve as viable alternatives to drugs and alcohol use and help the patient remain abstinent. Finally, a detailed examination of the consequences, both long- and short-term, of their substance use, is used as a strategy to build or reinforce the patient's resolve to reduce or eliminate their substance use.

Classical conditioning concepts also play an important role in CBT, and particularly in interventions directed at re-

ducing some forms of craving for drugs. Just as Pavlov demonstrated that repeated pairings of a conditioned stimulus with an unconditioned stimulus could elicit a conditioned response, he also demonstrated that repeated exposure to the conditioned stimulus without the unconditioned stimulus would, over time, result in extinction of the conditioned response. Thus, the therapist attempts to help the patient understand and recognize conditioned craving, identify his/her own idiosyncratic array of conditioned cues for craving, avoid exposure to those cues, and cope effectively with craving when it does occur without using the drug so that conditioned craving is reduced and eliminated over time.

Learning serves as an important metaphor for treatment process throughout. CBT therapists tell patients that a goal of the treatment is to help them "unlearn" old, ineffective behaviors and "learn" new ones. Patients, particularly those who are demoralized by their failure to change their substance use, or for whom the consequences of addiction have been severe, are frequently surprised to think about substance use as a type of skill, as something they have learned to do over time: In effect they have learned a complex set of skills that enabled them to acquire the money needed to buy drugs and alcohol (which often led to another set of licit or illicit skills), avoid detection, and so on. Patients who can reframe their self-appraisals in terms of being "skilled" in this way can often see that they also have the capacity to learn a new set of skills, this time, though, skills that will help them remain abstinent (5).

UNIQUE FEATURES

Durability

While CBT is not necessarily more effective than other evidence-based therapies for substance use disorders, where it appears to stand out is in its durability. An important development in our conception of substance use disorders is that they are chronic relapsing disorders and thus treatment should be conceived of as producing behavior change and maintaining it over the lifespan, rather than brief, disjointed, acute episodes of care (6). Thus, a major disadvantage of many addiction pharmacotherapies in this context is that they can be very effective while the patient is taking them, but relapse is common once the medication stops.

CBT, however, is associated with particularly durable effects. Several studies have documented a "sleeper effect," in which patients exposed to CBT continue to improve even after they leave treatment (7–9). This is illustrated in Figure 44.1, which shows patterns of drug use within treatment and during the follow-up period for CBT versus supportive clinical management among cocaine-dependent individuals. The durability of effects from CBT is found in its applications to other areas (10) as well, and may be associated with its emphasis on conveying effective, generalizability skills that may benefit the individual long after they leave treatment.

Figure 44.1. “Sleeper effect” of CBT. Severity of cocaine use within treatment (pretreatment end) and through follow-up (end-12 months) by treatment condition (CBT vs. supportive clinical management). (Data from Carroll KM, Rounsaville BJ, Nich C, et al. One year follow-up of psychotherapy and pharmacotherapy for cocaine dependence: delayed emergence of psychotherapy effects. *Arch Gen Psychiatry*. 1994;51:989–997.)

Unique and Common Factors of CBT

All behavioral or psychosocial treatments include both common factors as well as unique factors or active ingredients (11). Common factors refer to dimensions of treatment that are shared across most therapies. These common factors include the provision of education, a convincing rationale for the treatment, enhancing expectations of improvement, the provision of support and encouragement, and in particular the quality of the therapeutic relationship. A positive therapeutic relationship, or alliance, has repeatedly been associated with better outcome in a range of psychotherapies (12), including those for substance use disorders. A positive working relationship is an essential component of virtually all therapies, but, by itself, is not necessarily sufficient to produce change.

Unique factors refer to a treatment’s “active ingredients” or those techniques and interventions that distinguish or characterize particular psychotherapies. While common factors are shared, unique factors are those that are not shared across different therapies. CBT, like most therapies, consists of a complex combination of common and unique factors. For example, in CBT mere delivery of skills trainings without grounding in a positive therapeutic relationship leads to a dry, overly didactic approach that alienates or bores most patients and ultimately has the opposite effect of that intended. It is important to recognize that CBT is thought to exert its effects through this intricate interplay of common and unique factors and a major task of the therapist is to achieve appropriate levels of balance between attending to the relationship and delivering skills training. For example, without a solid therapeutic alliance, it is unlikely that a patient will either stay in treatment, be sufficiently engaged to learn new skills, or to share successes and failures in trying new approaches to old problems. Conversely, empathic delivery of skills training as tools to help the patient manage his/her life more effectively, with the therapist giving the message of “I see you really struggling with your craving for cocaine [for example], I think we can come up with some effective ways to help you understand what is happening better and help you deal with it,” may form the basis of a strong working alliance (5).

To specify CBT in terms of its common and unique factors and to clarify the range of therapist interventions that are

consistent and inconsistent with this approach, CBT interventions will be described in terms of the system recommended by Waltz and colleagues (13): First, CBT’s essential and unique interventions, that is, active ingredients that are specific or unique to CBT. Second, CBT’s recommended interventions, those that are thought to be “active” and important, but which are not necessarily unique to CBT. Third, interventions, behaviors, or processes that are acceptable within the therapy but are not essential or unique. Finally, interventions, behaviors, or processes that are proscribed, or not consistent with this approach. Each of these has been explicated in a detailed process rating system (14) and validated in several randomized clinical trials of CBT.

Essential and Unique Interventions of CBT

In CBT, the key active ingredients that distinguish it from other therapies and the elements that must be delivered in order for the patient to be considered as being “adequately exposed” to CBT include

- Conducting functional analyses of substance use
- Providing individualized skills training in strategies such as recognizing and coping with craving, monitoring, challenging, and changing thoughts about substance use, problem-solving skills, planning for emergencies, recognizing seemingly irrelevant decisions, and refusal skills.
- Examining the patient’s cognitive processes related to substance use
- Identifying and debriefing the past and future high-risk situations
- Encouraging and reviewing extrasession implementation of skills (homework)
- Practicing skills within sessions

Recommended Interventions

Interventions that are essential, but not necessarily unique to CBT include the following:

- Discussing, reviewing, reformulating the patient’s goals for treatment
- Monitoring substance use and craving
- Monitoring general functioning
- Exploring positive and negative consequences of substance use

- Exploring the relationship between affect states and substance use
- Providing feedback on urinalysis results
- Setting a clear agenda for each session
- Making process comments as indicated
- Discussing the advantages of an abstinence goal and exploration of the patient's ambivalence
- Meeting resistance with exploration and a problem-solving approach
- Supporting patient efforts to institute behavior change, assessing the level of family support

Acceptable Interventions

Interventions that are not required or strongly recommended as part of CBT but are not incompatible with this approach include

- Being involved in self-help activities as a coping skill
- Identifying means of self-reinforcement for abstinence
- Exploring discrepancies between patient's stated goals and actions
- Eliciting concerns about substance use and consequences (e.g., decision balance)

Proscribed Interventions

Interventions that are proscribed because they are distinctive of other forms of empirically validated approaches to treatment include the following (note, however, that CBT can be combined effectively with other approaches):

- Extensive self-disclosure by the therapist
- Use of a confrontational style or a confrontation-of-denial approach
- Requiring the patient attend self-help groups (as in Twelve-Step Facilitation)
- Use of disease model language or slogans (as in Twelve-Step Facilitation)
- Extensive exploration of interpersonal aspects of substance use (as in interpersonal or supportive-dynamic approaches)
- Extensive discussion or interpretation of underlying conflicts or motives (as in supportive-dynamic approaches)
- Provision of direct reinforcement for abstinence (e.g., vouchers, tokens, as in contingency management [CM] approaches)

EVIDENCE OF EFFICACY

CBT has been shown to be effective across a wide range of substance use disorders (15–18), including alcohol dependence (19,20), marijuana dependence (21,22), cocaine dependence (23–26), and nicotine dependence (27–29). CBT has also been shown to be compatible with a number of other treatment approaches, including pharmacotherapy (30,31) and traditional counseling approaches (32) and thus can be implemented in a wide range of settings. These findings are consistent with evidence supporting the effectiveness of CBT across a number

of other psychiatric disorders as well, including depression, anxiety disorders, and eating disorders.

CBT has been used with a range of substance use disorders for over 30 years. As our understanding of CBT has deepened over time, this series of studies has been marked by progressively larger effect sizes for CBT over comparison or control conditions. This is illustrated in our series of randomized controlled trials on CBT at Yale. In our first randomized trial, we conducted a direct comparison of CBT with another active therapy, Interpersonal Psychotherapy (IPT), adapted for cocaine users. In that trial, CBT was not found to have a main effect over IPT, but was found to be significantly more effective among the more severely dependent cocaine abusers (33), suggesting that the higher levels of structure and emphasis on skills may have been particularly helpful for the more severely impaired cocaine users.

Severity of cocaine dependence as a moderator of CBT effects was also replicated in our next study (23). This study used a 2 × 2 factorial design, where desipramine was compared with placebo and CBT compared to supportive Clinical Management, a supportive psychotherapy control condition. This study was also the first to describe that after the study treatments were terminated, those that had been assigned to CBT continued to reduce the frequency of their cocaine use throughout the 1-year follow-up (the “sleeper effect”) (8). Evidence of continued improvement associated with CBT in turn led to increasing interest in mechanisms that might underlie this effect, with skill training and behavioral practice through homework assignments as prime candidates, as described in more detail in the sections below.

Thus, in our next study, which was the first to report a significant main effect for CBT over supportive Clinical Management and which replicated the “sleeper effect” for CBT over a 1-year follow-up (34), we also evaluated the acquisition of coping skills in CBT and their relationship to outcome in this population. We developed and validated a role-play task for assessing the acquisition of coping skills in CBT (35); the task involved the patient listening to a series of audiotaped high-risk situations (e.g., “what would you do if you found yourself at a party where you didn't think cocaine would be available, and then noticed a lot of people going in and out of a back room?” “What would you do if you started feeling really intense craving?”). The patient's responses were audiotaped and then rated for quality of response, type of coping response, and number of responses generated using a rating method demonstrated to be highly reliable. In this study, evaluation of the role play task demonstrated the following: (1) coping skills increased significantly after CBT, (2) patients demonstrated increases in coping skills that were parallel to those taught in the treatment they had been assigned (i.e., differential acquisition of specific behavioral and cognitive coping strategies in CBT with respect to alternate behavioral therapies), and finally, (3) greater acquisition of CBT-specific behavioral and cognitive coping skills was associated with significantly less cocaine use over the 1-year follow-up (34).

In our most recently completed trial (36), 121 cocaine-dependent individuals were randomized to one of four conditions in a 2×2 factorial design: disulfiram (250 mg/day) plus CBT, disulfiram plus IPT, placebo plus CBT, and placebo plus IPT. Across outcome measures and for the full intention-to-treat sample (as well as across all subsamples including treatment initiators and treatment completers), patients assigned to CBT reduced their cocaine use significantly more than those assigned to IPT, and patients assigned to disulfiram reduced their cocaine use significantly more than those assigned to placebo. Effects of CBT plus placebo were comparable to those of the CBT–disulfiram combination. This was our first trial to identify a significant main effect for CBT over another active behavioral therapy (IPT). Furthermore, although retention was a significant predictor of better drug use outcomes, the CBT by time effect remained statistically significant after controlling for retention. Thus, this series of trials has demonstrated increasingly strong effects for CBT over time and our follow-up studies have consistently indicated high durability of CBT compared to other approaches.

Another particularly exciting development in the field of drug dependence treatment has been the very strong empirical support for CM approaches, where participants receive incentives (i.e., vouchers redeemable for goods and services, chances to draw prizes from a bowl) contingent on demonstrating acquisition of treatment goals (e.g., submitting drug-free urine specimens, attending treatment sessions) (37). Given that CM has strong immediate effects but those effects tend to weaken after the contingencies are terminated, while CBT tends to have more modest effects initially but is comparatively durable, several investigators have begun to evaluate various combinations of CBT and CM, reasoning that the relative strengths and weaknesses of these may be offset by combining them. For example, Rawson and colleagues (9) recently compared group CBT, voucher CM, and a CBT/CM combination in conjunction with standard methadone maintenance treatment for cocaine-using methadone maintenance patients. During the acute phase of treatment, the groups assigned to CM had significantly better cocaine use outcomes than the group assigned to CBT. However, during the follow-up period, a CBT “ sleeper” effect emerged again, where the group assigned to CBT essentially caught up to the CM groups by the 52-week follow-up (9). Similar results were found for a parallel study conducted among a large sample ($N = 171$) of stimulant-dependent individuals treated as outpatients (38), where CM was associated with better retention and substance use outcomes during treatment but outcomes for CBT and CM were comparable at 1 year.

Epstein and colleagues (39), conducted a similar study, again in the context of intensive methadone maintenance, where participants were offered CM, group CBT, or a combination of CM plus CBT, in addition to standard individual counseling. Results largely paralleled those found in the Rawson study, in that the investigators reported large initial effects for CM, with drop off after the termination of the contingencies, and the best 1-year outcomes for the CM + CBT combination.

OPTIMAL USE, CBT TECHNIQUES, AND STRATEGIES

At the most simple level, most CBT approaches attempt to help individual patients recognize the situations in which they are most likely to use, avoid those situations when appropriate, and cope more effectively with a range of problems and problematic behaviors associated with substance use by implementing a range of cognitive and behavioral coping strategies. Specific techniques vary widely with the type of cognitive behavioral treatment used, and there are a variety of manuals, protocols, and training programs available that describe the techniques associated with each approach (5,40–43).

As noted earlier, two key defining features of most cognitive behavioral approaches for substance use disorders are (a) an emphasis on a functional analysis of drug use, that is, understanding drug use with respect to its antecedents and consequences, and (b) an emphasis on skills training. Cognitive behavioral approaches include a range of skills to foster or maintain abstinence. These typically include strategies for (a) Understanding the patterns that maintain drug use and developing strategies for changing these patterns. This often involves self-monitoring of thoughts and behaviors that take place before, during, and after high-risk situations or episodes of drug use. (b) Fostering the resolution to stop substance use through exploring positive and negative consequences of continued use (also known as the decisional balance technique). (c) Understanding craving, craving cues, and the development of skills for coping with craving when it occurs. These include a variety of affect regulation strategies (distraction, talking through a craving, “urge surfing,” and so on). (d) Recognizing and challenging the cognitions that accompany and maintain patterns of substance use. (e) Increasing awareness of the consequences of even small decisions (e.g., which route to take home from work), and the identification of “seemingly irrelevant” decisions that can culminate in high-risk situations. (f) Developing problem-solving skills, and practicing application of those skills to substance-related and more general problems. (g) Planning for emergencies and unexpected problems and situations that can lead to high-risk situations. (h) Developing skills for assertively refusing offers of drugs, as well as reducing exposure to drugs and drug-related cues.

These basic skills are useful in their application to helping patients control and stop substance use, but it is essential that therapists also point out how these same skills can be applied to a range of other problems. For example, use of a functional analysis can be used to understand the determinants of a wide range of behavior patterns, skills used to cope with craving can easily be applied to other aspects of affect control, the principles used in the sessions on seemingly irrelevant decisions can easily be adapted to understanding a wide range of behavior chains, and substance use refusal skills can easily be transferred to more effective and assertive responding in a number of situations. We think it is essential that, when therapists teach coping skills, they emphasize and demonstrate that the skills can be applied immediately to control substance

use, but can also be used as general strategies that can be used across a wide range of situations and problems the patient may encounter in the future.

Broad-spectrum cognitive behavioral approaches, such as those described by Monti and colleagues (41) and adapted for use in Project MATCH (40), expand to include interventions directed to other problems in the individual's life that are seen as functionally related to substance use. These interventions may include general problem-solving skills, assertiveness training, strategies for coping with negative affect, awareness of anger and anger management, coping with criticism, increasing pleasant activities, enhancing social support networks, and job-seeking skills, among others.

In comparison to many other behavioral approaches, CBT is typically highly structured. That is, CBT is generally brief (12 to 24 weeks) and organized closely around well-specified treatment goals. Usually an articulated agenda exists for each session and the clinical discussion remains focused around issues directly related to substance use. Progress toward treatment goals is monitored closely and frequently, with frequent monitoring of substance use through urine toxicology screens, and the therapist takes an active stance throughout treatment. Generally, sessions take place within a weekly scheduled therapy "hour." In broad-spectrum cognitive behavioral approaches, sessions often are organized roughly in thirds (the 20/20/20 rule) (5), with the first third of the session devoted to the assessment of the patient's substance use and general functioning in the past week and report of current concerns and problems; the second third is more didactic and devoted to skills training and practice; and the final third allows time for therapist and patient to plan for the week ahead and discuss how new skills will be implemented (5). The therapeutic relationship is seen as principally collaborative. Thus, the role of the therapist is one of consultant, educator, and guide who can lead the patient through a functional analysis of his/her substance use, aid in identifying and prioritizing target behaviors, and consult in selecting and implementing strategies to foster the desired behavior changes.

While structured and didactic, CBT is a highly individualized and flexible treatment. That is, rather than viewing CBT treatment as cookbook "psychoeducation," the therapist carefully matches the content, timing, and nature of presentation of the material to the individual patient. The therapist attempts to provide skills training at the moments the patient is most in need of them. That is, the therapist does not belabor topics such as breaking ties with cocaine suppliers with a patient who is highly motivated and has been abstinent for several weeks. Similarly, the therapist does not race through material in an attempt to "cover" all of it in a few weeks; for some patients, it may take several weeks to master a basic skill.

Extrasession Practice as a Possible Mediator of CBT

In CBT, therapists encourage patients to practice new skills; such practice is a central and essential component of treatment. The degree to which the treatment is a "skills training"

over merely a "skills exposure" approach has to do with the degree to which there is opportunity to practice and implement coping skills, making extrasession practice and homework all the more important. It is critical that patients have the opportunity to try out new skills within the supportive context of treatment. Through first-hand experience, patients can learn what new approaches work or do not work for them, where they have difficulty or problems, and so on. There are many opportunities for practice within CBT, both within sessions and outside of them. Within each session, there are opportunities for patients to rehearse and review ideas, raise concerns, and get feedback from the therapist.

As noted earlier, there has been growing interest in understanding not only what treatments work, but how they work. Understanding the mechanisms of action of CBT and other empirically validated therapies has heretofore received very little attention in the literature, but is an area of great importance. Understanding treatment mechanisms can not only advance the development of more effective treatment strategies, but also result in more powerful, efficient, and ultimately less-expensive treatments.

The converging evidence suggesting that CBT is a particularly durable approach has led to increased focus on unique or distinctive aspects of CBT that might account for its durability. Encouraging clients to implement and practice skills outside of sessions via homework assignments is one possible mechanism for this effect. Homework encourages practice of skills outside sessions and possibly generalization of skills to other problems, and emphasis on extrasession practice assignments is a unique feature of CBT (44). Moreover, investigators evaluating CBT in nonsubstance use psychiatric disorders have noted the importance of homework in CBT's effectiveness.

The relationship of homework compliance, skills acquisition, and outcome in CBT has received comparatively little attention in the substance abuse literature. Thus, in a recent trial for cocaine dependence treatment (45), we evaluated homework completion in detail, collecting data on the specific type of homework assigned and how well it was done (e.g., fully, partially, no attempt made) at every session. We found strong relationships between homework compliance and outcome. Compared with the participants assigned to CBT who did not do homework or who did it only rarely, the participants who did homework consistently *stayed in treatment significantly longer, had more consecutive days of cocaine abstinence* (a strong predictor of long-term outcome), and *fewer cocaine-positive urines during treatment*. Similar effects were found for the subset of participants who completed treatment in this study, suggesting that the effects of homework compliance on better substance use outcomes were not completely accounted for by differential retention. In addition, we found strong relationships between homework compliance and acquisition of coping skills, as well as between homework completion and participants' ratings of their confidence in avoiding use in a variety of high-risk situations. Participants who completed homework had significant increases over time in their self-reported confidence

in handling a variety of high-risk situations, while scores for the subgroup that did not do homework did not change over time.

Farabee and colleagues (46) evaluated the extent to which cocaine users reported engaging in a series of specific drug-avoidance activities (e.g., avoiding drug-using friends and places where cocaine would be available, exercising, using thought-stopping) after CBT versus alternate treatments (e.g., CM and a control condition). They found that, by the end of treatment, participants assigned to CBT reported more frequent engagement in drug-avoidance activities than participants in the comparison treatments. Furthermore, the frequency of drug-avoidance activities was strongly related to better cocaine use outcomes over the 1-year follow-up. Taken together, these studies suggest that CBT interventions that foster the patients' engagement in active behavior change may play a key role in CBT's comparative durability.

SPECIAL CONSIDERATIONS

Training and Competence in CBT

The growing evidence base for CBT and the increased emphasis on incorporating empirically supported therapies into clinical practice has also led to greater focus on training and dissemination. Although standard methods used to train clinicians to use CBT in clinical efficacy trials have generally been associated with high levels of treatment fidelity and comparatively small levels of variation in treatment delivery, these methods (intensive didactic workshop training plus structured feedback on supervised training cases) had not been empirically evaluated, nor are they commonly used in training clinicians to use novel approaches (47).

A comparatively new development in dissemination and technology transfer is the application of rigorous clinical trials methodology to evaluate different methods of training clinicians to implement empirically validated therapies such as motivational interviewing and CBT. In one study (48), 78 clinicians were assigned to one of three training conditions: (1) review of the NIDA CBT manual only ("Manual Only") (5), (2) access to a web-based training site, which included additional frequently asked questions, role plays and practice exercises, plus the manual ("Web"), or (3) a 3-day didactic seminar plus up to three sessions of supervision from a CBT expert trainer based on actual session tapes submitted by the participants ("Seminars + Supervision"). Outcomes focused on clinician behavior and included (a) between-group comparisons of the clinicians' ability to demonstrate key CBT techniques based on structured role plays administered before and after training, and (b) scores on a CBT knowledge quiz. The videotaped role plays were scored by independent raters, blind to the participants' training condition as well as time (e.g., pre- vs. post training) and on an adherence/competence ratings of specific CBT techniques from the Yale Adherence and Competence Scale (YACs) (14).

Although all groups demonstrated improved adherence and competence scores over time, the only training condition that reached levels of skill consistent with those required of clinicians participating in our CBT efficacy trials was the Seminar + Supervision condition, with intermediate ratings for the Web condition. The mean effect size for the Seminar + Supervision versus Manual only condition comparisons was consistent with a large effect (0.69), while the average effect size for the Web versus Manual only condition contrasts was consistent with a medium size effect (0.30). In addition, the Seminar + Supervision condition was associated with significantly more clinicians reaching criterion levels for adequate fidelity than those assigned to the Manual only condition (54% vs. 15%).

These findings underscore that merely making manuals available to clinicians has little enduring effect on clinicians' ability to implement new treatments. This has important implications for current efforts to disseminate new treatments. These findings also suggest that face-to-face training followed by direct supervision and credentialing may be essential for effective technology transfer and raise questions regarding whether practitioners should feel competent (from an ethical perspective) to administer an empirically supported treatment on the basis of reading a manual alone. Finally, the findings suggest that standard strategies used to train clinicians in clinical trials can be effective for community-based clinicians and may be pursued as a strategy for future dissemination trials and bridging the gap between research and practice.

Addressing Limitations of CBT

Despite CBT's emerging empirical support, future research is needed to address its limitations. CBT is a relatively complex approach, in that it is comparatively complicated to train clinicians to use this approach or to implement it effectively in clinical practice. As a result, competent delivery of CBT has been shown to be very rare in clinical practice. Independent review of clinician audiotapes from the "treatment as usual" condition in a multisite trial supported by the NIDA Clinical Trials Network indicated that, although the clinicians professed using a high level of CBT in their clinical work, interventions associated with CBT (e.g., skill training, focus on cognitions) were extremely rare (49).

Another relative weakness of CBT may be the cognitive demands it places on patients, in that they are asked to learn a range of new concepts and skills, including to monitor and remember cognitions and inner states, implement new skills while in stressful situations, and so on. Recent data suggests that substance users with higher levels of cognitive impairment may have poorer outcome in CBT than those who are less impaired (50). This suggests that clinicians using CBT strategies should monitor the cognitive skills of their patients, and in cases where the patients may have memory, attention, or impulse control problems, to adapt the implementation of CBT accordingly, with slower progression through concepts, frequent repetition of material and checking back with the

patient to assess understanding, and providing more structure on extrasession assignments.

Potential strategies for addressing these issues include greater emphasis on understanding CBT's mechanisms of action, so that ineffective components of CBT can be removed and treatment delivery simplified. A more novel strategy is to harness the ability and breadth of technology to standardize CBT and make it more widely available to those that may benefit from it. We have developed a computer-assisted version of CBT, called CBT4CBT (computer-based training in cognitive behavioral therapy). The content of CBT4CBT is based closely on our NIDA CBT manual (5), but it is delivered in six sessions, or modules, and makes extensive use of the multimedia capabilities of computers to convey CBT principles and illustrate implementation of new cognitive and behavioral strategies (51). That is, key CBT concepts are taught through short movies, or vignettes, which feature engaging characters in realistic settings confronting a number of challenging situations as well as a number of interactive games and exercises to teach CBT strategies. Thus, users are able to see multiple examples of how CBT principles can be implemented, rather than hear sometimes too abstract or incomplete presentations from their therapists.

In a clinical trial where CBT4CBT was delivered in addition to standard outpatient treatment, exposure to the program was associated with significantly fewer drug-positive urine specimens submitted and longer durations of abstinence during treatment (51). In addition, data from a 6-month follow-up indicated the durability of these effects in that the "sleeper effect" of CBT appeared to extend to its computer-based version (52), which appeared to have been mediated by significantly higher levels of skill acquisition among those who used the CBT4CBT program (53). Finally, participants' level of neuropsychological functioning did not appear to be associated with outcome in the CBT4CBT program, perhaps because little or no reading of text was required, users can control the rate of speed of material presented, can repeat material as often as they wish, and they can select the types of exercises and issues they would like to address, thereby reducing the "cognitive load" of CBT. Although CBT4CBT and other computer-assisted programs have great potential to make empirically supported therapies more widely available and to broaden the base of substance abuse treatment, and some of the early data on their effectiveness is very encouraging, substantially more testing and evaluation is needed before they can be widely distributed.

SUMMARY

CBT is a behavioral approach that has strong theoretical and empirical support with a variety of substance abusing populations, as well as a broad range of disorders that tend to co-occur with addiction, including depressive and anxiety disorders. Moreover, these approaches can be combined and integrated effectively with a range of other empirically sup-

ported behavioral therapies as well as pharmacotherapies. CBT also appears to be particularly durable, an important feature among the addictions, which are characterized by frequent relapse. In recent years, clinical researchers have recently emphasized moving these approaches more broadly into the clinical community, and thus a range of practical resources (e.g., books, videotapes, manuals, training resources, and programs) for implementing them effectively in clinical practice are available, and data from recent trials evaluating computer-assisted version of CBT have been promising. Thus, due to its comparatively strong evidence base, flexibility, broad applicability across a range of patient types and settings, and durability, CBT should be a component of all substance abuse clinicians' repertoire.

Contingency Management in the Treatment of Substance Use Disorders: Trends in the Literature

Stephen T. Higgins ■ Stacey C. Sigmon ■ Sarah H. Heil

Substance use disorders (SUDs) are highly prevalent in the United States, as they are in virtually all other developed countries, and tremendously costly both economically as well as in terms of personal loss. While there has been a great deal of progress in developing evidence-based treatments for SUDs, there is no question that new and more effective interventions are needed. One widely recognized need is for interventions that are explicitly designed to increase the likelihood of initiating and sustaining behavior change over time, that is, interventions to combat the waxing and waning of commitment or motivation over time that is a hallmark of SUDs. The focus of this chapter is on contingency management (CM), a treatment approach that is particularly well suited to that task.

CM interventions involve the systematic application of reinforcing or punishing consequences to promote and sustain behavior change (1). When used in the treatment of SUDs, CM interventions are usually focused on increasing abstinence from drug use, but also can address areas such as increasing clinic attendance, adherence to medication, and other therapeutic regimens. Investigators have been exploring the use of CM interventions for treatment of SUDs since the 1960s, but there has been tremendous growth in this area of investigation in the past two decades. That growth is illustrated in Figure 45.1, which shows the cumulative number of yearly citations on the topic of SUDs identified through a PubMed search of the term contingency management. The level of growth is striking and as will be characterized below associated with a high degree of efficacy across different types of SUDs, special populations, and therapeutic targets.

There are sound scientific rationales for the use of CM in treating SUDs. CM is based on the principles of operant conditioning, that is, the study of how environmental consequences alter the future probability of voluntary behavior. Behavior that is followed by reinforcing consequences increases in future probability while behavior that is followed by punishing consequences decreases. There is overwhelming scientific evidence that drug use, including drug use by those with SUDs, conforms to the principles of operant conditioning (2). Additionally, an emerging area of behavioral economic research on delay discounting documents that individuals with SUDs exhibit a greater discounting of the value of temporally delayed reinforcement than do matched controls without SUDs (3). Considering that most of the naturalistic reinforcement for dis-

continuing drug use (improved physical health, family life, employment) are delayed in time while those derived from drug use are relatively immediate, it makes sense that systematically providing substitute reinforcement contingent on therapeutic progress as is done in CM might be helpful in bridging the temporal gap between discontinuing drug use and reaping naturalistic rewards for doing so (2). Moreover, chronic drug use can directly diminish frontal lobe cortical functions (executive functions) that underpin effective goal-directed behavior across time and one's ability to focus on longer-term outcomes. Such diminished frontal lobe functioning quite plausibly leaves individuals with SUDs more vulnerable to the mesolimbic-based, relatively immediate reinforcement that drug use represents (3). CM appeals to that same mesolimbic brain reward system to promote recovery from SUDs—that is, CM uses the same processes that drive addiction, but to promote recovery. A final rationale is that in addition to increasing activity in mesolimbic brain areas, response-contingent incentives increase activity in brain regions associated with top-down cortical functions underpinning attention, error monitoring, and other executive functions that are important to successful long-term goal seeking (4,5) and are often diminished among those with SUDs (6).

VOUCHER-BASED CONTINGENCY MANAGEMENT

This chapter is focused on voucher-based CM, which is the most thoroughly researched form of CM used in the treatment of SUDs (1). With this approach, patients earn vouchers exchangeable for retail items, or a comparable monetary-based consequence, contingent on meeting therapeutic goals—usually abstinence from drug use, but sometimes attendance at therapy sessions or compliance with medication regimens. Interventions involving vouchers exchangeable for backup prizes (7) or where cash payments were used (8) are included as part of the voucher-based literature in this chapter.

Basic Elements of Voucher-Based CM

Behavioral Principles and Core Procedures

In this section, we review some basic elements of implementing an effective CM intervention. All CM interventions involve the systematic use of the basic behavioral science

Figure 45.1. Cumulative plot of the number of citations identified in a PubMed search of the term “contingency management” involving substance use disorders (SUDs). The search included all citations through October of 2009.

principles of positive or negative reinforcement and positive or negative punishment. Voucher-based CM emphasizes positive reinforcement involving the delivery of a reinforcing stimulus (e.g., voucher) contingent on the occurrence of a therapeutic goal. The other principle used in voucher-based CM is negative punishment, which involves the removal of a reinforcing stimulus (e.g., special privileges) contingent on the occurrence of an undesirable response. As is outlined further below, this punishment component of voucher-based CM is in the form of a reset contingency wherein the value of vouchers that can be earned is reduced contingent upon evidence of recent drug use or failure to attend a scheduled test to confirm compliance with the contingency. In summary, then, voucher-based CM relies largely on systematic and frequent use of positive reinforcement and a modest use of negative punishment to increase abstinence, deter relapse, and to encourage compliance with scheduled assessments and other therapeutic targets.

Effective voucher-based CM interventions usually include the following features: (1) a well-articulated contract, in writing when possible, to stipulate what behavior change is expected of the patient, what the consequences will be when the behavior change does and does not occur, and the start and stop dates of the intervention; (2) an operationally defined therapeutic target that allows for independent observer agreement on the occurrence or nonoccurrence of the target; (3) use an objective means of verifying occurrence of the target behavior whenever possible; (4) a well-specified schedule for monitoring compliance with the contract; (5) a schedule that includes frequent opportunities for the patient to interact with and learn from the reinforcement contingencies; (6) a minimal number of behaviors that are simultaneously being targeted for change; (7) short temporal delays between verifying compliance with the therapeutic target and delivering the programmed consequences; (8) a consequence of sufficient magnitude, intensity, or value to function as an effective reinforcer. Importantly, the last two points (delay in delivering

consequences and magnitude/intensity/value of the consequence) are fundamental to effective use of reinforcement and were demonstrated to be statistically significant moderators of treatment effect size in our prior meta-analysis on voucher-based CM (9).

An Exemplar of Voucher-Based CM: Smoking Cessation in Pregnant Women

To provide a concrete example of an effective voucher-based CM program, in this section we describe the intervention and related results from a study on smoking cessation among pregnant women (10). This study was selected to serve as the exemplar because the voucher program used is relatively prototypical and the results achieved provide an excellent example of the substantial improvements in outcomes that can be achieved through effective use of the voucher-based CM approach.

Participants in this study were 82 women who were still smoking upon entering prenatal care. They were randomly assigned to an abstinence-contingent voucher condition wherein vouchers exchangeable for retail items were earned contingent on biochemically verified abstinence from recent smoking or to a noncontingent control condition wherein vouchers were delivered independent of smoking status. The details of the voucher conditions were described in the written consent form, which was supplemented by discussion with staff upon treatment assignment, and all study participants had to pass a brief written quiz designed to document understanding of the voucher contingencies before commencing with treatment. In addition to the vouchers, women received whatever was usual care for smoking cessation through their obstetric providers.

Women began their cessation effort on a Monday and reported to the clinic daily for 5 consecutive days for abstinence monitoring. The frequency of abstinence monitoring decreased to twice weekly in week 2 where it remained for the next 7 weeks, then decreased to once weekly for 4 weeks, and then to every other week until delivery. This schedule provided ample opportunity for frequent reinforcement of abstinence. During the postpartum period, abstinence monitoring was increased to once weekly again for 4 weeks related to the increased risk of relapse postpartum, and then decreased to every other week through 12 weeks postpartum at which point the voucher program was discontinued. Voucher values in the abstinence-contingent condition began at \$6.25 for a negative test on the first day of the cessation effort and escalated by \$1.25 for each consecutive negative specimen up to a maximum of \$45.00 where it remained through the remainder of the intervention save for positive results or a missed visit. These values were tested in an earlier pilot trial and shown to be effective (11). Positive test results or failure to provide a scheduled specimen reset the value of vouchers back to their initial low level, but two consecutive negative tests restored the voucher value to the pre-reset level consistent with the punishment component noted above. If a woman abstained completely throughout the antepartum and postpartum periods, she could earn approximately \$1150 in

purchasing power; mean voucher earnings in this condition was $\$461 \pm 456$. Women in the noncontingent-voucher condition received vouchers independent of smoking status and at values of $\$15.00$ per visit antepartum and $\$20.00$ per visit postpartum, which were estimated based on our earlier pilot study to be comparable to average earnings in the contingent condition. Mean voucher amount provided to women in the noncontingent condition was $\$413 \pm 163$, which did not differ significantly from earnings in the contingent condition. Smoking status was biochemically verified based on breath CO specimens ≤ 6 ppm during the initial 5 days of the intervention and urine cotinine (≤ 80 ng/mL) from week 2 through the remainder of the study. Because of cotinine's relatively long half-life, it cannot be used to verify smoking status in the initial days of the quit attempt. Two ultrasound examinations were performed at approximately 30- and 34-weeks gestation for the purpose of estimating fetal growth.

Biochemically verified 7-day point-prevalence abstinence was significantly greater among women in the contingent-compared to the noncontingent-voucher conditions at the end-of-pregnancy assessment (41% vs. 10%) and 12-week postpartum assessments (24% vs. 3%) (Fig. 45.2). Mean weeks of continuous abstinence during the antepartum period was also significantly greater in the contingent- than the noncontingent-voucher conditions, with those in the former achieving 9.7 ± 1.9 weeks compared to 2.0 ± 0.8 weeks among those in the latter. Additionally, a significantly greater percentage of women assigned to the contingent- than the noncontingent-voucher conditions sustained abstinence through the third

Figure 45.2. Point-prevalence abstinence at the end of pregnancy, 12, and 24 weeks postpartum. Women in the contingent condition ($n = 37$) received voucher-based CM contingent on biochemically verified smoking abstinence, and those in the noncontingent condition ($n = 40$) received vouchers independent of smoking status. *Indicates a significant difference between conditions ($p < 0.05$). (Reprinted with permission from Heil SH, Higgins ST, Bernstein IM, et al. Effects of voucher-based incentives on abstinence from cigarette smoking and fetal growth among pregnant women. *Addiction*. 2008;103:1009–1018.)

trimester (27% vs. 3%), which is the trimester where fetal growth appears to be especially impacted by maternal smoking. Treatment effects were no longer significant at the 24-week assessment (8% vs. 3%) in this trial whereas they had been in the prior trial (27% vs. 0%). Collapsing across trials, a treatment effect is discernible at the 24-week assessment (16% vs. 2%), but that should be confirmed in future trials that are better powered to estimate treatment effects after the intervention is discontinued.

Ultrasound assessments of treatment effects on fetal growth showed there was a significantly greater increase in estimated fetal weight in the contingent compared to the noncontingent treatment conditions (Fig. 45.3, top panel). In addition, estimated growth rates for two of the three individual parameters used to compute fetal weight (fetal femur length, fetal abdominal circumference) were significantly greater in the contingent than the noncontingent conditions (Fig. 45.2, bottom panels). We consider these fetal-growth effects to provide important physical evidence of the substantive contributions that CM can make to improving treatment outcomes among pregnant women with SUDs.

Overall, the increases in abstinence and fetal growth observed in this trial are quite promising. This work is being followed-up with further scientific efforts to improve outcomes with pregnant smokers and with plans to extend the approach into community practice.

Reviewing the Literature

Our group previously published a meta-analysis on voucher-based CM (9). That review covered the years 1991 to 2004, with March 2004 representing the last publication month from which studies were included. In this section, we provide a review of the voucher-based CM literature picking up where the earlier review left off, while omitting the one published report from 2004 that was included in the prior review (12). The review for the present chapter ends in October 2009, related to meeting the chapter submission deadline for this edited volume.

We included studies that met the following criteria: (a) involved contingent vouchers or a related monetary-based CM intervention, (b) published in a peer-reviewed journal, (c) included an experimental comparison condition, (d) used a research design wherein treatment effects attributable to CM could be dissociated from other aspects of treatment, and (e) was an original prospective, experimental study that reported previously unpublished data (i.e., not retrospective or a subset of a previously published study). There are three differences between these inclusion criteria and those used in the prior review that merit mention. First, in the prior review studies were excluded if they were not conducted with individuals seeking or enrolled in treatment for SUDs. We have elected not to use that inclusion criterion in the present study as excluding individuals who are not in treatment excludes the vast majority of individuals with SUDs and because CM interventions can be used effectively to alter drug use in nonclinical settings. Second, we previously excluded studies involving fewer than

Figure 45.3. Mean (\pm SEM) rates of growth in estimated fetal weight (**top panel**), fetal femur length (**bottom left panel**), and fetal abdominal circumference (**bottom right panel**) between ultrasound assessments conducted during the third trimester. See Figure 45.1 for description of conditions. *Indicates a significant difference between conditions ($p < 0.05$). (Reprinted with permission from Heil SH, Higgins ST, Bernstein IM, et al. Effects of voucher-based incentives on abstinence from cigarette smoking and fetal growth among pregnant women. *Addiction*. 2008;103:1009–1018.)

10 subjects. While studies involving small sample sizes can be misleading when estimating effect size, which was the main purpose of the prior review, specifying a minimal number of subjects is arbitrary. Instead, we now include studies that met the other inclusion criteria independent of sample size as long as they included inferential statistics so that all studies had a common criterion for supporting inferences about treatment efficacy. Third, the present review does not attempt a quantitative review as was done in the meta-analysis, although descriptive summaries of the proportion of trials reporting statistically significant treatment effects of the voucher intervention are reported. Time and other resource limitations precluded us from conducting another meta-analysis. We required use of a no-voucher or noncontingent-voucher control condition for inclusion in the meta-analysis related to our goal of accurately estimating effect size of the contingent voucher condition, but that criterion was omitted for the present review. We still required inclusion of an experimental comparison condition, but it could be in the form of an alternative type or intensity of treatment.

The literature search for the present review was conducted using PubMed, the search engine of the U.S. National Library

of Medicine, using the search terms “vouchers” and “contingency management,” alone and paired with the terms “drug dependence,” “substance abuse,” and “cigarette smoking.” Reference sections of published papers were also browsed. These are largely the same search terms as were used in our prior review.

Results of the Review

Across the 5-year period, the search identified 72 controlled studies published in peer-reviewed journals where voucher-based CM was used to treat SUDS and related problems for a yearly average of 14.4 reports. Interestingly, the earlier review covering 13.25 years identified 55 controlled studies or 4.2 reports/year. This more than threefold increase in reports/year on voucher-based CM is consistent with the striking growth in this area of treatment outcome research noted above and illustrated in Figure 45.1. Five of these reports were excluded from further consideration due to failure to meet inclusion criteria, leaving 67 reports that satisfied inclusion criteria.

Consistent with the prior review, the vast majority of studies (50 reports or 75%) focused on increasing abstinence from

drug use. The remaining studies fall into two categories, (1) those examining either the efficacy of a contingency requiring abstinence from drug use and other therapeutic goals or comparing contingencies on abstinence to those on other therapeutic goals (10 reports or 15%) and (2) another set of reports examining the efficacy of contingencies on other therapeutic goals including adherence to medication regimens, retention in community SUDs treatment, and attendance at work therapy (7 reports or 10%). Also consistent with our prior review is the overwhelming degree of support for efficacy. Statistically significant treatment effects of CM were reported in 88% (59/67) of the reports reviewed, with that breaking down further to 90% (45/50) among studies focused on abstinence only, 70% (7/10) among studies targeting abstinence and other behaviors or comparing those two approaches, and 100% (7/7) among studies targeting medication compliance, treatment retention, and attendance at work therapy. The somewhat lower level of success in studies targeting behavior change for multiple targets simultaneously compared to more focused targets is also consistent with prior CM reviews (9).

Trends in the Recent Literature

In this section, we have organized the studies into what we deem to be seven trends discernible in approximately 5 years of the voucher-based CM literature covered by this review. While studies are often of relevance to more than one trend, we assigned each report to a primary trend. The trends identified were (a) extending the intervention to additional SUDs, (b) treatment of special populations, (c) extending use into community settings, (d) improving longer-term outcomes,

(e) combining the intervention with pharmacotherapies, (f) investigating various parametric questions, and (g) using the intervention as a research tool rather than treatment intervention per se. Each of the 67 studies included in the review was assigned to one of those seven trends, with each of the trends including a specific table (Tables 45.1 to 45.7) listing key characteristics from each of the studies included under that trend. We comment briefly on each of the trends below. It merits mention that additional studies are cited in the text and reference section below because of their relevance to a point of discussion, but unless they are also listed in one of the tables they were not among the 67 studies included in the review.

Extending the Intervention to Additional Substance Use Disorders

While once the major trend in this area of investigation, extension of voucher-based CM to new types of SUDs is only a small part of current research efforts (see Table 45.1). In the present review only two examples of this type of research were identified. One involved trials further establishing the efficacy of voucher-based CM in the treatment of marijuana dependence and the other extending its efficacy to treatment of methamphetamine dependence. Three excellent controlled trials added support to other trials already in the literature on the efficacy of voucher-based CM for increasing abstinence in marijuana-dependent individuals (13–15). Evidence on the efficacy of voucher-based CM in treating methamphetamine dependence surfaced initially in trials among mixed samples of cocaine- and methamphetamine-dependent patients. A controlled trial by Rawson et al. (16) showing the efficacy of

TABLE 45.1 Extending the intervention to additional SUDs

Study	<i>n</i>	Setting	Voucher duration (weeks)	Maximum voucher earnings	Voucher delivery	Statistically significant treatment effect?	Voucher target(s)
Budney et al. (13)	90	DF	12	\$570.00	I	Y	Marijuana use
Carroll et al. (14)	136	DF	8	\$540.00	I	Y	Marijuana use
				\$340.00	I	Y	Counseling attendance
Kadden et al. (15)	240	DF	7	\$385.00	I	Y	Marijuana use
Rawson et al. (16)	171	DF	16	\$988.75	I	Y	Cocaine + methamphetamine use

Note: Numbers next to each citation refer to its position in the reference section; *n*, sample size, all groups combined; setting, setting in which study occurred; DF, drug-free clinic; M, medication clinic; MM, methadone maintenance; NTS, not a treatment setting; voucher duration (weeks), number of weeks that voucher intervention was in place; maximum voucher earnings, total possible voucher earning across duration of the intervention; statistically significant treatment effect, presence or absence of significant treatment effect at $p < 0.05$; voucher target, the target of the voucher intervention. Voucher delivery: I, immediate (at the same visit the reinforcement was earned); D, delayed (at a visit after the reinforcement was earned).

CM alone and in combination with cognitive-behavior therapy for increasing abstinence and retention in these “stimulant-dependent” samples among patients enrolled in methadone therapy is an excellent example. Included in the section below on extending voucher-based CM to community clinic settings are two multisite trials that also support the efficacy of CM in treating these mixed samples of cocaine- and methamphetamine-dependent patients (17,18).

Extending the Intervention to Special Populations

The use of voucher-based CM to treat SUDs in special populations is a trend that was discernible in the prior review and that continues to gain momentum in the period covered by the present review (Table 45.2). For example, nine reports in the present review described results from studies testing the efficacy of voucher-based CM for smoking cessation in special populations, including adolescents (19), college students (20–22), pregnant women (10,11), and individuals enrolled in treatment for other SUDs (23,24), and one with individuals residing in rural areas isolated from usual smoking-cessation services (25). All reported significant treatment effects although all but the Heil et al. (10) trial in pregnant women were relatively preliminary investigations.

Another special population with whom voucher-based CM has promise is the dually diagnosed, with four studies on that topic identified in this review and all reporting significant treatment effects (26–29). Two of the studies supported the feasibility of using contingent vouchers to promote abstinence from cocaine and alcohol (26) and marijuana (29) in the dually diagnosed population while the two other studies (27,28) represented a more thorough investigation of the efficacy of contingent vouchers for promoting abstinence and job seeking among veterans enrolled in compensated work therapy. Considering that compensated work therapy programs operate in Veterans Hospitals located throughout the United States, they service large numbers of veterans suffering with SUDs and other psychiatric disorders, and improvements in the program are needed, this appears to be a promising area where voucher-based CM could make a substantive contribution.

Other studies in special populations identified in the review further supported a well-established application of contingent vouchers to increase participation in vocational training among chronically unemployed, intravenous drug abusers (30,31). Two randomized clinical trials were identified supporting the efficacy of contingent vouchers for increasing adherence with antiretroviral medications in HIV-positive illicit drug-dependent individuals while the incentives were in place, although effects dissipated following termination of the intervention (32,33). The studies on vocational training are part of the programmatic research effort by Silverman and colleagues on the use of abstinence-contingent work therapy as a form of maintenance therapy discussed above. The studies on adherence with antiretroviral medications suggest that some form of contingent-vouchers maintenance therapy may be an important future direction to investigate with that population as well. Lastly, the present review identified one study

supporting the efficacy of voucher-based CM for improving outpatient retention of pregnant illicit drug abusers (34), but this is an area of investigation ripe for further development.

Extending the Intervention into Community Clinics

An important research effort has been on moving voucher-based CM from university-based research clinics into community clinics. That effort is succeeding on multiple fronts that were discernible in the present literature review (Table 45.3). One direction in this effort has been led by Petry and colleagues using an adaptation of the original voucher-based CM intervention that amounts to using lower-value incentives. In at least six controlled studies that were identified in the present review, the intervention was shown to increase abstinence and/or clinic attendance/treatment retention among illicit drug abusers enrolled in community clinics, including the two multisite trials noted above (7,17,18,35–37). This research effort is important because with lower-value incentives community clinics operating on limited budgets are likely to be more open to adopting this evidence-based intervention. Important to keep in mind, though, and often misunderstood, is that there is overwhelming evidence that the size of the treatment effect obtained with voucher-based CM decreases as the value of the incentives decreases, and there is no evidence that Petry and colleagues have surmounted that obstacle. They have shown that one can use lower-value incentives than are typically used in conventional voucher arrangements and still improve outcomes in community clinics, which is important. What they have not shown empirically is that their adaptation of the original schedule arrangement has any influence on outcome or that they can obtain larger treatment effects at lower costs compared to prototypical voucher programs. Indeed, in two trials conducted by Petry and colleagues (37,44) where their arrangement was compared to a prototypical voucher arrangement using comparable incentive values, there were no significant differences between the two arrangements in treatment outcomes.

Sometimes overlooked but quite impressive are successful efforts by other investigators to use lower value CM programs in community clinics (38,39). Again, there is no evidence to suggest that these investigators have devised a method for producing treatment effect sizes comparable to those achieved at higher voucher values but at a more affordable cost, but, rather, they are showing that costs can be lowered to more affordable levels and still retain significant benefit in terms of improving treatment outcomes.

Another research development relevant to the successful dissemination of voucher-based CM into community clinics in the United States and abroad is a project conducted in Spain wherein vouchers exchangeable for goods donated by community businesses were efficacious in treatment of cocaine dependence (40). Lastly, but very importantly, Volpp and colleagues (8) reported a successful controlled trial using monetary reinforcement of abstinence from cigarette smoking among employees of a large corporation. Moving the voucher-based CM into work settings offers tremendous opportunity for successful dissemination of this approach, especially if employers are willing to cover intervention costs.

^aCalculated based on expected average max earnings stated in text.

Important to mention in this section are three additional international examples relevant to the goal of integrating CM into community practices. First, a project is currently under way in the United Kingdom (UK) examining the feasibility of nationwide adoption of voucher-based CM for treatment of SUDs following a recommendation in that direction from the National Institute on Clinical Excellence, an independent body in the UK responsible for providing national guidance on health promotion (45). Second, voucher-based CM specifically for smoking cessation among pregnant women has been implemented into routine clinical practice in certain locations in the UK. For example, a program entitled “Give it up for Baby” in Tayside, Scotland uses vouchers exchangeable for grocery items to promote smoking cessation with economically disadvantaged mothers, the group most at risk for smoking during pregnancy (46). Third, while not targeting SUDs, some mention of conditional cash transfer (CCT) programs warrants mention in any discussion on dissemination of CM into community practices. CCT programs are aimed at eliminating chronic poverty and are operating in many low- and middle-income countries worldwide (47). In these programs, mothers earn cash supplements contingent on adherence with infant inoculations, supplemental feeding, and school enrollment and attendance, among other health-related goals. Tens of millions of families are participating in these programs, which, without question, represent the largest CM effort ever undertaken.

Combining the Intervention with Pharmacotherapies

A clear trend involving studies with voucher-based CM and medications is evident in the present literature review (Table 45.4), with some studies examining the relative efficacy of voucher-based CM and medications, others investigating combined effects, and still others looking at whether CM can enhance compliance with medications known to be efficacious but where adherence is problematic (48–57). Eight of the 10 trials report results supporting the efficacy of the CM intervention, but beyond that the results from this emerging and potentially very important area of investigation are quite mixed. Perhaps the clearest finding is one by Oliveto and colleagues (52) showing that the efficacy of voucher-based CM for cocaine abstinence among opioid-dependent patients enrolled in substitution therapy was conditional on an adequate dose of the medication. That study provided important experimental confirmation of what was long part of voucher-based CM for treating opioid-dependent populations. Results from a trial by Poling et al. (53) offer a suggestion that combining bupropion therapy with CM for treatment of cocaine dependence facilitates the efficacy of the medication. The Poling et al. trial is a novel and interesting finding that while less intuitive than the Oliveto et al. (52) finding is logically comparable, and if replicable suggests great promise for combining CM and pharmacotherapy.

This area of investigation is currently lacking any programmatic direction that is readily discernible, but certainly appears to have great potential. Worth mentioning is that the community CM program for smoking cessation among pregnant smokers described above combines the intervention with

free nicotine replacement therapy for mothers who are interested in both and where a pharmacist or provider agrees that pharmacotherapy is indicated (46).

Investigating Longer-Term Outcomes

From early in the development of the voucher-based CM approach to treatment of cocaine dependence there has been interest in its longer-term outcomes. Research on how to directly improve longer-term outcomes has taken two complementary directions that are discernible in the results of the present review (Table 45.5). The first seeks to build on correlational data suggesting that key to fostering longer-term abstinence is increasing during-treatment abstinence. In an experimental test of this notion conducted with cocaine-dependent outpatients, Higgins et al. (58) demonstrated that increasing during-treatment abstinence by using vouchers with greater monetary value also improves longer-term abstinence levels during a 2-year period of posttreatment follow-up.

The second direction of research on this topic of improving longer-term outcomes is focused on voucher-based maintenance therapy. This important effort is being led by Silverman and colleagues who are systematically investigating whether integrating voucher-based CM for abstinence from drug use with vocational training initially and then paid employment thereafter may be a means for developing a self-sustaining intervention that can remain in place long-term (59–62). As would be expected in such an ambitious undertaking, some revisions in the protocol have been necessary (59), but the two most recent trials have resulted in positive outcomes that are quite promising in terms of supporting the feasibility of establishing an efficacious maintenance intervention of voucher-based CM for treatment of chronically unemployed, urban, intravenous cocaine- and opioid-dependent outpatients (60,61).

Conducting Parametric Studies

As is appropriate and necessary in treatment development, many studies in the CM literature address various parametric questions about this treatment approach. We identified 13 reports of that nature in the present literature review (Table 45.6). The focus of these studies ranges broadly, but includes a wealth of potentially important, creative, and essential investigations about how to optimize and further expand this efficacious treatment approach. Examples include experiments on prototypical voucher-based CM combined with computer delivered therapy (63), Internet-based CM delivered alone and without regular in-person interaction (64), different scheduling arrangements to optimize outcomes (65,66), and the possibility of using group rather than individual reinforcement contingencies (67). Some of these studies offer important but clearly incremental advances, while others offer novel advances. All are important and underscore the health of this area of research.

Using the Intervention as a Research Tool

An application of substantial scientific value but rarely discussed is the use of voucher-based CM as a research tool. A recent trial by Mueller et al. (75) provides another interesting

Voucher delivery: I, immediate (at the same visit the reinforcement was earned); D, delayed (at a visit after the reinforcement was earned).

example (Table 45.7). In this instance, CM was used as a research tool in examining the potential contribution of individual differences in executive function to relapse vulnerability in a laboratory model of smoking abstinence. Our group has effectively used CM in a series of experimental studies focused on examining how an initial period of smoking abstinence alters relapse risk (76–79).

The potential utility of voucher-based CM as a research tool seems to have tremendous unrealized potential. The technology gives researchers the potential to experimentally alter drug use practices in severely addicted individuals for sustained periods of time while they reside in their usual drug-using environments. The questions that can follow from that are enormous, including, for example, changes in brain function and structure as well as behavioral and lifestyle outcomes.

SUMMARY/CONCLUSIONS

Voucher-based CM is an efficacious approach to the treatment of SUDs that is based on a clear and compelling set of scientific principles and evidence-based rationales. The approach also has a set of reasonably well-articulated recommended practices for effective CM treatment that we reviewed above. By coupling our review of those core principles and recommended practices with a detailed example of how they can be put into action in the form of a voucher-based CM treatment for pregnant smokers, we hope that readers interested in adopting this approach may be able to gain helpful practical insights from this chapter on how to do so.

Rather than focus the review on the entire almost 20 years of voucher-based CM research, we elected to examine

the 5 most recent years. The results from that review show a field that is growing at a very healthy pace, with a total of 72 controlled studies published in peer-reviewed journals over 5 years at a rate of 14.4 articles/year. Importantly, this pace of growth does not appear to have compromised efficacy. Overall, 88% of the articles reviewed in this chapter reported statistically significant treatment effects, which is consistent with the high levels of efficacy that were noted in our earlier review (9).

In trying to organize this rapidly growing literature, we identified seven trends. The practice of extending the approach to new SUDs appears to be leveling off as it would have to. The developments noted in the present review with marijuana and methamphetamine use disorders are important, especially considering the prevalence of the former and the high toxicity and individual and community disruption associated with the latter. The one relatively glaring hole in an otherwise impressive record of extending CM to all major SUDs is alcohol use disorders. No studies on that topic were identified in the present review, which is in keeping with earlier reviews. The major obstacle to extending CM to alcohol use disorders has been technical. That is, reliable methods for biochemically verifying recent abstinence have been associated with detection windows that are too short (e.g., breath alcohol levels) or too long (e.g., gamma-glutamyltransferase) for effective use in CM interventions. Whether recent technological developments such as continuous transdermal alcohol-monitoring devices will permit a break in this logjam remains to be seen, but this is an area with great potential for growth and where voucher-based CM may be able to make important contributions.

^aSix lab visits.

The use of voucher-based CM with special populations is an exciting and growing area with potentially important contributions being made with pregnant women, adolescents, and those with other psychiatric disorders, among other groups. Recent developments with pregnant cigarette smokers and in vocational training with dually diagnosed veterans appears to hold particular promise in terms of this treatment approach becoming widely used in clinical practice. An area where we see unrealized potential is in the use of voucher-based CM in treating pregnant women dependent on illicit drugs. There is no programmatic body of CM research focused specifically on this population.

Efforts to move voucher-based CM into community clinics have been tremendously successful in terms of demonstrating efficacy in those settings. Where progress has been slower is in adoption of the practices into routine clinical care, especially in the United States. As was noted above, efforts are under way exploring broad implementation in the UK where they have a single-payor health care system, but in the US system how to pay for incentive-based interventions remains a major obstacle to broad dissemination into community SUDs clinics. Important to recognize, though, is that there are other important community venues for intervening on SUDs besides treatment clinics. Indeed, employment settings, drug courts, other criminal justice settings, community agencies such as Women, Infants, and Children (WIC) offices and community health centers may eventually prove to be a better match with the voucher-based CM approach than community SUDs treatment clinics.

Progress is being made toward using voucher-based CM to improve longer-term outcomes. There is strong evidence that

voucher-based CM interventions produce effects that carry over into the posttreatment period and progress is being made in how to improve upon that situation by increasing during-treatment success. The development of longer-term or maintenance CM interventions is a parallel and essential effort that is also progressing well. Indeed, when one considers the broad agreement that SUDs are chronic relapsing disorders, the need for maintenance interventions is obvious. Again, it may be the case that the venues for implementing such longer-term interventions ends up being something other than or at least in addition to conventional community SUDs treatment clinics.

Also rather clear is the importance of effectively combining voucher-based CM with pharmacotherapies. This review revealed numerous efforts in that direction, but as yet nothing that is particularly promising other than the use of voucher-based CM in methadone and other opioid-substitution clinics.

Attention to various parametric questions about effective CM treatment is an ongoing theme in this literature that all signs indicate will and should continue. Despite the striking growth in the number of studies appearing in the voucher-based CM literature and high rates of success in terms of significant findings, there is a daunting amount more to be learned about how to optimize the use of financial incentives for behavior change around SUDs as well as other health-related behavior. We anticipate that this is an area that will see growing attention as government and private enterprises attempt to curb the spiraling health care costs associated with SUDs and other health-related behaviors.

Last, but by no means least, we see promising growth in the use of voucher-based CM as a research tool. That was

evident in trials on neuropsychological factors (75) as well as the effects of initial abstinence on relapse risk (76–79). This remains a highly underutilized strength of voucher-based CM, but the trend from the present review shows growth in this area that is likely to continue as evidence accumulates on the scientific advantages of doing so.

Motivational Interviewing and Enhancement

Carlo C. DiClemente ■ Onna R. Van Orden ■ Katherine S. Wright

INTRODUCTION

One of the true innovations in the field of substance abuse treatment in the past 15 years has been the adoption of sophisticated motivational interventions. Lack of motivation to change is common in substance abuse stemming from the capacity of substances to create habitual addictive patterns of behavior that include physiologic and psychological dependence. This has led some to call addictions “diseases of denial” and to suggest that confrontation, experiencing severe consequences, and “hitting bottom” are the most effective methods for breaking through the addicted individual’s denial. For the most part, this perspective has changed dramatically over the past 15 years. There is growing recognition that lack of motivation is not simply a problem of addiction but is a part of all human intentional behavior change (1–3). Motivation is multidimensional involving a series of tasks that include creating concern, decision making, firm intentions, commitment, planning, and sustained implementation (4). These tasks are not new and are critical for understanding individual behavior change whether it happens through self-change or with the assistance of treatment or mutual help programs (5).

Motivational interviewing (MI) was developed as an intervention style and a set of strategies based on motivational principles to address the typical motivational conundrum faced by treatment providers: most treatments are action-oriented, but most patients are ambivalent, unmotivated, and not ready for change. MI is best thought of as an intervention that attempts to empower the individual and evoke change rather than an intensive treatment. This chapter will describe the MI approach, offer some evidence for efficacy of this treatment, and describe how it can be used in substance abuse treatment.

HISTORY OF MOTIVATIONAL INTERVIEWING

MI was born out of two converging lines of research that emerged at the end of the 1970s and the beginning of the 1980s. The seminal work by Edwards and colleagues indicated that brief interventions of advice and information were as effective as more extensive formal treatments when used with a broad range of individuals with alcohol problems (6). These findings spurred Miller to begin developing and evaluating brief interventions for excessive drinking. Such inter-

ventions, like the Drinker Check-Up, were designed to influence problem drinkers to change their drinking behavior using an assessment format that included objectively and empathically delivered feedback. Early on, minimal interventions were viewed as more relevant for problem drinkers rather than heavier or dependent drinkers. This was influenced by the belief that “true alcoholics” would not be able to benefit from these interventions because dependence compromised and crippled motivation. In fact, inability to change despite trying to do so became one of the symptoms that supported a dependence diagnosis adopted by the DSM-III-R. Nevertheless, evaluations of the Drinker Check-Up program indicated that many individuals with serious alcohol problems were able to moderate, if not quit, drinking (7). Interest grew among providers in using minimal, motivational interventions for substance abuse, primarily for alcohol abuse and dependence.

At the same time, Prochaska and DiClemente were developing the Transtheoretical Model, which described intentional behavior change in a series of stages that individuals negotiated by use of a number of behavior change principles or processes (8). This model was proposed as an integrative, eclectic framework that could make sense of the puzzling outcomes of many treatment comparison trials indicating that different types of therapies seemed to produce equivalent outcomes when evaluated in clinical trials (9). This model delineated preaction stages (Precontemplation, Contemplation, and Preparation/Decision Making) indicating that there were tasks and steps that were necessary to get individuals ready for action. Their early research also indicated that there may be separate sets of strategies that could be used to influence early-stage transitions, which might differ from action-oriented strategies that would be more important in the later action stages (Action and Maintenance) (10). It should be noted that many researchers were focusing on decision-making as well as beliefs and intentions contributing to the zeitgeist that led to the creation of cognitive-behavioral treatments that focused both on cognitive variables as well as behavioral learning principles as critical ingredients for change (11).

Miller began to concentrate on motivation and brought together these two lines of research in his review of motivation in substance abuse (12). He also co-sponsored with Nick Heather the third International Conference on the Treatment of Addictions Behaviors held in Berwyck, Scotland in 1984, the theme of which was self-regulation and the stages of

change (13). On a sabbatical in Australia, Bill Miller teamed up with Welsh researcher, Stephen Rollnick, and together they developed what is now known as MI (2). Their work made explicit critical elements of successful brief interventions and focused on early-stage motivational challenges that individuals must resolve for successful modification of their problematic substance use. Although originally focused on addictions, this approach came to be used for a variety of health behavior problems (1,14). MI also became an integral intervention component for developing Screening, Brief Intervention, Referral, and Treatment (SBIRT) approaches for early intervention in drug abuse and other problematic health behaviors (15). In addition, MI interventions were developed into an independent, brief treatment called Motivational Enhancement Treatment (MET) (16). Both the first and second editions of the MI book became widely used as a training manual that described the basic principles and strategies as well as how the approach has been adapted for a variety of problems and integrated into many different intervention settings. Today MI is being used in pretreatment interventions as a component of a larger integrated approach, as a free-standing treatment (MET), and as a basic brief intervention used by a multidisciplinary and heterogeneous group of providers. Most importantly, the emergence of MI has reflected and promoted a dramatic change in perspective about how to approach and interact with individuals with substance abuse and how to engage motivational considerations in a constructive, respectful, and empowering manner.

UNIQUE FEATURES OF MOTIVATIONAL INTERVIEWING

MI is not a complete therapy intended to provide support, coping skills, and problem solving over a long period of time. As its name indicates, it is a way of talking and interacting with an individual that is designed to activate the person's concern, considerations, and intentions to change and to support the individual's sense of confidence and efficaciousness in making the change. It is specifically intended to help resolve ambivalence, to promote consideration of values, to reevaluate the current status quo and the potential for change, and to support realistic self-efficacy and planning to make a change. It consists of a *style* of interacting that can be used throughout the provider's encounter with a substance abuser as well as a series of *strategies* that can be used to address various obstacles and considerations that hinder the flow of motivation and change for specific clients. Table 46.1 provides an overview of these features of MI. In addition, specific skills are needed for practitioners to be able to implement these strategies.

The style or spirit of MI is marked by critical attitudes and values that underlie the entire approach. The key dimensions of the MI-style are Collaboration, Evocation, and Autonomy. Important elements that characterize an MI encounter between the provider and the client are empathy,

respect, a collaborative relationship, belief in the capacity for change, and elicitation of motivational considerations, commitment, and change language from the client. Spirit and style are core elements that distinguish MI from other approaches that are more expert-oriented, openly directive, confrontational, and therapist-dominated. Many of the core MI elements are similar to those described in a good therapeutic or working relationship between therapist and client. However, MI-style is a unique combination of elements from Carl Rogers' nondirective approach, from humanistic/existential therapy, and from emerging scientific principles of communication, interpersonal interaction, engagement, and motivation.

The core MI strategies include expressing empathy, using open-ended questions, reflective listening, summarizing and clarifying client thoughts and experiences, affirming client strengths and capacity, eliciting change talk, rolling with resistance, asking permission before giving advice, and presenting a menu of options. There are also more specific techniques that can be used in each of these areas that are outlined in Table 46.1. The objective of the use of these strategies and techniques is to elicit and promote "change language" from the client. Change language consists of any client statements and expressions that reflect a Desire, Ability, Reasons or Need to change or a Commitment to take some action to change (DARN-C language). On hearing any DARN-C language, providers are expected to emphasize them and encourage exploration by reflecting on these client expressions using reflective listening techniques or highlighting them in various types of summaries (collecting, linking, and transitional).

Implementing MI requires practitioners to have or develop both the style of communication and the basic skills to enable them to use the strategies and techniques outlined in Table 46.1. The style, strategies, and skills that comprise MI may come more naturally to some health practitioners than to others. The style requires a respectful, empowering attitude toward the client and the intervention process. MI is neither intended to undermine the role of the provider as a professional, who has important knowledge and specific skills and aids, nor to blur the boundary between client and professional. However, an MI practitioner would need to have attitudes and communication skills that are consonant with collaboration, empathy, listening before speaking, tolerance of client ambivalence and lack of motivation, and the ability to collect, understand, reflect, and summarize what is being said in the encounter. The ability to listen and pay attention not only to clients' words, but also to their demeanor, emotions, and language is at the heart of being able to engage in reflective listening and to offer accurate and provocative reflections. Minimizing assumptions and prejudgments of client capacity, motivation, and ability to change is also critical to eliciting change talk and being affirming. Although many practitioners indicate that they are using MI in their practice, fewer seem to be using the entire scope of style, strategies, techniques, and skills that are outlined and

TABLE 46.1 Key elements of a motivational style of counseling

Style	Strategies	Techniques
<i>Collaboration</i> Even power distribution Client involved in decisions	<i>Open-ended questions</i> Elicit longer responses <i>Affirm the client</i>	Open-ended questions <i>Begin with words such as “how”, phrases such as “tell me about...” or statements that implicitly ask for a response</i>
<i>Evocation</i> Communicate belief in the capacity for change Understand client experience	Provide tailored support <i>Reflective listening</i> Clarify client’s meaning <i>Summarizing statements</i>	<i>Affirm the client</i> <i>Notice strengths</i> <i>Acknowledge efforts</i>
<i>Autonomy</i> Respect Acknowledge client's freedom	<i>Rolling with resistance</i> Come alongside client	<i>Be appropriate to setting and culture</i> Reflective listening
<i>A Motivational Style of Counseling: “a skillful clinical style for eliciting from patients their own good motivations for making behavior changes.”^b</i>	<i>Eliciting change talk</i> Highlight and resolve ambivalence <i>Empathy</i> Acceptance supports change	<i>Simple reflection</i> <i>Amplified reflection</i> <i>Understatements</i> <i>Double-sided reflection</i>
<i>Motivational Counseling Strategies: methods to enhance client engagement in the change process, supported by the use of several motivational counseling techniques.</i>		Summarizing statements <i>Collect</i> <i>Link</i> <i>Transition</i>
<i>Motivational Counseling Techniques: specific behaviors that will enable a counselor to perform effective motivational counseling strategies.</i>		Rolling with resistance <i>Reframe</i> <i>Shift focus</i> <i>Enhance discrepancy</i> Additional skills <i>Avoid blurting out responses</i> <i>Ask permission to give advice</i> <i>Present a menu of options</i> <i>Attend to DARN-C language^a</i>

^aDARN-C is an acronym for the client’s Desires, Abilities, Reasons, and Needs for change, and their use of Commitment language to enhance self-efficacy for change.

^bRollnick S, Miller WR, Butler CC. *Motivational Interviewing in Health Care: Helping Patients Change Behavior*. New York, NY: Guilford Press; 2008:6.

demonstrated by the developers of the MI approach. Simply using open-ended questions and reflections do not encompass the broad scope of knowledge, skills, and behaviors needed to fully implement MI. Because of its popularity, there are many adaptations of MI (AMI) that do not include all of the elements and are not executed with the rigorous skill development, feedback and supervision, and detailed analyses of taped sessions that reflect a more comprehensive and faithful application of MI (17).

EFFICACY OF MI WITH DIFFERENT POPULATIONS

A large number of studies have evaluated MI and AMI across a wide range of behaviors. The following review will describe findings in this literature highlighting the efficacy of MI with various types of addictive behaviors and populations and update the reviews of its application to various substances and in a variety of settings (3). In their review on AMI interven-

tions prepared for the second edition of the MI book, Burke, Arkowitz, and Dunn concluded that “in general, AMIs are more effective than no treatment . . . are not significantly different from credible alternative treatments . . . and are efficacious, both as stand-alone treatments and as preludes to other treatments” (pp. 241–242).

In a later meta-analysis of randomized controlled trials (RCT) testing the efficacy of AMI across health behaviors, Burke, Arkowitz, and Manchola used strict criteria for inclusion as an AMI RCT, including random assignment, control group, and adequate measures. In addition, they included only studies of individual therapy with interventions that used MI techniques separate from other treatments. They found 15 studies focused on alcohol, 5 with drug addictions, and just 2 for smoking cessation that met these criteria. These authors concluded that “AMIs were equivalent to other active treatments and yielded moderate effects (from 0.25 to 0.57 [Cohen’s *d*]) compared with no treatment and/or placebo for problems involving alcohol, drugs, and diet and exercise”

(p. 843) (18). These reviews indicate that AMI interventions are efficacious but not necessarily better than other credible interventions.

Techniques of MI, however, may be more efficacious when addressing preaction motivational tasks and engagement with the intervention. One multisite drug-abuse treatment study found that MI strategies integrated into the initial intake and evaluation sessions of outpatient treatment were associated with significantly better treatment retention at 28-day follow-up. However, the intervention did not impact self-reported overall substance use at either 28-day or 84-day follow-up (19). Miller, Yahne, and Tonigan also found a single session of MI early in either inpatient or outpatient substance abuse treatments did not produce an increase in self-reported percent days abstinent from substances at either 3, 6, 9, and 12 months posttreatment as validated by urine toxicology and collateral reports (20). Limited exposure to MI especially when joined with a more extensive treatment does not appear to be effective to produce differential changes in substance use behavior compared to active controls among a heterogeneous group of treatment-seeking substance abusers. However, AMIs did demonstrate some positive effects on treatment engagement and retention in inpatient or outpatient substance abuse programs. Studies focused on specific substances of abuse may provide a better test of potential efficacy of MI approaches. These are reviewed below, with the caveat that additional research is needed on the efficacy of MI for the treatment of specific substances of abuse, particularly illicit substances.

Alcohol

MI interventions for alcohol abuse and dependence have been studied more extensively than for any other addictive behavior. A large number of studies examined MI and AMI types of interventions for alcohol use, abuse, and dependence and found that AMI interventions had a moderate advantage compared either with other interventions or no intervention at all. Vasilaki, Hosier, and Cox, updating three previous reviews, concluded that brief interventions using MI were particularly effective in reducing alcohol consumption (21). The review included only RCTs that examined MI as a treatment to reduce alcohol consumption in comparison to no treatment or a comparison treatment. They reviewed 22 RCTs, published between 1983 and 2003, that satisfied Miller and Rollnick's definition of MI as "a client-centered, directive method for enhancing intrinsic motivation to change by exploring and resolving ambivalence," (p. 328) among other criteria. Only 15 studies were included in the final meta-analysis, as 7 did not meet the methodologic quality criteria for inclusion. Nine compared brief MI with no treatment and nine compared it to other treatments with three studies falling into both categories. Mean duration of the MI intervention across these studies was 87 minutes.

The strongest conclusion of this review was that MI was significantly more effective in reducing alcohol consumption

at a 3-month follow-up among nondependent drinkers when compared with no-treatment controls. When compared to other treatments, results were mixed. MI had greater efficacy than a standard care or treatment-as-usual (TAU) control in four studies. In five studies, MI was more effective than a comparison treatment (CBT, skills-based counseling, and directive-confrontational counseling), but in three other studies MI was equivalent to an alternative treatment. One of these was the large-scale, multisite alcohol treatment study, Project MATCH, in which researchers utilized, with high fidelity, a treatment condition comprised of four comprehensive MET sessions and found it produced comparable results to two other more extensive 12-session treatments (22). The review concluded that MI was useful as a brief intervention and more successful when the client was a young adult who was a heavy drinker rather than an older adult with more severe dependence. It is notable, however, that in none of these studies was MI found to be less effective than other treatments or a no-treatment control (21).

Group differences in efficacy tended to be greater at 3-month compared to 6-month follow-ups, perhaps suggesting that its effects may fade with time. This does not always seem to be the case, however, since other studies have found support for sustained reductions in alcohol-related problems as well as reductions in the quantity and frequency of drinking at 12-month follow-up interviews (23). Studies of reduction in drinking with AMI interventions have also shown support for its use in screening and brief interventions across a number of settings (24,25).

In alcohol studies examining MI as a treatment option compared to no treatment, MI fared well. Heavy-drinking participants receiving one individual sessions of MI reduced their drinking throughout the 6-week follow-up period (26). Another study showed both MI and control groups reducing their drinking over a 2-month follow-up period, with subjects in the MI condition significantly reducing their binge-drinking above and beyond the comparison group (27). McCambridge and Strang also found significant reductions in alcohol use 3 months after a single MI session, although this may have been a subclinical sample (28). However, in other RCTs, no differences were found between MI and no-treatment or TAU control groups on drinking outcomes (29,30). In one such study, both MI and control groups reduced their alcohol consumption at the 6-month postintervention follow-up point but did not differ from one another (30). In another, the significant difference between MI and the control group found at the third month had disappeared by the sixth month of follow-up (29).

In summary, MI has demonstrated efficacy compared to no treatment, TAU, and some comparison treatments for alcohol abuse and dependence. Results appear to be strongest with younger and less-dependent drinkers. There are also some indications that these brief interventions may produce effects that fade in some groups of drinkers. The research supports use of MI for brief interventions and for outpatient treatment for individuals with a range of excessive drinking problems.

However, the exact parameters of who can most benefit from these types of interventions and in which settings they are most effective have not yet been definitively determined.

Opiates

RCTs involving AMI with opiate abusers, either as brief interventions or strategies included throughout treatment, demonstrate inconsistent evidence of treatment efficacy. Out-of-treatment heroin users who received a single, brief motivational intervention during a routine medical visit showed higher rates of abstinence from heroin 6 months later (24). However, in another RCT examining methadone maintenance treatment retention street-recruited injection drug users who received four sessions of MI aimed at entering drug treatment and reducing drug use did not stay in treatment longer than those receiving a four-session risk reduction intervention aimed at safer injection and sex behaviors (31). Earlier studies of MET have also found little support for efficacy in the treatment of opiate users in terms of outcomes and mixed effects on treatment engagement (18).

Amphetamines or Stimulants

There are few studies of MI with amphetamine or stimulant users that were RCTs. However in one RCT, Baker and colleagues compared the effectiveness of two treatment conditions containing one initial MI session followed by either two or four cognitive-behavior therapy sessions with a control group receiving only a self-help booklet to reduce amphetamine use (32). Participants in both treatment groups were significantly more likely than those in the control group to report abstinence from amphetamines, although not confirmed with urinalyses. Abstaining participants also reported less benzodiazepine use, tobacco smoking, polydrug use, injecting risk-taking behavior, criminal activity level, psychiatric distress, and depression.

Cocaine and Crack

Few RCTs have evaluated MI with cocaine users. However, in the same RCT examining heroin use, Bernstein and colleagues found that out-of-treatment cocaine users who received a single, brief MI session during a routine medical visit showed higher rates of abstinence from cocaine at 6-month follow-up, findings consistent with prior reviewed studies of motivational interventions for cocaine use with low-motivated participants (24).

Tobacco

In their meta-analysis of controlled trials examining efficacy of AMIs, Burke, Arkowitz, and Manchola concluded that there was not yet enough evidence to support MI for smoking cessation (18). Few studies met their criteria for an AMI controlled trial. Since that review, however, McCambridge and Strang

found a moderate effect size for the reduction of self-reported tobacco use at 3-month follow-up compared to an education-only group for a single MI session with over 200 young persons (ages 16 to 20) using alcohol, cannabis, and/or tobacco (28). Conversely, another study compared abstinence rates across four treatment groups of African American light smokers (<10 cigarettes per day) and found that receiving more directive, advice-oriented health education counseling combined with either nicotine gum or placebo gum was associated with higher cotinine-verified abstinence rates at 6 months compared to a treatment that included an MI component (33).

For older adult patients in the CARES program, there was some support for MET tailored for smoking cessation and delivered by nurses during homecare visits to patients who smoke. A sample of these patients showed more than twice the abstinence rates and significantly more quit attempts and fewer cigarettes smoked per day than those who received only the AHCPR guideline smoking cessation treatment (34). Although there are not many RCTs in this area, MI strategies are often incorporated into smoking cessation interventions in primary care, quitlines, and group formats.

Cannabis

The evidence is mixed for efficacy of MI or MET use in treatment of cannabis abuse or dependence. Few RCTs focus on cannabis use alone and studies vary widely with regard to number of sessions (1 to 12), length of posttreatment follow-up periods (3 to 15 months), and populations (adolescents and young adults, with or without nonacute psychotic disorders or other substance dependencies). Two multisite RCTs involved in the Cannabis Youth Treatment (CYT) used MET in combination with Cognitive Behavioral Therapy (CBT) as part of three of the five treatment options studied. MET was delivered in 2 individual sessions, followed by either 3 CBT group sessions in the first condition (MET/CBT5) or 10 CBT group sessions in the second (MET/CBT12). A third treatment option, called the Family Support Network, added parent education meetings, home visits, and case management. The fourth and fifth treatment options involved case management, 10 to 14 sessions with a therapist, and additional skills training. All five CYT interventions showed significant, positive posttreatment clinical outcomes, measured as rates of abstinence and community functioning up to 12 months later. Minimal differences were found between the conditions, and the MET/CBT5 and MET/CBT12 were found to be among the most cost-effective interventions (35).

McCambridge and Strang found reductions in substance use after 3 months following the single MI session that was greater for heavy alcohol and cannabis users than for heavy cigarette smokers (28). In addition, cannabis use was reduced more in youth considered “high-risk.” Another study found greater reductions in cannabis use after a nine-session treatment combining MET with CBT compared with a two-session treatment of MET alone (36). Baker and colleagues reported less promising results in patients with nonacute psychotic

disorders; after 10 sessions of MI combined with CBT compared to TAU, short-term improvements were found for reduction of cannabis use but differences disappeared at the 12-month posttreatment rating (37). The populations involved in these studies of MI interventions for cannabis treatment differ from traditional substance treatment studies: psychiatric populations, adolescents, and pregnant women.

EFFICACY OF MOTIVATIONAL INTERVIEWING WITH SPECIAL POPULATIONS

MI has also been used and evaluated with special populations with a variety of substance abuse problems. Special populations, as the title suggests, bring to treatment special considerations that can influence the efficacy of MI-style interventions. In the context of substance use, these populations often experience unique psychosocial, developmental, or contextual factors that can impact change in a variety of ways. Such factors can influence the dose and strategies of motivational interventions that are needed as well as evaluations of efficacy. Empirical studies of these populations warrant separate discussion.

Psychiatric Populations

Two RCTs involving larger doses of MI incorporated throughout treatment for drug abuse showed positive effects of MI on substance use outcomes in dual diagnosis or psychiatric treatment settings. One study of 129 stabilized outpatients meeting DSM criteria for drug dependence (cocaine, heroin, or cannabis) and serious mental illness (schizophrenia, schizoaffective disorder, or major affective disorders), evaluated the efficacy of Behavioral Treatment for Substance Abuse in Severe and Persistent Mental Illness (BTSAS), a multicomponent intervention that included a session MI at baseline, 3 months, and 6 months during treatment, social skills training, and urinalysis evaluation with monetary contingency management for abstinence (38). Compared to a sample of patients receiving supportive discussion treatment, BTSAS participants showed significantly higher percentage of clean urine samples throughout the intervention, longer time to dropout, and higher ratings on self-reported community functioning and quality of life. Utilizing a tailored MI and CBT combined intervention, Baker and colleagues conducted an RCT with a sample of persons with nonacute psychotic disorders. Compared to those receiving TAU, participants receiving one-to-four sessions of MI followed by five-to-ten CBT sessions showed reductions in amphetamine use at 12-month follow-up, although not significantly different from those receiving TAU (37). Reductions in self-reported depression found at 6-month follow-up were also noted for the MI group.

Although general effectiveness for smoking cessation is not established, brief MI interventions may be effective for promoting smoking cessation among patients with serious mental illness. A single MI session with a sample of tobacco smokers with schizophrenia or schizoaffective disorder pro-

duced higher rates of contacting tobacco treatment providers and attending a first counseling session for smoking cessation, as compared to educational interventions or advice alone (39). Such findings are promising considering the exceptionally high rates of smoking among adults with SMI.

Adolescents

In addition to the positive findings of studies using MI with cannabis using adolescents, recent studies have demonstrated effectiveness in promoting modification of smoking behavior among adolescents. In a multisite RCT conducted in 37 high schools, specially trained school nurses delivered four one-on-one MI, style smoking cessation interventions to students who smoked in the past month *and* were interested in quitting. Students in the MI condition reported significantly greater abstinence rates and likelihood of quitting at both 6-week and 3-month follow-up compared to a TAU group (40). One MI session in a medical setting given to nontreatment-seeking adolescent smokers demonstrated greater reductions in smoking at 3-month follow-up, biochemically confirmed, as compared to those who received only standardized brief advice to quit smoking (41). Finally, MI used with adolescent problem drinkers demonstrated a sustained decrease in the average number of drinking days per month and frequency of high-volume drinking over a 12-month period compared to controls (42). There is solid support for using MI approaches with adolescents for harm reduction, prevention, and intervention.

Pregnant Women

MI-style interventions have shown promise in helping pregnant smokers to quit or reduce smoking and move along the stages of change, using brief interventions as well as more extensive and manualized interventions (43). However, recent RCTs have produced nonsupportive findings when examining substance use outcomes. MI added to standard health care information researchers provided at home by specially trained midwives did not produce reduction or cessation compared to the standard care (44). Four sessions of individually delivered MET provided to pregnant smokers in methadone maintenance in a hospital-based prenatal program were not more effective than standard care for smoking cessation. Another study of drug abusing pregnant women (cocaine, marijuana, amphetamine or methamphetamine, alcohol, or PCP), compared substance use outcomes between two groups of women referred for treatment (45). Both groups received TAU and either three sessions of MI or an educational control treatment. Treatment condition had no effect on retention or substance use outcomes in this trial. In contrast, cost-effectiveness research comparing MI to usual care has demonstrated an estimated savings in maternal medical costs, quality-adjusted life-years and life-years by selecting MI interventions for relapse prevention among low-income pregnant smokers over other special clinical interventions (46).

SUMMARY

The evidence for the efficacy of MI across substances of abuse and special populations is supportive overall. However, a number of studies have results that are equivocal or fail to support the superiority of this approach. In areas where it has been evaluated more extensively (alcohol, cannabis, and some health behaviors), there is evidence that it is a viable brief intervention, is more efficacious than some comparison treatments, and is usually better than standard care at least for shorter-term outcomes. With other substances, like opiates and cocaine, evidence is less available and what exists is partially supportive. There also seem to be important problem and population dimensions that impact efficacy and effectiveness. Greater severity seems to decrease efficacy of brief interventions, as would be understandable. Some problem areas, like smoking, have yet to demonstrate superiority of MI approaches for cessation, but there is promising evidence for reduction with younger populations. AMIs also seem useful with special populations and can be used with psychiatric and adolescent populations, but the evidence for use with pregnant women is mixed and may depend on the outcome desired and the multiple problems faced by this population.

Overall, MI has received empirical support as an intervention for (a) brief interventions, (b) as an adjunct to other treatments, and (c) sometimes as a free-standing treatment depending on the type of substance, severity of the problem, and the multiplicity of client problems. It has also been successfully used with various special populations including those with psychiatric problems and with adolescents. Its utility with pregnant women seems more problematic in stringent tests of the intervention. Evidence for the superiority of MI to other credible and viable interventions and treatments, however, has yet to be established in many areas. The utility of AMI approaches for treatment engagement and retention is promising but also needs additional controlled research.

HOW THE TREATMENT IS OPTIMALLY USED

Since MI is predominantly a style of interacting that includes a number of strategies and techniques, it can take many different forms and be adapted for use in many different settings. It seems to have been used most successfully as an intervention to address ambivalence and defuse resistance to change in brief interventions. However, this approach has been adapted for use in a more extensive, though still rather brief formats, including MET and also incorporated as a component in combination treatments with cognitive-behavioral approaches (47). As noted in the review above, there is evidence for effectiveness for each type of use with one or another of the substances of abuse. Optimal use of MI would depend on the type of problem and population, the objective of the intervention, the skill and training of the providers, and the nature of the intervention setting. We will describe and reference applications that have been used in various studies.

Burke, Arkowitz, and Dunn concluded that the state of the current research was such that very little is known about pre-

cisely how MI works to elicit various treatment outcomes (3). Some research indicates that the impact may be mediated by the motivational style of warmth and empathy communicated by the counselor, or the effect of offering tailored assessment feedback, or by promoting treatment participation which then affects behavioral outcomes. Nonetheless, it appears that both brief and more extensive MI-style treatments show efficacy. Following are descriptions of the unique features of each MI treatment that has shown significant effects in at least one of the following outcomes: substance use, substance-related problems, treatment engagement, retention or compliance, quality of life, and general functioning. Developers of these various MI-style interventions have been working to better understand the optimal combination of MI dose and strategy for promoting change in substance abuse.

Brief Interventions

Brief motivational interventions tend to take place in one-to-four sessions either as a substitute for treatment, a brief motivational intervention in an opportunistic setting or moment, or as a part of a screening brief intervention, referral, and treatment protocol. Brief interventions are administered instead of, or early in, treatment and sometimes as a pretreatment intervention to engage a client in treatment. These interventions focus on applying the styles, strategies, and select techniques of MI in order to help the client resolve ambivalence about change and move toward reducing or abstaining from substance use. Brief MI interventions also can be used to promote engaging in treatment creating a supportive environment for the client through empathy and active listening. Variations depend upon the setting and client goals.

Primary Care/Medical/Health Care Settings

Although patient-centered communication is becoming a standard element of medical student education, MI offers a very specific way to interview and negotiate change with patients particularly about chronic disease risk behaviors including smoking, diet, cancer screening, physical activity, and alcohol and drug use (1). Brief health behavior change interventions (from 5 to 20 minutes) by general and specialty medical practitioners or other health care providers (nurses, physician assistants, or behavior change specialists) often have incorporated MI strategies in their design (18). These interventions can be structured and well-defined like the Five A's for smoking cessation: Ask about current substance use, Advise clients to consider reducing or quitting their substance use, Assess their readiness to quit, Assist client in finding options for treatment or change plan, and Arrange for a follow-up (48). These interventions can also consist of a semistructured individual interview during a routine medical visit and have also been incorporated in home health care visits for elderly and for pregnant women (24,44).

Screening and brief interventions for alcohol and drug abuse that often incorporate an MI-style and one or more of the strategies and techniques (open-ended questions,

reflective listening, summarizing, and choice) are being used in many different opportunistic as well as substance abuse treatment settings. The amount of time allocated to these types of interventions ranges from 20 minutes to roughly an hour in a single session; settings range from emergency rooms or trauma centers to rural health care centers; and treatment can be focused on alcohol or drug use behaviors with patients including college students, young adult, and heavy or hazardous drinkers (21,23,25–28). Slightly longer brief MI-based interventions consisting of a couple of sessions or with additional feedback and/or contact by phone or mail have also been used with various populations in health care settings (36).

Pretreatment and Addictions Treatment

MI strategies have also been incorporated into one, 2-hour assessment and evaluation session or in pretreatment sessions at the beginning of substance abuse treatment programs (18,19). MI has also been extended into a stand-alone treatment that has been manualized for use in alcoholism treatment in the form of MET (16) that consists of four one and a half hour sessions spread over 12 weeks. This treatment has been used in other treatment trials (UK alcoholism treatment trial, UKATT) and has been adapted for use with various types of substances (49). However, more frequently, AMI have combined it with other forms of treatment either by making MI-style and strategies part of the entire program or by combining MI sessions with additional CBT sessions or combining the two types of treatment into an eclectic mix (50). MI has also been combined with other treatments for managing substance abuse problems in individuals with mental illness (38).

SPECIAL CONSIDERATIONS

There are a number of important considerations and concerns about MI that affect evaluations and recommendations for use. We will describe these in the following categories: fidelity and training, evaluations challenges, and barriers to effective use of MI.

Fidelity and Training

Many practitioners have been exposed to MI in presentations, workshops, and trainings. Some of the assumptions, principles, and techniques are familiar and similar to what practitioners believe are basic skills already learned in their formation as clinicians (empathy, listening, and respect for clients). However, the familiarity is deceptive and the ease of implementation is overestimated by many. What individuals mean when they assert that they are using MI varies greatly. The developers have been very cognizant of the need for screening and extensive training of practitioners (51,52). They have also used detailed evaluations of taped interactions to assess fidelity to the MI approach in various research studies (17). Evaluating MI-consistent and -inconsistent behaviors

of practitioners seem to be critical for fidelity and effectiveness with the inconsistent behaviors predictive of worse outcomes (53). Although style and strategies/techniques have been taught, the essential skills needed to execute MI approaches with fidelity have not been clearly delineated. It does seem that clinicians who have difficulty being or appearing empathic or being nonjudgmental about the specific behavior being discussed, have difficulty sitting back and listening, cannot tolerate ambivalence, or get hooked by resistance behaviors will have a difficult time using MI (54). Adequate training and selection of practitioners is a critical consideration for implementing MI with fidelity.

In professional communications and evaluations it is also important to be clear when using or assessing MI approaches. Practitioners and programs should clearly identify how they are using MI in their program. Are they incorporating only the style and spirit, only some strategies, or are they trying to adopt the entire approach? MI is primarily motivational. What are they doing to assist and support other dimensions of behavior change for their clients? When combining MI with other approaches, how are practitioners making sure these treatments are compatible and what is the explicit strategy for integration or combination of MI with the other approaches? These are critical questions for implementation and especially for evaluation of MI as a brief or more extensive interventions technique.

Evaluation Challenges

In addition to fidelity of implementation and the skill and practices of the individual practitioners who are using MI in the various settings described above, there are a number of other challenges for accurate evaluation of MI. Caution should be used in reading studies and evaluations in the literature. It is not clear what are the appropriate outcomes for evaluating MI interventions. Behavior change is often the intervention goal, yet MI is focused on the motivational dimensions of change and empowerment of the individual to choose to change. Goals of clients and goals of interventions vary greatly. An abstinence-based alcoholism treatment program could have a client with a personal goal of moderation, and successful MI would be marked by reduction in use and not necessarily abstinence. A variety of other outcomes would be appropriate beyond drinking or drug use: stage movement, harm reduction, treatment engagement and retention, general functioning, quality of life, and reduction of substance-related consequences. In fact, some studies have shown that results may include some of these outcomes, like reduction in consequences, without necessarily seeing differences in drinking levels (42).

Another important dimension to be considered in the evaluation of MI is the heterogeneity of the individuals included in the intervention. Dramatic differences were observed in the ages, gender, problem severity, consequences, and sociodemographic characteristics of participants in the previously reviewed studies. Results often indicate that sometimes individuals with less severe problems and sometimes

those with more consequences benefit most from MI. Studies with adolescents, who might be considered good candidates for this approach because of adolescent oppositionality, have had positive but mixed findings. Initial indications are that MI works equally well for men and women but there are a number of smoking cessation studies with pregnant women where these women have not responded to this approach. When treatment goals include behavior changes needed to address multiple problems or health behaviors, most interventions find this challenging, and MI is no exception. Motivation for each problem area may be distinct, and brief interventions are more problematic with reciprocally complicating conditions. In terms of populations and settings, the critical dimensions of with whom and how MI works have not yet been resolved.

A final consideration about the evaluation of MI pertains to researchers conducting the studies. Burke and colleagues noted in their review that studies conducted by proponents of MI produced higher effect sizes, on average, than other studies. This could be due to investigator allegiance effects and/or execution of MI in terms of training and supervision, or the intense monitoring involved in these studies. However a practical implication of this observation is that well-implemented and supervised MI has greater efficacy.

Barriers to Implementing MI

There are a number of barriers that practitioners and trainers of MI approaches should address in their work and the following seem to be among the most important:

- Most clinics use closed-ended questions during intake procedures to establish diagnosis and treatment options. Although often necessary for efficient triaging of patients, this type of interaction is contrary to the spirit and strategies of MI. Shifting between intake mode and MI mode presents a challenge since interactions with the client have been established in the intake that are difficult to change. Efforts must be made to distinguish intake mode from MI intervention to reduce confusion.
- MI promotes client talk and provider listening. During brief interventions providers are often fearful that promoting client talk will extend the session beyond what is feasible, allowable, reimbursable, and practical. Providers who have only limited time need to be taught not only how to promote client conversation but also how to direct and manage client conversations to meet the demands of the setting and the time allocated for this intervention. Using transitional and closing summaries, skillful messaging about having heard the client's concerns, and effective management of boundaries imposed by limits of time are critical to health care providers implementing and keeping brief interventions brief.
- Standardizing MI interventions is difficult and creating manuals that overdetermine provider behaviors and responses are problematic. Programs that want to include

MI have to provide for some structure as well as some flexibility in implementation.

- MI is not nondirective. Individuals beginning to learn MI often mistake reflective listening as never giving advice or setting limits. Nothing could be further from the truth. Miller and Rollnick describe MI as a directive but nonconfrontational approach that does not eliminate the role and expertise of the provider (3).

CONCLUSION

MI is an innovative style of interacting with individuals who have substance abuse problems that includes a set of strategies and techniques and also demands a specific skill set. Although not a complete therapy designed to intervene intensively during the entire scope of the change process from lack of interest and ambivalence to sustained change, its style and principles can be used to engage, motivate, and guide individuals throughout the change process. MI can be used as a brief intervention or combined with multiple other types of treatments either as a backdrop or a companion treatment. There is a growing body of research that indicates efficacy for a variety of populations and problems. However, supporting evidence is not unequivocal and there is a need for additional research on the scope of its effectiveness. Practitioners can incorporate MI-style and strategies with benefit especially in addressing the needs of less motivated clients. Careful implementation while paying attention both to the limitations and the multiple potential ways of integrating MI into both prevention and treatment of substance abuse is recommended.

Dennis C. Daley ■ G. Alan Marlatt ■ Antoine Douaihy

Substance use disorders (SUDs) represent a serious public health problem in the United States. They are associated with many serious medical, psychiatric, family, occupational, legal, financial, and spiritual problems. SUDs not only cause impairment and suffering on the part of the affected individual, but they also create a significant burden for the family and society (1). The conceptual model of addiction as a chronic disorder requiring long-term management has been widely accepted within the substance abuse treatment field (2). Despite the fact that longitudinal studies have repeatedly demonstrated that substance abuse treatment is associated with major reductions in substance use, other studies showed that the majority of individuals relapse at some point following a treatment episode and many of them subsequently reenter treatment (3). To better understand addiction, it is useful to take a “life course perspective,” in which substance use, treatment, relapse, and recovery are not viewed as discrete and single events but rather as stages in a chronic and cyclical process where drug use patterns and treatment episodes influence later experiences (4,5). Relapse prevention (RP) is a cognitive-behavioral approach with the goal of identifying and addressing high-risk situations for relapse, and assisting individuals in maintaining desired behavioral changes. RP strategies are often incorporated into individual and group treatment manuals. RP techniques may be supplemented by other treatments for SUDs such as pharmacotherapy or mindfulness meditation (6,7).

This chapter provides an overview of relapse and RP. We define lapse, relapse, and recovery, and review treatment outcome studies, empirical studies of RP approaches, relapse precipitants, models of RP, and the recent conceptualization of relapse as a dynamic process. We then integrate the RP literature by discussing cognitive and behavioral strategies that clinicians can implement with patients with any type of SUD to reduce lapse and relapse risk. Finally we briefly discuss future research directions and their relevance to clinical care.

OVERVIEW OF LAPSE, RELAPSE, AND RECOVERY

Lapse and Relapse

The term *lapse* refers to the initial episode of alcohol or other drug use following a period of abstinence, whereas the term *relapse* refers to failure to maintain behavior change over time: “a breakdown or setback in the person’s attempt to change or

modify a target behavior” (8). Other conceptualization of relapse includes complex multidimensional composite indices of outcome/relapse, taking into account the different aspects of return to problematic behavior and the presence or absence of related consequences that go beyond the simple concept of abstinence-lapse-relapse and fit more into the concept of a harm-reduction approach (9). So relapse can be viewed not only as the event of resumption of a pattern of substance abuse or dependence, but also as a process in which indicators or warning signs appear prior to the individual’s actual substance use (2).

A lapse may end quickly or lead to a relapse of varying proportions. Shiffman (10), for example, reported that 63% of smoking lapsers who called his Stay-Quit line were smoking 2 weeks later; only 37% were able to stop their lapses. Other studies had shown that a lapse does not necessarily lead to a full-blown relapse in users of opiates (11) and tobacco (12). Based on different conceptualization and methodologic approaches to understanding relapse, relapse is better understood as both a dichotomous outcome and a process involving a series of prior related events and the predictors of these events interfering with behavior change (13). A dynamic conceptual and clinical assessment model would better capture all the variables of relapse as it unfolds across time (14). The effects of the initial lapse are mediated by the person’s affective and cognitive reactions. A full-blown relapse is more likely with the individual who has a strong perception of violating the abstinence rule (self-blame and loss of perceived control that individuals experience after the violations of self-imposed rules) (15). Although some individuals experience a full-blown relapse and return to pretreatment levels of substance abuse, others use alcohol and drugs problematically, but do not return to previous levels of abuse or dependence and suffer less-harmful effects as a result. Relapsers vary in the quantity and frequency of substance use as well as in the medical and psychosocial sequelae that accompany a relapse.

Recovery

Most researchers implicitly define “recovery” in terms of substance use only and most often as abstinence, either total abstinence or from the specific substance under study (4). Several terms have been used such as remission, resolution, abstinence, and recovery. Some authors use DSM-IV Criteria (16) to define recovery. The emphasis on abstinence and equating it with recovery has been connected with the

influence of abstinence-based 12-step recovery principles and it has been also embraced by the American Society of Addiction Medicine definition of recovery as “overcoming both physical and psychological dependence to the psychoactive drug while making a commitment to sobriety” (17). Recovery was generally described as a process rather than an end point, and even among participants who did not define recovery in terms of substance use, abstaining from all mood-altering substances was perceived as a prerequisite to the other benefits of recovery (18). McLellan and colleagues have pointed out that “Typically the immediate goal of reducing alcohol and drug use is necessary but rarely sufficient for the achievement of the longer-term goals of improved personal health and social function and reduced threats to public health and safety—that is, recovery,” (2: p. 448). Therefore recovery from SUDs is the process of initiating abstinence from alcohol or other drug use, as well as making intrapersonal and interpersonal changes to maintain this change over time. Specific changes and improvements vary among people with SUDs and can occur in any of the following areas of functioning: physical, psychological, behavioral, interpersonal, family, social, spiritual, and financial (13). It is generally accepted that recovery tasks are contingent on the stage or phase of recovery the individual is in (19). Recovery is mediated by the severity and degree of damage caused by the SUD, the presence of a comorbid psychiatric or medical illness, and the individual’s perception, motivation, gender, ethnic background, and support system. Gender similarities and differences have been more recently explored in the treatment, relapse and recovery cycle. Women are one third less likely to transition from one status to another (recovery, treatment, incarceration, and using) and predictors of transitioning to different statuses vary by gender (20). Numerous longitudinal studies have shown that on average, people reached sustained abstinence only after three to four episodes of different kinds of treatments over a number of years (4,21). Scott and colleagues (4) showed that over a 2-year period, 82% of drug users transitioned one or more times between use, incarceration, treatment, and recovery. An average of 32% changed over 90 days, with movement in every direction, and treatment increased the likelihood of getting to recovery (6). The risk of relapse is particularly problematic in the first 3 years of abstinence and never completely goes away (22). Although some individuals may achieve full recovery, others achieve a partial recovery. The latter may experience multiple relapses over time.

Recovering from a SUD involves psychoeducation, increasing self-awareness, developing coping skills for sober living, and following a program of change (13). The program of change may involve professional treatment, participation in self-help programs (Alcoholics Anonymous [AA], Narcotics Anonymous [NA], Cocaine Anonymous [CA], Crystal Meth Anonymous [CMA], Rational Recovery, SMART Recovery, Men or Women for Sobriety, or Dual Recovery Anonymous [DRA]), psychotherapy, pharmacotherapy, case management, and self-management approaches. The information and skills learned as part of RP offer an excellent mechanism to prepare for the maintenance phase of recovery. In the earlier phases

of recovery, the individual typically relies more on external support and help from professionals, sponsors, or other members of support groups. As recovery progresses, more reliance is placed on oneself to handle problems and the challenges of living a sober lifestyle. Flynn and colleagues (23) followed a group of opioid users 5 years after treatment and compared those who were in recovery and those who were not. The subjects in recovery were more likely to benefit from family and friends as a support group. In addition, those subjects were nearly four times more likely to perceive themselves as improving their quality of life.

TREATMENT OUTCOME STUDIES

Numerous reviews of the treatment outcome literature, as well as studies of specific clinical populations receiving treatment, document variable rates of relapse among alcoholics, smokers, and drug abusers. Despite the high relapse rates reported in some studies, treatment has a positive effect on multiple domains of functioning for treated alcoholics and drug-dependent individuals. Outcome is best viewed by considering multiple domains: substance use, as well as social, familial, and psychological functioning. SUDs are not unlike other chronic or recurrent medical or psychiatric conditions in that recovery is not a linear process and relapses do occur, yet significant improvements are often made.

Miller and Hester reviewed more than 500 alcoholism outcome studies and reported that more than 75% of subjects relapsed within 1 year of treatment (24). In another analysis of the alcohol treatment outcome literature, Miller and colleagues reported that there was a “significant” treatment effect on at least one alcohol measure for at least one follow-up point for 146 of 211 studies (25, p. 17).

McLellan and colleagues reviewed more than 100 clinical trials of drug abuse treatment and found that most patients show favorable outcomes at the 1-year follow-up period: 40% to 60% are continuously abstinent and 15% to 30% are not using drugs addictively (26). Catalano and colleagues reviewed studies of relapse rates and found relapse rates ranging from 25% to 97% for opioid addiction and from 75% to 80% for tobacco dependence within 1 year of treatment (27). Relapse rates were lowest among opiate addicts who graduated from a therapeutic community in which they resided for a minimum of 18 to 24 months. Hoffmann and Harrison (28) followed 1957 adult patients with alcohol and/or drug problems who were treated in five different treatment centers in the St. Paul, Minnesota, area. They reported that approximately 50% of patients were abstinent for the entire 2-year period. The Comprehensive Assessment and Treatment Outcome Research (CATOR) group, an independent evaluation service for the substance abuse field, followed 8087 patients from 38 inpatient programs and 1663 patients from 19 different outpatient programs for 1 year (29). Sobriety rates at 1 year were 60% for inpatient and 68% for outpatient subjects successfully contacted at 6 and 12 months. Even when these rates are adjusted and assume a 70% relapse rate for missing cases, sobriety rates at 1 year are 44%

and 52% for the inpatient and outpatient cohorts. Numerous reports by the National Institute on Drug Abuse, and the Center for Substance Abuse Treatments document the following positive outcomes for treatment of alcohol and drug abuse: cessation or reduction of substance use; decreases in posttreatment medical care and medical costs; decreases in work problems including absenteeism and working under the influence; decreases in traffic violations and other arrests; and improvement in psychological, social, and family functioning (30).

Individuals who relapse do not always return to pretreatment levels of substance use. The actual quantity and frequency of use may vary dramatically. A cocaine or heroin addict who injected large quantities of drugs on a daily basis for years may return to substance use after treatment. Yet this individual may not return to daily use, and the quantity of drugs used may be significantly less than the pretreatment level. Because drug and alcohol use is only one outcome measure, an individual may show improvement in other areas of life functioning despite an actual lapse or relapse to substance use. Patients who remain in treatment the longest have the best outcomes (30). A recent review exploring gender differences in alcohol and substance abuse relapse showed that for women, marriage and marital stress were risk factors for alcohol relapse and among men, marriage lowered the relapse risk (31). Recent research is attempting to identify predictors of treatment performance and outcome (32).

Empirical Studies of RP

A growing number of studies have evaluated the effectiveness and efficacy of RP approaches for SUDs. Carroll (33) reviewed 24 randomized controlled trials on the effectiveness of RP among smokers (12 studies), alcohol abusers (6 studies), marijuana abusers (1 study), cocaine abusers (3 studies), the opiate addicted (1 study), and other drug abusers (1 study). Carroll reported that the strongest evidence for efficacy of RP is with smokers and concluded that “there is good evidence for RP approaches compared with no-treatment controls ... [and that] outcomes where RP may hold greater promise include reducing severity of relapses when they occur, durability of effects after cessation, and patient-treatment matching” (33: p. 53). Patients with higher levels of impairment along dimensions such as psychiatric severity and addiction severity appear to benefit most from RP when compared to those with less-severe levels of impairment. Thus, RP may be especially helpful for patients with co-occurring psychiatric disorders.

A meta-analysis of 26 clinical trials by Irvin and colleagues involving 9504 participants supports the efficacy of Marlatt and Gordon’s RP model (34). This analysis found the strongest treatment effects for RP with participants who had problems with alcohol and polysubstance use, the effects were weaker for smoking and cocaine. Randomized trials of RP for smoking showed that additional support elements such as stress management and abstinence “resource renewal” may be needed in a smoking intervention (35).

Carroll and colleagues (36) conducted a study of outpatient cocaine abusers in which they compared RP to interpersonal psychotherapy (IPT). RP was more effective than IPT for patients with more severe cocaine problems and, to some extent, for those with higher psychiatric severity. In another study of outpatient cocaine abusers, Carroll and colleagues (37) compared the outcomes of 12 weeks of treatment in which patients were randomized to psychotherapy (cognitive-behavioral RP or an operationalized clinical management condition) and pharmacotherapy (desipramine hydrochloride or placebo). Patients were followed for 1 year and the research team found a significant psychotherapy-by-time effect, indicating a delayed improved response to treatment for patients who received RP. A study by Wells and colleagues (38) of outpatient cocaine abusers comparing RP and 12-step counseling found that subjects in both treatment conditions reduced their use of cocaine, marijuana, and alcohol use at 6 months post-treatment. However, subjects in the 12-step counseling condition showed greater improvement in alcohol use when compared to those receiving RP at the 6-month follow-up period. Another study followed 121 patients with cocaine dependence that were randomized to one of four conditions in a 2×2 factorial design: disulfiram plus CBT, disulfiram plus IPT that did not include RP components, placebo plus CBT, and placebo plus IPT. The patients assigned to CBT reduced their cocaine use more significantly than those assigned to IPT, and patients assigned to disulfiram reduced their cocaine significantly more than those assigned to placebo. In addition, the CBT \times time effect remained statistically significant after controlling for retention, which was a significant predictor of better drug use outcomes (39).

A study of inpatient alcoholic veterans found that results consistently favored veterans receiving RP over those receiving a discussion group (40). Subjects in the RP group drank less, had fewer episodes of intoxication, experienced less severe lapses for shorter periods of time, and stopped drinking significantly sooner after a relapse compared to subjects in the discussion group. Another study of alcoholics receiving inpatient treatment found that there was greater treatment adherence and satisfaction, reduced lengths of inpatient treatment, and fewer alcohol-related arrests among patients receiving RP compared to patients receiving other treatment modalities (41). A study of hospitalized male alcoholics found that patients treated with RP compared to interpersonal process therapy drank on fewer days, drank less alcohol, completed more aftercare, and had a slightly higher rate of continuous abstinence at 6-month follow-up (42).

Two large studies comparing the effectiveness of CBT to other active treatments that emphasize the use of 12-step fellowship have demonstrated no difference between conditions at follow-up. Results of Project MATCH (Matching Alcoholism Treatments to Client Heterogeneity), a large-scale multisite, randomized clinical trial of three manual-driven treatments (cognitive-behavioral therapy: CBT; motivational enhancement therapy: MET; twelve-step facilitation therapy: TSF), showed significant reductions in days of alcohol use and drinks per day at both the 1- and 3-year

follow-up periods (43). The second study was naturalistic, involved veterans, and showed that patients in all three conditions (CBT, TSF, or a combination of both) performed equally well at 1-year follow-up (44).

Recent randomized controlled trials support the reported efficacy of combined CBT-like therapies and naltrexone for alcohol-dependent individuals (45). The COMBINE (Combined Pharmacotherapies and Behavioral Intervention) study suggested that medical management of an alcohol-dependent patient with a physician providing treatment with naltrexone and basic advice and information is as effective as CBT. That trial enrolled 1383 alcohol-dependent subjects and randomly assigned them to one of eight groups that could include naltrexone, acamprosate, or both of the drugs, with or without what was identified as a cognitive-behavioral intervention (CBI). One group received the CBI alone without the placebo. The patients who received a medication also received medical management that was fairly rigorous (9 appointments over 16 weeks), during which a physician or a nurse discussed the patient's diagnosis and progress and suggested attendance to AA. Those who got the CBI received up to 20 sessions, which was comparable with a streamlined version of outpatient alcoholism treatment. Subjects receiving medical management with naltrexone, CBI or both, fared better on drinking outcomes, whereas acamprosate showed no evidence of efficacy, with or without CBI. Putting it more into clinical implications, the percentage of subjects with a good clinical outcome were 58% for those who received only medical management and placebo, 74% for those who received medical management with naltrexone only, 74% for those who received medical management with naltrexone and CBI, and 71% for those who received medical management with placebo and CBI. The subjects were followed for a year after the 16-week treatment, and although the patterns of efficacy remained much the same, there were appreciable falloff for all groups (46–48).

Some data support the view that the response to RP treatment is quite comparable between cocaine-dependent individuals and those dependent on methamphetamine (49). Rawson and colleagues conducted a study with methamphetamine-dependent individuals assessing the effectiveness of the Matrix treatment protocol which is based on cognitive-behavioral principles of Marlatt and Gordon, 1985 (8) and used in an intensive outpatient treatment setting (50), versus “treatment as usual” in eight community treatment organizations. The in-treatment gains made by participants in the Matrix suggest that this treatment approach has positive effects.

The empirical literature on evaluating RP strategies for cannabis dependence has incorporated other strategies. A multisite study involving 450 marijuana-dependent individuals demonstrated that an integrated CBT and Motivational Interviewing (MI) was more effective than MI alone, which in turn was more effective than a delayed treatment control condition (51). There are no efficacy studies evaluating RP specifically for abuse of club drugs, hallucinogens, inhalants, and steroids (52).

The most recent meta-analysis that focused solely on smoking and included 42 studies of controlled trials with at least 6 months follow-up, most of which used skills training

approaches, showed small and no significant effects for the behavioral interventions (53). These findings are in contrast with the strong meta-analytic evidence for the efficacy of interventions consistent with RP for smoking cessation reported in the U.S. Public Health Services Clinical Practice Guideline (54).

Two trials have compared the delivery of RP in individual versus group format and found no difference in group versus individually delivered RP (55).

Several studies have included spouses in the RP intervention (56). A study of the first relapse episodes and reasons for terminating relapses for men with alcoholism who were treated with their spouses found that the relapses of patients receiving RP in addition to behavioral marital therapy were shorter than those of patients not receiving the RP (56). In a study of married alcoholics, O'Farrell and colleagues (57) found that in couples assessed to be “high distress,” abstinence rates were highest for those who received behavioral marital therapy in combination with RP. Alcoholics who received RP after completing behavioral marital therapy had more days of abstinence, fewer days drinking, and improved marriages than did those who received only behavioral marital therapy (58). A more recent study (59) evaluated conjoint treatments in 90 men with alcohol problems and their female partners. Couples were followed for 18 months after treatment. Across the three outpatient treatments (alcohol behavioral couples therapy: ABCT; ABCT/RP; ABCT with interventions encouraging AA involvement: AA/ABCT), drinkers who provided follow-up data maintained abstinence on almost 80% of days during follow-up with no differences in drinking or marital happiness outcomes between groups.

There are limitations to studies on RP. First, some studies have used RP as the single treatment intervention for cessation of drinking rather than for maintenance of change once drinking was stopped. Second, studies usually do not differentiate between subjects who are motivated to change substance use behavior and those who have little or no motivation to change. Third, in some studies, sample sizes are small and there is not enough power to detect statistical differences between experimental and control conditions. Fourth, studies do not always use random assignment or operationalize the therapy being compared against RP, making it difficult to determine what factors contribute to treatment effects. And last, the follow-up period is often short-term (6 months or less). Despite these limitations, however, there is empirical evidence that RP strategies enhance the recovery of individuals with SUDs. Furthermore, RP is now listed on SAMHSA's National Registry of Evidence-based Programs and Practices (NREPP) website (www.nrepp.samsha.gov) as an “Evidence-based Practice.”

RELAPSE DETERMINANTS

Research by Marlatt and colleagues led to classifying relapse for alcoholics, smokers, heroin addicts, gamblers, and overeaters in two broad categories, intrapersonal and interpersonal determinants (8). Intrapersonal determinants

contributing to relapse include: emotional states, coping, outcome expectancies, self-efficacy, craving, and motivation. According to this research, the category that most frequently affected relapse of alcoholics, smokers, and heroin addicts was negative emotional states. Thirty-eight percent of alcoholics, 37% of smokers, and 19% of heroin addicts relapsed in response to a negative affective state that they were unable to manage effectively.

Intrapersonal Determinants

1. *Emotional States*: In the original relapse taxonomy (8) and in the replication of the taxonomy (60), negative affect was the best predictor of outcomes. Baker and colleagues have recently identified negative affect as the primary motive for drug use. According to this model, excessive substance use is motivated by positive and negative affective regulation such that substances provide negative reinforcement when they provide relief from negative affective states (61). Thus, clinicians should incorporate interventions to help patients regulate their emotions and decrease negative emotional states.
2. *Coping*: Coping has been shown to be a critical predictor of substance use treatment outcomes and is often the strongest predictor of behavioral lapses in the moment (62,63). Several types of coping have been identified such as stress, temptation, cognitive and behavioral coping, as well as approach and avoidance coping. Active cognitive and behavioral coping strategies have been shown to be significantly related to abstinence outcomes, whereas the use of avoidance coping tends to be associated with negative outcomes (63).
3. *Outcome Expectancies*: Outcome expectancies are typically described as an individual's anticipation of the effects of a future experience. Anticipation of the effects of a substance has been identified as one of the primary cognitions related to substance use and relapse (64). Outcome expectancies may be affecting substance use behavior via the relationship between negative emotional states and beliefs about substances relieving negative affect (65). Both negative and positive expectancies are related to relapse, with negative expectancies being protective against relapse and positive expectancies being a risk factor for relapse (12). Individuals endorsing positive expectancies at the beginning of treatment may benefit from an intervention challenging them (66).
4. *Self-efficacy*: Self-efficacy is defined as the degree to which an individual feels confident and capable of performing a certain behavior in a specific situational context (67). Self-efficacy is a predictor of outcomes across all types of addictive behaviors, including gambling, smoking, and drug use (68). Increased self-efficacy following RP intervention was related to improved outcomes (69). Most likely the relationship between self-efficacy and outcomes is bidirectional, meaning that individuals who are more successful report greater self-efficacy and individuals who have relapsed report lower self-efficacy. The mechanism by which self-efficacy influences outcome is not clear (69). Thorough assessment of self-efficacy during treatment and interventions designed to strengthen it are major components of any RP intervention.
5. *Motivation*: Motivation may be related to the relapse process in two distinct ways: the motivation for behavior change and the motivation to engage in the problematic behavior. This illustrates the issue of ambivalence experienced by many patients attempting to change an addictive behavior (70). The ambivalence is related to both self-efficacy and outcome expectancies. The transtheoretical model of change incorporates five stages of readiness to change: precontemplation, contemplation (ambivalence), preparation, action, and maintenance. Each stage characterizes a different level of readiness for change, with precontemplation indicating the lowest level of change (71). Motivation to change is transactional, reflected in and affected by interpersonal interaction. The transtheoretical model of change provides a framework for understanding the change process and MI provides a means of facilitating the change process. Thus, assessment of motivation and commitment to change during treatment and interventions such as MI designed to resolve ambivalence and strengthen motivation are critical components of any RP intervention.
6. *Craving*: Craving is possibly the most studied and poorly understood construct in the field of SUD research. Addiction research did not show any significant association between subjective craving and objective measures of relapse (72). For example, Sayette and colleagues (73) demonstrated that cue exposure was predictive of nicotine craving, but only for smokers who are deprived of nicotine. Craving has been described as a cognitive experience focused on the desire to use a substance and is often related to the expectancies for the desired effect of the drug, whereas urge has been defined as the behavioral intention to use a substance. Studies on the role of cue reactivity in addiction showed that drug-related stimuli elicit craving but cue reactivity is not a consistent predictor of relapse. Cue reactivity could have an impact on the treatment of addictive behaviors (74).

Interpersonal Determinants

Interpersonal precipitants of relapse include relationship conflict, social pressure to use substances, and positive emotional states associated with some type of interaction with others (8,75). Functional social support or the level of emotional support is highly predictive of long-term abstinence rates across several addictions (76). The quality of social support or the level of support from nonsubstance abusers has also been related to relapse (76). Stanton provided an overview of interpersonal dynamics as a high-risk situation for relapse. However, the relationship between interpersonal factors and relapse is not entirely clear (77). Clearly, the role of social support is a critical component of RP. An extension of RP that involves including spouses or significant others in conjoint

therapy, such as behavioral marital therapy (78), has strong empirical support (59).

OVERVIEW OF MODELS OF RP

A variety of models of RP are described in the literature. The more common approaches include (a) Marlatt and Gordon's cognitive-behavioral approach, which has been adapted for other clinical populations such as sex offenders, overeaters, and individuals with problems controlling sexual behaviors; (b) Annis' cognitive-behavioral approach, which incorporates concepts of Marlatt's model with Bandura's self-efficacy theory; (c) Daley's psychoeducational approach; (d) Gorski's neurologic impairment model; (e) Zackon, McAuliffe, and Chien's addict aftercare model; (f) the Matrix neurobehavioral model of treatment of Rawson et al., which includes RP as a central component of treatment; (g) Washton's intensive outpatient model; (h) the coping/social skills training model of Monti et al.; and (i) the Cue Extinction (CE) model developed by Childress et al. (79).

Many inpatient, partial hospital, and outpatient treatment programs have incorporated various aspects of these RP approaches. Some programs offer specific "relapse tracks" that are geared specifically for patients who have relapsed following a period of sustained recovery. The focus of these programs is primarily on problems and issues associated with relapse (79). Despite their differences, these RP approaches have many components in common. They focus on the need for individuals with a SUD to develop new coping skills for handling high-risk situations and relapse warning signs; to make lifestyle changes to decrease the need for alcohol, drugs, or tobacco; to increase healthy activities; to prepare for interrupting lapses so that they do not end in a full-blown relapse; and to prepare for managing relapses so that adverse consequences may be minimized. All RP approaches emphasize the need to have a broad repertoire of behavioral, cognitive, and interpersonal coping strategies to help prevent a relapse. Most are time-limited or brief, making them more feasible in the current climate of managed care.

The Cognitive-Behavioral Model of Relapse

Marlatt (8) proposed a cognitive-behavioral model of the relapse process shown in Figure 47.1, which centers on identifying high-risk situations and the individual's response to the situations. A high-risk situation is defined as a circumstance in which an individual's attempt to refrain from a particular behavior (ranging from any use of a substance to heavy use) is threatened. The high-risk situation is defined as any experience, emotion, setting, thought, or context, and varies from person to person and within each individual. High-risk situations often arise without warning (80). If the individual lacks an effective coping strategy and/or confidence to deal with the situation (low self-efficacy), the tendency is to give in to temptation. The decision to use or not use is then mediated by the individual's outcome expectancies for the initial effects

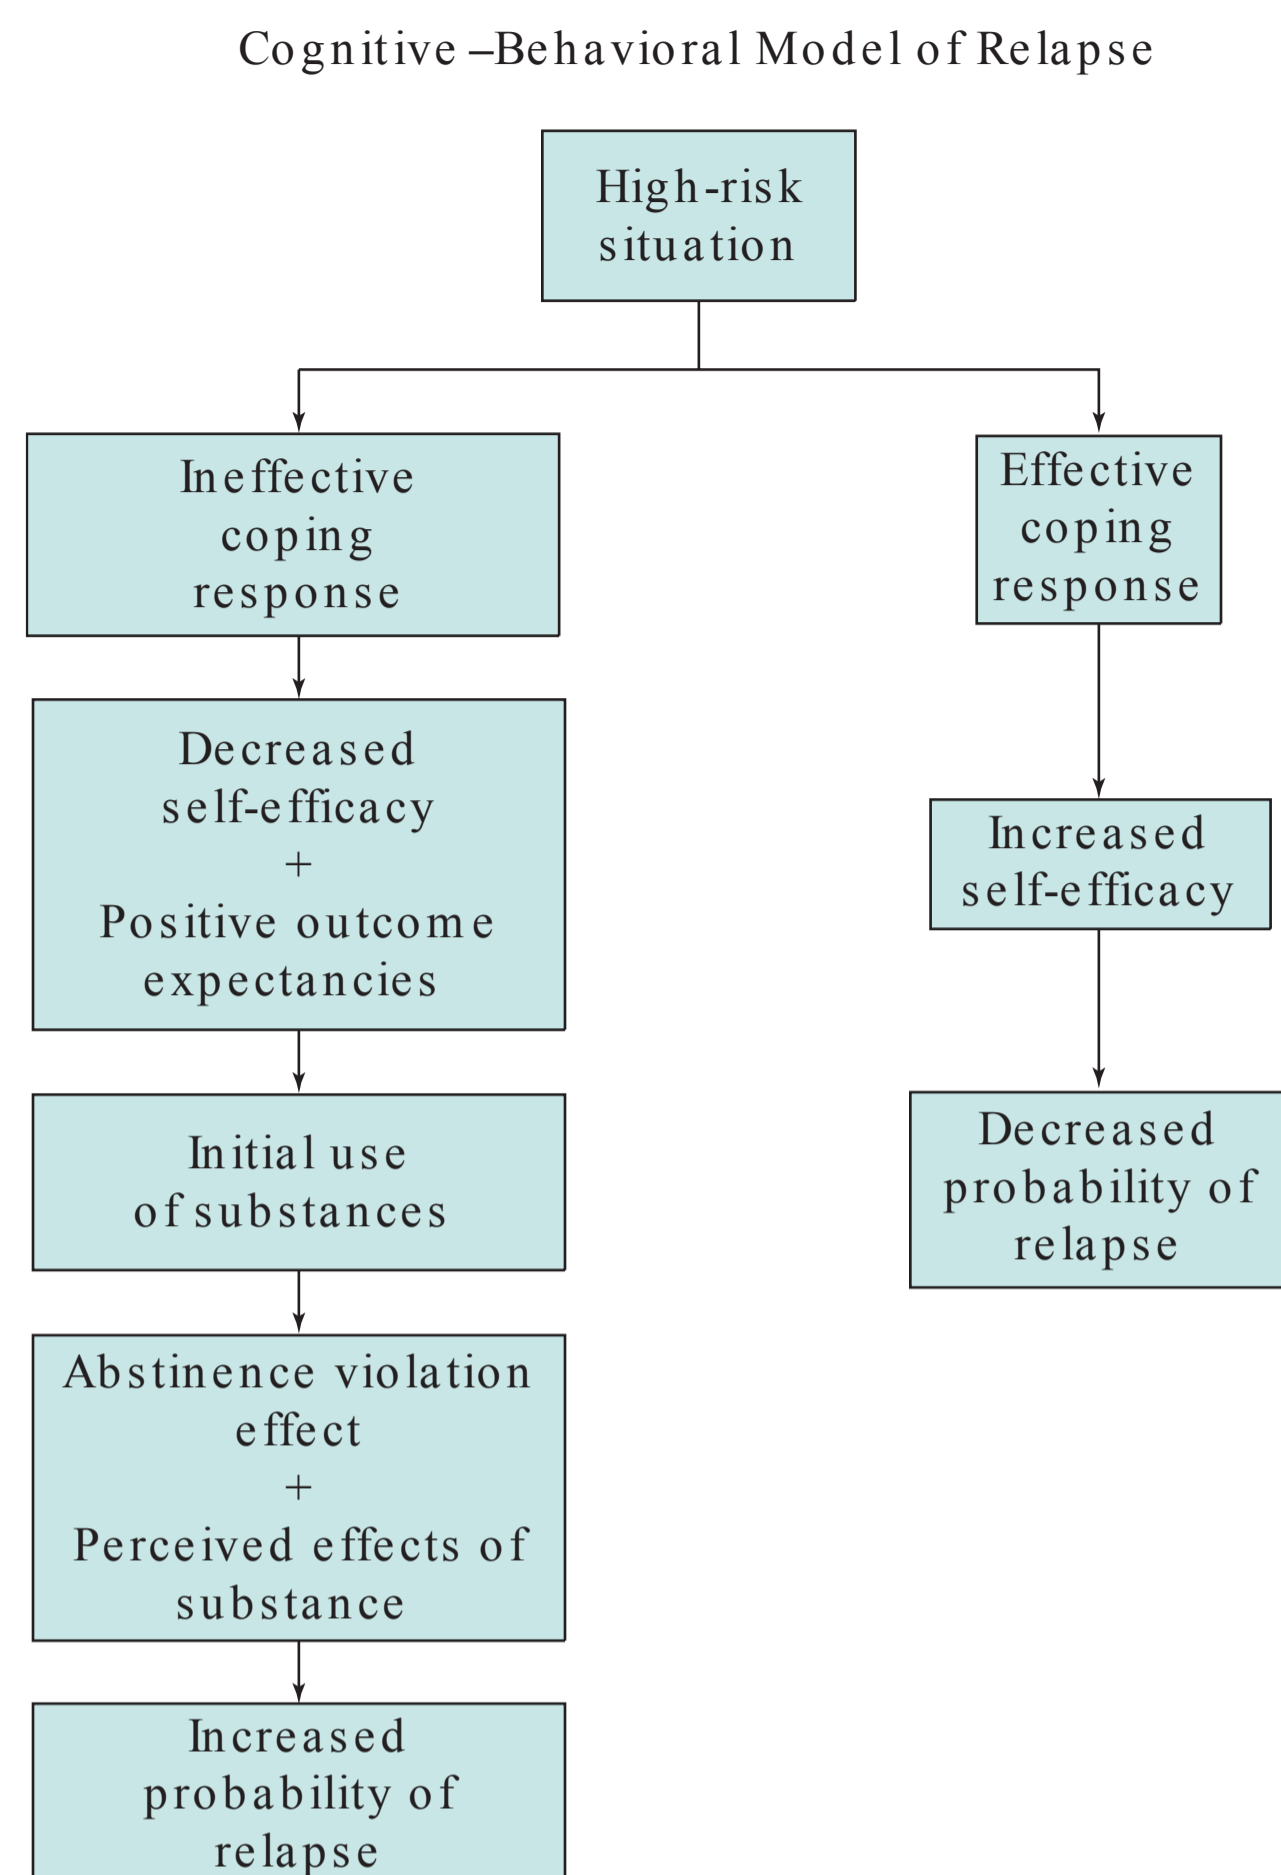

Figure 47.1. Cognitive-behavioral model of relapse.

of using the substance. Individuals who decide to use the substance may be vulnerable to the "abstinence violation effect," which is the self-blame and loss of perceived control that individuals experience after the violation of self-imposed rules, which undermines their commitment to abstinence goals. The lapse is more likely to lead to a full-blown relapse if the individual perceives it as an irreparable failure.

The Cognitive-Behavioral Model of Relapse, Revised

This reconceptualized cognitive-behavioral model of relapse focuses on the dynamic interactions between multiple risk factors and situational determinants. Seemingly insignificant changes in levels of risk (e.g., slight decrease in mood ratings) may kindle a downward spiral of increased craving leading to a lapse episode often initiated by a minor cue (14). For example, increased level of stress may trigger a high-risk situation in which a decrease in coping ability considerably increases the likelihood of the person's using an ineffective coping response, thereby leading to an increased probability of a lapse (81). As shown in Figure 47.2, the reconceptualized dynamic model of relapse allows for several configurations of distal (e.g., years of dependence,

Dynamic Model of Relapse

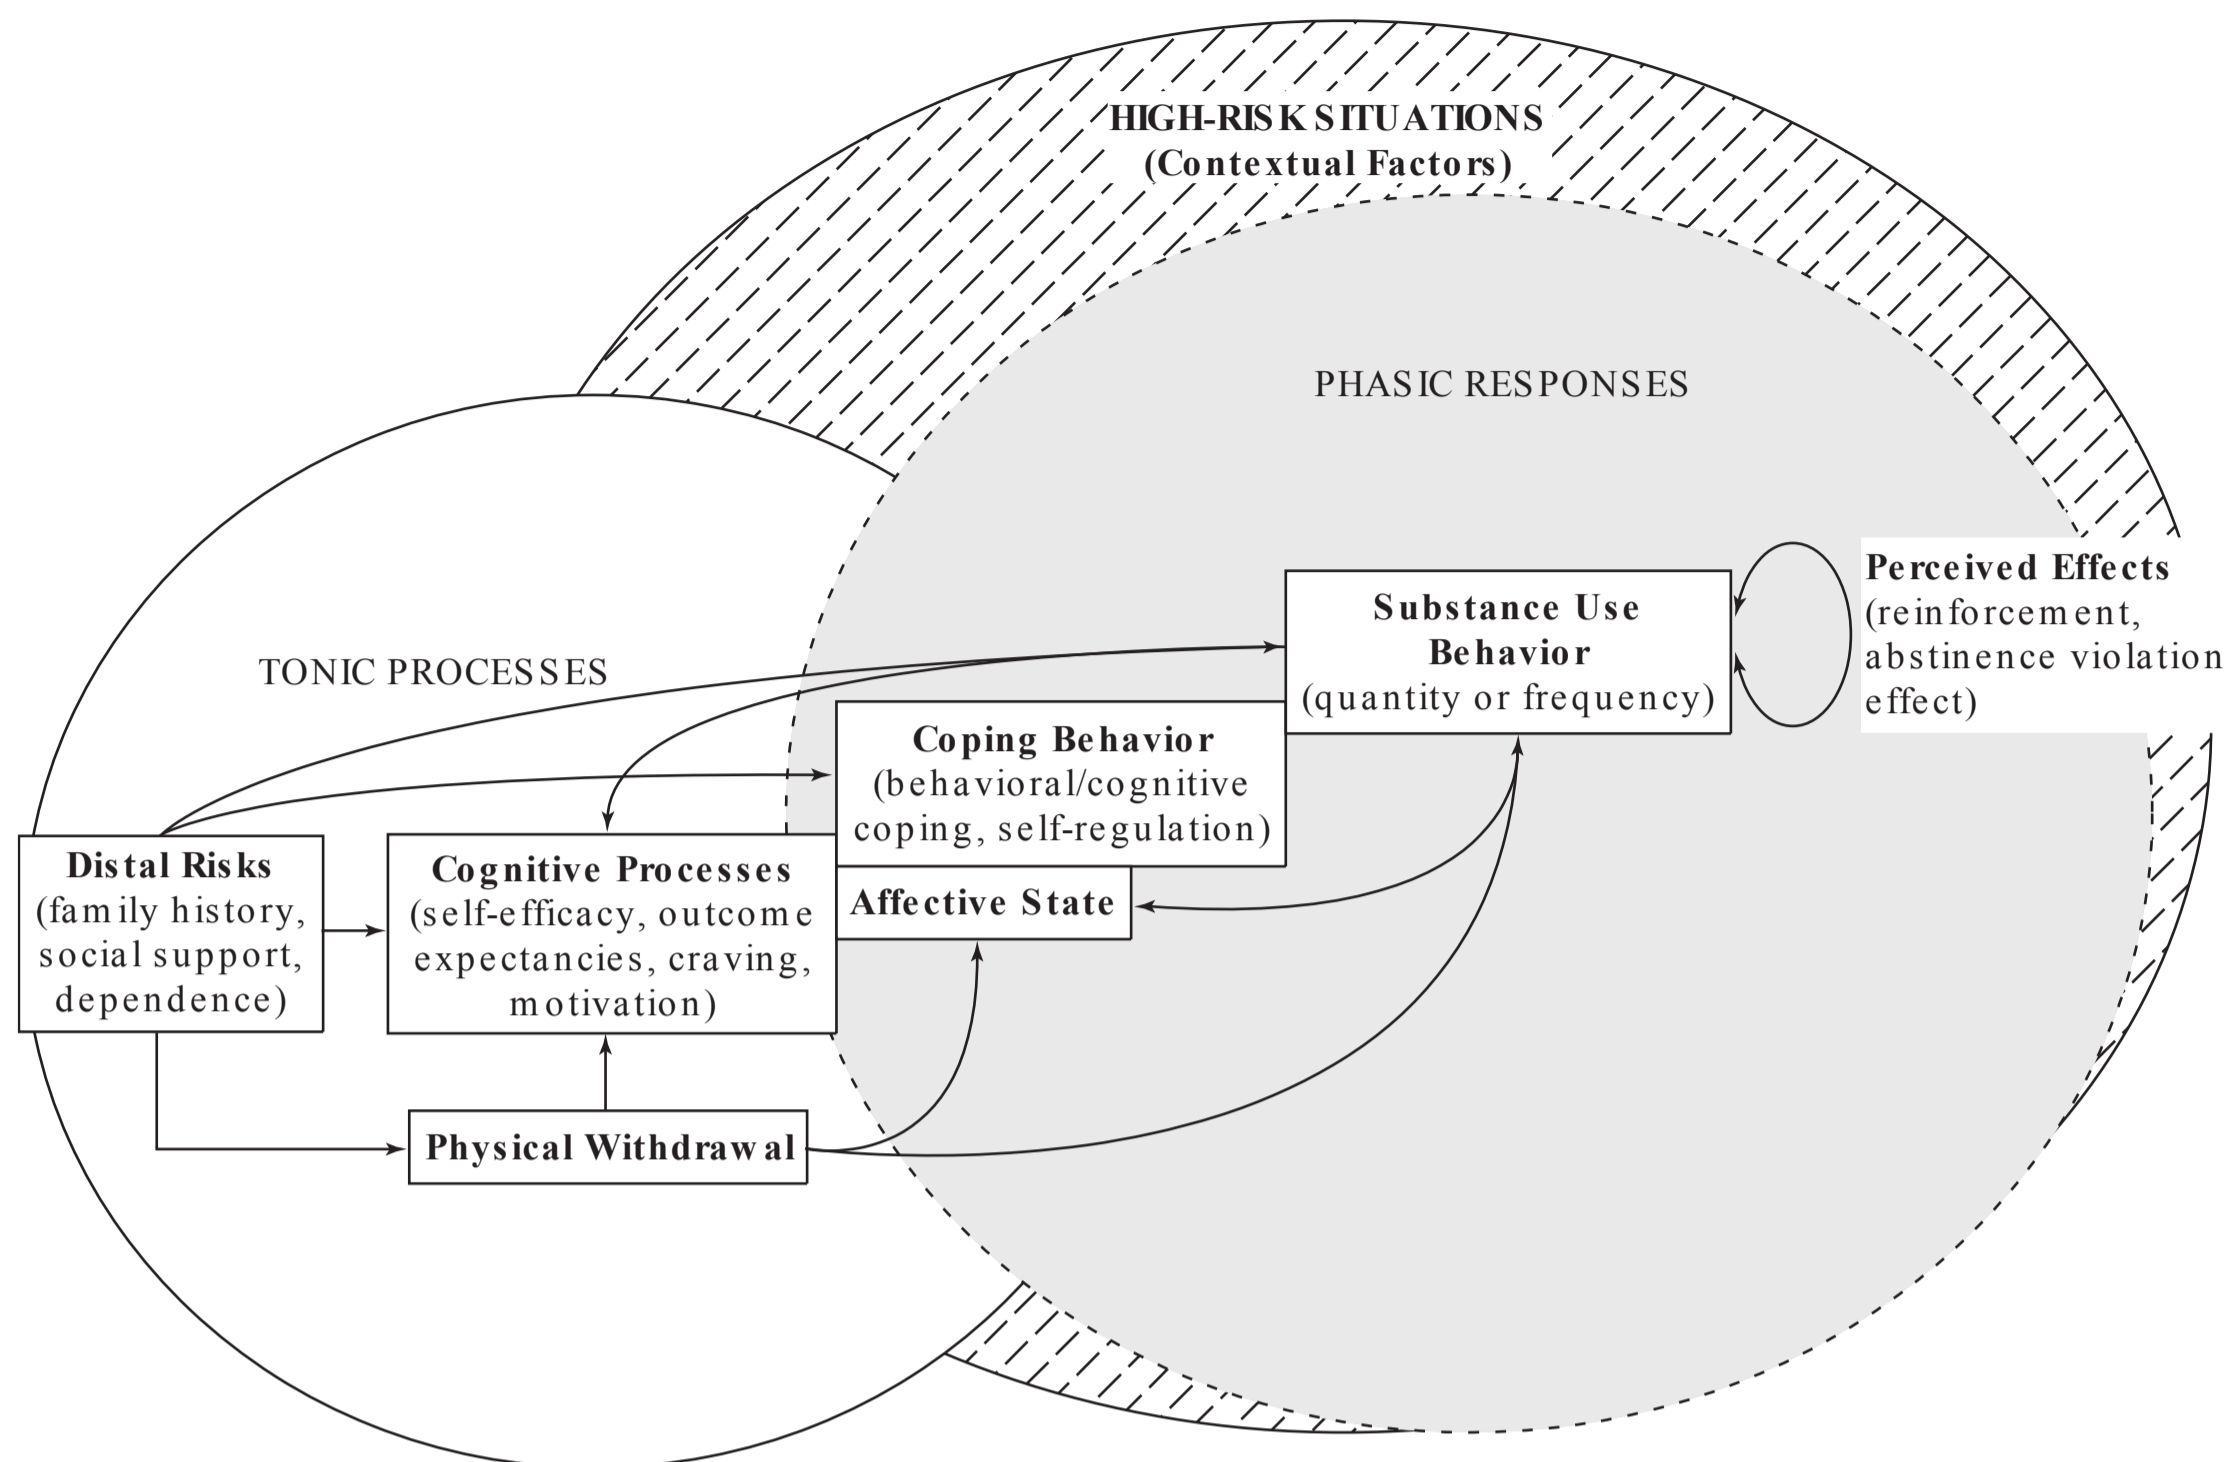

Figure 47.2. Dynamic model of relapse.

family history, social support, and comorbid psychiatric disorders) and proximal (e.g., emotional states, craving, cognitive vigilance, and situational response efficacy) relapse risks (14). Distal risks (solid lines) are defined as stable predispositions that increase an individual's vulnerability to lapse, whereas proximal risks (dotted lines) are immediate precipitants that actualize the statistical probability of a lapse. Connected boxes are hypothesized to be nonrecursive—that is there is a reciprocal causation between them (e.g., coping skills influencing drinking behaviors and in turn drinking influences coping (11). These feedback loops (indicated by double-headed arrows) allow for the interaction between coping skills, cognitions, craving, affective state, and substance use behavior. The role of contextual factors is indicated by the large striped circle in Figure 47.2, with situational cues (e.g., walking by the liquor store) playing an important role in the relationship between risk factors and substance use behavior. The white and gray circles represent tonic and phasic processes (the phasic one is contained within the high-risk situation circle). The circle on the far left (solid border) represent tonic processes which indicate the individual's vulnerability to relapse. Tonic processes provide the foundation for the possibility of a lapse. The phasic response (dotted border) incorporates situational, cognitive, affective, physical states, and coping skills. The phasic response is conceptualized as the turning point of the system where behavior response may lead to a sudden change in substance use behavior. On the other hand, an individual can de-escalate the risk of relapse by

utilizing effective coping strategies. Recent empirical studies demonstrate that responding in a high-risk situation is related to both distal and proximal risk factors operating within the two phasic and tonic processes. Understanding the complexity of the relapse process alerts the clinicians about the importance of a comprehensive assessment about the individual's background, coping skills, substance use history, self-efficacy, and emotional states. The consideration of how these factors are intertwined within a high-risk situation allows the clinicians to help patients continually assess their own vulnerability to relapse.

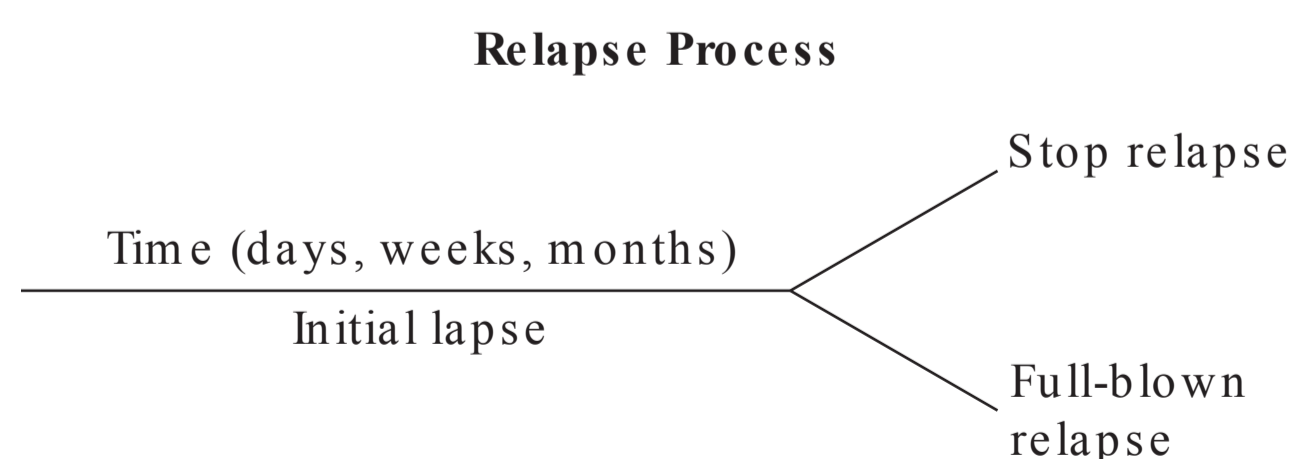

CLINICAL RP INTERVENTIONS

This section discusses practical RP interventions that can be used in multiple treatment contexts. These interventions reflect the approaches of numerous clinicians and researchers who have developed specific models of RP and/or written patient-oriented RP recovery materials and the authors' experience working with patients with alcohol dependence and drug addictions, including patients with comorbid psychiatric conditions. The interventions reflect the models of RP discussed earlier. Whereas some of these interventions can be used by the patient as part of a self-management recovery program, other interventions involve eliciting support or help from family members or significant others. The literature emphasizes individualizing RP strategies, taking into account the patient's level of motivation, severity of substance use, gender, ego functioning, and sociocultural environment.

The use of experiential learning (e.g., role playing, fantasy, behavioral rehearsal, monodramas, psychodrama, bibliotherapy, use of workbooks, interactive videos, and homework assignments) is recommended to make learning an active experience for the patient. In treatment groups, action techniques provide numerous opportunities for the clinician to elicit feedback and support for individual patients, identify common themes and issues related to RP, and practice specific interpersonal skills. The use of a daily inventory is also recommended (82). A daily inventory aims to get patients to continuously monitor high-risk situations and identify relapse risk factors, relapse warning signs, or significant stressors that could contribute to a lapse or relapse.

Help Patients Understand Relapse as a Process and as an Event

Patients are better prepared for the challenges of recovery if they are cognizant of the fact that relapse occurs within a context and that clues or warning signs typically precede an actual lapse or relapse to substance use. Although a relapse may be the result of an impulsive act on the part of the recovering individual, more often than not, attitudinal, emotional, cognitive, and/or behavioral changes usually manifest themselves prior to the actual ingestion of substances. An individual's clues or warning signs can be conceptualized as links in a relapse chain (8,13). Many relapsers reported to the authors that their warning signs appeared days, weeks, or even longer before they used substances (Fig. 47.3). Patients under treatment for the first time can benefit from reviewing common relapse warning signs identified by others in recovery. The authors have found it helpful to have relapsers review their experiences in great detail so that they can learn the connections among thoughts, feelings, events or situations, and relapse to substance use. An evaluation of one of the authors' psychoeducational model of RP and a workbook used in conjunction with this program by 511 patients found that "Understanding the Relapse Process" was rated as the most useful topic (83).

Relapse warning signs:
 Attitude changes
 Thought changes
 Mood changes
 Behavior changes

Figure 47.3. Relapse process.

Help Patients Identify Their High-Risk Situations and Develop Effective Coping Strategies to Deal with Them

The need to recognize the risk of relapse and high-risk factors is an essential component of RP. High-risk factors, or critical incidents, typically are those situations in which patients used alcohol or other drugs prior to treatment. High-risk factors usually involve intrapersonal and interpersonal situations (84). Because the availability of coping skills is a protective factor reducing relapse risk, the clinician should assess coping skills and help the patient develop new ones as needed (13).

Numerous clinical aids have been developed by researchers and clinicians to help patients identify and prioritize their individual high-risk situations and develop coping strategies to aid in their recovery (13). For some patients, identifying high-risk factors and developing new coping strategies for each are inadequate, because they may identify large numbers of risk factors. Such patients need help in taking a more global approach to recovery and may need to learn specific problem-solving skills. Marlatt (8), for example, suggests that in addition to teaching patients "specific" RP skills to deal with high-risk factors, the clinician should also use "global" approaches such as skill training strategies (e.g., behavioral rehearsal, covert modeling, and assertiveness training), cognitive reframing (e.g., coping imagery and reframing reactions to lapse or relapse), and lifestyle interventions (e.g., meditation, exercise, and relaxation). Figure 47.4 summarizes one paradigm for conceptualizing high-risk factors.

Help Patients Identify and Manage Alcohol or Drug Cues as well as Cravings

There is a growing body of research suggesting that patients' desire or craving for alcohol or other drugs can be triggered by exposure to environmental cues associated with prior use (72). Cues such as the sight or smell of the substance of abuse may trigger cravings that become evident in cognitive (e.g., increased thoughts of using) and physiologic (e.g., anxiety) changes. The advice given in AA, NA, CA, and CMA: "avoid people, places, and things" associated with substance abuse, was developed as a way of minimizing exposure to cues that trigger cravings that can be so overwhelming that they contribute to a relapse. A practical suggestion is to encourage patients to remove from their homes substances as well as paraphernalia (pipes, mirrors, needles, etc.) used for taking drugs. Cue exposure treatment is one method used to help reduce the intensity of the patient's reactions to cues (85). This treatment involves exposing the patient to specific cues associated with substance use. Cue exposure also involves teaching or enhancing coping skills (e.g., systematic relaxation, behavioral alternatives, visual imagery, and cognitive interventions) to improve the patient's confidence in his or her ability to resist the desire to use.

Because it is impossible for patients to avoid all cues that are associated with substance use, the clinician can

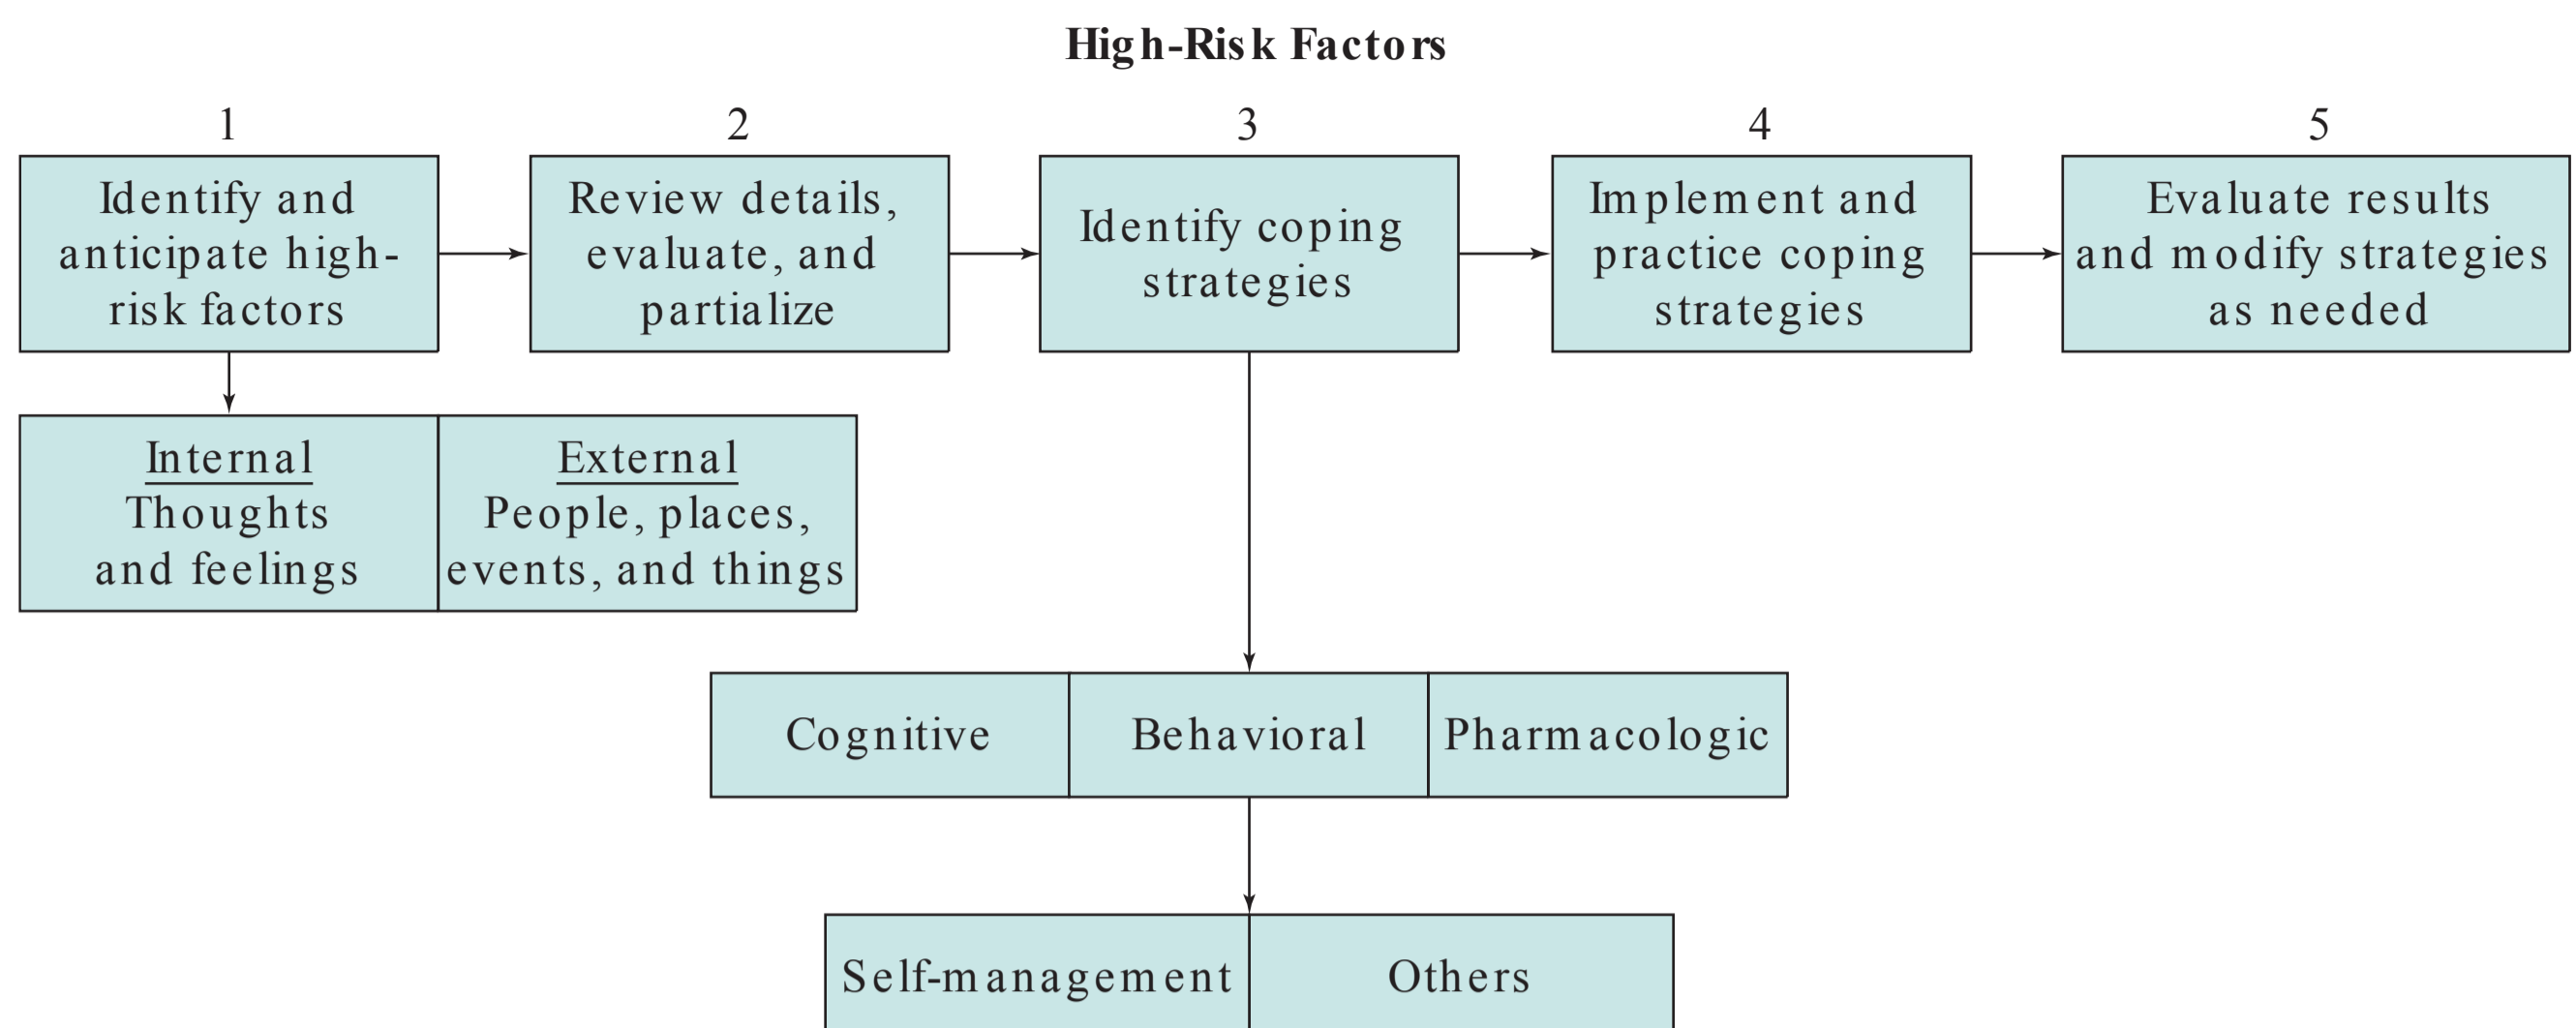

Figure 47.4. High-risk factors.

teach the patient a variety of practical techniques to manage cravings (13). Patients should learn information about cues and how they trigger cravings for alcohol or other drugs. Monitoring and recording cravings, associated thoughts, and outcomes can help patients become more vigilant and prepared to cope with them. Helpful cognitive interventions for managing cravings include changing thoughts about the craving or desire to use, challenging euphoric recall, talking oneself through the craving, thinking beyond the high by identifying negative consequences of using (immediate and delayed) and positive benefits of not using, using AA/NA/CA/CMA recovery slogans and delaying the decision to use. Behavioral interventions include avoiding, leaving, or changing situations that trigger or worsen a craving, redirecting activities or getting involved in pleasant activities, getting help or support from others by admitting and talking about cravings and hearing how others have survived them, attending self-help support group meetings, or taking anticraving medications such as naltrexone or acamprosate. Shiffman and colleagues (10) recommend that ex-smokers carry a menu card that lists various ways to cope with a craving to smoke, a strategy that can also address alcohol or other drug cravings. Another effective way to cope with urges to use substances is a meditation imagery technique known as “urge surfing” (8,86). To help patients deal with the urge to use without giving in, they are taught to visualize the urge as a rising ocean wave that they will learn to “surf” without getting “wiped out” by the craving. Figure 47.5 represents a paradigm that the authors have found useful when helping patients understand and manage cravings.

Help Patients Understand and Deal with Social Pressures to Use Substances

Direct and indirect social pressures often lead to increased thoughts and desires to use substances, as well as anxiety regarding one’s ability to refuse offers to drink alcohol or use other drugs. Figure 47.6 outlines one method of helping

patients understand and deal with social pressures. The first step is to identify high-risk relationships (e.g., living with or dating an active drug abuser or alcoholic) and situations or events in which the patient may be exposed to or offered substances (e.g., social gatherings where people smoke cigarettes or drink alcohol). The next step is to assess the effects of these social pressures on the thoughts, feelings, and behaviors of the patient. Planning, practicing, and implementing coping strategies is the next step. These coping strategies include avoidance and the use of verbal, cognitive, or behavioral skills. Using role playing to rehearse ways to refuse offers of drug or alcohol is one very practical and easy-to-use intervention. The final step of this process involves teaching the patient to evaluate the results of a given coping strategy and to modify it as needed. Pressures to use alcohol or other drugs may result from relationships with active drug users or alcoholics. The patient needs to assess his or her social network and learn ways to limit or end relationships that represent a high risk for relapse.

Help Patients Develop and Strengthen a Supportive Recovery Social Network

Several authors have addressed RP from a broader perspective that involves the family or significant others (78). O’Farrell and colleagues (57,58) developed a RP protocol for use in combination with behavioral marital therapy. Involvement of immediate families or significant others in the recovery process provides them with an opportunity to deal with the impact of substance use on their lives as well as their own issues (e.g., enabling behaviors, preoccupation, feelings of anger, shame, and guilt). Families are then in a much better position to support the recovering member. The authors have seen family members sabotage the recovery of the addicted member in a multiplicity of overt and covert ways. Such behavior is usually an indication that they have not had an opportunity to deal with their own issues or heal from their emotional pain.

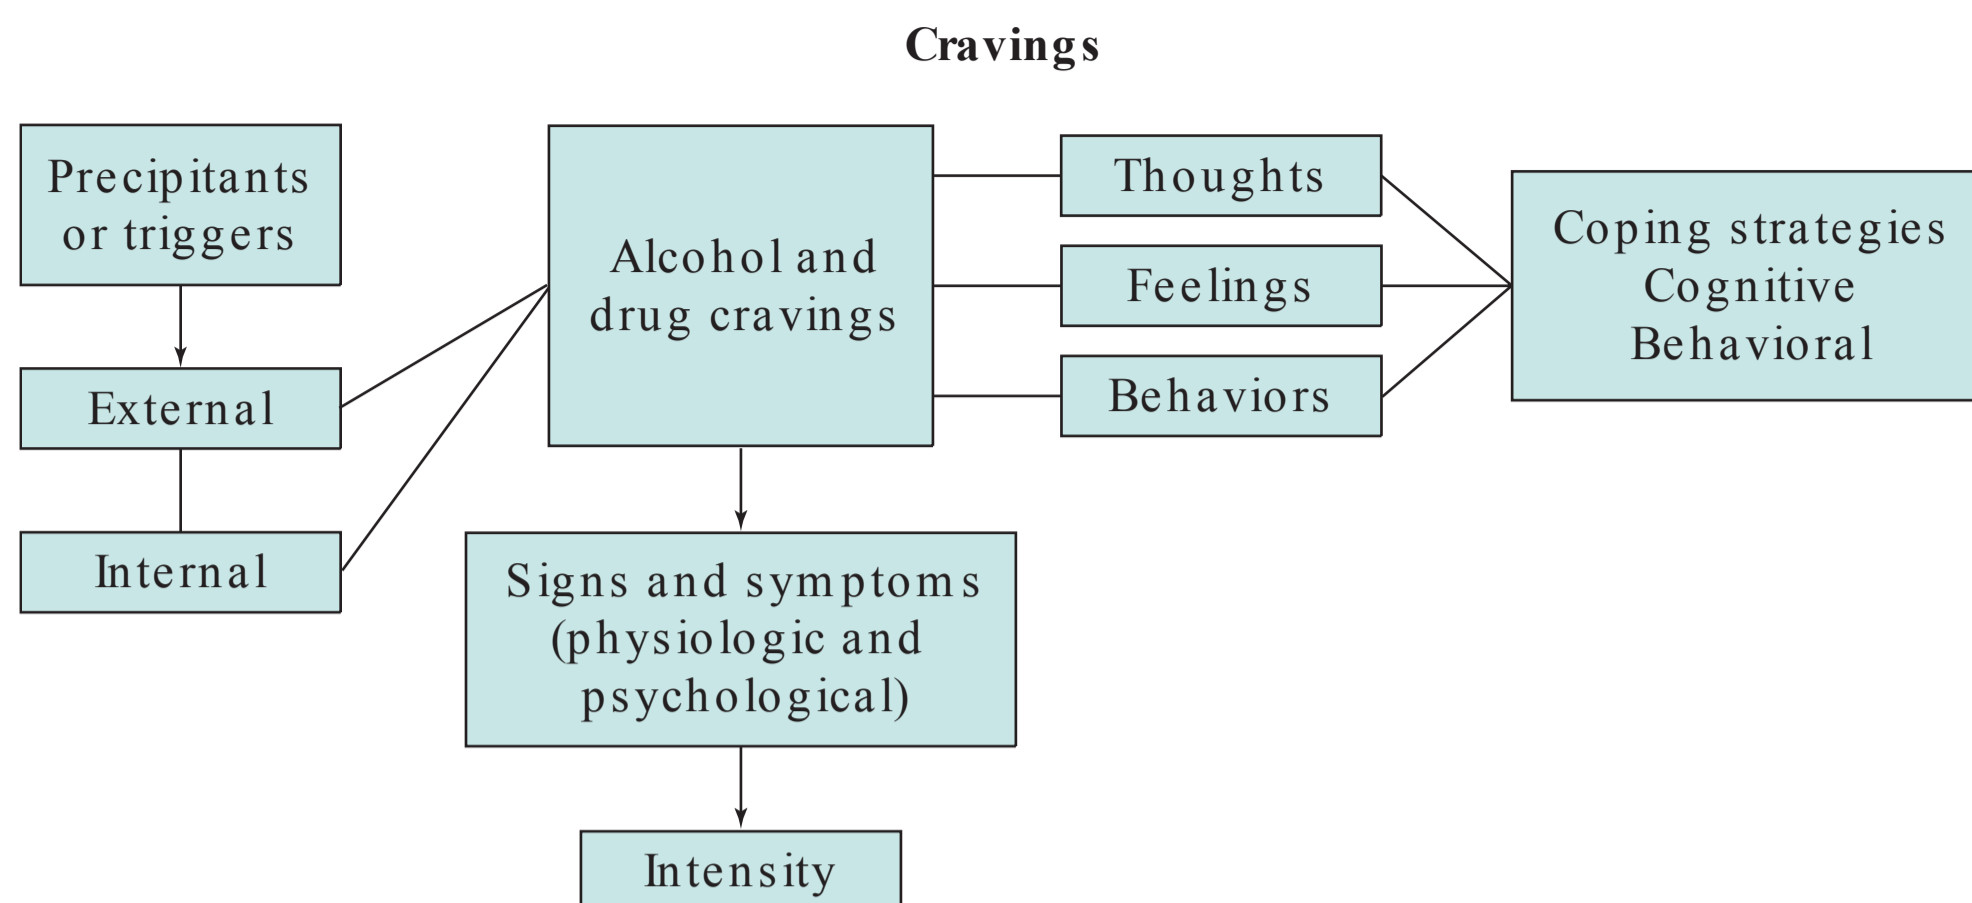

Figure 47.5. Cravings.

Patients can be encouraged to get involved in AA, NA, CA, CMA, or other support groups. Sponsors, other recovery and personal friends, and employers may become part of an individual's RP network (87). Patients generally should not try to recover in isolation, particularly during the early stages of recovery. Following are some suggested steps for helping patients develop a RP network. First, the patient needs to identify whom to involve in or exclude from this network. Others who abuse substances, harbor extremely strong negative feelings toward the recovering person, or generally are not supportive of recovery usually should be excluded. The patient should then determine how and when to ask for support or help. Behavioral rehearsal can help the patient practice ways to make specific requests for support. Rehearsal also helps increase confidence as well as clarifies thoughts and feelings regarding reaching out for help. Many patients, for example, feel guilty or shameful and question whether or not they deserve support from others. Yet others have such strong pride that the thought of asking others for support is very difficult to accept. Rehearsal may also clarify the patient's ambivalence regarding ongoing recovery, and it helps better understand how the person being asked for support may respond. This prepares the patient for dealing with potential negative responses from others. Patients should be advised to emphasize that recovery is ultimately their

responsibility. An action plan can then be devised, practiced, implemented, and modified as needed. Some patients find it helpful to put their action plan in writing so that all of those involved have a specific document to refer to. The action plan can address the following issues: how to communicate about and deal with relapse warning signs and high-risk situations; how to interrupt a lapse; how to intervene if a relapse occurs; and the importance of exploring all the details of a lapse or relapse after the patient is stable so that it can be used as a learning experience. Having a plan can make both the recovering person and family feel more in control even if faced with the possibility of an actual relapse. Additionally, it helps everyone take a proactive approach to recovery rather than sit back passively and wait for problems to occur. The authors' clinical experience has been that patients and families who are involved in such discussions are much more likely to intervene earlier in the relapse process than those not involved in these discussions.

Help Patients Identify and Develop Effective Coping Strategies to Manage Negative Emotional States

Negative affective states are associated with relapse across a range of addictions (8). Several investigators reported that depression and anxiety were major factors in a substantial

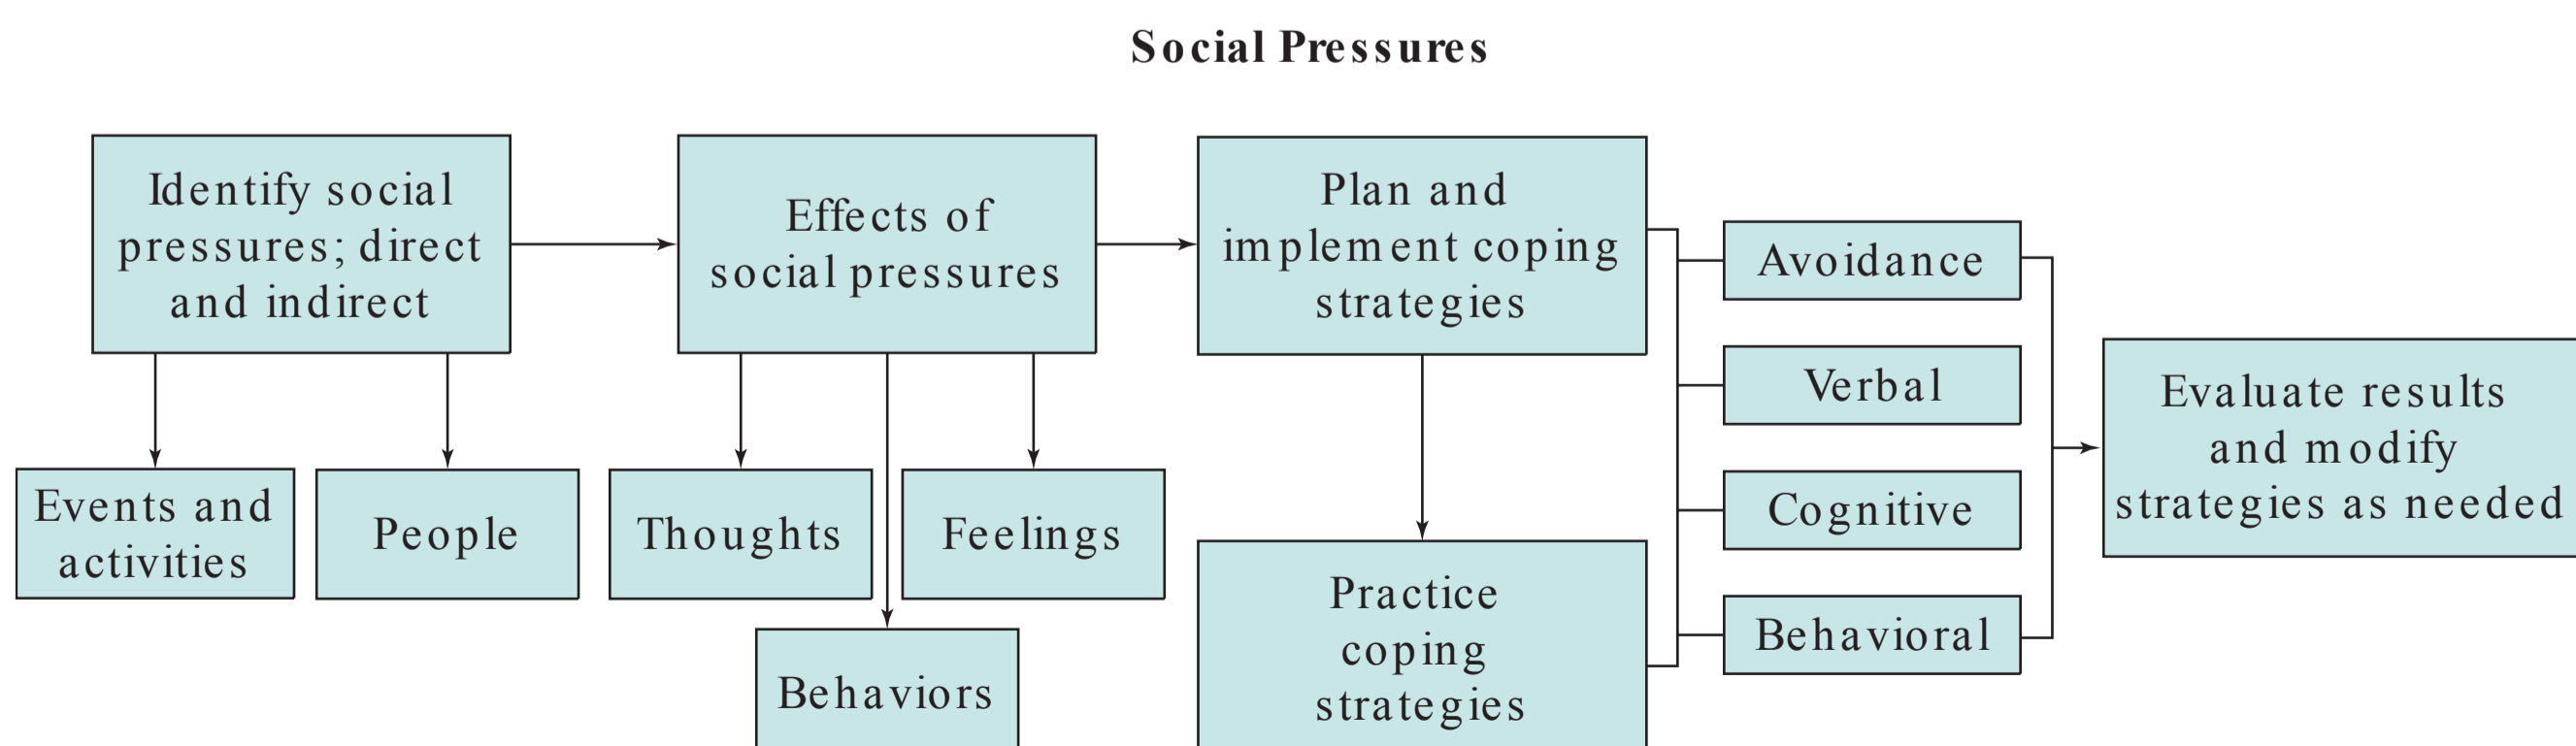

Figure 47.6. Social pressures.

number of relapses (88). Shiffman and colleagues (10) found that coping responses for high-risk situations were less effective for smokers who were depressed. Other negative affective states associated with relapse include anger, anxiety, and boredom. The acronym HALT used in 12-step Programs (which stands for, “don’t get too hungry, angry, lonely, or tired”) speaks to the importance of the recovering alcoholic’s or drug addict’s not allowing himself or herself to get too angry or lonely. These two emotional states are seen as high-risk factors for many.

Helping patients improve their ability to identify and manage their emotions is a helpful treatment strategy (13). Interventions for helping patients develop appropriate coping skills for managing negative emotional states vary, depending on the sources, manifestation, and consequences of these emotions. For example, strategies for dealing with depression that accompanies the realization that addiction caused havoc in one’s life may vary from those for dealing with depression that is part of a bipolar or major depressive illness that becomes manifest after the patient is substance-free and creates significant personal distress.

Help Patients Identify and Learn Strategies to Cope with Cognitive Distortions

Cognitive distortions or errors in thinking are associated with a wide range of mental health and SUDs (89). These distortions have also been implicated in relapse to substance use as well. Twelve-step programs refer to cognitive distortions as “stinking thinking” and suggest that recovering individuals need to alter their thinking if they are to remain alcohol- and drug-free. Teaching patients to identify their cognitive errors (e.g., black-and-white thinking, “awfulizing,” overgeneralizing, selective abstraction, catastrophizing, or jumping to conclusions) and evaluate how these affect the relapse process is often very helpful. Patients can then be taught to use counter thoughts to challenge their faulty beliefs or specific negative thoughts. The authors provide patients with a sample worksheet to help them learn to change and challenge relapse thoughts. This worksheet has three directives: (a) list the relapse-related thought; (b) state what is wrong with it; and (c) create new statements. A list of seven specific thoughts commonly associated with relapse is used to prompt patients in completing this therapeutic task. These examples include, “relapse can’t happen to me”; “I’ll never use alcohol or drugs again”; “I can control my use of alcohol or other drugs”; “a few drinks, tokes, pills, lines won’t hurt”; “recovery isn’t happening fast enough”; “I need alcohol or other drugs to have fun”; and “my problem is cured.” Patients seldom have difficulty coming up with additional examples of specific thoughts that can contribute to a relapse. Many of the AA, CMA, and NA slogans were devised to help alcoholics and drug addicts alter their thinking and survive desires to use substances. Slogans such as “this, too, will pass,” “let go and let God,” and “one day at a time” often help the individual work through thoughts of using.

Help Patients Work Toward a Balanced Lifestyle

In addition to identifying and managing high-risk relapse factors, recovering individuals often need to make more global changes to restore or achieve a balance in their lifestyle (8,13). Development of a healthy lifestyle is seen as important in reducing stress that makes one more vulnerable to relapse. The patient’s lifestyle can be assessed by evaluating patterns of daily activities, sources of stress, stressful life events, daily hassles and uplifts, balance between wants (activities engaged in for pleasure or self-fulfillment) and shoulds (external demands), health and exercise patterns, relaxation patterns, interpersonal activities, and religious beliefs. Helping patients develop positive habits or substitute indulgences (e.g., jogging, meditation, relaxation, exercise, hobbies, or creative tasks) for substance abuse can help to balance their lifestyle (13,90).

Help Patients Develop a Relapse Management Plan

Since addiction has been clearly identified as a chronic relapsing illness, it is highly recommended that patients have an emergency plan to follow if they lapse, so that a full-blown relapse can be avoided. If a full-blown relapse occurs, however, the patient needs to have strategies to stop it. The specific intervention strategies should be based on the severity of the patient’s lapse or relapse, coping mechanisms, and prior history of relapse. Helpful interventions include getting patients to use self-talk or behavioral procedures to stop a lapse or relapse, asking family, 12-step sponsors, friends, or professionals for help, carrying an emergency card with names and phone numbers of others who can be called on for support, or carrying a reminder card that gives specific instructions on what to do if a lapse or relapse occurs (13). Marlatt recommends developing a relapse contract with patients that outlines specific steps to take in the event of a future relapse. The aim of this contract is to formalize or reinforce the patient’s commitment to change. Analyzing lapses or relapses is a valuable process that can aid ongoing recovery. This helps to reframe a “failure” as a “learning” experience and can help the individual prepare for future high-risk situations.

Consider the Use of Pharmacologic Intervention as an Adjunct to Psychosocial Treatment

Because some patients benefit from pharmacologic interventions to attenuate or reduce cravings for alcohol or other drugs, enhance motivation to stay sober, and increase confidence in their ability to resist relapse, a therapist should consider using a pharmacologic intervention as an adjunct to psychosocial treatment (91). None of the medications approved for the treatment of alcohol dependence has proven effective without some form of concurrent behavioral intervention. In addition, research shows that the combined effects of the pharmacologic and behavioral treatment are additive for smoking cessation (92). Medications can also be

very helpful in preventing relapse to opioid dependence. Unfortunately, despite a significant number of clinical trials with good outcomes, medications are still underutilized by physicians treating patients with addictions.

Assess Patients for Co-occurring Psychiatric Disorders and Facilitate Specialized Treatment if Needed

Numerous studies of community samples, psychiatric treatment populations, and substance abuse treatment populations evidence high rates of dual diagnoses (SUD co-occurring with a psychiatric disorder) (93). Dual-diagnosis patients are at higher risk for substance use relapse than those with only a substance use diagnosis resulting from the effect of psychiatric symptomatology on motivation, judgment, and functioning. In addition, dual-diagnosis patients who resume substance use frequently fail to adhere to psychiatric treatment and comply poorly with pharmacotherapy, psychotherapy, and/or self-help program attendance (94). In a quality assurance/improvement study conducted by one of the authors of 25 substance abusers with mood disorders and 25 substance abusers with schizophrenia who were rehospitalized as a result of significant worsening of psychiatric condition, it was found that alcohol and drug abuse relapse played a significant role in 60% of these psychiatric relapses. In a study comparing psychiatric patients with ($n = 127$) and without ($n = 102$) substance abuse comorbidity, one of the authors found that the patients with co-occurring disorders were significantly more likely to relapse and be hospitalized (95). RP strategies can be adapted and tailored to the specific problems and symptoms of the patient's psychiatric disorder. Monitoring target moods or behaviors, participating in pleasant activities, developing routine and structure in daily life, learning to cope with persistent psychiatric symptoms associated with chronic or recurrent forms of psychiatric illness, and identifying early warning signs of psychiatric relapse and developing appropriate coping strategies are helpful interventions for dual diagnosis patients (13).

Negative mood states that are part of an affective disorder (major depression, bipolar disease, etc.) or anxiety disorder (phobia, panic disorder, etc.) may require pharmacotherapy in addition to psychotherapy and involvement in self-help programs. Patients on medications for these or other psychiatric disorders may also benefit from developing strategies for dealing with well-meaning members of self-help programs who encourage them to stop their medications because it is perceived as detrimental to recovery from their SUD.

Facilitate the Transition to Follow-up Outpatient Treatment For Patients Completing Residential or Hospital-Based Treatment

Many patients make significant gains in structured, hospital-based or residential substance abuse treatment programs only to have these negated as a consequence of failure

to adhere to ongoing outpatient or aftercare treatment (96). Interventions used to enhance treatment entry and adherence that lower the risk of relapse include the provision of a single session of motivational therapy prior to discharge from inpatient treatment, the use of telephone or mail reminders of initial treatment appointments, integrating motivational interventions in early recovery, and providing reinforcers for appropriate participation in treatment activities or for providing drug-free urines. Studies of patients with schizophrenia and a SUD (97) or patients with mood and SUDs (98) show that providing a single motivational therapy session prior to hospital discharge leads to a nearly twofold increase in the show rate for the initial outpatient appointment. Patients who show for their initial appointment and successfully “enter” outpatient treatment have a reduced risk of treatment dropout and subsequent psychiatric and/or substance use relapse.

CONCLUSION

Relapse is complex, dynamic, and unpredictable. A variety of RP clinical treatment models have been developed for patients with alcohol, tobacco, or other addictions. Many of the cognitive and behavioral interventions described in these RP approaches can be adapted for use with patients who have additional problems, such as other compulsive disorders, impulse control disorders, or comorbid psychiatric illnesses. RP interventions aim to help patients maintain change over time and address the most common issues and problems raising vulnerability to relapse. Studies indicate that RP has efficacy in reducing both relapse rates and the severity of lapses or relapses. RP strategies can be used throughout the continuum of care in primary rehabilitation programs, dual-diagnosis hospital programs, residential programs, halfway houses, or therapeutic community programs, as well as in partial hospital, outpatient, and aftercare programs integrated with other treatments such as pharmacotherapy. In addition, family members can be included in educational and therapy sessions and involved in the development of RP plans for members with SUDs. Many of the RP approaches described in the literature could play an important role in the development of short-term or brief interventions such as MI. Incorporating the RP techniques within the brief intervention will be beneficial for patients attempting to abstain or reduce their substance use after treatment and they can be provided in individual or group sessions, making them attractive and cost effective. RP techniques need to be studied more rigorously in diverse samples of populations including ethnic minority groups and adolescents. Future research should focus on refining the understanding of the dynamic reconceptualization of the relapse process and developing better data analytic methods for assessing behavior change. Clinical researchers should focus their efforts on better dissemination of RP strategies to community-based providers of drug and alcohol services. Neuroimaging studies are needed to better understand the underlying neuronal substrates of craving, decision-making, and the implications for RP.

Maternal and Neonatal Complications of Alcohol and Other Drugs

Karol Kaltenbach ■ Hèndrèe Jones

INTRODUCTION

Attention given to the concerns over the use of licit and illicit substances by pregnant women by both researchers and members of the public has varied considerably over the past several decades. The approaches to this public health problem have included a spectrum of punitive and treatment-oriented approaches with both extremes alternating as the principal or primary approach.

The public's concern and the subsequent behavioral and medical research on the effects of prenatal exposure to substances is grounded in the theory that disturbances during development in utero are a direct result of these substances altering the physical and/or nervous system of the child. Considerable research conducted in the area has approached the issue using a behavioral teratology frame of reference. Behavioral teratology investigates how substances that may or may not be inconsequential to the mother may harm the developing embryo and fetus. The type, duration, and severity of the harm are dependent upon multiple factors including the exposure dosage and the time during gestation when the exposure occurs. Moreover, harm to the central nervous system (CNS) during development may not manifest itself until later in development (1). As will be illustrated in this chapter, pre-clinical or animal model studies provide data to elucidate the biologic mechanisms that relate to both the negative effects of prenatal exposure to substances as well as protective effects of interventions to ameliorate or reverse the effects of this exposure. Both animal and clinical data also emphasize that the mechanisms associated with effects of prenatal exposure to substances on the fetus or child are multifactorial and encompass physiology, biology, genetics, epigenetics, dynamic relations between child and caregiver, and the environmental contexts in which the child develops.

This chapter summarizes the literature regarding the maternal and neonatal complications of licit (alcohol, nicotine, benzodiazepines, prescription opioids, and inhalants) and illicit (heroin, cocaine, amphetamines, hallucinogens, and marijuana) substances. Unfortunately, the political and regulatory

distinction between legal and illegal substances has led the public to erroneously assume that there is a relationship between the legality of a substance and its ability to negatively impact fetal development and growth. As will be illustrated in this chapter, if substances were ranked in terms of the severity of their devastating consequences to fetal and maternal health, the two legal substances of alcohol and tobacco would likely decidedly trump the negative consequences associated with illicit substances such as cocaine, heroin, and marijuana. While the public and scientific communities have paid an enormous amount of attention to in utero cocaine effects, the effects associated with prenatal cocaine exposure appear more subtle than the prenatal effects of tobacco (2) and tobacco is used by the vast majority of women who use cocaine during pregnancy. Thus, it should be recognized that although the information in this chapter is ordered by classes of substances, these classes simply serve as organizing principles rather than representing the typical pattern of the ways drugs are used by women who become pregnant. In reality, pregnant women frequently use multiple substances that may have additive or even synergistic effects on the health and well being of the mother, fetus, and neonate.

This chapter is divided into 11 sections. The first section provides a summary of the prevalence of substance use by pregnant women. The second section summarizes the social characteristics and historical overview of the use of licit and illicit substances by pregnant women. The remaining sections summarize the information known about the maternal and neonatal consequences of prenatal exposure to alcohol, opioids, cocaine, amphetamine, inhalants, marijuana, nicotine, benzodiazepines, and hallucinogens, together with information relevant for the health care provider in regard to the use of these drugs by pregnant women.

Prevalence

According to U.S. national survey data from pregnant women of childbearing age (between 15 and 44 years of age, inclusive), 5.1% reported using illicit drugs in the past month. This

**Illicit Drug Use in the Past Month
By Age of Females of Childbearing Age
National Survey of Drug
Use and Health data 2007–2008**

Figure 48.1. Illicit drug use in the past month by age of females of childbearing age. (From National Survey of Drug Use and Health Data, 2007–2008.)

rate is similar to the rates reported since 2003 among pregnant women. However, this rate was significantly lower than the rate (9.8%) for nonpregnant women in the same childbearing age group (3). When this age group is categorized into subgroups, the same pattern of less reported use among pregnant than nonpregnant women was observed, except among girls 15 to 17 years of age (Fig. 48.1). In this latter subgroup, those girls who were pregnant had a higher rate of reported substance use in the past month relative to those girls who were not pregnant, that is 21.6% versus 12.9% (3). There is evidence to suggest that illicit drug use decreases over the course of pregnancy with 7.2%, 5.0%, and 2.8% of pregnant women reporting past month use of illicit drugs in the first, second, and third trimester, respectively (Fig. 48.2).

Examining the classes of substances used by pregnant women in the last month, 3.8% reported marijuana use, 0.8%

used opioids (including heroin, OxyContin, and pain relievers), 0.4% used cocaine, and 0.2% used inhalants (3). Alcohol use in the past month was reported by 10.6% of pregnant women, while 4.5% reported binge drinking, and 0.8% reported heavy alcohol use. Similar to illicit drug use, these rates were significantly lower than the rates reported for their same-age nonpregnant counterparts, 54.0%, 24.2%, and 5.5%, respectively (3).

Among childbearing-age women, past month cigarette use was lower among pregnant (16.4%) than nonpregnant (27.3%) women (Fig. 48.2). Similar to the patterns seen with past month illicit drug use, the pattern of fewer pregnant than nonpregnant women reporting use was seen in each age subgroup with the exception of 15- to 17-year-old girls, for whom the rate of cigarette smoking appeared somewhat higher for pregnant than nonpregnant girls (20.6% vs. 14.7%). Moreover, the same pattern of decreasing numbers of women reporting cigarette use over the trimesters was also evident (3).

HISTORICAL OVERVIEW

Drug use by women and pregnant women in particular is certainly not a contemporary phenomenon. Stephan Kandall (4) provides an excellent discussion of the history of drug use among women in the United States from the mid-1800s, but it has only been since the end of the 20th century that significant attention has been directed at the use of licit and illicit substances by women with concern regarding use during pregnancy. The confluence of changes include the experience gained from the thalidomide tragedy (that drugs taken during pregnancy may be a teratogen); the strong stance by the Surgeon General in 1965 that smoking may be hazardous to your health; changes in federal drug policy during the 1960s that included treatment as an important approach; and the scientific report of the association between maternal drinking and infant abnormalities in 1971 that led to a new concern regarding the effects of drug use during pregnancy.

**Drug Use in the Past Month
by Females of Childbearing Age:
Pregnancy and Trimester Status**

Figure 48.2. Drug use in the past month by females of childbearing age: pregnancy and trimester status. (From National Survey of Drug Use and Health Data, 2007–2008.)

However, this focus has not necessarily led to a strong cumulative body of scientific evidence, as both public and scientific interest is often driven by the politics of the day. For example, there has been a steady focus on delineating the effects of prenatal alcohol and nicotine exposure, in concert with consistent public health education to reduce/eliminate the use of these substances during pregnancy, including advisories from the Office of the Surgeon General on Alcohol Use in Pregnancy in 2005, and Treating Tobacco Use and Dependence in 2008. Yet, the trajectory of attention on illicit drugs is more restricted in that studies investigating the effects of illicit prenatal drug exposure are usually conducted primarily during the time periods in which societal concern is the greatest. For example, the majority of studies investigating opioid exposure were conducted in the late 1970s and early 1980s corresponding to the aftermath of the widespread heroin addiction of the 1960s; as the crack/cocaine epidemic spread throughout the country in the late 1980s and early 1990s attention shifted to prenatal cocaine exposure; and with the recent upsurge in the illegal manufacture of methamphetamines, we are just now beginning to accrue data on methamphetamine exposure. This dichotomy reflects some of the issues between use of licit and illicit drugs. Alcohol use in moderation is socially acceptable and has deep-seated cultural and religious roots; for pregnant

women, the message is simply abstinence during pregnancy. (However, for pregnant women who are alcohol dependent, the problems are very complex and are often intertwined with tobacco and illicit drug abuse.) While there has been significant emphasis on the health risks associated with smoking and society has progressively embraced group zero tolerance, that is, no smoking in public facilities, the decision to smoke is viewed as an individual choice, and again the message for pregnant women is to cease smoking or at least reduce daily consumption during pregnancy. For both alcohol and tobacco the approach is driven by a public health perspective; whereas by definition, the use of illicit drugs constitutes illegal activity and carries with it moral judgment and punitive responses.

Social Characteristics

When addressing the complications of maternal drug abuse or dependence during pregnancy, it is important to understand the overall context in which maternal drug abuse usually occurs. In the early 1980s, notable work by Beth Reed and others (5) was some of the first to recognize that the issues of maternal drug dependence must be addressed within the context of the fundamental role gender plays in defining identity; coping skills; psychological social and cultural realities; and

TABLE 48.1 Needs of pregnant women with substance abuse problems and the services they require

Presenting issues	Services
Medical comorbidities	Obstetrical services
	Nutritional counseling
	HIV, sexually transmitted infections and hepatitis B and C testing and counseling
	Smoking cessation intervention
	Appropriate sub-specialty referrals, for example, cardiology, pulmonology, hepatology, dental
Psychiatric comorbidities	Psychiatric services
	Pharmacologic and behavioral treatment
Childhood and/or current exposure to physical, sexual, and psychological abuse	Trauma specific services
	Referral to Rape Crisis Centers, Help lines for court and legal information
Family relationship problems	Family therapy services
	Referral of partner/family member to substance abuse treatment
Lack of education and vocational training	GED or other employment training or services
Involvement with criminal justice	Community legal services
	Referral to drug court
Involvement with child protective services	Child assessment and referral services
	Parenting intervention services, especially for the care of newborns and young children
	Child care within substance abuse treatment program

available resources. Drug-dependent women most often suffer from low self-esteem, depression, and anxiety; are usually the primary caregivers for their children; have a high incidence of victimization; and are involved in relationships with men who are also drug dependent (6). This early work of Reed is supported by work of Comfort and Kaltenbach (7) and others in the nineties and by Jones et al. (8) and others in the subsequent decade. Although the actual prevalence varies across studies, the consistency in the data allows for a general characterization. Overall, substance abusing pregnant women tend to have completed approximately 11 years of education, are most likely to be unmarried, have a history of substance abuse in their families, have a history of physical and sexual victimization, have significant health and/or mental health problems, have current problems with criminal justice, have current and/or past involvement with Child Protective Services, lack stable housing, and are unemployed with poor vocational training. As such they are a very vulnerable population with little support and few if any resources (7). Yet they are often the targets of prejudicial and judgmental treatment by health care providers and coercive policies implemented by child welfare systems, juvenile/family court, and the criminal justice system. Although no state statute makes it a crime for pregnant women to become pregnant or give birth, in extreme cases, “fetal abuse” statutes have been used to prosecute pregnant women. “Fetal abuse” statutes are those statutes in which existing child abuse statutes were applied to include maternal prenatal conduct, have been used to prosecute pregnant women for drug use (9). In these cases, where the fetus was determined to be a “child,” pregnant women have been arrested for possession of a controlled substance, delivering drugs to a minor or charged with child abuse. By 2000, some 200 pregnant women in 30 states had been prosecuted on such interpretations of fetal abuse (10).

These actions frequently deter women from seeking prenatal care and treatment for their substance use disorders. Their chaotic lifestyle and lack of prenatal care results in an array of medical and obstetrical complications, reducing the chances of a healthy pregnancy outcome regardless of the effects of the drug(s) they are abusing. Table 48.1 delineates the complex needs of pregnant women with substance use disorders and the services that should be provided in addition to substance abuse treatment.

ALCOHOL

Effects of Prenatal Exposure to Alcohol on the Neonate

Considerable research has consistently shown the adverse physical and behavioral effects on children whose mothers consumed alcohol during pregnancy. The early literature on this topic described a fetal alcohol syndrome (FAS) that included three defining aspects. The first aspect consists of facial malformations that can include small eyes, inner epicanthal folds, a thin upper lip, a long smooth philtrum, and midfacial hypoplasia. The second aspect is notable delays in growth and

growth restriction (in head size and physical height). These delays are evident prenatally and there is typically failure to catch up at any point in life postnatally. The third aspect is CNS/neurodevelopmental abnormalities (e.g., neurologic hard or soft signs, behavioral problems, learning disabilities as appropriate for age) (11,12). Because there are some individuals who were prenatally exposed to alcohol who exhibit some but not all FAS aspects, newer terms have been developed to refine the characterization of their problems. These terms include alcohol-related neurodevelopmental disorder (ARND), alcohol-related birth defects (ARBD), and the largest umbrella term, fetal alcohol spectrum disorder (FASD). FASD encompasses all adverse effects demonstrated in individuals prenatally exposed to alcohol (12). FASDs are estimated to occur in 2% to 4% of all live births and are associated with severe cognitive, behavioral, adaptive, social, and emotional regulatory outcomes. These primary problems can set the occasion for vulnerabilities in childhood- or adult-onset secondary problems, particularly in the domains of psychiatric illnesses, including substance use disorders, social relations, school performance, and legal issues (see Paley & O’Connor (13) for a review).

An important question in both the clinical and research domains is whether there is a “safe” amount of alcohol to consume during pregnancy. Heavy (three or more drinks per week or one or more drink per day) alcohol consumption during pregnancy is associated with low birth weight and preterm birth and these outcomes are proximate causes of neonatal morbidity and death and predictors of long-term developmental outcomes (14). A summary of FASDs would be incomplete without the acknowledgment of the importance of the animal models that have confirmed the exact nature and extent of the effects of prenatal alcohol exposure on the fetus by demonstrating the linkage between in utero alcohol exposure and compromised physical attributes and behavior (see Kelly et al. (15) for a review).

Information for Clinicians Regarding Alcohol Exposure During Pregnancy

Ideally, the use of alcohol during pregnancy should be avoided as no “safe” amount of alcohol has been identified. While some women are able to spontaneously quit their use of alcohol before or upon pregnancy awareness, other women are not in a life position to accomplish this behavior change. Thus, it is important to identify as early as reasonably possible pregnant women who are drinking in order to provide them with opportunities for intervention to change their drinking behavior.

In the absence of reliable biomarkers to detect alcohol consumption over many days or weeks, screening methods have by necessity relied on self-report. Although denial and stigma are always concerns for inaccurate reporting, there are alcohol use screening tools designed for pregnant women. The T-ACE is one tool that has been validated for screening pregnant women for at-risk alcohol consumption. The T-ACE is recommended by the American College of Obstetricians and Gynecologists (ACOG) and the National Institute on

Alcohol Abuse and Alcoholism for screening and can reliably detect alcohol use across all ethnic/racial minority groups. It asks four questions about a woman's *tolerance* for alcohol, if she has ever been *annoyed* by other people criticizing her drinking, if she has ever felt she needs to *cut down* her drinking and if she ever has an *eye-opener* drink first thing in the morning (16).

Following a positive screen for at-risk drinking, pregnant women need to be assessed for current dependence on alcohol. Those women who are determined to be dependent need treatment in specialty centers. For those women who are not dependent, research shows the benefits of brief interventions, administered by health professionals in the context of care visits, for reducing at-risk drinking (14). ACOG also offers a FASD tool kit for assisting health care providers in screening, intervention, and assistance for pregnant patients with at-risk drinking (14).

While there is continually growing evidence to document the associated negative effects of prenatal exposure to alcohol on the fetus, neonate, and child, the research agenda has recently expanded to include a focus on understanding the complex interactions that exist between caregivers and the child prenatally exposed to alcohol. How these dynamics can alter the subsequent behavior of the child in his/her maturity is also of interest. Animal models have proven to be instrumental in providing guidance for how environmental enrichment and exercise are related to improvements in alcohol's developmental effects (15).

Alcohol exposure may produce epigenetic (gene expression is changed in absence of changing the organism's actual DNA) effects as a result of the direct actions of alcohol on the DNA of the in-utero exposed child or from changes which result from compromised caregiver–infant behaviors early in postnatal life (15).

Although much is known about the adverse effects associated with prenatal exposure to alcohol, the effects of this substance in combination with other substances, including, particularly, cigarette smoking, has received less scientific attention. There is some evidence to suggest a synergistic effect of prenatal exposure to both alcohol and cigarette smoking on low birth weight, premature birth, and prenatal growth restriction (17).

OPIOIDS

Effects of Prenatal Exposure to Opioids on the Neonate

Although there are a number of drugs classified as opioids, including buprenorphine, codeine, fentanyl, heroin, hydrocodone, methadone, meperidine, morphine, and oxycodone, the primary opioids used/abused by pregnant women are heroin, oxycodone, methadone, and buprenorphine (3). Opioids are not categorized as a teratogen (18), but they do easily cross the placenta. Infants exposed to opioids in utero are born passively dependent and neonatal abstinence occurs in 55% to 94% of newborns (19).

Neonatal abstinence is characterized by signs and symptoms of CNS hyperirritability; gastrointestinal (GI) dysfunction; respiratory distress; and vague autonomic symptoms that include yawning, sneezing, mottling, and fever. Infants generally develop tremors, which may progress to the point where they occur spontaneously without any stimulation. A high-pitched cry, hyperactive Moro reflex, increased muscle tone, sleep disturbances, and irritability are also present. Respiratory dysregulation is indicated by nasal stuffiness and rapid respiration. The rooting reflex is increased and infants often suck frantically on their fists or thumbs, yet have difficulty feeding because of an uncoordinated sucking reflex. Additional GI dysfunction is characterized by regurgitation and diarrhea (20).

Infants undergoing withdrawal must be assessed to determine the severity of the withdrawal and whether to initiate pharmacotherapy to treat it. The most widely used assessment instrument used in U.S. hospitals is the Neonatal Abstinence Score (20) commonly referred to as the Finnegan score (21). There are several other scoring instruments, for example, Green and Suffet (22), Lipsitz (23), and a number of hospitals use a “modified” Finnegan (8). Whatever scoring system is utilized, the purpose is to objectively assess the onset, progression, and diminution of abstinence symptoms. It provides a mechanism for determining if pharmacotherapy is indicated, monitoring the infant's response to treatment, and initiating a taper when control is achieved. For example, using the Finnegan score, infants are assessed 2 hours after birth and then every 4 hours at a minimum. Pharmacotherapy is indicated when the total abstinence score is 8 or greater for three consecutive scores, or 12 or greater for two consecutive scores. Once abstinence is controlled using the prescribed dosage schedule, the dose administered to achieve control is maintained for 72 hours and then a dosage reduction schedule is initiated (20).

The American Academy of Pediatrics (19) recommends opioid therapy for the treatment of opioid abstinence. Short-acting opioids administered orally are well tolerated by neonates, can be easily titrated to control abstinence, and offer a wide margin of safety between therapeutic and toxic doses (24). There are limited data evaluating the efficacy of different drug regimes in the treatment of neonatal abstinence (see American Academy of Pediatrics (19) for a review); however, there appears to be clinical consensus that use of diluted tincture of opium or morphine sulfate is indicated, as they have been reported as the most commonly used agents in hospitals throughout the United States (21). Buprenorphine has recently been investigated as a treatment option. Kraft et al. (25) conducted a randomized open-label study of the use of buprenorphine in comparison to standard of care neonatal opium solution in the treatment of 26 neonates in opioid withdrawal, and reported the mean length of treatment for infants receiving neonatal opium solution was 32 days compared with 22 days for infants receiving buprenorphine. While these findings were not significant ($p < 0.077$), there is a suggestion of improved efficacy that requires further investigation. Clonidine for

neonatal opioid withdrawal has also been recently evaluated in a randomized, double blind clinical trial by Agthe et al. (26). They found the addition of oral clonidine with the use of diluted tincture of opium reduced the length of treatment by 27% compared to infants receiving diluted tincture of opium and placebo. Both of these studies reflect renewed interest in empirically determining the efficacy of treatment medications for neonatal abstinence.

There is significant variability in the onset and duration of neonatal abstinence. The time of onset of withdrawal ranges from shortly after birth to 2 weeks of age but on average, occurs within 72 hours after birth (20). In addition to individual variability, abstinence due to methadone exposure is more prolonged and more severe than for heroin exposure (27). Although the data to date are quite limited, there is also some suggestion that abstinence due to buprenorphine exposure requires less medication and a shorter hospital stay than for methadone-exposed infants (8). There are relatively no data to date on the characterization of neonatal abstinence from oxycodone exposure. Variability in neonatal abstinence can also be due to concomitant drug use. Benzodiazepine use among methadone maintained pregnant women has been found to increase the length of treatment for neonatal abstinence by an average of 14.4 days (28). Nicotine has also been reported to increase the duration of neonatal abstinence in infants born to methadone maintained women (29).

The type of opioid used may also have an effect on perinatal outcomes, including prematurity and birth weight. Infants exposed to heroin have high rates of intrauterine growth restriction and prematurity (30) and infants exposed to both heroin and methadone have lower birth weights than infants born to women enrolled in a methadone maintenance program (31). In a study by Kandall et al., infants born to women receiving methadone maintenance had a mean birth weight of 2961 g, which has been an exceptionally consistent finding across studies for the past 30 years (31). There are few data comparing infants born to women maintained on methadone and those born to women maintained on buprenorphine but available data suggest that birth weight does not differ (8).

Although neurodevelopmental outcomes assessed by the NICU Network Neurobehavioral Scale (NNNS) have found infants exposed to opioids differ from nondrug exposed comparison infants on orientation scores and stress abstinence scores at 1 month of age, with adjustment for covariates of socio-economic status (SES), birth weight and polydrug use, there were no significant effects (32). The Maternal Life Style Study (discussed in more detail under section “Cocaine” in this chapter) examined cognitive, motor, and behavioral outcomes at 1, 2, and 3 years of age in a cohort of 1227 children (cocaine exposed $n = 474$; opioid exposed $n = 50$; cocaine and opioid $n = 48$; and nondrug exposed $n = 655$). After controlling for covariates, including frequency and quantity of substance use per trimester, maternal education, SES, home environment, maternal/caregiver IQ, and maternal psychological symptoms, there were no significant differences on the

Bayley Scales of Infant Development between the opioid exposed infants and other groups (33).

Information for Clinicians Regarding Opioid Exposure During Pregnancy

Different opioids manifest different clinical issues for opioid-dependent pregnant women. Heroin use is illegal and is characterized by a chaotic lifestyle; medical complications associated with parenteral opioid use can include hepatitis, HIV, septicemia, and cellulitis. Obstetrical complications are related to a lack of prenatal care. Moreover, the effects of heroin last only 3 to 5 hours, so the fetus is subjected to repeated episodes of opioid withdrawal, increasing the risk of morbidity and mortality (34). It is essential that efforts be made to engage pregnant heroin-dependent women in treatment.

Methadone is a synthetic opioid medication that is used in the treatment of opioid dependence and methadone maintenance is recommended as the standard of care in the management of opioid dependence during pregnancy (35). Effective methadone maintenance prevents the onset of withdrawal for 24 hours, reduces or eliminates craving, and blocks the euphoric effects of other opioids. In pregnancy, methadone prevents erratic maternal opioid drug levels, and protects the fetus from repeated episodes of withdrawal (34). Additionally, through regulation, it ensures that prenatal care will be available. In the United States, methadone may only be prescribed for maintenance within a licensed opioid treatment program (OTP). Under federal methadone regulations, 42CFR8.12, pregnant women must be given priority for admittance to an OTP and the program must, at a minimum, coordinate prenatal care with a medical provider if they do not have the capacity to provide obstetrical services. When effective methadone maintenance is provided with a comprehensive program that includes prenatal care, the incidence of obstetric and fetal complications and neonatal morbidity and mortality can be reduced (34).

One of the most contentious clinical issues in providing methadone maintenance to pregnant women is the question of dose. A prevailing concern has centered on whether there is a dose response to the severity of neonatal abstinence. Recommendations have often proposed low methadone doses in an attempt to reduce or eliminate neonatal abstinence. Although there have been well over 30 studies that have investigated the relationship between dose and severity of withdrawal, the findings are contradictory. While a number of studies have reported significant relationships, the majority found no relationship. As such there is not compelling evidence to reduce maternal dose to avoid neonatal abstinence. Conversely, there is evidence that higher doses are associated with less illicit drug use (36) and reducing methadone dose may lead to illicit substance use, and hence increase risk to both mother and fetuses (34).

Although methadone has been used for the treatment of opioid dependence for over 40 years, recent concerns have emerged regarding an association between methadone and

QTc interval prolongation, with torsade de pointes associated with very high dose methadone. There have been a number of publications with recommendations such as obtaining a pretreatment ECG, a follow-up ECG within 30 days, and annually. For patients with QTc interval greater than 500 msec it has been recommended that consideration be given to discontinuing or reducing methadone dose (37). To date, there are no data on QTc intervals in pregnant opioid-dependent women maintained on methadone so this presents a unique challenge for clinical care in this population.

Buprenorphine, a partial mu-opioid agonist, was approved for use in the treatment of opioid dependency in the United States in 2002; however, it was not approved for use in pregnancy. Nevertheless, there are many instances in which a woman has been successfully maintained on buprenorphine when she becomes pregnant. In such cases, the prescribing physician and patient may decide that the benefits of remaining on the current medication outweigh any risk. To date, there are only published data from two small, randomized clinical trials on the safety and efficacy of buprenorphine compared to methadone in the treatment of pregnant women (8,38). However, there are a large number of studies, primarily case reports and prospective studies from Europe, in which buprenorphine has been used with pregnant women. The reports indicate that buprenorphine during pregnancy provides the same benefits as other opioid agonist medications (39). Moreover, there is limited evidence to suggest that infants born to women maintained on buprenorphine may have less severe neonatal abstinence and require less treatment compared to methadone (8).

The presence of methadone or buprenorphine in breast milk has been an important question in the clinical management of opioid dependence during pregnancy. There are limited data regarding buprenorphine, but the evidence indicates that only small amounts of buprenorphine pass into breast milk and the well-established poor oral bioavailability of buprenorphine suggests that absorption via breast milk may be low (40). From as early as 1974, there have been a number of studies that have reported low concentrations of methadone in breast milk (see Jansson et al. (41) for a review) and in 2001, the American Academy of Pediatrics (42) recommendation on drugs and breast-feeding eliminated the dose restriction on methadone, making methadone maintenance treatment compatible with breast-feeding regardless of maternal dose. The general recommendation is that opioid maintained mothers can breast-feed if they are not HIV positive, not using illicit drugs, and do not have a disease or infection in which breast-feeding is contraindicated.

COCAINE

Effects of Prenatal Exposure to Cocaine on the Fetus and Neonate

Cocaine is an alkaloid prepared from the leaves of the *Erythroxylon coca* plant. It blocks the presynaptic reuptake of the neurotransmitters norepinephrine and dopamine,

producing an excess of transmitter at the postsynaptic sites. Activation of the sympathetic nervous system by this mechanism produces vasoconstriction, an acute rise in arterial pressure, tachycardia, and a predisposition to ventricular arrhythmias and seizures (43). Cocaine use rose dramatically in the 1980s and was accompanied by ubiquitous media coverage due to numerous high-profile deaths and the shift from expensive cocaine powder to the far cheaper crack/cocaine. The minimal cost and potent euphoria that crack/cocaine provided gave rise to the “cocaine epidemic” including significant use among pregnant women. This led to major concerns on the effects on the fetus and neonate as cocaine easily crosses the placenta. The animal and adult literature on the effects of cocaine on the cardiovascular system provided support for such concern as did the potential for the potent vasoconstrictive properties of cocaine to cause congenital malformations.

The first studies on the effects of prenatal cocaine exposure published in the mid-1980s reported alarming outcomes with increased incidence of spontaneous abortion, abruptio placentae, premature labor and delivery, intrauterine growth restriction, risk of congenital malformation of the genitourinary tract, neurobehavioral effects, and risk of perinatal cerebral infarction (see Volpe (44) for a review). However, subsequent studies in the late 1980s and early 1990s have failed to replicate the early findings. In response to such disparities Lutiger et al. (45) conducted a meta-analysis to evaluate the reproductive risks of cocaine. The reproductive effects assessed included rates of small for gestational age (SGA) births, low birth weight, prematurity, abruptio placentae, malformation, spontaneous abortion, fetal demise, and Sudden Infant Death Syndrome (SIDS). They reviewed 45 scientific papers reporting on the effects of cocaine used during pregnancy and identified 20 eligible for meta-analysis. They included comparisons of four groups; no drug use, cocaine alone, polydrug users who did not use cocaine, and polydrug users who used cocaine. None of the comparisons found an increased risk of abruptio placentae, cardiac malformations, or sudden infant death associated with cocaine use. They found very few adverse reproductive effects were associated with cocaine when the polydrug cocaine use group was compared to the noncocaine polydrug use group. When the comparison groups consisted of no drug use, the polydrug cocaine group had a higher risk of spontaneous abortions; similarly they found in comparisons of the cocaine alone and no drug use groups, there was a higher risk for in utero death in addition to genitourinary tract malformations for the cocaine alone group. They concluded that the discrepancies suggest that a variety of adverse reproductive effects commonly associated with prenatal cocaine exposures may be caused by confounding factors clustering in cocaine users.

In addition to contradictory reproductive risk data, there were also inconsistent findings regarding adverse neurobehavioral effects and developmental outcomes. In an effort to provide a critical synthesis of existing studies, Frank et al. (46) conducted a review of all articles published between 1984 and

2000 that included the words cocaine, crack/cocaine, pregnancy, prenatal exposure, delayed effects, children, and related disorders. Seventy-four published articles were identified. Studies were then excluded if they failed to mask children's exposure status; had no control group; subjects were not prospectively recruited; samples were largely confounded with exposure to opioids, methamphetamines or phencyclidine; and/or samples were predominately comprised of HIV positive mothers. Thirty-six studies met the inclusion criteria for this analysis. These studies were comprised of 17 independent cohorts from 14 cities; some cohorts were the subjects reported in multiple articles, either at different ages or with analyses of different variables. In summary, their review found that after controlling for tobacco and alcohol exposure, cocaine did not effect physical growth and that for children up to age 6, there is little impact of prenatal cocaine exposure on children's scores on nationally normed cognitive assessments (see Frank et al. (46) for a full review).

To address the many methodologic issues in the cocaine literature prospectively, the Maternal Lifestyle Study (MLS), a multisite longitudinal study was implemented through the NICHD Neonatal Research Network. This study included a cohort of 522 cocaine exposed and 655 comparison mother/child dyads. In addition to a large cohort, this study included extensive assessment on the multiple domains of child, mother, and environment and was designed to address the multiple associated factors that impact our understanding of the effects of prenatal cocaine exposure including polydrug use, the caregiving environment, sample size, and medical conditions (47). The MLS study has confirmed that cocaine exposure is not associated with mental, motor or behavioral deficits through 3 years of age after controlling for birth weight and environmental risks (33), but has also demonstrated that cocaine may effect areas of the brain that are not manifested until later in development. Specifically, the neural systems most likely to be affected by cocaine exposure are involved in discrete neurobehavioral functions such as attention, arousal, and motivation.

Two studies from the same longitudinal cohort examined the effect of prenatal cocaine exposure on attention and response inhibition as measured by continuous performance tests (CPTs) at ages 5 and 7 in a sample of 219 cocaine exposed and 196 comparison children and found cocaine associated increases in omission errors at ages 5 and 7, slower reaction times, and decreased consistency in performance at age 7 (48). They also investigated the risk for developing a learning disability by age 7 (cocaine exposed $n = 212$, comparison $n = 197$), and found that the cocaine exposed children had a 2.8 times greater risk of developing a learning disability by age 7 than the nonexposed children (49).

Several other studies have focused on a specific function. Singer et al. (50) examined their cohort at 9 years of age and found that the cocaine exposed group ($n = 192$) had poorer perceptual reasoning IQ than a noncocaine exposed group ($n = 179$). Mays et al. (51) examined performance on a spatial working memory task in 75 cocaine exposed and 55 nondrug exposed 8- to 10-year-old children. In this study, cocaine

exposed children had significantly slower correct moves per second and number of errors per trial. The clinical significance of these studies remains unclear. Much more research is needed to both definitely establish the presence of subtle impairments in attentional states and executive functions and what may be mediating factors in children of mothers who used cocaine during their pregnancy.

Information for Clinicians Regarding Cocaine Exposure During Pregnancy

Women who use cocaine during pregnancy have a complex array of obstetrical/medical risks, including a high incidence of alcohol, tobacco and marijuana use, syphilis, gonorrhea, and hospitalizations related to violence (32), making their obstetrical management difficult. To date, there are no specific medical treatments for cocaine use in pregnancy; referrals should be made to either outpatient or residential treatment programs.

Unlike opioids, cocaine does not produce an abstinence syndrome but infants may initially exhibit signs of irritability, tremulousness, and liability after birth. While these are transient, they may both exacerbate and be exacerbated by the caregiving environment. Mothers may benefit from individualized direction and support on how to structure the caretaking environment to provide an optimal environment for her newborn.

Breast-feeding is contraindicated for mothers who are using cocaine because cocaine is present in breast milk and may produce an acute neurotoxic disorder including irritability, hypertonia, tremors, and seizures (42).

AMPHETAMINES

Effects of Prenatal Exposure to Amphetamines on the Fetus and the Neonate

Amphetamine and methamphetamine are commonly known stimulants. They have a somewhat different mechanism of action from cocaine. Amphetamine and methamphetamine reverse the action of the monoamine transporters. They also stimulate dopamine, norepinephrine, and serotonin release and increase the availability of these neurochemicals at the postsynaptic receptor. Methamphetamine is a known potent drug with neurotoxic effects. A review of the effects of prenatal exposure to amphetamines and methamphetamines concluded that cleft palates, cardiac anomalies, and deficits in fetal growth are evident in both animal studies and documented human exposure cases (52).

There are very limited data regarding the long-term outcomes following prenatal exposure to amphetamine and/or methamphetamine. The largest study to date, the Infant Development, Environment, and Lifestyle (IDEAL) Study, demonstrated that in general, both the prevalence and frequency of methamphetamine use decreased from the first to the third trimester of pregnancy (84.3% vs. 56.0% vs. 42.4%, and 3.1 vs. 2.4 vs. 1.5 days/week). Among this group of

methamphetamine-using pregnant women, one third were deemed as consistently high users throughout pregnancy and had fewer prenatal care visits than those groups who were able to reduce their use during pregnancy (53). Prenatal exposure to amphetamines has been associated with low birth weight, with infants being 3.5 times more likely to be small for gestational age, and showing decreased arousal, movement disorders, and increased stress in the neonatal period (54). The cognitive function in children ages 3 to 4 years showed that compared to non-methamphetamine-exposed children, methamphetamine-exposed children had poorer performance on a visual motor integration task as well as evidence of abnormal acceleration of neuronal and glial development in these brain regions (55).

Information for Clinicians Regarding Amphetamine Exposure During Pregnancy

The identification of amphetamine use during pregnancy can be challenging and no self-report tools exist that are specific for pregnant women. There are biologic tests available that can detect the recent use of amphetamines and methamphetamine. At delivery, biologic matrices such as umbilical cord, meconium, urine, and hair have been used to determine the presence of these drugs at birth. While it is possible to identify a pregnant woman and her in-utero exposed neonate and to characterize the detrimental effects of this substance exposure on her and her child, treatment interventions to reduce or eliminate such use are needed. To the best of our knowledge, there are no specific behavioral or medication treatments that have been designed and/or have evidence to support their use in pregnant women who use amphetamine or methamphetamine. Specific to pregnant women, ensuring prenatal care attendance, regular assessment for fetal growth, and intervention with other substance use (e.g., concurrent alcohol use is prevalent in these stimulant users) seem especially important for these pregnant women.

INHALANTS

A diverse group of chemicals are known as organic solvents (frequently known as inhalants). These chemicals have multiple household and industrial uses. Most people encounter solvents in their daily life with the use of items such as cleaning fluids and glues (containing aromatic hydrocarbons like toluene or benzene), paint stripper or correction fluid (containing alkyl halides like 1,1,1-trichloroethane [TCE]), fuels or lighter fluids (aliphatic hydrocarbons like propane, gasoline, butane), air fresheners (aliphatic nitrites like isoamyl), nail polish remover (like ketones), and nitrous oxide which was used in pressurized whip cream dispensers and is still used in medical and dental settings. With awareness and proper use, most individuals experience only low-level exposure to these chemicals. There are infrequent occasions when industrial accidents have exposed individuals to acute, high levels of these chemicals. There are also individuals who voluntarily expose themselves to repeated high-levels

of organic solvents. The voluntary exposure or abuse of organic solvents is typically performed by inhaling vapors to become intoxicated. The various inhalation routes include “bagging” (inhaling fumes after spraying into a bag), “huffing” (inhaling solvent fumes from a cloth placed over nose and mouth), “sniffing” or “snorting” (see Jones and Balster (56) for a review).

Associated Effects of Prenatal Exposure to Abused Inhalants on the Neonate

While there are numerous types of organic solvents that have been reported to be abused, there are few data about abuse of these inhalants during pregnancy. As such, only those organic solvents with the most human prenatal exposure data are discussed below. While little is known about the specifics of abused inhalants during pregnancy, it is known that these types of substances are quite toxic and can be fatal if misused.

Toluene

The initial report concluding an association between inhalant abuse during pregnancy and negative birth outcome was published in 1979. It was in this report that the term “fetal solvent syndrome” was used to describe the constellation of physical effects including low birth weight, small head size, and facial dysmorphism that was present in children born to mothers with known abuse of toluene during pregnancy (57). Since that time, there have been numerous other case reports describing the effects of prenatal exposure to abused inhalants on the child. The largest report provided a summary of 35 deliveries from 15 solvent-abusing women. These cases were compared to a control group of infants and showed that, on average, toluene-exposed neonates were at increased risk for being premature, of lower birth weight, smaller birth length, smaller head circumference, and to have intrauterine growth restriction. Developmental follow-up of the toluene-exposed children showed that compared to a control group, on average, there was growth restriction in terms of height and weight as well as developmental delays in cognitive, speech, and motor skills (58).

Given the similarities between toluene and alcohol, a direct comparison of the teratologic effects of prenatal toluene and alcohol exposure has been undertaken. There were both overlapping and unique anomalies associated with prenatal exposure to either substance. Similar features included a thin upper lip, midfacial hypoplasia, and small palpebral fissures. Head and facial features that appeared unique to toluene were micrognathia, ear anomalies, a narrow bifrontal diameter, abnormal scalp hair patterns, down turned corners of the mouth, and a large fontanelle (59). Craniofacial features unique to fetal alcohol exposure included a more pronounced hypoplasia of the philtrum and nose (59). The reasons underlying the similar physical alterations may be either similar mechanisms of action of the two drugs, the restricted range of craniofacial abnormalities that can occur at birth, and/or the fact that the toluene-exposed children may have also been prenatally exposed to alcohol during gestation.

Gasoline

There is at least one report of two infants born to a mother who repeatedly sniffed gasoline during pregnancy. Both neonates had low birth weight, and were small in length and head circumference for their gestational age. Following delivery, they exhibited hypotonia followed by hypertonia. At later follow-up they were observed to have minor facial and physical abnormalities (60).

It is important to remember the complexities of the lives of women who abuse substances while pregnant and the inhalant literature, like other in utero literature, often minimizes the possible contribution of multiple factors such as nutrition, licit substance use (nicotine and alcohol), stress, and psychiatric comorbidities that may play important yet undefined roles in exacerbating or mitigating the effects on maternal and neonatal outcomes.

Information for Clinicians Regarding Inhalant Abuse During Pregnancy

Signs and symptoms of toluene or other solvent abuse can include: stains (e.g., paint) on the body or clothing, a noticeable chemical odor, sores around the mouth and/or nose, irritated eyes and/or nose, drunken appearance, nausea, anorexia, irritability, or excitability (see Jones and Balster (56) for review). More recently, solvent withdrawal signs have been discussed in the literature and may include fatigue and difficulty concentrating, fast heart beat, depressed mood, trembling, or twitching (61). Given the short duration of action, it is unlikely that tests of bodily fluids will be able to detect the use of inhalants or their metabolites. Thus, asking questions to women suspected of abusing inhalants during pregnancy about the amount and frequency of their inhalant use in a nonjudgmental and neutral manner may be the most effective method for determining abuse.

Renal tubular acidosis is one of the most frequent signs of solvent abuse. The effects of acidosis on pregnancy outcome are concerning. Maternal acidemia has been shown to decrease blood flow and oxygenation, which can compromise fetal development. While a reversible complication, renal tubular acidosis can result in hypokalemia, hypophosphatemia, hypomagnesemia, hypocalcemia, and rhabdomyolysis. Chronic use can result in neurotoxic damage with cerebellar degeneration and cortical atrophy. Hypokalemia and hypophosphatemia can result in debilitating muscle weakness. Further, hypokalemia may also result in cardiac arrhythmias. Hypomagnesemia can result in severe hypocalcemia and a related parathyroid hormone suppression (62).

While it is possible to identify a pregnant woman who abuses inhalants and to characterize the detrimental effects of the abuse on her and her child, treatment interventions to reduce or eliminate such abuse are needed. To the best of our knowledge, there are no specific treatments for pregnant women who abuse inhalants. Specific to pregnant women, ensuring prenatal care attendance and regular assessment for preterm labor, fetal growth, and renal tubular acidosis seems especially important for these pregnant women. Currently,

there are no medications or treatments that reverse acute solvent intoxication.

In terms of the neonate, there have been reports of a neonatal withdrawal following prenatal exposure to abused solvents (63). However, standardized measures to evaluate such withdrawal are lacking. It might be expected that mothers showing signs of intoxication at delivery should have neonates monitored for alcohol-like withdrawal signs, so that appropriate intervention can be provided to the neonate.

MARIJUANA

Effects of Prenatal Exposure to Marijuana on the Fetus and Neonate

Reports and studies of the effects of in utero exposure to marijuana have shown modest and inconsistent effects. For example, of five reports that include prospective and retrospective studies using a combination of methods to determine marijuana exposure, only one showed a significant effect on birth outcomes (64). A prospective study characterizing prenatal marijuana exposure showed significant effects on birth weight adjusted for gestational age and length at birth (65). In contrast, the IDEAL study demonstrated that marijuana use was not significantly related to the examined fetal growth parameters of gestational-age adjusted birth weight and being SGA (66).

Interestingly, several studies have reported a mixture of negative and beneficial effects of in utero exposure to marijuana even in those studies that controlled for maternal weight gain due to marijuana's appetite stimulant effects. For example, a prospective study of prenatal marijuana exposure during gestation showed a modest but significantly negative effect of marijuana use during the first trimester of pregnancy on birth length, yet an average increase of 139 g in birth weight in women reporting one or more marijuana joints per day in the third trimester (67).

Information for Clinicians Regarding Marijuana Exposure During Pregnancy

While the majority of the evidence supports minimal to no effects associated with prenatal exposure to marijuana on birth outcomes, the literature is limited by methodologic challenges such as reliance on self-report, few prospective studies assessing exposure over the entire pregnancy, and controlling for multiple environmental and individual factors that could relate to the outcomes observed (64).

Although the current literature does not support a consistent negative pattern of effects on birth outcomes following prenatal exposure to marijuana, this absence of evidence should not be taken as reassurance that prenatal exposure to marijuana is without risks. There is accumulating evidence showing that the endocannabinoid system plays a major role in CNS patterning. This patterning occurs in areas that are relevant for mood, memory, and reward. A recent review suggested a possible association with in utero marijuana exposure

and genetic changes of neural systems that are relevant to endocannabinoid function (68).

There are also data to support the conclusion that prenatal marijuana exposure has a negative relationship with executive functioning which is largely mediated by the prefrontal region of the brain which develops somewhat later in childhood maturation (69).

Like other substances that have been discussed in this chapter, there are tools to detect the presence of marijuana in multiple biologic matrices. The window of detection of the presence of marijuana in the mother during pregnancy and/or the neonate at birth may be somewhat longer compared to the other substances that are abused. As of yet, treatment interventions (behavioral, medication, or a combination of the two) to reduce or eliminate marijuana use during gestation are lacking. To the best of our knowledge, there are no specific behavioral or medication treatments that have been designed and/or have evidence to support their use in pregnant women.

NICOTINE/TOBACCO PRODUCTS

Effects of Prenatal Exposure to Tobacco Products on the Fetus and Neonate

Like alcohol, considerable attention has focused on characterizing and understanding the adverse effects on children born to mothers who smoke cigarettes or use other nicotine-containing products during pregnancy. The rates of cigarette smoking women who continue to smoke cigarettes after finding out that they are pregnant decreased in the United States for several decades and have now plateaued. Women who smoke cigarettes during pregnancy are more likely to be younger, single, have less academic success and/or employment stability, and depend on governmental medical assistance compared to their nonsmoking counterparts (70). Women who continue to smoke cigarettes and/or tobacco products during pregnancy are more likely to have spontaneous abortions, ectopic pregnancies, premature rupture of membranes, placenta previa, placenta abruption, fetal growth restriction, preterm birth, and SIDS relative to women who do not smoke during pregnancy (71,72). The adverse effects of secondhand smoke are also evident with increases in the risk for SIDS and infant respiratory distress (see Pauly & Slotkin (70) for a review).

While the exact mechanisms underlying the negative prenatal and neonatal effects of smoking have yet to be elucidated, it is known that nicotine binds to nicotinic acetylcholine receptors (nAChRs). These receptors are ligand-gated ion channels that are present throughout the fetal nervous system. Pre-clinical studies have shown that nicotine and its activation of nAChRs results in alterations in neuronal activity and life. However, the presence of other chemicals in addition to nicotine makes it difficult to disentangle the in utero effects of nicotine relative to the other chemicals in human exposures (73).

The negative effects associated with prenatal tobacco exposure during pregnancy have been reported to extend from the neonatal period into adolescence. A recent review on this topic concluded that prenatal tobacco exposure is associated with

negative effects in infancy (e.g., attention levels, self-regulation ability), childhood (e.g., inattention and externalizing behaviors), and adolescence (attention deficit hyperactivity disorder and nicotine dependence (74)).

Information for Clinicians Regarding Tobacco Exposure During Pregnancy

Given the negative effects on both mother and fetus associated with prenatal exposure to tobacco products, there is a need to examine the current treatments for tobacco cessation in pregnant women.

The cessation of cigarette use during pregnancy can result in beneficial effects, with quitting smoking as late as the last trimester resulting in a near normal–birth weight infant (75). Currently, uncertainty exists about the use of nicotine replacement therapy during pregnancy given the modest ability of these medications to achieve smoking cessation in pregnant women while also minimizing harm to the fetus and children exposed to these type of medication (70). Other medications such as bupropion, which acts to inhibit the presynaptic reuptake of dopamine and norepinephrine, may hold promise for reducing both smoking and depression, which is a frequent comorbid disorder found in pregnant smokers.

Given that any medication has some associated risk, and definitive efficacy and safety data are lacking for medication treatments, behavioral interventions should be the first line of treatment for smoking cessation during pregnancy. One of the most promising interventions for reducing tobacco use in pregnant women is voucher-based reinforcement therapy that is delivered contingent upon smoking abstinence. This intervention has been shown to effectively reduce cigarette smoking and improve fetal growth (76). However, the optimal choice of treatment for cigarette smoking during pregnancy depends on multiple factors including the patient's desire for a particular treatment, her previous treatment response, and any patient-specific medical precautions/contraindications (77).

BENZODIAZEPINES

Benzodiazepines are among the most frequently prescribed medications to pregnant women. Commonly prescribed benzodiazepines are diazepam (Valium); alprazolam (Xanax); lorazepam (Ativan); clonazepam (Klonopin); and chlordiazepoxide (Librium). Benzodiazepines affect the inhibitory neurotransmitter gamma-aminobutyric acid (GABA) and appear to act on the limbic, thalamic, and hypothalamic levels of the CNS to produce sedative and hypnotic effects, reduction of anxiety, anticonvulsant effects, and skeletal muscle relaxation (78).

Effects of Prenatal Exposure to Benzodiazepine on the Fetus and Neonate

The only benzodiazepine that has been systematically studied among pregnant women is diazepam. Initial reports found an increased incidence of cleft lip and cleft palate with exposure

to diazepam during pregnancy, but prospective studies do not support these findings and most reviewers have concluded that diazepam is not teratogenic (78).

Neonatal abstinence syndrome has been reported for infants with prolonged interuterine exposure to diazepam with symptoms closely resembling opioid withdrawal (79). Symptoms include hypertonia, irritability, abnormal sleep patterns, inconsolable crying, tremors, bradycardia, cyanosis, poor sucking, apnea, diarrhea, vomiting, and risk of aspiration of feeds (78). If treatment is indicated, phenobarbital is the recommended medication (24).

Information for Clinicians Regarding Benzodiazepine Exposure During Pregnancy

While benzodiazepine use during pregnancy may be indicated for treatment of specific medical problems, they have a high potential for abuse when used with other depressants such as alcohol and opioids. Benzodiazepine dependence is one of the major challenges faced by clinicians providing methadone maintenance for opioid dependence and it is especially problematic in the treatment of pregnant women. The abuse of benzodiazepines in methadone maintained patients has the potential to increase the CNS depressant effects of methadone and as such is considered a risk factor for fatal overdose. Exacerbating this risk is that abuse of benzodiazepines is associated with poor psychological functioning and less reduction in illicit drug use (80). Management of benzodiazepine use is further complicated both by the potential for seizures in rapid withdrawal and by patient resistance to a benzodiazepine taper due to fear of seizures. Withdrawal from benzodiazepines should be conducted by a prolonged gradual taper accompanied with extensive psychological support.

Infants born to women maintained on methadone who use/abuse benzodiazepines require significantly longer treatment for neonatal abstinence than infants born to methadone maintained women who do not use benzodiazepines (28). Effective management of the abstinence is made more difficult because of possible delayed onset of benzodiazepine withdrawal, which can occur as late as 12 to 21 days after birth. In addition, opioids used in the treatment of neonatal abstinence have no effect on withdrawal from a nonopioid. While phenobarbital is recommended as a drug of choice for nonopioid related withdrawal (19,24), the optimal treatment for infants with concomitant opioid and benzodiazepine withdrawal is not known (28).

Breast-feeding is contraindicated for mothers using diazepam as diazepam has the potential to cause lethargy, sedation, and weight loss in infants. There is little data on breast-feeding while taking alprazolam but based on available evidence of a case report and a cohort study of five cases, caution is indicated. No adverse effects have been reported with the use of lorazepam or chlordiazepoxide during breast-feeding (78). However, as previously discussed, breast-feeding is contraindicated with any illicit drug use, and in the case of misuse of prescription drugs it would be prudent to follow this same guideline.

HALLUCINOGENS

Hallucinogens, including LSD, Peyote, and PCP/Phencyclidine, all cause serious negative psychological effects and because of their erratic nature their use can be dangerous (e.g., “bad trips” and flashbacks associated with LSD use, and seizures and coma associated with high doses of PCP). Despite severe adverse outcomes related to these drugs, there is very little data on their effect in pregnant women. The limited data that exist include a few small retrospective studies, case reports, and one prospective study examining perinatal outcome associated with maternal PCP use.

Effects of Prenatal Exposure to PCP on the Fetus and Neonate

In a study that screened over 2000 pregnant women for PCP use early in pregnancy, a verbal history of use was reported by 149 pregnant women and current use documented by urine drug screens was identified in 23 pregnant women. Data collection was completed for 94 study patients, including 14 with confirmed current use, and 94 matched controls. The control group was unique from most studies in that they differed from the study group only in PCP use and the mean number of other drugs used; both groups frequently abused marijuana, cocaine, barbiturates, alcohol, and glue. Significantly more abnormal neurobehavioral findings, that is, decreased attention and depressed neonatal reflexes, were associated with maternal phencyclidine use, both in the sample which included all users and the subsample of confirmed users. Moreover, multiple regression analyses showed the number of abnormalities was related to PCP use and not other drugs. No significant relationships were found between abnormal anatomic findings and maternal PCP use. The authors qualify their results with the caution that while this study suggests PCP is not an anatomic teratogen, it does not confirm it (81). The abnormal neurobehavioral findings are consistent with a case study that reported two infants whose mothers used PCP during pregnancy to have symptoms similar to opioid withdrawal, that is, jitteriness, hypertonia, and hyperreflexia (82).

Information for Clinicians Regarding PCP Exposure During Pregnancy

As with most of the drugs discussed in this chapter, there are no specific treatment interventions to reduce or eliminate PCP use during pregnancy. As reported by Golden et al. (81), pregnant PCP users were characterized as using multiple drugs so general behavioral drug treatment interventions should be utilized.

For infants who exhibit moderate to severe CNS hyperirritability, treatment with phenobarbital is suggested (24). Breast-feeding is contraindicated as PCP has been found in breast milk (42).

SUMMARY

As previously discussed, information for each class of drug was presented independently for purposes of organization but most pregnant women with a substance use disorder use/abuse multiple drugs. There are numerous iterations of combinations, for example, opioid-dependent women may use and/or be dependent on cocaine, alcohol, marijuana, and/or benzodiazepines, cocaine users typically use and/or are dependent on alcohol and/or marijuana and opioids, methamphetamine users may also use alcohol and marijuana, and a large majority who use illicit drugs smoke cigarettes. The use of multiple drugs may have additive or synergistic effects on both the mother and neonate.

It is also important to understand that while the focus of this chapter is on the use of alcohol and other drugs during pregnancy, the substance use almost always precedes the pregnancy. All too frequently, the situation reflects a woman with a chronic substance use disorder who becomes pregnant, and thus brings to the pregnancy multiple bio-psycho-social problems that may impact on the health and well being of both her and her child.

As such, the effect of drug use during pregnancy is often confounded by numerous factors including multiple drug use, psychiatric comorbidities, exposure to violence and victimization, lack of prenatal care, poor nutrition, and living in an impoverished community. Attention to the use of drugs during pregnancy should be viewed within the context of multiple risks, the need to eliminate vulnerabilities, stigma and prejudice, and to the need to provide comprehensive care to promote a healthy outcome for both mother and child.

Medical Complications of Drug Use/Dependence

Joshua D. Lee ■ Jennifer McNeely ■ Marc N. Gourevitch

Medical illness takes a heavy toll among drug users. Four principal factors contribute to drug users' higher risk for many medical conditions. Direct toxicities of illicit drugs are responsible for a wide variety of medical sequelae (e.g., cocaine-related cardiotoxicity). Behaviors associated with drug use (injection, exchanging sex for money or drugs) place drug users at elevated risk for specific conditions (such as endocarditis and sexually transmitted diseases [STDs]). Socioeconomic disadvantage and poverty engender life circumstances (e.g., congregate housing) that confer increased environmental risk for infections such as tuberculosis. Finally, diminished access to and effective use of care, and disruption of daily routines by active drug use (impeding self-care behaviors such as adherence with medication or appointments) adversely affect clinical outcomes.

This chapter begins by reviewing general principles of care for drug users with medical conditions, with additional attention to issues of overlapping syndromes, medication adherence, and prevention of common complications. We then review a range of specific illnesses associated with injection drug use (IDU) and with noninjection use of heroin and cocaine. Medical syndromes associated with acute use of specific drugs (e.g., intoxication, overdose, and withdrawal) are covered elsewhere in this volume.

CARE OF DRUG USERS WITH MEDICAL CONDITIONS

The Doctor–Patient Relationship and Principles of Care

To gather from patients the information needed to provide effective care, the relationship between patient and clinician must be grounded in trust. This may take time to establish, and is fostered by the physician's adoption of a nonjudgmental, engaged stance. Shame and diminished self-esteem are prevalent traits among drug users. Physicians should avoid critical remarks regarding ongoing drug use, as patients often respond by withholding clinically important information they think might provoke such reactions in the future.

Like other chronic illnesses, substance use is a persistent condition typically characterized by exacerbations and remissions. Clinicians are generally comfortable managing exacerbations of other chronic diseases and familiar with strategies to induce remission or to slow progression of diseases they

cannot cure. When a drug user resumes drug use after a period of abstinence, however, clinicians often become discouraged or angry. Clinicians who accept relapse as a common clinical presentation of drug use, and who are aware of available treatment options, are likely to remain more successfully engaged with the drug-using patient, enhancing the quality and continuity of care provided.

The issue of confidentiality frequently arises when caring for the drug-using patient. A direct approach is most effective here as well. When the physician is part of a larger treatment team with the common expectation that patient data will be shared among team members, such an arrangement is best made clear to the patient toward the beginning of the relationship. Splitting and perceived betrayal can thereby be minimized. The physician must be familiar with the laws governing confidentiality of patients' substance abuse behaviors and treatment. Appreciation of this issue by the treating clinician will enhance development of trust in the clinician by the patient.

To engage the patient most effectively, the provider must determine and address the patient's agenda. While the clinician may be eager to bring a patient's hypertension under control, the patient may be more concerned about his insomnia. By inquiring about and addressing the primary concerns of the patient, the clinician reveals interest in helping the patient, who may in turn be more open to working with the physician to address medical conditions that are of less immediate concern to the patient.

Inquiring in a nonjudgmental fashion about concurrent drug use should be routinely performed at most, if not all, visits. Type of substance, frequency of use, and route of administration are particularly important to ascertain. When examining the drug-using patient, attention should be focused on the systems directly affected by the substances the patient is known to use, while not neglecting evidence of use of other drugs. Special attention should be paid to the presence of a variety of signs. Injection ("track") marks may be recent (appearing as fresh punctate marks, often with mild surrounding erythema) or old (linear scars representing the confluence of multiple past injection sites). They are found wherever veins are accessible, most often in the antecubital fossae, on the forearms, hands, and legs, and less commonly in the neck and groin. Lymphedema of the hands, fresh or old healed abscesses, and cellulitis are common among current or former injectors. A cardiac murmur consistent with mitral

or tricuspid regurgitation may suggest a past or current history of endocarditis. The nasal septum should always be examined for erosion or infection, suggesting intranasal drug use.

Drug users, often heavy users of the health care system, typically receive fragmented care. For example, a patient's substance abuse treatment, human immunodeficiency virus (HIV)-related care, general primary care, and psychiatric care may each be delivered by distinct providers at distinct sites. Integrating care improves health care outcomes, and should be a goal of service delivery (1,2). The more information the physician has on hand regarding the components of a patient's care, the greater the chances that medication interactions or complications from overlapping medical and psychiatric comorbidities will be averted. It is incumbent on the clinician to inquire about concurrent drug use and related treatment, new medications, and new diagnoses when patients receive care in more than one location. Effective integration of drug use-related and general medical care can be achieved through a variety of models (3,4).

Overlapping Symptoms and Syndromes

A clinical challenge that arises when assessing and caring for the drug-using patient is distinguishing symptoms and signs related to drug use itself from those of comorbid medical and psychiatric conditions.

Constitutional symptoms, while frequently related to drug use and withdrawal, may also reflect systemic illness. Thus, fever after drug injection may reflect use of an impure drug mixture or the first sign of endocarditis. Myalgias, chills, nausea, vomiting, and diarrhea—all hallmarks of withdrawal from narcotics and alcohol—may likewise reflect gastroenteritis or another infectious process, or the side effects of interferon treatment for hepatitis C infection. Weight loss, commonly associated with heavy cocaine use, must also prompt consideration of systemic infection (e.g., tuberculosis), malignancy, or HIV infection. Dyspnea in the crack smoker may be caused by chronic pulmonary dysfunction related to drug inhalation, or to asthma, or to community-acquired or HIV-related pneumonia. Seizures may occur in the context of drug withdrawal (e.g., alcohol or benzodiazepines) or as a result of prior trauma or intercurrent infection. The same principles apply to the overlap between many psychiatric syndromes and syndromes of intoxication or withdrawal.

Adherence

Studies of adherence among drug users have focused largely on adherence to antiretroviral therapy among HIV-infected drug users. Though lack of adherence to treatment recommendations is widespread in the general population, particular emphasis has been given to defining correlates of adherence among substance users, reflecting a general sense that substance users may have difficulty adhering to medical treatments, and concern that poor adherence among persons

with HIV infection will foster development and transmission of resistant virus (5,6).

Active drug or alcohol use has been identified as one of the few relatively consistent predictors of poor adherence, and this is particularly true for cocaine users (7). However, past history of drug or alcohol abuse has not been consistently associated with poor adherence, and a number of studies have found that persons no longer actively using drugs, as well as some active users, are able to adhere to antiretroviral therapy with success comparable to that of nonusers. For both active and former substance users, engagement in substance use treatment, particularly if on-site primary care is available, seems to facilitate access and adherence to HAART (highly active antiretroviral therapy) and other medical therapies (4). Untreated depression is strongly associated with poor adherence (8).

Interactions between medications and methadone can pose a unique barrier to adherence among drug users receiving methadone treatment. It is critical that such interactions be identified in clinical practice, as precipitation of opioid withdrawal by an antiretroviral agent that induces methadone metabolism may result in resumption of heroin use or non-adherence with the medication that is causing (or perceived to be causing) the interaction (9). Salient examples of medications that precipitate clinically significant increases in cytochrome P450-mediated methadone metabolism include the nonnucleoside reverse transcriptase inhibitors efavirenz and nevirapine, the tuberculosis antibiotic rifampin, and the anticonvulsant phenytoin. Though much less common, medications such as fluoxetine that inhibit methadone metabolism can precipitate oversedation and, theoretically at least, overdose. As a rule, it is important to remain alert to possible interactions between methadone and antiretrovirals or other medications; this is reviewed extensively elsewhere (see Chapter 53 in this volume) (10).

Assessing adherence in clinical settings can be challenging. Despite its tendency to overestimate adherence, self-report remains the most practical measure, and is most likely to facilitate discussion between patients and providers about the reasons for nonadherence. Self-report appears most valid when patients are asked about the number of missed doses within a short time frame (1 to 7 days), and when assessments are gathered on more than one occasion and responses are averaged over time. Clinicians' estimates of patient adherence have been repeatedly shown to be inaccurate and should not be substituted for a thorough adherence assessment.

Prevention of Complications

Disproportionate emphasis is often placed on drug treatment over prevention of the potential adverse consequences of use. Harm reduction takes a different approach, placing priority on minimizing the negative sequelae of drug use and promoting healthy behaviors, and acknowledging that abstinence may not be an immediate goal for all patients. This is similar to the way that physicians treat other chronic diseases,

such as diabetes, hypertension, and HIV. The goal is to minimize adverse consequences associated with the condition—in this case, illicit drug use. Despite the fact that a “cure” (i.e., sustained abstinence) may not be a realistic near-term solution for many drug users, much can still be done to minimize the impact of drug use on the patient’s health. In creating the opportunity for patient and provider to work together toward meaningful and achievable behavioral change, this approach can be more effective and engaging for patient and provider alike.

Harm reduction interventions can encompass a wide range of activities, from basic medical care, to social work and mental health services, to instruction in safer injection techniques. Cornerstones of the harm reduction approach are interventions that address major causes of morbidity and mortality among drug users, namely IDU, overdose, and sexual risk behavior.

Injection Drug Use

Injection drug use (IDU), through the use of shared injection equipment, remains an important driver of the HIV/AIDS and hepatitis C virus (HCV) epidemics. Over one third (36%) of AIDS cases in the United States, and the majority of cases among women, can be attributed directly or indirectly to IDU (11). HCV is the most common blood-borne infection in the United States, and IDU is the leading risk factor for transmission (12). The majority of these infections can be prevented through the once-only use of syringes and other injection equipment, as recommended by the U.S. Department of Health and Human Services (13). Though rates of new HIV infections have decreased among IDUs, largely as a result of increased access to sterile syringes, education, and resultant changes in injection behaviors, access to clean injecting equipment remains a challenge for many users (14). For health care and other treatment providers, providing counseling on the importance of once-only use of syringes and assisting clients with access to sterile syringes are essential components of preventive care for IDUs, and present opportunities for improved communication and establishment of trust between patient and provider.

While there is state-by-state variation in laws, syringes may be legally obtained by three methods: over-the-counter purchase, prescription, and through syringe exchange programs (SEPs) or authorized agencies (15). Each of these options has advantages and disadvantages, and different methods may be preferred by different groups of IDUs. Syringe exchange is the most widely studied, with effectiveness in reducing the spread of HIV demonstrated in multiple studies and federal government reviews (16). Syringe exchange is legal in many states, and there are now about 200 programs operating in 38 states and territories of the United States (17). Despite a 21-year ban on U.S. federal funding, (finally lifted at the end of 2009), many SEPs have been supported by state and local government funds, as well as private charity. Yet the effectiveness of the SEP approach is limited by lack of accessibility, with limited locations and hours of operation. Pro-

viding sterile injection equipment in pharmacies, either over the counter or by prescription, offers a potential solution, but may also be limited by cost, availability, and an individual’s reluctance to disclose that they are engaged in IDU.

Overdose

Drug overdose is a leading cause of death among young adults, second only to motor vehicle accidents in deaths due to unintentional injury (18). In 2005, the latest year for which data are available, there were over 22,000 drug overdose deaths, far exceeding the number of deaths due to homicide in the United States (19). In recent years drug overdose deaths have risen dramatically, increasing by 68% between 1999 and 2004 (18). This increase is primarily attributed to deaths caused by use of potent prescription opioid analgesics, while deaths due to heroin and other illicit drugs have remained essentially stable.

Nonetheless, drug overdose remains common among illicit drug users. The overall mortality rate among out-of-treatment drug users is exceedingly high; six times that of an age-matched sample in a recent British study, which found that the majority (68%) of these deaths were attributable to overdose (20). A New York City study found that over 57% of users interviewed had witnessed at least one drug overdose, and over half knew someone who had died of an overdose (21).

While rates are increasing among adolescents and young adults, the 25- to 44-year age group is at greatest risk for fatal drug overdose. While less is known about overdose among prescription drug users, among heroin users it appears that long-term injectors are at greatest risk, particularly when using opioids in combination with benzodiazepines or alcohol (22). Returning to use after a period of opioid abstinence (and subsequent decreased tolerance), such as following an episode of drug treatment or incarceration, is associated with a significantly increased risk of overdose. Older users, and particularly those with other medical problems, are also at high risk for fatal overdose (22).

Overdose deaths can be prevented, and health care and other service providers working with substance users, particularly opioid users, have important contributions to make toward this goal. Persons leaving substance abuse treatment or incarceration should be educated about overdose risk, particularly that associated with potent or long-acting prescription opioids and using opioids in combination with alcohol, sedatives, and cocaine. In many U.S. cities (e.g., New York City, San Francisco, Baltimore, Chicago, Pittsburgh), and some rural areas (e.g., Wilkes County, North Carolina), service providers are distributing naloxone to drug users and teaching them how to administer it in case of opioid overdose. Naloxone (“Narcan”) is a potent opioid antagonist commonly used medically to reverse opioid overdose. It can be administered as an intramuscular injection or intranasally, and has a favorable safety profile with essentially no abuse potential. Evaluation of the New York City program showed that distribution and administration to IDUs is feasible and safe, and

indicated that such programs may be able to reduce overdose deaths on a larger scale (23).

Sexual Risk Behavior

Because of the disinhibiting effects of many drugs, the stimulant effects of others, and the relationship of drug procurement to risky sexual behavior, substance users are also at higher risk for sexually transmitted diseases (STDs), including HIV. Substance users are more likely to encounter circumstances where they have less authority over their sexual activity, because of engagement in commercial sex work, exchange of sex for drugs, and intimate partner violence (24).

Stimulant use is associated with increased sexual risk behavior among heterosexuals as well as men who have sex with men (MSM) (25). It is strongly correlated with HIV incidence among MSM, with users of methamphetamine and crack cocaine reporting higher numbers of sexual partners and exchanging sex for drugs or money, and those who use drugs during sex being more likely to engage in unprotected intercourse and other high-risk sexual behaviors (26,27). Binge alcohol use is also an important, but sometimes overlooked, factor in high-risk sexual behavior (28). Injection drug users also remain at high risk for sexual spread of HIV, with the majority (63%) reporting unprotected vaginal sex and almost half (47%) having more than one sexual partner (29).

Providers working with active substance users should always ask about high-risk sexual activity and screen for past or current intimate partner violence. Substance users should be counseled on the importance of condom use and other safe sex practices for prevention of HIV and other STDs, and engaged in discussion of the risks of sexual activity under the influence of alcohol and other drugs. Screening for intimate partner violence and regular testing for HIV and STDs is recommended for all substance users (further discussed below).

Immunization

Active substance users are at high risk for a number of vaccine-preventable infections. Substance users should receive annual vaccination against influenza. Tetanus booster vaccination every 10 years is recommended for the general population, and should be strictly observed for IDUs given the association of tetanus with IDU. Pneumococcal vaccination is recommended for individuals with unhealthy alcohol use, HIV, and other chronic conditions (including heart, lung or liver disease, diabetes, sickle cell disease), and thus is indicated for many substance users. All illicit drug users who lack immunity to hepatitis A should be vaccinated. Hepatitis B vaccination is explicitly recommended for IDUs, and the Centers for Disease Control and Prevention (CDC) guidelines recommend universal vaccination of adults attending drug treatment, STD clinics, correctional facilities, and other settings serving populations at high risk for infection. HAV and HBV vaccines are further discussed in the section “Viral Hepatitis” below.

CARDIOVASCULAR DISEASE AND CANCER: CONFLUENT RISKS AND ASSOCIATED OUTCOMES

Leading Health Indicators

The leading causes of mortality in the United States are heart disease and cancer, which together account for nearly half of all deaths annually (30). Stroke (cerebrovascular diseases, 6%), chronic lower respiratory diseases including COPD (5%), and accidents (5%) complete the top five causes of death. Each of these conditions are strongly associated with addictive disorders, with tobacco and alcohol making the greatest contribution overall but drugs such as opioids, cocaine, and amphetamine taking a heavy toll as well. A recent study estimated that tobacco smoking was the leading modifiable risk factor for mortality, outstripping hypertension, diet, exercise, and being overweight, and accounting for approximately 467,000 (or 1 of every 5 to 6) deaths, while alcohol resulted in a net 64,000 excess deaths annually (31). Globally, disease burdens linked to tobacco are projected to increase (32).

Cardiovascular Disease

Tobacco and Cardiovascular Disease

Tobacco control efforts are based on well-understood causal associations between smoking and both heart disease as well as malignancy. For the most part, tobacco addiction prevention and treatment takes place largely outside of the domain of the traditional addiction treatment delivery system. The importance of addressing smoking cessation among patients presenting with other substance use disorders cannot be overstated, as the comorbidity of tobacco dependence with alcohol, opioids, and stimulant abuse and dependence is exceptionally high (33).

Nicotine, the principal addictive component of both inhaled and smokeless tobacco, is a CNS stimulant and associated with increases in blood pressure and heart rate. Nicotine itself, however, has not been clearly implicated as a cause of atherosclerosis, lipid abnormalities, sudden cardiac death, or stroke in humans (34–36). Consistent with this finding is the fact that nicotine replacement therapy (NRT) has not been linked to increased CVD events or death. Rather, NRT is a mainstay of secondary CVD prevention among smokers following myocardial infarction or other cardiac events (37,38). Nicotine, then, is the compound within tobacco products that by virtue of its addictive properties drives repeated exposure to the over 4000 known components in cigarette smoke including carbon monoxide and free-radical-promoting volatile chemicals (34,39). The cumulative effect of cigarette smoke compounds on the chronic user is an intravascular environment of hypoxia, inflammation and decreased immune function, abnormal lipid metabolism, and platelet, thrombotic, and vasomotor dysfunction, all of which act synergistically to initiate and promote atherothrombotic disease progression.

Smoking cessation and sustained abstinence are thus critical CVD risk reduction goals. Nurses' Health Study data indicate that women who quit smoking may reduce CVD mortality risk to that of never-smokers within 10 to 14 years of quitting, and all-cause mortality to normal levels within roughly 20 years (40,41). The impact on individuals' risk profiles of reducing the quantity of cigarettes smoked but continuing to smoke is less clear (42,43).

Alcohol and Cardiovascular Disease

Unique among addictive substances, alcohol relates to CVD risk and mortality in a "J"- or "U"-shaped fashion. Multiple large epidemiologic studies have observed a similar relationship: moderate alcohol use is protective against cardiac events including myocardial infarction and stroke compared to no use, while excessive, chronic use is clearly harmful. Among the general population, moderate alcohol use, defined as ≤ 2 drinks/day (men)/ ≤ 1 drink/day (women), when previously established and in the absence of alcohol or other addictive disorders, may be considered a component of a healthful "lifestyle." Persons coping with alcohol and other drug use disorders, however, can be unequivocally counseled toward abstinence, as failure to control daily drinking promotes precursors, particularly hypertension, and eventual CVD and death. On balance, roughly 90,000 deaths in the United States (2005) can be attributed to alcohol including those due to CVD, compared to 26,000 deaths from CVD, stroke, and diabetes averted due to moderate alcohol use (31).

The cardioprotective effects of moderate alcohol use appears to reflect increased high density lipoproteins (HDLs), vasodilation and lowered blood pressure, enhanced insulin sensitivity and with it lowered risk for hyperglycemia and diabetes, and reduced risk of inflammation, thrombosis, and arrhythmias. In contrast, chronic, heavy alcohol use fosters a maladaptive hyperautonomic state marked by catecholamine up-regulation and hypertension, promotion of thrombosis and arrhythmias, lipid dysregulation, insulin resistance and diabetes, and direct myocardial toxicity that can result in alcoholic cardiomyopathy and heart failure. Risks extend to binge drinking as well, a risk factor (as is daily heavy drinking) for atrial fibrillation.

Cocaine, Stimulants, MDMA, and Cardiovascular Disease

Cocaine is a clear cardiotoxin and proarrhythmic agent, and any level of use is associated with increased risk of CVD, sudden cardiac death, and stroke. Among persons 18 to 45 years of age in the United States, cocaine accounts for up to 25% of acute myocardial infarctions (44). Despite this high population-attributable risk, cocaine-associated myocardial infarctions occur in only 1% to 6% of patients who present to emergency departments with cocaine-associated chest pain (45,46). Although all cocaine users are at risk, most patients with cocaine-associated myocardial infarction are young, nonwhite, male, cigarette smokers, without other risk factors for atherosclerosis, and with a history of repeated cocaine use. Only half of such

patients have evidence of atherosclerotic coronary artery disease on subsequent angiography (47).

The most common medical symptom associated with cocaine use is chest pain, which may reflect myocardial ischemia or infarction. Cocaine use increases the risk of acute myocardial infarction by several mechanisms, including coronary vasoconstriction or vasospasm, increased adrenergic activity (which intensifies myocardial oxygen demand by increasing blood pressure, ventricular contractility, and heart rate), and increased platelet adhesion, aggregation, and intravascular thrombosis (48,49). In one recent study, users of cocaine had a transient 24-fold increase in the risk of myocardial infarction in the hour immediately following cocaine use (50). The occurrence of myocardial infarction after cocaine use is unrelated to the quantity ingested, route of administration, or blood levels of cocaine or its metabolites (49,51). In addition to acute myocardial ischemia and infarction, cocaine use is linked to dissection of the thoracic aorta and coronary arteries, cardiac rhythm and conduction abnormalities, left ventricular dysfunction, dilated cardiomyopathy, hypertension, and tachycardia. Cocaine use may be a stronger independent risk factor than other drugs for endocarditis, particularly involving left-sided valves (52).

Cocaine, amphetamine, methamphetamine, and MDMA intoxication can all be marked by tachycardia, hypertension, chest pain, arrhythmias, myocardial ischemia, infarction, and sudden death. Though longitudinal observational data linking stimulant abuse or dependence to CVD is lacking, it is likely that chronic stimulant dependence heightens the risk of atherosclerotic heart disease, cardiomyopathies, and sudden death from arrhythmias and infarction (53).

Opioids, Cannabis, and Cardiovascular Disease

Opioid- and cannabis-dependent populations are at higher risk for ischemic heart disease, largely reflecting comorbid tobacco and alcohol dependence. Injection use of opioids, and resulting embolic and infectious complications, including endocarditis, also poses obvious cardiac risks. Methadone, the opiate agonist used in the pharmacotherapy of opioid dependence, has been associated in some patients with prolongation of the QTc interval on the electrocardiogram and uncommonly with ventricular arrhythmia (torsade de pointes). Other data hint at a potential cardioprotective effect of long-term exposure to opiates (54). Isolated cannabis use and dependence have not been clearly linked to excess mortality or CVD, and most longitudinal cohort studies linking cannabis smoking to heart disease are confounded by tobacco use (55).

Management of Ischemic Heart Disease in Persons with Substance Abuse

In persons with substance abuse or dependence, care for hypertension, lipid disorders, diabetes, and heart disease is best addressed in concert with individuals' addiction treatment. Lack of engagement in substance abuse treatment should not, however, preclude careful attention to and care of these comorbid medical conditions.

Regarding modifiable risk factors, all adults should be screened for hypertension, high cholesterol (men age ≥ 35 , women age ≥ 45 with no other risk factors), and excess weight, with diabetes screening recommended for adults with blood pressure of $\geq 135/80$ mm Hg (56). A low-salt, high-fiber diet and regular exercise are beneficial both as primary and secondary CVD prevention. Men ≥ 40 years, postmenopausal women, and those with CVD risk factors including smoking should consider daily aspirin therapy. Smoking cessation, elimination of unhealthful alcohol use, and avoidance of cocaine and other stimulants are clearly of particular importance among patients with drug abuse or dependence.

Hypertension control should be focused on reaching and maintaining a “goal blood pressure” of below 140/90 mm Hg, or lower ($<130/80$ mm Hg) in the setting of diabetes, proteinuric chronic kidney disease, or known CVD. Treatment should follow national guidelines (57). Of note, clonidine, a central alpha-2-agonist and oft-encountered antihypertensive medication among addicted persons, is not appropriate as monotherapy for hypertension due to lack of efficacy, the need for twice daily dosing, reports of its abuse as a sedative, and the risk of potentially fatal rebound hypertension.

While primary CVD prevention in the form of cholesterol lowering is of modest benefit to those with this single modifiable risk factor, the benefit to those with known CVD or multiple risk factors can be quite substantial. Statin therapy, the cornerstone of lipid management, has consistently reduced CVD events and total mortality in large randomized control trials. Fibrate and nicotinic acid therapies are generally less well tolerated but are also effective. Antiplatelet and antithrombotic therapy is recommended both as primary prevention (aspirin) and following an ischemic event (aspirin, clopidogrel). The increased risks of major bleeding must be taken into account among those with platelet dysfunction, bleeding disorders, liver failure, or other predisposing conditions, such as gastric ulcers, all of which are more common in alcohol-dependent patients.

Cancer

Tobacco and Lung Cancer

Unlike cardiovascular disease or other common cancers (e.g., breast or colon cancer), in which a constellation of modifiable factors such as weight, blood pressure, and diet combine with tobacco dependence to heighten disease and mortality risk, lung cancer has cigarette smoking as by far its most important cause. This is true of both non-small-cell (85% of all lung cancers; includes squamous cell and adenocarcinoma) and small-cell (15%) tumors (58). Lung cancer is the leading cause of cancer death in the United States (158,664 deaths in 2006) and globally, and lung cancer incidence and death rates closely follow geographic variations in smoking rates (59). This reflects a lack of effective lung cancer screening mechanisms, as well as persistently poor rates of remission and survival following diagnosis. The importance of primary prevention, centering on tobacco control efforts, cannot be overstated. Unlike CVD, in which

smoking cessation is an important component of treatment and secondary prevention, there are few second chances following a lung cancer diagnosis. Five-year survival in the United States following a diagnosis of any lung cancer remains quite low (around 15%), with little improvement over the last 40 years.

Generally, lung and other cancers evolve as cumulative environmental exposures interact with genetic susceptibility. Over time, direct tissue injury from tobacco smoke promotes premalignant genetic mutations and tissue changes including dysplasia, clonal patches, and angiogenesis, which progress to malignant cell invasion, early-stage cancer, and eventual metastasis (58). Returning to baseline levels of lung cancer risk comparable to that of never-smokers occurs slowly following successful cessation. In women, while a significant (21%) reduction in risk appears within the first 5 years of quitting, excess risk compared to never-smokers may take up to 30 years to disappear (40). From a perspective of lung cancer risk reduction, then, current smokers should be encouraged to quit as soon as possible and should be supported in abstinence for as long as possible.

Tobacco and Other Cancers

Smoking, smokeless tobacco use, and second-hand smoke are causative factors in most nonlung malignancies, including leukemias, head and neck and esophageal cancers, and cancers of the pancreas, liver, stomach, cervix, kidney, large bowel, and bladder (60). In addition, chronic tobacco use mediates the majority of lung and nonlung cancers in persons dependent on other substances, including alcohol, stimulants, cannabis, and opioids. Of note, smoking is not clearly linked to increased risk for colorectal or breast cancers, both of which are more common in heavy drinkers.

Alcohol and Cancer

Alcohol consumption is a risk factor for the second and third most common causes of cancer mortality in 2006, colorectal cancer (55,170 deaths United States) and breast cancer (41,430 deaths), though a dose-dependent association between alcohol intake and colorectal cancer risk is not firmly established (61). Alcohol may increase estrogen and androgen levels in women, among other plausible mechanisms for alcohol's promotion of breast cancer (62). Alcohol is linked to most cancers of the digestive tract, particularly squamous cell carcinomas, including those of the oral cavity, head and neck, esophagus, and liver (hepatocellular carcinoma [HCC]), though it is not associated with stomach cancers. HCC arises in the setting of cirrhosis, the most common cause of which is heavy alcohol consumption, and the risk of alcohol-induced HCC is heightened in the setting of viral hepatitis. The effectiveness of screening for breast and colorectal cancers is well established in the general population, though guidelines do not vary by level of alcohol use (56). Colorectal cancer screening in all adults consists of fecal occult blood testing, sigmoidoscopy, or colonoscopy beginning at age 50 to age 75 years. Screening mammography every 1 to 2 years is recommended for women age ≥ 40 years.

Viral Causes of Cancer among Drug Users

HIV, human papilloma virus (HPV), hepatitis B virus (HBV), and HCV are each prevalent among drug users and associated with increased risk of malignancy. Cervical cancer screening is recommended for all women who have been sexually active and have a cervix (56).

ALCOHOLIC PANCREATITIS, LIVER DISEASE, AND VIRAL HEPATITIS

Addiction and Gastrointestinal Disease

Disorders of the intestinal tract and liver among addicted persons are primarily mediated by chronic heavy alcohol use and viral hepatitis. As noted above, alcohol and tobacco use are strongly associated with head and neck and esophageal cancers, particularly squamous cell carcinomas, and tobacco is a strong risk factor in gastric cancers. Excessive alcohol use in the setting of viral hepatitis (often contracted through high-risk sexual behavior or IDU) confers particularly high risk of hepatocellular injury, development of cirrhosis, and HCC.

Alcoholic Pancreatitis

Pancreatitis and alcoholic liver disease are well-known consequences of chronic alcohol misuse. The incidence of acute pancreatitis in developed countries correlates with rates of alcohol consumption as well as with gallbladder disease, the two chief causes of pancreatitis (63). Mortality varies by center, with rates of 5% to 30%. Death from pancreatitis usually follows multiorgan failure (0 to 2 weeks from onset) and sepsis (>2 weeks). Overconsumption of ethanol results in toxic levels of its metabolites, including acetaldehyde and fatty acid ethyl esters, which are thought to increase production of digestive and lysosomal enzymes by pancreatic acinar cells and thereby initiate the cascade of inflammatory and autodigestive pancreatic injury.

The management of acute pancreatitis consists largely of supportive measures, including pain control, intravenous fluids, fasting, electrolyte corrections, and insulin-based control of hyperglycemia. Alcohol abstinence is of course mandatory. Risk factors for disease severity include older age (>55 years), obesity, organ failure at admission, and pleural effusion or pulmonary infiltrates. Single or multiple episodes of acute pancreatitis may result in chronic pancreatitis, marked by fibrosis and mononuclear infiltrate (vs. neutrophilic in acute pancreatitis), chronic abdominal pain often following meals, and pancreatic insufficiency with fat malabsorption and glucose intolerance.

Alcoholic Liver Disease

Alcoholic liver disease ranges across a spectrum from asymptomatic fatty liver to alcoholic hepatitis, cirrhosis, and end-stage liver failure. Alcohol is primarily metabolized by the liver by way of the alcohol dehydrogenase pathway. Chronic, heavy

alcohol use may also induce secondary microsomal enzyme oxidation pathways. Both pathways generate toxic metabolites including acetaldehyde and free radical oxygen intermediates. Hypoxia associated with alcohol metabolism, increased levels of cytokines, neutrophil migration, and liver macrophagic Kupffer cell activation all contribute to hepatocellular injury, chronic inflammation, and eventual fibrosis.

The incidence of alcoholic liver disease is quite variable, with cirrhosis developing in approximately 50% of persons who consume at least 1 pint of spirits (roughly 210 g of ethanol) daily for >20 years (64). Most persons consuming eight or more standard drinks per day, however, will develop precursor conditions such as alcoholic fatty liver. Physical signs that often accompany the presence of alcohol-related liver disease include right upper quadrant pain, enlarged or reduced liver edge, general muscular atrophy, bleeding disorders, and peripheral neuropathies. Elevated serum transaminase levels, particularly a ratio of elevated AST to ALT of >2 in the setting of chronic heavy alcohol use, is highly suggestive of alcoholic liver disease. Imaging (including ultrasound, CT, or MRI) can detect fatty changes, cirrhosis, or liver tumors. Liver biopsy is not required for the diagnosis of alcoholic liver disease, but is often used to exclude other causes of liver disease and to establish disease severity.

Alcoholic fatty liver is a direct, reversible effect of ethanol ingestion, and usually does not progress to alcoholic hepatitis or cirrhosis. It is often asymptomatic or characterized by mild abdominal pain; laboratory tests are often normal. Alcoholic fatty liver is characterized by macrovesicular steatosis and mitochondrial distortion, and is usually indistinguishable from other causes of fatty liver including obesity, pregnancy, drug toxicity, or viral hepatitis. Alcoholic hepatitis is characterized by fever, hepatomegaly, jaundice and anorexia, and elevated serum transaminase levels, and can be accompanied by ascites in fulminant cases. Neutrophil infiltration and Mallory bodies on biopsy are highly suggestive of alcoholic injury as opposed to viral hepatitis. Cirrhosis may coexist with alcoholic hepatitis, and both usually begin in the pericentral liver with progression to panlobular regions. Cirrhotic fibrosis is the accumulation of scar or extracellular matrix. Progression of cirrhosis is marked by portal hypertension, varices, ascites, and lower body edema, jaundice, coagulopathies, and eventual fulminant hepatic failure with encephalopathy.

Abstinence from alcohol use is a critical goal among persons with alcohol-related hepatitis and cirrhosis, while the presence of alcoholic fatty liver indicates a person should clearly reduce if not cease drinking. Early alcoholic cirrhosis may be partially reversible with abstinence, and 5-year transplant-free survival among persons with cirrhosis and clinical decompensation is approximately twice as high among persons able to abstain (60%) compared to those who continue to drink (30%) (65). Liver transplant is highly effective in end-stage alcoholic liver disease, though this has traditionally been offered only to highly selected patients agreeing to abstinence and with good social support and functioning. A period of ≥ 6 months of abstinence, though somewhat arbitrary, has become a standard pretransplant criteria, and

usually involves a pledge of abstinence as well as enrollment in a comprehensive treatment program (66).

Viral Hepatitis

Hepatitis A

Hepatitis A virus (HAV) is the leading cause of acute viral hepatitis in the United States, and results in significant morbidity and health care costs (67). Hepatitis A is a nonenveloped ribonucleic acid (RNA) virus that is excreted in stool and usually transmitted by fecal–oral contact, although transmission through blood is also possible. Most cases of HAV occur during community-wide outbreaks, but a high proportion of these cases occur in persons who report using drugs (68). The prevalence of anti-HAV antibodies is particularly high among drug users; in one study, the prevalence among injection drug users was twice that in the general population (69).

Transmission between drug users is hypothesized to occur primarily by the fecal–oral route when people gather together to smoke, snort or swallow drugs, and secondarily by percutaneous transmission through sharing needles and other injection supplies. Drug use (including injection and noninjection use) is now recognized as a significant risk factor for transmission of hepatitis A, and drug users are among the groups recommended for HAV vaccination.

Hepatitis A is generally an acute, localized disease, with uncommon cases involving relapse or extrahepatic manifestations. Unlike hepatitis B, a carrier state does not exist for HAV. The usual incubation period for HAV is 28 days (range: 15 to 40 days), and most adults are asymptomatic during acute infection. When symptoms occur, they typically include a mild prodromal illness of fever, headache, malaise, and nonspecific gastrointestinal symptoms, followed by dark urine, jaundice, tender hepatosplenomegaly, and postcervical lymphadenopathy. This classic presentation occurs in more than 80% of symptomatic patients and is self-limited, lasting less than 8 weeks. Most patients are treated supportively and experience complete resolution by 3 to 6 months. Importantly, a rarer and more severe form of HAV has been described in patients with hepatitis C or other chronic liver disease, and is associated with fulminant liver failure and a high mortality rate (up to 35%) (70).

The diagnosis of acute HAV is made by detecting anti-HAV antibodies in patients with symptoms consistent with hepatitis. Abnormal liver enzyme tests are not specific for hepatitis A. IgM anti-HAV antibodies can be detected 1 to 2 weeks after exposure and persist for 3 to 6 months. IgG anti-HAV antibodies can be detected 5 to 6 weeks after exposure and persist for decades, conferring lifelong protection against HAV reinfection. The high prevalence of HAV exposure among drug users suggests that this population is at particularly high risk for HAV infection. In addition, chronic hepatitis caused by hepatitis B or C is extremely common among injection drug users, making them more susceptible to developing severe fulminant hepatitis with acute HAV superinfection. HAV as well as HBV vaccination of drug users is therefore indicated to both protect the individual from a potentially fatal condition, and

to reduce HAV transmission to others. HAV vaccine is administered intramuscularly as two injections given 6 months apart. In addition to the HAV vaccine, a combined HAV/HBV vaccine (Twinrix) has been shown to be effective in IDUs (69). While IDU may reduce vaccine immunogenicity, HAV vaccination has been shown to be effective in IDU populations, though they are more likely than the general population to require both vaccinations of the scheduled 2-vaccine series to obtain full immunity (69). Because of the high prevalence of prior infection and anti-HAV antibodies among drug users, HAV serology should be checked in adults and experienced IDUs, though providers may choose to give the first dose of vaccine prior to receiving these results.

Hepatitis B

As many as 1.4 million people in the United States are living with chronic hepatitis B (HBV) infection, with new infections occurring at a rate of over 40,000 annually despite the availability of an effective vaccine (71). The prevalence of HBV infection among IDUs is particularly high (40% to 80%), accounting for an estimated 4% to 12% of all chronic HBV infections in the U.S. population (72). Hepatitis B is a deoxyribonucleic acid (DNA) virus that is predominantly acquired through sexual contact (homosexual and heterosexual), but also by IDU and occupational exposure. Among drug users, HBV is transmitted parenterally through the sharing of needles and other contaminated injection equipment, or high-risk sexual behavior (73). HBV acquisition is a relatively early event for most injection drug users, with 50% to 70% of injectors seroconverting within the first 5 years of initiating injection (74). In one study, HBV incidence ranged from 12% to 31% per year among young (age 18 to 30 years) injection drug users (75). Young IDUs thus manifest the highest incidence of new HBV infections in the United States, with transmission linked to injection practices (sharing needles and other injecting equipment) and high-risk sexual behavior (not using a condom and/or having multiple sexual partners) (76). It is now recommended that injection drug users be routinely screened for hepatitis B infection (serologic testing for HBsAg) if they are not known to be immune (73).

The outcome of acute HBV infection is variable. Approximately 40% of patients develop clinical symptoms of acute hepatitis, though fulminant hepatic failure is a rare complication, affecting just 1 in 1000 patients (71). The incubation period, defined by the appearance of clinical symptoms, ranges from 1 to 6 months. Early in infection, circulating HBV surface antigen (HBsAg) can be detected prior to the development of either clinical symptoms or elevated hepatic transaminases. This is followed by the production of hepatitis B e antigen (HBeAg), and then by elevations in transaminases. The first evident immune response is the production of antibodies to HBV core antigens (anti-HBc), which appear shortly after HBsAg. Anti-HBc plays no role in host defense, but is a reliable marker of past HBV infection. HBV surface antibody (anti-HBs) confers immunity to hepatitis B and may be present in those who have been successfully vaccinated against HBV as well as in those with a history of HBV infection.

Among all patients with acute hepatitis B, 5% to 10% develop chronic infection with persistent HBsAg positivity. Chronic HBV is associated with cirrhosis and hepatocellular cancer, and leads to 4000 deaths from cirrhosis and 800 deaths from HCC annually in the United States (77). While all those with active infection should be evaluated for treatment, not all will require immediate therapy. Treatment has the potential to reduce the risk of progressive chronic liver disease and its longer-term complications such as HCC, while also reducing the individual's infectivity to others. There are multiple treatment options for chronic HBV, including interferon- α and nucleoside reverse transcriptase inhibitors (lamivudine, adefovir, entecavir, telbivudine, tenofovir). All patients should be evaluated for HIV infection prior to starting HBV therapy, since coinfection rates are high, response to HBV treatment can be blunted in HIV-infected persons, and HBV monotherapy can engender HIV resistance to antiretroviral treatment.

The hepatitis B vaccine is immunogenic, effective, and safe. Though vaccination has been recommended for injection drug users by the CDC since 1982, uptake in this population has remained consistently low (less than 30%) (69). Multiple barriers to successful vaccination among IDUs include generally poor access to health care services, lack of awareness of the need for vaccination among drug users and health care workers alike, and the relative complexity of the vaccine schedule (75). The recommended vaccine consists of three intramuscular injections at 0, 3, and 6 months. The full sequence results in protective levels of anti-HBs in more than 90% of young (≤ 40 years old) healthy adults, though its effectiveness is somewhat diminished in persons who are older, smoke, are overweight, or are immunocompromised (by HIV-infection, diabetes mellitus, renal failure, or chronic liver disease). Though completion of all three doses is recommended, protective antibodies develop in 30% to 55% of adults after a single dose, and in up to 75% after two doses, so a significant proportion of those who do not receive the full series may still be protected (75). An alternative schedule with just two doses, administered 6 months apart, may result in anti-HBs levels similar to those obtained with the three-dose schedule (78).

Drug treatment programs as well as syringe exchange and targeted street outreach programs have been successful in achieving high rates of vaccination completion (70% to 85%) among injection drug users. Vaccination of the entire population during infancy or early adolescence, as has been recommended by the CDC since 1991, will eventually reduce the incidence of HBV infection, but this guideline has yet to be fully implemented, with the result that many adults remain susceptible to HBV infection. Greater efforts are necessary to vaccinate drug users against HBV, and should involve all potential settings in which drug users have contact with health care providers. These include drug treatment programs, health departments, jails and prisons, needle exchange programs, ambulatory clinics, and hospital emergency rooms. Drug users should be screened with HBV serologies (HBsAg and either anti-HBc or anti-HBs) but

(as with HAV vaccination) the first dose of vaccine may be given at the same visit after blood is drawn for testing (73).

Hepatitis C

Approximately 4 million people have evidence of exposure to HCV in the United States, of whom 78% have chronic infection (12). HCV is the most common chronic liver disease in the United States, and accounts for the majority of liver transplants. Hepatitis C is a retrovirus with six major genotypes, genotype 1 being most common in the United States and Europe. It is very efficiently transmitted by contact with infected blood, and more rarely through sexual exposure. In the United States, up to 8% of HCV-infected persons are HIV coinfecting (79).

IDU is the primary route of transmission of HCV infection (12). Among injectors, there is considerable geographic variation in HCV seroprevalence but rates are consistently high, ranging from 14% to 51% in major U.S. cities (80). Acquisition of HCV infection is often rapid following initiation of drug injection, with greater than one in three IDUs becoming infected within the first 5 years after initiating injecting (81). Transmission risk increases with injection frequency and with injecting a mixture of cocaine and heroin ("speedball") (81). Sharing of drug preparation equipment, including cookers and the filtration cotton, is also clearly associated with incident infection. Although sharing of intranasal cocaine sniffing equipment (e.g., straws) has also been considered a possible route of HCV transmission, these data are inconclusive (81). Sexual transmission of HCV, although much less efficient than injection-related transmission, can also be a route of infection among drug users. Multiple sex partners and comorbid STDs increase the risk of sexual acquisition of HCV (82), and noninjection drug users trading sex for money or drugs may be at particularly high risk.

Most patients do not seek medical attention during acute infection with hepatitis C because clinical manifestations are often mild, though 20% to 30% may experience fatigue, abdominal pain, poor appetite, or jaundice during the acute phase (82). Following initial infection with HCV, approximately 15% to 20% of persons appear to permanently clear the virus, and 80% to 85% of persons develop chronic infection. HCV-induced cirrhosis develops in an estimated 15% to 20% of those with chronic infection, and HCV-related end-stage liver disease (ESLD) now constitutes the most common indication for liver transplantation in the United States (83). Factors associated with accelerated progression of HCV-related liver disease include coinfection with HIV, older age at time of infection, and alcohol consumption. HCC develops almost exclusively in HCV-infected individuals who have developed cirrhosis, at a rate of 1% to 4% per year (83).

Among those who naturally ward off chronic infection, there is no evidence that protective immunity develops against future reinfection with HCV. Nevertheless, reinfection of injectors appears to be a relatively uncommon occurrence (84). This is of particular relevance to injection drug users and others who may be repeatedly exposed to the virus over time.

Serologic determination of HCV infection is generally accomplished by testing for the presence of anti-HCV antibodies. Serum levels of HCV RNA are assessed in antibody-positive persons. If HCV RNA is absent in the presence of anti-HCV antibodies, the patient is assumed to have cleared the infection. Those with detectable HCV RNA should undergo genotype determination, as this will influence subsequent treatment. Because of the substantial overlap in risk factors and implications for treatment, HIV testing should be offered concurrently with testing for HCV. HCV treatment eligibility is determined primarily by considering the extent of plasma viremia, hepatic fibrosis, and inflammation. The National Institutes of Health's *2002 Consensus Development Conference Statement on Management of Hepatitis C* explicitly states that persons should not be excluded from receiving HCV treatment solely on the basis of active drug or alcohol use, and methadone treatment is also not considered a contraindication to treatment (85). This position was reiterated in the more recent American Association for the Study of Liver Disease (AASLD) practice guidelines (12). As with all patients with chronic medical conditions, the decision to embark on a sustained course of treatment, during which side effects are likely and a successful response uncertain, must be made on a case-by-case basis. Factors to consider include the patient's motivation, past adherence with chronic therapies, HCV genotype, medical and psychiatric comorbidities, likelihood of success, and engagement in medical care.

Currently, best HCV treatment results are obtained with a combination of pegylated interferon alpha, administered by subcutaneous injection, and ribavirin, taken orally. Response to treatment is typically evaluated after 12 weeks: if an insufficient drop in HCV viral load is observed, treatment is discontinued. Of the three HCV genotypes most prevalent in the United States, genotypes 2 and 3 are most responsive to treatment, which is typically continued for 6 months in such patients. Twelve months of treatment is considered standard for persons with genotype 1 infection. A patient is deemed to have a successful end-of-treatment response (ETR) when HCV viremia is undetectable after treatment completion. A sustained viral response (SVR) is defined as persistence of viral eradication (as measured by nondetectable viremia) 6 months following completion of treatment, and is the best predictor of long-term treatment response. Rates of SVR in clinical trials approximate 45% following 48 weeks of treatment of patients with genotype 1 infection, and 80% following 24 weeks of treatment of patients with genotypes 2 and 3 infections. Treatment duration is longer and rates of SVR lower in those coinfecting with HIV and HCV, but given the opportunity for HCV treatment to alleviate the rapid progression of liver disease in these patients, treatment is recommended except in those cases where its adverse effects outweigh potential benefits (12).

Although it remains uncertain whether a SVR to treatment signifies a true "cure" of the patient's HCV infection, prevention of long-term sequelae of HCV infection is clearly associated with successful treatment (86). Repeat treatment

of nonresponders (those unable to clear virus) and relapsers may be considered based on the initial therapy received and patient characteristics. Treatment of nonresponders with maintenance pegylated interferon is an area of active investigation but is not currently recommended, based on initial results indicating that while HCV viremia and markers of inflammation are reduced, there is no significant difference in progression to cirrhosis (12). Newer therapies, including protease inhibitors and derivatives of current treatment agents (interferons and ribavirin) are currently under investigation, and some have shown promising results in clinical trials.

Side effects from treatment with pegylated interferon and ribavirin are significant. Major complications of interferon are constitutional symptoms and psychiatric manifestations. Depression, prevalent to begin with among HCV-infected drug users, is often precipitated or worsened by treatment of HCV with interferon (86). Screening for depression and other psychiatric disorders at baseline and periodically during treatment is an important component of care. The major complications of ribavirin are hematologic, with significant anemia, neutropenia, or both often complicating treatment.

Configuring services to optimize delivery of hepatitis C treatment to eligible drug users is challenging. Several of the stages of care (e.g., screening, evaluation of eligibility for treatment, which typically involves liver biopsy, and treatment itself) are often conducted by distinct health care providers. To the extent possible, integration of the several aspects of the patient's care is an important goal (87). For patients engaged in substance abuse treatment, providing hepatitis C related care on-site at the treatment program is an attractive option, facilitating interdisciplinary management of the medical, psychiatric, and substance abuse treatment aspects of care (88). For example, patients receiving methadone maintenance treatment often request an increase in their methadone dose during combination treatment of their HCV infection, presumably because of the similarity between interferon-related side effects and the symptoms of opioid withdrawal. Other patients, learning that they are infected with HCV decades after they stopped injecting, may be profoundly discouraged by this unwanted "blast from the past," to the point that it jeopardizes their recovery. Such complex clinical issues are ideally addressed in an interdisciplinary setting. Patients' access to the various members of the treatment team can be facilitated when they are colocated in a common site. SEPs provide another promising setting into which HCV-related services can effectively be integrated for active drug users (89).

In several studies, only a small proportion of eligible HCV-infected drug users enroll in HCV treatment, and even fewer complete the treatment course (90,91). Improved strategies for provider and patient education, defining surrogate markers for fibrosis that could spare the step of liver biopsy, developing less-toxic therapies, and successfully treating comorbid psychiatric and substance abuse disorders, are urgently needed in view of the very heavy burden of HCV infection among persons with a history of substance abuse.

Efforts to prevent HCV transmission and acquisition, often given less attention than diagnosing and treating existing infection, are vitally important. HCV antibody testing should be widely offered to all persons with current or former drug or alcohol misuse. Persons testing negative should receive tailored counseling. If they are injecting drugs, use of sterile syringes and not sharing any injecting related equipment should be discussed and encouraged. IDUs should receive sterile injecting equipment and/or referral to SEPs or pharmacies that dispense syringes, and safer routes of use (e.g., intranasal) suggested, while simultaneously working with the patient to reduce or eliminate their drug use. Safer sex practices, particularly for persons with multiple partners, should be supported as well. Persons testing positive for HCV, if injecting drugs, should be counseled not to share needles and syringes or other injecting equipment such as cookers, cotton, and other implements that could come into contact with blood.

Secondary prevention efforts include routine vaccination against hepatitis A and hepatitis B for all HCV-infected persons. Evidence suggests that hepatitis A can be particularly fulminant in some HCV-infected persons (71), and some data implicate hepatitis B as a factor associated with accelerated progression of HCV-related liver disease. Increasingly it is recommended that HIV treatment be initiated earlier in patients who are coinfecting with HCV, even among those with higher CD4 counts, based on some evidence that HAART may decrease liver damage in this population (92). Alcohol consumption is associated with more rapid progression of HCV-related liver disease and with diminished response to treatment (93). There is uncertainty as to whether a modest degree of alcohol consumption is detrimental, because most studies have found this effect to be associated with moderate to heavy levels of drinking. Counseling HCV-infected persons to eliminate or at least minimize alcohol consumption is strongly encouraged.

Hepatitis D

Hepatitis D (delta) virus (HDV), an incomplete RNA virus that requires coinfection with active HBV to become active, is transmitted in the same manner as HBV and is prevented by HBV vaccination. It is endemic in the Mediterranean region and in parts of Asia, Africa, and South America and appears to have been spread to nonendemic areas such as the United States and Northern Europe by IDU. Outbreaks of severe and fulminant hepatitis, primarily as a result of coinfection with HDV and HBV, have been reported in injection drug users and their sexual contacts (94).

There are two mechanisms of HDV infection: coinfection with HBV, and superinfection of HBsAg carriers. In coinfection, HBV and HDV are acquired together, and there is a higher incidence of fulminant hepatic failure (up to 20%) than with HBV infection alone. Thirty percent of patients with acute fulminant hepatitis B have coinfection with HDV, and the case fatality rate is almost 5%. Similarly, when a chronic HBV carrier is superinfected with HDV, subsequent liver disease is more severe and more rapidly progressive than

with HBV infection alone (95). HDV superinfection should be strongly considered when a stable chronically infected HBV carrier has an exacerbation of chronic liver disease or an episode resembling acute hepatitis B. Treatment for chronic HDV in patient with evidence of liver disease may be beneficial, but optimal treatment regimens are not clearly defined and are best undertaken as part of a clinical trial.

Other Viral Causes of Hepatitis

Other viruses have the potential to cause hepatic disease among drug users as well, including Epstein–Barr virus, herpes simplex virus, and cytomegalovirus, each of which may bring about hepatitis-associated illnesses. Most often these viruses are spread through direct contact, but they can be spread parentally as well. Although relatively rare in comparison to HAV, HBV, HCV, and HDV, it is important to consider these pathogens in the differential diagnosis of hepatitis among drug users.

SEXUALLY TRANSMITTED DISEASES

Sexually transmitted diseases (STDs) are common among substance users, often associated with sexual risk incurred in the setting of intoxication (particularly among users of stimulants such as cocaine and amphetamines) as well as with exchange of sex for money or drugs. Crack use is particularly strongly associated with sex in exchange for money or directly for drugs, and crack-smoking sex workers report very-high-risk sexual practices, as well as low rates of condom use. STDs that present commonly among drug users include syphilis, gonorrhea, chlamydia, genital herpes simplex virus, HPV, and trichomoniasis. In addition, HIV is transmitted among drug users both sexually and parentally; a full discussion of HIV infection is found elsewhere in this volume.

Syphilis

Syphilis is a readily curable, bacterial genital ulcer disease caused by *Treponema pallidum*. After declining throughout the 1990s, the number of reported cases of syphilis in the United States began increasing in 2001, with current rates of 3.8 cases per 100,000 being almost double those of a decade ago (96). This increase has been largely driven by outbreaks in some cities among men who have sex with men (MSM), with drug and alcohol use playing a significant role in transmission. Among drug users, rates of incident syphilis are very high, with lifetime prevalence ranging from 2% to 19% (97). Risk behaviors consistently associated with syphilis incidence among drug users include crack cocaine use, multiple sex partners, and the exchange of sex for money or drugs (98).

Patients who have syphilis may seek treatment for clinical signs of primary infection (usually a painless chancre), secondary infection (manifestations that include but are not limited to skin or mucocutaneous lesions), or tertiary infection (typically neurologic or cardiac complications). Latent infections, or those lacking clinical manifestations, are detected by

serologic testing. Latent syphilis acquired within the preceding year is referred to as early latent syphilis; all other cases of latent syphilis are either late latent syphilis or latent syphilis of unknown duration (98).

Because of their high risk for syphilis exposure, drug users should be screened annually with RPR (rapid plasma reagin) or VDRL (Venereal Disease Research Laboratory) nontreponemal tests. Given the high rate of false-positive nontreponemal tests, positive results should be confirmed with a treponemal antibody test (e.g., FTA-ABS, TP-PA). Nontreponemal titers usually correlate with disease activity; a fourfold change in titer, equivalent to a change of two dilutions (e.g., from 1:16 to 1:4 or from 1:8 to 1:32), indicates a clinically significant difference between two nontreponemal test results obtained using the same serologic test. Nontreponemal tests usually become nonreactive with time after treatment; however, in some patients, nontreponemal antibodies can persist at a low titer for a long period of time, sometimes for the life of the patient. Most patients who have reactive treponemal tests will have reactive tests for the remainder of their lives, regardless of treatment or disease activity. However, 15% to 25% of patients treated during the primary stage revert to being serologically nonreactive after 2 to 3 years. Treponemal antibody titers correlate poorly with disease activity and should not be used to assess treatment response. HIV serology should be checked in all patients with serologic evidence of syphilis.

Like all other patients, drug users with STDs should be treated with single-dose regimens, if possible. Benzathine penicillin (2.4 million units) is the preferred single-dose regimen for early syphilis (primary, secondary, or early latent), and has been used effectively for more than 50 years to achieve clinical resolution and to prevent sexual transmission and late sequelae. Treatment of late latent or tertiary syphilis, which requires a series of three weekly injections of benzathine penicillin (total of 7.2 million units), usually does not affect transmission and is intended to prevent occurrence or progression of late complications (99). All treatment requires follow-up quantitative nontreponemal tests to assess treatment response. High rates of compliance with screening and treatment for syphilis among drug users have been achieved when these services are offered on-site in substance-abuse treatment programs (99).

Gonorrhea and Chlamydia

Gonorrhea (*Neisseria gonorrhoeae*) and chlamydia (*Chlamydia trachomatis*) are the most common bacterial STDs in the United States, with an estimated 600,000 cases of gonorrhea and close to 3 million cases of chlamydia each year (97). As with syphilis, rates of gonorrhea and chlamydia are much higher among drug users than among the general population. In cross-sectional studies of drug-using populations, close to half reported having had gonorrhea, and rates of current gonorrhea or chlamydia infection exceeded 5% (100).

These bacterial infections are a major cause of urethritis and proctitis in men, and cervicitis and pelvic inflammatory disease (PID) in women. However, because they are often asymptomatic, particularly in women, gonococcal and chlamydial

infections are often detected only by screening tests. Screening is essential to prevent complications, including ascending infection, infertility, ectopic pregnancy, and chronic pelvic pain. In recent years, screening of women has been facilitated by highly sensitive new tests that do not require a pelvic exam or urethral swab, but instead amplify nucleic acid obtained from urine using a ligase chain reaction for *C. trachomatis* and *N. gonorrhoeae* (NAAT testing). Regular screening for gonorrhea and chlamydia is now recommended for sexually active women by the United States Preventive Services Task Force (56). Annual screening of substance-using women and of substance-using MSM should be performed.

Several antibiotics are effective in the single-dose treatment of gonorrhea, with cephalosporins including cefixime (Suprax) and ceftriaxone (Cefizox) being preferred. With increasing rates of quinolone resistance, ciprofloxacin (Cipro), ofloxacin (Floxin), and levofloxacin (Levaquin) are not recommended for the treatment of gonorrhea among MSM or in areas with high rates of resistance (99). Treatment of gonorrhea and chlamydia is generally offered simultaneously, because of the frequency of dual infection. Efficacious regimens for the treatment of chlamydia include azithromycin (Zithromax) or doxycycline (Vibramycin), but azithromycin is preferred because it can be given in a single, directly observed dose. As with other STDs, patients should be instructed to notify and refer their sex partners for testing and treatment.

Genital Herpes

Genital herpes simplex virus type 2 (HSV-2) infection is the most common infectious cause of genital ulcer disease, with at least 50 million persons infected in the United States (99). Although most cases of genital herpes are caused by HSV-2, genital infections with herpes simplex virus type 1 (HSV-1) are increasingly recognized. Serologic evidence of HSV-2 infection increases with age and number of sexual partners, and is more common among drug users. In recent studies, the prevalence of antibodies to HSV-2 among drug users has ranged from 44% to 58% (101).

The classic presentation of HSV-2 is with multiple vesicular or ulcerative genital lesions, but many infections may be asymptomatic. Shedding of virus occurs even in the absence of lesions, and HSV-2 transmission usually occurs at times of subclinical or asymptomatic shedding.

Optimal management of genital herpes includes antiviral therapy (with acyclovir [Zovirax], famciclovir [Famvir], or valacyclovir [Valtrex]), along with appropriate counseling on the natural history of infection, risk for sexual and perinatal transmission, and methods to prevent further transmission (99). Systemic antiviral drugs partially control symptoms when used to treat recurrent episodes, and may be used as daily suppressive therapy in those with frequent recurrences (≥ 6 per year). However, these drugs neither eradicate latent virus nor affect the risk for, frequency of, or severity of recurrences after the drug is discontinued. Recognizing the symptoms and signs of clinical episodes of HSV infection and promptly seeking treatment are key factors in reducing transmission rates.

Human Papilloma Virus

HPV infections are the causative agents for genital wart disease and cervical carcinoma, and are transmitted primarily through sexual contact. The prevalence of HPV is as high as 50% among sexually active adolescent and young adult women, and risk factors for HPV include number of sexual partners, early age of first sexual intercourse, drinking and drug use related to sexual behavior, and partner's number of sexual partners.

The two major manifestations of genital HPV infection are external genital warts, usually caused by HPV-6 and HPV-11, and squamous intraepithelial lesions of the cervix that are detected by cytologic screening. The major types of HPV associated with squamous intraepithelial lesions are HPV-16, -18, -31, -33, and -45. These HPV types also cause squamous cell cancer of the vagina, vulva, anus, and penis. A vaccine against HPV types 6, 11, 16, and 18 (Gardasil) has recently become available, and is recommended for girls and women age 9 to 26. It is best administered prior to onset of sexual activity, but does have utility in women who have been exposed to HPV if they have not been infected with all four types covered by the vaccine. Vaccination does not preclude the need for routine cervical cancer screening. Women who use drugs should be screened with Papanicolou (Pap) smears according to standard guidelines. Testing for HPV is often used to determine which women with low-grade cervical abnormalities on Pap require additional evaluation, but its utility as a primary screening test is still under review. At present, no therapy has been identified that effectively eradicates persistent subclinical HPV infection.

Trichomoniasis

Trichomonas vaginalis is a protozoan that causes vaginitis in women, and is highly prevalent among drug-using women. Recent availability of self-administered vaginal swab tests has obviated the need for pelvic exams followed by wet mount microscopy or vaginal culture in screening for trichomonas, making routine testing more feasible for a larger number of women. Because it is frequently asymptomatic, screening for trichomoniasis should be routine among drug-using women. Recommended treatment is with metronidazole or tinidazole, both of which can be given as a single dose (99). Patients should be counseled to abstain from alcohol during treatment and for 24 hours following completion of metronidazole and 72 hours after tinidazole. As with other STDs, sexual partners should also be treated.

SKIN AND SOFT-TISSUE INFECTIONS

Skin and soft-tissue infections are more common both among injection and noninjection drug users compared to general populations. Methicillin-resistant *Staphylococcus aureus* (MRSA) has become the most common causative agent of community-acquired soft-tissue infections. Isolates are usually not susceptible to beta-lactam antibiotics previously used most widely,

including first-generation cephalosporins (i.e., cephalexin) and extended-spectrum penicillins (i.e., amoxicillin-clavulanate) (102,103).

Frequent, recurrent abscesses and cellulitis are prevalent among injection drug users, developing at a rate of roughly one episode every 3 years (104). Risk of abscess has been associated with route of injection, with intramuscular ("muscling") or subcutaneous ("skin popping") injection conveying greater risk for abscess than intravenous injection. Other risk factors identified include higher injection frequency (105) and injecting a mixture of cocaine and heroin (speedball) (105). Common sites of abscess are, in order of descending frequency, arm, leg, buttocks, deltoid, and head/neck (106).

The bacteriology of injection-associated abscess has been better defined than that of cellulitis, reflecting the greater likelihood of isolating an organism. *Staphylococcus aureus* is the most common pathogen in these infections, followed by *Streptococcus* species. The majority of *S. aureus* isolates in both the community and hospital settings now demonstrate resistance to beta-lactam antimicrobials (methicillin, oxacillin, dicloxacillin, cefazolin, cephalexin), while susceptibility to vancomycin, clindamycin, rifampin, trimethoprim-sulfamethoxazole, and tetracycline is generally high (107). Mixed aerobic/anaerobic infections are more common among injection-associated abscesses than abscesses identified in other clinical settings. Studies of the microbiologic flora in heroin and on injection equipment have also been conducted. While a variety of organisms were identified in this manner, *S. aureus* was not, suggesting that the injection drug user's skin, not the drug or equipment used, is the likely source for staphylococcus-related abscesses (108). Indeed, strains of *S. aureus* isolated from drug users presenting to the hospital with serious *S. aureus*-related infections are similar to the strains colonizing the same population of drug users in the community (109).

Prevention of skin and soft-tissue infections among non-injectors consists of good general and hand hygiene, avoidance of skin-skin contact, and treatment and decolonization of MRSA case clusters and household contacts. Among injectors, attention to sterile injection equipment and techniques is vital, including routinely cleansing the injection site with alcohol or soapy water prior to injection and sterilization of drug being injected by heating prior to injection ("cooking"—a step taken to help dissolve the drug), which may inactivate harmful bacteria (110).

Treatment of abscess typically requires incision and drainage, and small (≤ 5 cm) wounds may not require adjunctive antibiotics (111). Larger lesions or those with surrounding cellulitis or systemic symptoms require antibiotics for 1 to 2 weeks, depending on response. In the emerging era of MRSA, evidence-based guidelines for the presumptive treatment of soft-tissue infections are not yet established. Reasonable choices for empiric MRSA coverage include clindamycin, trimethoprim-sulfamethoxazole, and tetracyclines, and therapy designed to cover both MRSA and group A streptococci would include a beta-lactam and one of these

older MRSA-active agents. Rifampin as an element of combination therapy is also supported by susceptibility data, though it is important not to use it alone to avoid rapid development of resistance. Fluoroquinolones, including ciprofloxacin, should not be used alone for the same reason, and because fluoroquinolone resistance is prevalent among MRSA isolates (112). Parenteral therapy including vancomycin should be considered for patients with extensive tissue involvement and diabetes or other immunodeficiencies.

INFECTIVE ENDOCARDITIS

In the pre-HIV era, endocarditis was the infection most classically associated with IDU, and it remains common among injectors today. An estimated 2% to 5% of active IDUs per year will develop infective endocarditis (IE), and the risk is even higher among those who are HIV-infected (113). IE remains a highly morbid condition among IDUs, with estimates of mortality ranging from 7% to 37%, although rates may be lower (approximately 10%) among those with right-sided endocarditis (114).

IE among drug users can affect any heart valve. Although native valve endocarditis in the general population is most often left-sided, IE is more commonly right-sided (tricuspid valve) when associated with IDU. This is thought to be due to a variety of factors, including direct valvular endothelial damage from impurities of the drug injected into the venous system (rendering right-sided valves most susceptible to bacterial infection), predilections of certain skin flora for right-sided valve surfaces, and direct effects on the valvular endothelium of specific drugs (which may present in higher concentrations to right-sided than to left-sided valves) (52).

Many organisms are reported to cause endocarditis among injecting drug users. Although both the skin and the injected drug are implicated as the source of the pathogen causing endocarditis, the skin is thought to be the prime source in most cases (115). Reports of the prevalence of specific pathogens vary by location and over time, likely reflecting diverse rates of colonization with specific pathogens, and variations in injection practices and source of drug. Overall, *Staphylococcus aureus* is most frequently reported, accounting for more than 50% of IE cases among IDUs, among whom methicillin-resistant infections are common (116). Other prevalent IE pathogens include streptococci and enterococci, and a variety of gram-negative and fungal infections can be seen as well. Polymicrobial presentations are more common among injection drug users than among others with endocarditis (116).

Persistent bacteremia is a hallmark of IE. The revised Duke criteria provide a consistent standard for diagnosis. Several authors have developed clinical prediction rules to determine the likelihood that a given febrile injector presenting to the emergency department has endocarditis. Such algorithms remain relatively inexact, however, leading many to conclude that most febrile injection drug users should be admitted to the hospital for observation or empiric treatment until the diagnosis of endocarditis can be excluded (116,117).

An extended course of parenteral antibiotics remains the mainstay of treatment of IE. Advances in treatment in the past decade include oral therapy for selected patients and shorter (2 weeks) duration of treatment for patients with uncomplicated right-sided methicillin-sensitive *S. aureus* endocarditis. Though use of such regimens is appropriately limited to cases meeting specific criteria, these advances are important for injecting drug users, as venous access is often problematic in those with a substantial injection history, and prolonged hospital stays are generally difficult for injectors and noninjectors alike. The presence of HIV infection does not diminish the efficacy of treatment for endocarditis. Significant HIV-related immunosuppression, however, is associated with increased endocarditis-associated mortality (118). Access to sterile injection equipment and adherence to sterile injection technique are the practices most likely to reduce injectors' risk of endocarditis. The principles of prevention discussed above in the context of skin and soft-tissue infections apply to endocarditis as well.

TUBERCULOSIS

Drug users are at increased risk for tuberculosis infection and disease. The prevalence of latent tuberculosis infection (LTBI) among drug users varies by locale and population studied, but rates of approximately 15% to 25% are typical (119,120). Drug users are heterogeneous with respect to their risk for LTBI, and research suggests that smokers of crack cocaine are at particularly high risk for tuberculosis infection (121).

It is uncertain whether drug use is associated with an increased risk of developing tuberculosis disease among persons with LTBI, though the presence of HIV infection clearly does increase this risk (121). Chemoprophylaxis is effective in reducing the likelihood of later developing active disease. Regular screening for and, when detected, treatment of LTBI should thus be offered to all drug users (122). The prevalence of tuberculin reactivity among HIV-seropositive drug users is generally lower than among HIV-uninfected persons, reflecting the diminished delayed-type hypersensitivity response associated with more advanced immunosuppression (123). Two-step ("booster") tuberculin skin testing may increase the sensitivity of this testing method. Interferon gamma release assays (QuantiFERON-TB Gold In-Tube and T-SPOT) are blood tests for TB that are now approved for use in place of the tuberculin skin test and may have increased sensitivity among substance-using populations, and also eliminates the need for patients to make a return visit to a health care provider for interpretation of skin test results (124).

Treatment of tuberculosis in drug users should follow standard guidelines (125). Because fragmented medical care is common in this population, it is particularly important to remain attentive to the possibility of multidrug resistant TB in those who are not appropriately responsive to treatment. Rifampin (Rifadin), one of the most effective antituberculosis medications, is a potent inducer of methadone metabolism, often precipitating opioid withdrawal symptoms in methadone-maintained persons. Carefully managed

methadone dose increases, or even splitting of the methadone dose so it is administered twice daily, can resolve this complication. Alternatively, rifabutin (Mycobutin), which has similar activity to rifampin but far less impact on methadone metabolism, can sometimes substitute for rifampin. Such changes should generally be made in consultation with an expert in tuberculosis treatment. Directly observed therapy (DOT) can be a highly effective means to optimize adherence with treatment for LTBI or of active tuberculosis, particularly for patients engaged in opioid-agonist treatment with methadone, or who live in a congregate setting (e.g., shelter, residential drug treatment) (126).

PNEUMONIA AND CHRONIC LUNG DISEASE

Community-acquired pneumonia is common among drug users, particularly those with HIV infection. Recent studies have determined that the incidence of pneumonia ranges from 4.4 to 14.2 per 1000 person-years among HIV-negative drug users, and from 47.8 to 90.5 per 1000 person-years among HIV-positive drug users (127,128). Pneumonia is also the most common reason for hospitalizations among drug users, accounting for 27% of hospital admissions in one study (129).

Many factors contribute to drug users' increased susceptibility to pneumonia, including depression of the gag reflex by alcohol and drugs, leading to aspiration of oropharyngeal and gastric secretions; impaired pulmonary function as a consequence of cigarette smoking; and weakened immunity as a consequence of malnutrition and continuous antigenic stimulation. In addition, HIV-infection is associated with a markedly increased risk of bacterial pneumonia, and recurrent bacterial pneumonia has been included as an AIDS-defining illness since 1993. The risk for pneumonia among HIV-infected drug users is approximately five times that of non-HIV-infected drug users.

Encapsulated bacteria, most commonly *Streptococcus pneumoniae*, followed by *Haemophilus influenzae*, are the most frequent causes of pneumonia in both HIV-positive and HIV-negative drug users, and are highly associated with classic symptoms of sputum production, chest pain, and fever (130). Atypical bacteria, including *Mycoplasma pneumoniae*, *Chlamydia pneumoniae*, and *Legionella* species are also common among drug users, and are more likely to cause dry cough and headache than classic pneumonia symptoms. *Pneumocystis carinii*, *Mycobacterium tuberculosis*, and *Mycobacterium avium* are common among HIV-infected drug users, as discussed further elsewhere in this volume. Pulmonary tuberculosis should always be included in the differential diagnosis of drug users with pneumonia, and annual tuberculin skin testing of drug users is recommended. In addition, pneumococcal vaccine and annual influenza vaccines should be offered to all drug users.

Chronic lower respiratory diseases including chronic obstructive pulmonary disease (COPD) are the fourth leading cause of death in the United States. Tobacco smoking is by far the most important environmental risk factor for COPD. Cannabis use, while associated with COPD-like symptoms in-

cluding airflow obstruction, chronic cough, bronchitis, and decreased exercise tolerance, is not a clear cause of COPD in studies that control for tobacco use (131).

Pulmonary Complications of Crack Cocaine Use

Crack cocaine and to a lesser extent intranasal cocaine use are associated with pulmonary complications. Intranasal cocaine may cause nonspecific bronchial irritation that results in wheezing in persons with a history of obstructive lung disease. Crack cocaine, on the other hand, can precipitate a broad spectrum of pulmonary complications, including asthma exacerbations (fatal and near-fatal asthma); barotrauma (pneumomediastinum and pneumothorax); noncardiogenic pulmonary edema; diffuse alveolar hemorrhage; recurrent pulmonary infiltrates with eosinophilia; nonspecific interstitial pneumonitis; bronchiolitis obliterans with organizing pneumonia; pulmonary vascular abnormalities; and "crack lung" (acute pulmonary infiltrates associated with chest pain, hemoptysis, and a spectrum of clinical and histologic findings) (132). Among crack smokers, the prevalence of respiratory symptoms (cough, black sputum production, wheezing, dyspnea, or hemoptysis) is greater than 50% (133).

DRUG USE AND NEUROLOGIC DISEASE

Tobacco, alcohol, and stimulant use are all clear risk factors for cerebrovascular events, including ischemic strokes and hemorrhage, which together comprise the third leading cause of mortality in the United States (137,119 deaths in 2006). As with CVD, smoking promotes atherosclerotic cerebrovascular disease progression and hypertension. Alcohol, as with cardiac events, relates to ischemic stroke risk in a J-shaped fashion, with moderate use being protective and heavy use increasing risk. Any alcohol use, however, appears associated with a greater risk of hemorrhagic stroke. Cerebral vasoconstriction has been implicated as the mechanism of acute cocaine-associated neurologic complications, including ischemic and hemorrhagic stroke, in several case reports and case-control studies (134). In addition, long-term cocaine and amphetamine use appears to predispose patients with incidental neurovascular anomalies, such as aneurysms and arteriovenous malformations, to present with intracranial or subarachnoid hemorrhages at an earlier point than nonusers.

Cocaine- or amphetamine-induced seizures are a relatively rare but severe manifestation of stimulant toxicity. These are usually single, tonic-clonic, resolve without intervention, and are more likely to occur in patients with a history of prior seizures. Altered mental status, delirium, and seizure are well-described symptoms of severe alcohol and sedative-hypnotic withdrawal.

Injection drug users are at increased risk for systemic infections that may affect the central nervous system, including endocarditis, viral hepatitis, and HIV. Endocarditis is associated with neurologic complications in 20% to 40% of patients, including cerebral embolism and infarction, hemorrhage from ruptured mycotic aneurysms, meningitis, encephalopathy, and

parenchymal, subdural, or epidural abscesses (135). HIV infection may cause neurologic complications either directly or through opportunistic infections that attack the central nervous system.

Focal central nervous system infections occur commonly among drug users, although most focal infections result from embolization of infected vegetations among patients with endocarditis. The most frequent focal infections are brain abscesses, which may also result from local spread of an ear or sinus infection, hematogenous dissemination from a distant focus, such as infection in the lung, skin, bone, or pelvis, or trauma with an open fracture or foreign body injury. Spinal epidural abscesses are also common, and are caused by direct local extension of vertebral osteomyelitis, hematogenous spread from distant infection, or blunt spinal trauma.

Toxin-mediated diseases, including tetanus and botulism, comprise an additional important category of central nervous system infections among injection drug users. These infections usually result from intramuscular or subcutaneous injection of drugs, which predisposes to the inoculation of *Clostridium* species and the release of disease-producing toxin. Tetanus is caused by *Clostridium tetani*, and causes intense, sustained muscular spasms that may be localized or generalized. Localized tetanus causes muscle rigidity, pain, and enhanced deep tendon reflexes, while generalized tetanus causes respiratory failure and requires treatment in an intensive care unit. Wound botulism is caused by *C. botulinum*, and has been associated in particular with the injection of black tar heroin (136). Wound botulism initially causes blurred vision, dysarthria, and dysphagia, but may lead to descending muscle paralysis and respiratory failure. A high index of suspicion is necessary to diagnose these uncommon but rapidly progressive toxin-mediated diseases among drug users who present with neurologic symptoms. All injection drug users should be immunized against tetanus.

OTHER MEDICAL COMPLICATIONS

While other medical sequelae of drug use cannot be properly reviewed here because of space limitations, the reader is directed to recent reviews of pulmonary (137) and renal (138) complications.

Psychiatric Complications of HIV-1 Infection and Drug Abuse

Harold W. Goforth ■ L Brett Caram ■ Jorge Maldonado ■ Pedro Ruiz ■
Francisco Fernandez

The human immunodeficiency virus type 1 (HIV-1) has infected 60 million individuals worldwide, of which 42 million are still living with the infection. The spread of the virus continues at a rate of 14,000 newly infected individuals per day, and 5 million persons contracted the virus in 2003 (1). According to the Centers for Disease Control and Prevention (CDC), the number of persons living with HIV in the United States is estimated to have been 384,906 as of December 2002, and a total of 501,669 have died from the disease (2). Progress has been made since the introduction of zidovudine (AZT) as the first antiretroviral agent, and the advent of highly active antiretroviral therapy (HAART) in 1996 decreased both the mortality and the incidence of AIDS. Unprotected sexual intercourse, injection drug use (IDU), and contaminated blood and blood product transfusions are well-known mechanisms of HIV-1 transmission. Other risk factors include crack cocaine use in women (3) and use of marijuana or volatile nitrites (“poppers”) in the male homosexual population (4).

Concurrent substance abuse and psychiatric disorders in patients who are infected with the HIV are common. Prevalence rates vary significantly across reported studies and range from 10% to nearly 70% depending on the study (5,6). As many as half of patients have at least one psychiatric disorder, and nearly 40% abuse drugs other than marijuana. Twelve percent met criteria for drug dependence during the previous 12 months (5). In addition, bipolar II disorder, cyclothymic, and hyperthymic temperaments have been linked with up to 70% of the HIV population (6) and are associated with increased novelty seeking and risk-taking behavior in this population, which is suggestive of increased rates of unsafe sexual practices and needle.

In an attempt to make clinicians more aware and more capable of managing these complex and challenging patients, we review the psychiatric complications associated with HIV infection, neurobehavioral aspects, neuropathology, and treatment options for psychiatric disorders associated with the HIV-1 infection.

SCOPE OF THE PROBLEM

The highest rates of HIV infection are in patients with dual diagnosis of severe mental illness and substance use disorder. In one study of HIV-positive participants with comorbid substance use and psychiatric problems ($n = 1848$), HIV preva-

lence was 4.7% in patients having a diagnosis of both substance abuse and mental illness, whereas HIV prevalence was only 2.4% in patients diagnosed with a substance abuse disorder alone. Psychiatric illness appeared to almost double the risk of HIV—especially in those with concurrent poor psychosocial supports (7). These findings were confirmed by a cross-sectional survey of 3806 adults living with HIV across four major metropolitan areas in the United States, which showed that 72% of respondents reported at least occasional use of various drugs, and 40% of respondents reported frequent use of various drugs—only 28% declared abstinence from all drugs (8). In the group reporting frequent use of drugs, more were likely to be identified as heterosexual, had public health insurance, and endorsed increased symptoms of depression (7,8), which illustrates the complexities of the relationship between the triply diagnosed of mental health-substance abuse and HIV infection.

DRUG ABUSE DISORDERS

Alcohol use alone has been linked to multiple risk factors associated with HIV, including STD histories, condom nonuse, multiple sex partners, and lower HIV-related knowledge. These risks appear to increase substantially with increasing amounts of alcohol use and those demonstrating abstinence from alcohol appear to have the lowest risk profile. The impact of alcohol upon these risk factors remains present even in the absence of other drug abuse (9).

Intravenous drug use (IVDU) has long been associated with an increased prevalence of comorbid psychiatric diagnosis—especially dysthymia and depression. Depressive syndromes in IVDU populations have also been linked to increased willingness to share needles, syringes, and other paraphernalia, which further increases the risk of HIV transmission (10,11). Even after controlling for multiple confounding variables including age, race, gender, number of days on which injection drugs were used, and the average number of injections per injection day, a diagnosis of depression is significantly associated with injection risk behavior (12). Other data confirm that depressed patients are more likely to engage in sex with IVDU populations, heightening an already substantial risk of transmission (13). Being physically abused as an adult and Latino race appears to be a significant predictor of depression among HIV-seropositive intravenous drug users of both genders. However, data show that women appear to

experience increased depressive symptoms as compared to men, and correlates of depression in both men and women include perceived functional limitation, greater negative feelings regarding condom use, lower social support, and a lower sense of empowerment/external locus of control (14).

Methamphetamine-dependent men who have sex with men (MSM) also demonstrate high lifetime rates of psychiatric disorders including major depression and anxiety disorders. Generalized anxiety disorder, specific phobia, bipolar disorder, and major depressive disorder have all been linked to higher rates of sexually transmitted infections including gonorrhea and HIV (15). Naturalistic interview studies have demonstrated the wide prevalence of a cycle of severe depression and anxiety in the context of methamphetamine use as well as persistent anhedonia. Almost all respondents in such studies reported that crystal methamphetamine was severely damaging to social relationships with a resultant increase in self-isolation, random sexual encounters, and increased numbers of sexual partners with a decreased likelihood of condom use (16).

PSYCHIATRIC DISORDERS IN HIV INFECTION

Common mental disorders among individuals with HIV and substance abuse include adjustment disorders, sleep disorders, depressive disorders, mania, dementia, delirium, pain, psychosis, and sleep disorders. A careful psychiatric assessment is necessary in order to engage in differential diagnostic considerations and differential therapeutics.

Mania and Bipolar Disease

Bipolar disease in the context of HIV is especially problematic in that it involves cyclical moods that not only predispose its sufferer's to the risk factors of depression, but also heightened risks of contracting HIV due to features of mania that include impulsivity, hypersexuality, and increased goal-directed behavior. Patients with comorbid HCV/HIV are at increased risk for comorbid psychiatric disorders including bipolar type (6). Severity of bipolar illness has also been associated with HIV risk profile including high rates of unprotected intercourse (69%), multiple partners (39%), sex with prostitutes (24%, men only), and sex trading (10%) (17).

Schizophrenia

Patients with serious and persistent mental illness (SPMI) have been noted to have approximately twice the incidence of HIV as compared to patients without SPMI, and there is also a greater incidence of infection with HCV (18). However, the source of this increased risk has been debated and some data suggest that in the absence of comorbid substance abuse, these patients do not share an elevated risk for acquiring HIV compared to other non-SPMI populations (19). Identification of comorbid SPMI is important in an HIV population given that comorbidity incurs a worse prognosis for both the schizophrenia as well as the HIV due to factors such as psychosocial instability and adherence (18).

Depression

Depression is the most common co-occurring mood disorder with HIV, with rates increasing in the context of advancing age. Depression has been closely linked to apathy in HIV-seropositive populations, and both apathy and depression are linked to combination antiretroviral therapy (CART) nonadherence (20), and a greater frequency of injection drug risk behavior among depressed injection drug users (12).

HIV-seropositive women are a special risk group with regard to depression and intravenous drug use, and they present with both increased severity of depression as well as an elevated incidence of depression (21). Women also report the poorest quality of life scores in the context of HIV infection, in spite of showing some protection against cognitive decline with respect to male counterparts (22). Drug use, violence, and depression have been deemed a “tripartite HIV risk” among African-American women and are underexplored areas of research—again highlighting the need for effective psychiatric services in this at-risk group.

PSYCHOSOCIAL ISSUES

Sexual Abuse

Childhood sexual experiences have been linked as a strong predictor to psychological distress as well as risk of substance abuse and HIV transmission risk (23,24). Among MSM, those with a history of childhood sexual abuse were more likely to engage in high-risk sexual behavior including unprotected receptive anal intercourse, engage in trading sex for money or drugs, report being HIV seropositive, and experience nonsexual relationship violence (24). Individuals who experienced forced sexual contact as a child have a higher risk for showing increased rates of substance abuse and HIV transmission risk as compared to a no exposure to sexual abuse group (23). An assessment of these groups should include a discussion of patterns of risk exposure and childhood sexual experience to better tailor interventions to the specific individual. The role of past trauma in placing individuals at risk of HIV has also been found in large populations of HIV-seropositive women, with posttraumatic stress disorder (PTSD) being associated with the practice of receptive anal sex and prostitution (25). Importantly, both childhood trauma and depression appear to predispose to ineffective coping, which may predispose this group to additional burdens of depression and disease.

Risk Taking Behavior

Previous cross-sectional data has illustrated a close relationship between substance abuse, depression, and behavior, but it is difficult to infer causal relationships from this data. Longitudinal data can better support causal associations, and one such study examining the relationship between depression and sexual risk behaviors in a community sample of 332 inner-city drug abusers found that increasing severity of depression predicted sexual encounters with multiple partners as well as sexual

encounters with known injection drug users (26). Other studies have confirmed a link between mental health and risk-taking behavior, even when controlling for substance abuse patterns, across a variety of populations. One study examining a subset analysis of STD clinic patients meeting criteria for major depressive disorder (13) found that depressed patients were more likely to have sex for money or drugs, have a greater number of lifetime sexual partners, and a higher likelihood of abusing alcohol or other substances. The HIV behaviors associated with depression persisted even when controlling for substance abuse.

Similarly, another longitudinal study examining HIV risk behaviors and drug use among Latino heroin and cocaine injectors not in treatment demonstrate a close association between both mental health and substance abuse. Intravenous drug users in this study reported high rates of both depression (52%) as well as severe anxiety (37%) and high rates of alcohol intoxication in the last 30 days (18%). Those showing polysubstance abuse (alcohol and IVDU) were more likely to share needles and paraphernalia, as well as engage in casual sex, prostitution, and unprotected sex (27). Similar patterns among comorbid mental health disorders, substance abuse, and increased sexual risk taking have also been identified in young age populations. One study examining a cohort of newly homeless youth who were followed longitudinally for up to 24 months demonstrated that drug use was a significant predictor of having multiple sexual partners as well as decreased condom use. Similarly, living in a nonfamily setting also was a significant predictor of sexual risk-taking behavior and condom use (28).

A large analysis of 736 enrolled MSM participants in the EXPLORE study described patterns of use with methamphetamines, poppers, and cocaine as well as sexual risk behavior. Younger participants were more likely to increase their use of drugs over time, and high-risk sexual behavior was more common during periods characterized by increased methamphetamine, popper, or sniffed cocaine use. Importantly, a within-person analysis found that both light drug use (less than weekly use) and heavy drug use periods were significantly associated with engaging in unprotected anal sex with HIV-seropositive or unknown status partners as compared to periods of no drug use (29). Importantly, these data suggest that a risk-reduction model of addressing substance abuse in this population is likely to be ineffective in reducing HIV transmission, while engagement in an abstinence model appears safer and more effective. Similar data regarding the risk of moderate alcohol use upon nonadherence also support an abstinence model over a risk-reduction one (30).

Adherence to CART

Previous studies examining the relationship between depression and HIV transmission have shown mixed results, but the role of depression upon adherence to CART has been confirmed in multiple studies on the subject. A recent longitudinal study on adherence rates from 2001 to 2004 of HIV-seropositive patients with concurrent mental illness and substance abuse demonstrated several concerning patterns. Almost 73% of participants met criteria for major depressive

disorder, and depression was linked to nonadherence (31). Given that mental health diagnosis and substance abuse problems are common among patients infected with HIV, a great deal of attention has been devoted to the study of these factors and their impact upon adherence. Large cross-sectional studies demonstrated that mental health diagnoses including depression, generalized anxiety disorder, or panic disorder predicted nonadherence to CART therapy over the previous week compared to non-psychiatrically ill counterparts. Nonadherence was also associated with cocaine, amphetamines, or sedative use in the previous month, but cocaine demonstrated the largest effect size in the drug abuse group, while generalized anxiety disorder showed the largest odds of nonadherence among the mental health diagnoses. However, alcohol abuse showed the largest odds ratio of nonadherence among all diagnoses combined (30). Based upon available data, a history of substance abuse in the absence of current abuse does not predict nonadherence, which illustrates the importance of active interventions designed to curb substance abuse and dependence.

The presence of depression has also been linked as an independent risk factor in not only nonadherence but also HIV disease progression, viral load, and CD8 activation. This pattern has been documented in a study of CART-treated HIV-infected drug users. Clinical predictors of disease progression included nonadherence to CART as well as a higher score of depressive symptoms following CART initiation that remained significant even after controlling for nonadherence behavior (32). Other affective syndromes including complicated bereavement and chronic grief have also been linked to disease progression in HIV-infected populations (33).

However, encouragingly, depressed HIV patients who receive psychiatric treatment with antidepressants are more likely than untreated patients to receive appropriate care for their HIV disease and increase adherence to HIV interventions. Antidepressant therapy for treatment of depression in this population has also been demonstrated to be associated with a lower monthly cost of medical care services based on at least one study examining merged Medicaid and surveillance data (34).

CENTRAL NERVOUS SYSTEM

When HIV was initially discovered, it was thought to affect only CD4 lymphocytes; however, it was recovered from brain, spinal fluid, and peripheral nerves in 1985, which showed its potential for direct central nervous system (CNS) infection. Since that time, HIV-1 has been shown to penetrate the blood-brain barrier (BBB) early in the course of the infection, is replicated in brain tissue using monocytes and multinucleated macrophages as hosts, and becomes an anatomic reservoir for the disease. The mechanisms whereby HIV-1 penetrates the nervous system remain inadequately understood, but the virus appears to enter the brain through endothelial gaps in brain capillaries, via the choroid plexus, or as a proviral form contained in a latently infected cell (monocyte), which differentiates into a macrophage once inside the CNS to become a productively infected cell. The virus is known to invade and destroy subcortical areas such as the basal ganglia and

temporolimbic structures, as well as support cells such as astrocytes, which share similar CD4 receptors with their well-known lymphocyte host (35). This effect may be exaggerated in substance-abusing populations (36).

Clinically, patients suffer from a wide spectrum of cognitive impairments related to CNS HIV disease including personality changes, and motor dysfunctions that range from subclinical symptoms without impairment of work or daily activities to severe dementia with paraplegia and incontinence. The prevalence of HIV-associated dementia (HAD) was approximately 30% in the 1990s, but has decreased to approximately 11% with the advent of HAART therapy (35). Its severity appears related in part to the degree of inflammatory response in the brain (33). In patients with moderate to severe dementia, multinucleated giant cells (MNGC) are found in 25% to 50% of patients (37). Microglial and glial changes, along with MNGC, can be found in any part of the CNS but are more common in deep white matter of the cerebral hemispheres, basal ganglia, and brainstem (37). White matter pallor with astrogliosis, diffuse or focal vacuolation associated with axonal or myelin loss, and cortical atrophy are other changes that are less commonly observed (38). Rather than a true demyelination process of the oligodendritic myelin sheath, the pallor is a result of an increase in interstitial water content, most likely caused by a leaky BBB.

Peripheral Nervous System Pathology and Myopathy in HIV-1 Infection

Patients with HIV-1 infection may also present with a wide variety of symptoms involving the peripheral nervous system (PNS). Distal symmetric peripheral neuropathy (DSPN) is the most common presentation among patients with generalized neuropathies (39). Initial symptoms include trophic changes in the lower extremities, paresthesias, sensory loss, edema, and weakness. Medication-induced neuropathies have a clinical presentation that is similar to DSPN except that they present concurrent with the use of antiretrovirals. Inflammatory demyelinating polyradiculoneuropathy may be acute (AIDP), presenting at the time of seroconversion and the initial manifestation of HIV-1 infection, or chronic (CIDP), presenting as subacute or chronic weakness in upper and lower extremities, diminished deep tendon reflexes, and mild sensory abnormalities. Cranial nerves may also be involved, and mononeuritis multiplex can present as an abrupt-onset mononeuropathy with periodic additional abrupt mononeuropathies in other distributions and may involve the cranial nerves as well. Pain may accompany any of the neuropathies and may be both severe and incapacitating. Less common presentations of PNS dysfunction include progressive polyneuroradiculopathy with early impairment of bladder and rectal sphincter control, and autonomic neuropathy with postural hypotension, diarrhea, and sudden arrhythmias with the risk of death (40).

Myopathy associated with HIV-1 infection has three different histologic findings: (a) polymyositis; (b) necrotizing myopathy without inflammatory infiltrates; or (c) nemaline rod myopathy. Clinically, myositis presents as painless progressive

weakness involving the shoulder and pelvic girdle muscles, elevated creatinine kinase, and electromyographic abnormalities. Treatment with prednisone alone or in combination with plasmapheresis is generally effective. Historically, one of the more important causes of myopathy among HIV-1–infected patients was related to AZT, which usually developed after 9 months to 1 year of treatment and manifest as leg weakness and wasting of the buttock muscles (40). However, AZT myopathy is more unusual now given that high doses of AZT are rarely used in favor of other available CART regimens.

Diagnosis and Management of HIV-1 Secondary Neurologic Complications

HIV-1 CNS involvement may occur at any time, but opportunistic infections and HIV-1–related malignancies affecting the nervous system are usually a late manifestation of the HIV-1 infection, occurring most often in patients with a CD4 count less than 50 cells/mm³. Table 50.1 indicates potential CNS pathologies secondary to HIV-1 infection. No significant differences in the incidence of neurologic disease between IVDUs and non-IVDUs have been reported (41).

Toxoplasma gondii infection is a common cause of focal intracerebral lesions in patients with AIDS. However, primary infection is usually asymptomatic. Focal encephalitis with headache, fever, confusion, and motor weakness is the most common clinical presentation. Individuals with toxoplasmosis encephalitis are almost uniformly seropositive for antitoxoplasma immunoglobulin G antibodies. Computed

TABLE 50.1 Neuropsychiatric infections/malignancies associated with HIV

Atypical aseptic meningitis
Cytomegalovirus (CMV) encephalitis
Herpes simplex virus encephalitis
Progressive multifocal leukoencephalopathy
Subacute encephalitis

tomography (CT) scan or magnetic resonance imaging (MRI) often shows multiple contrast enhancing lesions with associated edema. The majority of clinicians rely on empiric diagnosis, since definitive diagnosis requires a brain biopsy. Detection of *T. gondii* by PCR in cerebrospinal fluid (CSF), although highly specific, has low sensitivity and is usually negative once therapy has started. At times, individuals who are severely immune deficient may not mount an antibody response. Primary prophylaxis with daily DS TMP-SMX is recommended in toxoplasma-seropositive individuals with a CD4 count less than 100 cells/mm³. This can be discontinued when the CD4 count is >200 for 3 or more months. The initial choice of therapy for toxoplasmosis encephalitis includes pyrimethamine, sulfadiazine, and leucovorin (42,43).

Cryptococcus neoformans is a common cause of meningitis and the prevalent CNS fungal infection in patients with AIDS. The typical clinical presentation includes subacute meningitis with fever, malaise, and headache in a patient with a CD4 count of less than 50 cells/mm³. Cryptococcal antigen is invariably detected in CSF. Treatment usually includes amphotericin B deoxycholate combined with flucytosine for at least 2 weeks followed by fluconazole (44).

Other secondary neurologic infections associated with HIV-1 include progressive multifocal leukoencephalopathy (PML) secondary to polyoma virus JC virus, cytomegalovirus (CMV) infection encephalitis and polyradiculopathy, herpes simplex virus (HSV) encephalitis, neurosyphilis, mycobacterial infection, and other fungal infections. The incidence of PML after widespread use of HAART has significantly declined (45). There remains no established therapy for PML, and the main approach to care includes optimizing HIV therapy.

HSV encephalitis is a rare but life-threatening complication of HSV infection, especially in patients with advanced HIV-1 infection and other opportunistic infections of the CNS. CSF is usually positive by PCR. Treatment options include intravenous acyclovir and foscarnet. Syphilitic disease is accelerated in those infected with HIV, and there is wide-ranging debate on screening for neurosyphilis in HIV patients with a positive RPR. Fortunately, if diagnosed, intravenous penicillin is a highly effective and definitive treatment. Herpes zoster, CMV, mycobacterial, and fungal infections that produce CNS complications in HIV-1-infected individuals generally respond well to multimodal treatment (42,43).

Non-Hodgkin lymphoma is a complication of advanced HIV-1 disease that may involve the CNS. A diagnosis can be made via neuroimaging, but a tissue diagnosis is typically required before initiation of treatment. Multiagent chemotherapeutic treatment is effective but may be short-lived. Incomplete responses and rapid progression have been noted historically in up to half of the patients (46).

Neurobehavioral Evaluation in HIV-1 Infection

Mental Status and Neuropsychological Assessment

The HIV-1-associated cognitive/motor complex consists of a combination of cognitive, motor, behavioral, and affective disturbances that may be severe and sufficient for the diagnosis

of AIDS. It may be the presenting manifestation of HIV-1 infection or it may cause mild symptoms and may not be associated with significant impairment in the social or occupational functioning levels of these patients. Data support that asymptomatic HIV-1-positive patients have an elevated rate of cognitive dysfunction as compared to HIV-1-negative controls, but these are usually subtle impairments that are unrelated to the level of immunosuppression or to depression and are most evident in individuals with lower cognitive reserve. It is generally accepted by clinicians that HIV-1-related cognitive impairment can occur at any time during the course of the disease, but cognitive abnormalities in asymptomatic patients are associated with an increased risk of morbidity and mortality (47).

Although varying psychological tests have been used to determine or evaluate the earlier signs of HIV-1 effects on mental function, no definitive test can be used, either alone or in combination with others, to establish a diagnosis of HIV-1-associated cognitive/motor complex. A careful cognitive history can be an extremely useful adjunct in the differential diagnosis of the etiologies of cognitive dysfunction in HIV-1-infected patients with cognitive complaints.

The most significant signs of cognitive impairment related to HIV-1 infection include early, mild problems with abstraction, learning, language, verbal memory, and psychomotor speed that progress to more serious difficulties with attention and concentration, slowing of information processing, slowed psychomotor speed, impaired cognitive flexibility, impairment in nonverbal abilities of problem solving, visuospatial integration and construction, and nonverbal memory in the late phases of the infection. The early stages of cognitive impairment associated with HIV-1 affect psychomotor tasks (such as the Wechsler Adult Intelligence Scale digit symbol and block design, and the trail making test part B from the Halstead-Reitan Neuropsychological Test Battery), memory tasks (such as the delayed visual reproduction subtest from the Wechsler Memory Scale); and the delayed recall of the Rey-Osterrieth Complex Figure. Psychomotor and neuromotor tasks may reveal HIV-1-related cognitive dysfunction and are sensitive measures for the early detection of HIV-1-related cognitive impairment (48).

The neuropsychological tests used for assessment of dementia generally appraise complex language-associated functions (such as aphasia and apraxia), higher level cognitive functions of verbal and nonverbal abstract reasoning and problem solving, and perceptual functioning of the different sensory modalities. However, as more has been learned about the HIV-1-associated cognitive/motor complex, it has become apparent that these neuropsychological assessments are not reliably sensitive or useful for detecting the often subtle impairments of the early stages of HIV-1's effects on the CNS or function (48).

CSF Studies

CSF reflects changes consistent with HIV-1 infection, including the presence of HIV-1 virions, abnormally elevated IgG levels, HIV-1-specific antibodies, mononuclear cells, and oligoclonal bands. HIV-1 replicates in the brain with independent dynamics from other organs, making the CSF viral load more representative for the assessment of CNS

infection (49). It correlates with the degree of neurocognitive dysfunction and has a role in monitoring the response to antiretroviral medications in the CNS (48). Although other CSF studies have been used in the assessment of CNS compromise in HIV-1 infection, their use is now limited because serum viral load measurements have replaced them in clinical practice. CSF β_2 -microglobulin has shown a high correlation between its concentration and both the severity of the dementia and the level of systemic disease. Although elevation in the myelin basic protein and its degradation was found in patients with HIV-1–associated cognitive/motor complex and with PML, this was not seen in patients with other opportunistic infections. An abnormally low CSF CD4:CD8 ratio may have importance for treatment considerations and prognostic value for HIV dementia (49,50).

Neuroimaging

MRI and to a lesser extent CT and are useful tools in the diagnosis of secondary infections and brain tumors. Primary CNS HIV-1 infection can be associated with characteristic imaging features including cortical atrophy, ventricular enlargement, diffuse or patchy periventricular white matter abnormalities, and, in children, calcification of the basal ganglia and delayed myelination. MRI is more sensitive than CT, and is now considered the neuroimaging criterion standard. Both, however, are useful as diagnostic tools and have utility in assessing the prognosis of these patients (51).

Magnetic resonance spectroscopy (MRS) measures levels of metabolites in brain tissue. MRS in HIV disease, particularly HIV dementia, shows increases in choline and reductions in *N*-acetylaspartate suggestive of neuroinflammation and neuronal injury. In some studies, these findings correlate with the severity of the HIV dementia along with CD4 counts and viral load (52).

Electrophysiology

There is currently relatively little role for electrophysiology in the diagnosis and management of uncomplicated HIV patients outside of that subset in whom one is assessing for the presence of epilepsy or other CNS lesions. However, research data using electrophysiologic techniques has provided some interesting findings. The percentage of patients with abnormal electroencephalograms appears to increase as the systemic disease progresses, and a low amplitude pattern may be found in advanced dementia and atrophy on neuroimaging. In asymptomatic patients, studies have found conflicting results, but the best available data support a very limited role, if any, of CNS dysfunction in nonimmunocompromised HIV patients. Evoked potential studies have also been useful in detecting preclinical abnormalities in neurologically and physically asymptomatic HIV-1–seropositive patients by showing significant delays in latency of response to the brainstem auditory-evoked potential, somatosensory-evoked potentials from tibial nerve stimulation, and visual-evoked potentials. However, these are rarely used clinically at this point in time (53).

Treatment of Neuropsychiatric Disorders

Mental disorders secondary to medical conditions such as delirium, dementia, mood disorders, psychosis, and anxiety disorders are the most common neuropsychiatric conditions associated with HIV-1 infection (54). One of the most perplexing aspects of these presentations is that HIV-1–related neuropsychiatric manifestations very closely resemble other primary psychiatric (functional) disorders. Like syphilis, HIV-1 infection often confounds precise diagnostic criteria because of its characteristic as a “great imitator.”

Delirium

It is estimated that as many as 30% of hospitalized medical/surgical patients may have an undetected delirium process. Delirium is a predictor of outcome in hospitalized AIDS patients, and delirious patients have higher mortality rates, longer lengths of inpatient hospitalizations, and a greater need for long-term care as compared to a group of nondelirious AIDS patients with similar demographics and markers of medical morbidity (55). Standardized and validated instruments exist for delirium screening and should be used routinely (56).

There are diverse suggestions for the etiology of HIV-1–related delirium. However, it is important to attempt to determine the particular etiology for each individual patient because certain causes are life-threatening or may lead to permanent brain damage. These conditions include Wernicke encephalopathy, hypoglycemia, hyperglycemia, hypoxemia, hemodynamic instability with cerebral hypoperfusion, infections, metabolic disturbances, and electrolyte imbalances. Herpes and *T. gondii* encephalitis, cryptococcal meningitis, space-occupying lesions from cerebral tumors, PML, and neurotoxicities from antiviral agents should also be included in the differential diagnosis of delirium in HIV-1 patients. In a substance-abusing population, the detection of intoxication or withdrawal is important in the differential diagnostic considerations (57).

Prompt pharmacologic interventions may help remediate the various behavioral abnormalities associated with the delirium process. High-potency neuroleptics remain the standard of care for delirious patients, although their use in HIV-infected patients brings an increased risk of significant treatment-emergent side effects. At low doses, haloperidol and chlorpromazine (a low-potency neuroleptic) in both oral and intravenous formulations have been used effectively and with few adverse events in the treatment of delirium in hospitalized AIDS patients. Atypical antipsychotics are used now as first-line agents, and are both effective and better tolerated as compared to traditional neuroleptics. The experience, however, is still limited, especially in HIV-1–infected individuals, and they must be used with caution (58).

Lorazepam is useful in the management of severely agitated delirious HIV-1–infected patients when used in combination with a neuroleptic. Lorazepam alone, however, appears to be ineffective and is associated with worsening delirium (59). The notable exception to this is when treating delirium associated

with GABAergic withdrawal such as delirium tremens, benzodiazepine withdrawal, or barbiturate withdrawal. Benzodiazepines are the treatment of choice in these scenarios.

Dementia

It is beyond the scope of this chapter to review the different classes of antiretroviral drugs and their use in clinical practice in the context of HIV-cognitive impairment and dementia. The use of antiretroviral agents are generally recommended when CD4 count is below 350 cells/mm³ or plasma HIV RNA is above 100,000 copies/mL. There are no established guidelines for HIV-associated cognitive and dementing illness. Like that of systemic therapy, the use of antiretroviral therapy (ART) in HIV-cognitive impairment and dementia is to produce complete virologic suppression in both plasma and the CNS.

Various drugs that are effective against HIV-1 are approved by the Food and Drug Administration (FDA) for clinical use. Initial therapy for HIV has either a PI backbone or a nonnucleoside reverse transcriptase inhibitors (NNRTI) backbone, and then includes a dual NRTI component. It is recommended, currently, that therapy begin if a patient has HIV symptoms regardless of CD4 count, or in any asymptomatic individual with a CD4 count <350 cells/mm³. However, there is ongoing research regarding the exact optimal point at which to initiate HAART. With regard to CNS symptoms, studies show that CART improves cognitive functioning among patients with minor cognitive changes who are otherwise asymptomatic and reduces the neurocognitive deficits when used long-term, therefore reducing the risk of HAD (60).

CNS distribution of the NRTIs is best characterized of anti-HIV agents. AZT and stavudine are significantly better in terms of CNS penetration than didanosine, although the data regarding CNS penetrance with stavudine in clinically used doses are conflicting. Early data regarding abacavir are also promising with at least one study showing that it penetrates into CNS at levels high enough to inhibit local HIV populations. A recent review covering this data also notes that NRTIs are able to prevent infection of resting CD4 lymphocytes and macrophages to varying degrees depending on the specific agent (60).

NNRTIs including nevirapine, efavirenz, and delavirdine are increasingly important components of CART regimens and are highly active against HIV-1. In addition, they are detectable in the CNS even though they are highly protein bound, which may limit CNS access—especially for delavirdine. Efavirenz has been shown to reach effective CNS levels to inhibit local HIV replication and can be given once daily due to its long half-life. Nevirapine shows the least protein binding (60%) and is also quite lipophilic. It has shown an approximate 10 times greater propensity to cross the BBB than other NNRTIs, so it is likely the NNRTI of choice when targeting CNS symptoms (60).

Protease inhibitors are large-molecular-weight agents and are relatively highly protein bound, but they also show high lipophilicity. Unfortunately, they are actively removed from the CSF due to acting as substrates of P glycoprotein efflux transporter that pumps PIs across the BBB. Some reports have

suggested that nelfinavir, ritonavir, and lopinavir do not reach effective CSF concentrations. It has also been noted that available studies that evaluated the benefit of PI-based regimens also contained multiple NRTIs as part of the CART regimen. Indinavir may be the best penetrator into the CSF, but its dosing is inconvenient and difficult, so it is rarely used in favor of simpler regimens designed to promote adherence. Lopinavir has been shown to reach effective CSF concentrations to inhibit HIV replication as well. Saquinavir, nelfinavir, amprenavir, and ritonavir all appear to be weakly and insufficiently CNS penetrant to prevent the replication of local RNA populations (60). The optimal CART regimen for the treatment of cognitive impairment is not known (61). However, in future, optimizing CNS penetration of CART therapy by utilizing more CNS penetrant agents may be useful in further treating HIV associated cognitive disorders (62).

The psychostimulants such as methylphenidate and dextroamphetamine have been used effectively to manage symptoms of decreased concentration, or memory deficits among patients with HIV-related cognitive impairment and HAD. Case reports and uncontrolled clinical trials treating patients with methylphenidate (30 to 90 mg/day) or dextroamphetamine (30 to 60 mg/day) all showed significant improvement (63,64).

Mood Disorders

While mood disorders associated with HIV-1 infection are most frequently depressive, manic and hypomanic disturbances have also been described. The diagnostic process for evaluating mood disorders is complex, requiring careful consideration of the interaction of medical conditions, substances, and behavioral factors. Depressive spectrum disorders are commonly observed in patients with HIV-1-related disorders ranging from normal sadness to major affective disorders, as well as mood disorders that may be substance induced or a consequence of a general medical condition. Although it has been suggested that clinicians rely on psychological rather than somatic symptoms of depression to fulfill diagnostic criteria for depression in the medically ill, an all-inclusive approach is often the simplest and most clinically effective. Depression in medically ill patients is underdiagnosed and undertreated, and this is particularly true of HIV-1-infected persons who suffer an increased incidence of depression when compared with other medically ill patients or the general population (58).

Suicidal thoughts are frequently a symptom of depression, and patients need to be assessed carefully. Risk factors include social isolation, perceived lack of social support, adjustment disorder, personality disorder, alcohol abuse, HIV-1-related interpersonal or occupational problems, and a past history of depression. Other risk factors include current major depression, previous suicide attempt, and history of alcohol abuse. One should never blithely consider the notion of “rational suicide” as an understandable reaction to this devastating and socially stigmatized disease. Because of impaired decision-making capacities and cognitive inefficiencies associated with HIV-1 disease, it is vital that clinicians respond promptly to any and all

reports of suicidal ideation. A thorough assessment of the patient includes a realistic appraisal of the psychosocial situation and of the motivation for completing the suicide, along with any appropriate neurodiagnostic assessment to rule out a potentially reversible organic mental disorder (65).

Antidepressants with greater affinity for the central muscarinic receptor should be avoided for symptomatic HIV-1-infected patients, which can mask or aggravate HIV-1-related cognitive impairment or precipitate delirium. Another adverse side effect of these agents is the possibility of excessive drying of the mucous membranes, which introduces the possibility of oral candidiasis that is often refractory to treatment in HIV-1-infected patients. Antidepressants that are preferable for HIV-1-infected individuals include selective serotonin reuptake inhibitors (SSRIs), and other second-generation antidepressants such as bupropion, venlafaxine, mirtazapine, and psychostimulants (58).

Fluoxetine has been shown to be safe in HIV populations, but inhibition of the CYP450 2D6 and 3A4 isozymes is problematic in patients with HIV. Similarly, paroxetine is not recommended in this population for the same reasons. Sertraline and citalopram have also been shown to be effective and well tolerated. Venlafaxine is also a reasonable choice because of its low interactions with other drugs (58).

Patients being treated with lithium carbonate or monoamine oxidase inhibitors before their diagnosis with HIV-1 disease should usually continue to take that medication. Increased vigilance in toxicity monitoring with a concomitant dosage alteration may be necessary as HIV-1 disease progresses, especially when infectious complications cause severe diarrhea or any other form of fluid loss due to the emergence of nephrotoxicity and neurotoxicity from lithium toxicity (66). Psychostimulants such as methylphenidate and dextroamphetamine may be tried in depressed patients who are symptomatic of HIV-1 infection, in those depressed patients in whom rapid improvement in symptoms is needed or who are cognitively impaired or who suffer from both depression and dementia. Methylphenidate is a safe and effective treatment for these syndromes. Response usually occurs within hours of the first administration and includes psychomotor activation, appetite stimulation, and qualitative as well as quantitative improvement in higher cortical functions. The initial administration of methylphenidate is usually 5 to 10 mg orally, and an adequate therapeutic response usually requires less than 30 mg daily. Methylphenidate can be continued safely for several months after the patient's symptoms remit. Special care should be taken in using dextroamphetamine, which has been noted to unmask or aggravate abnormal involuntary movements in AIDS dementia patients. The use of psychostimulants in managing depressive or cognitive symptomatology in drug-abusing patients is questionable, so they should be used cautiously if at all (64).

Sleep Disorders

Insomnia is one of the most prevalent neuropsychiatric disorders in HIV-seropositive populations. Estimates as high as 70% have been noted in some studies, if one looks at the in-

cidence of insomnia across the HIV disease process. Insomnia has been linked to reduced quality of life as well as treatment nonadherence. However, there has been very limited research on the treatment of insomnia in this setting. Readers are referred to a comprehensive review of HIV-associated insomnia by Omonuwa and colleagues (67). Essentially, there appear to be four primary factors that impact the assessment and treatment of insomnia in individuals with HIV: (a) medications used to treat HIV, (b) antibiotics used to treat opportunistic infections, (c) the HIV infection itself, and (d) conditions frequently associated with HIV infection.

Insomnia is defined as persistent difficulty falling asleep, staying asleep, or nonrestorative sleep which is associated with impaired daytime function. Insomnia is common in the general population, but the prevalence of insomnia in HIV-positive individuals appears to be higher. It is easy to assume that HIV-associated insomnia is due to the stress of a highly stigmatized and potentially life-threatening physical illness, but this view is contradicted somewhat by a study of asymptomatic HIV-positive men, which showed that even prior to experiencing HIV/AIDS symptoms, there were more shifts to stage 1, increased awakenings, and lower sleep efficiency. The sleep changes that occur in HIV infection have been quantified in several studies employing polysomnography; however, the data are conflicting. There are reports of an increase in slow wave sleep that occurs primarily during later sleep cycles, but this finding has failed to be replicated in other studies. Similarly, increased sleep latency, a reduction in the percentage of stage 2 sleep, and an increase in the number of nocturnal awakenings have been reported but have not been confirmed by subsequent studies. The pathophysiology of insomnia in HIV is equally unclear. It is agreed that insomnia becomes highly prevalent in the later stages of HIV infection, and this may be due to disruption of sleep centers via HIV-mediated neurotoxic effects, medication effects, opportunistic infections, HAD, and chronic depression (67).

The NNRTI efavirenz has the distinction of being the antiviral medication best documented to be associated with sleep disturbances. Nervous system adverse events including dizziness, insomnia, and fatigue are among the most common associated with this medication. Sleep effects of efavirenz include difficulty with sleep initiation and maintenance, as well as vivid nightmares. An ambulatory polysomnographic study found that all patients on efavirenz had longer sleep latencies, reduced sleep efficiency, and reduced REM sleep. Efavirenz serum levels appear to correlate with changes in sleep. However, the sleep disruption associated with efavirenz appears to self-extinguish in the majority of patients over time, and every effort should be made to support the infectious disease team during this time so that patients can remain on this agent if needed (67).

A large number of different prescription medications are used to treat insomnia. These medications can be broadly categorized as benzodiazepines, nonbenzodiazepine hypnotics, antidepressants, and antipsychotics. The benzodiazepines are a relatively old group of compounds that exert a therapeutic effect on sleep via allosteric modulation of the γ -aminobutyric acid (GABA) receptor complex and enhance the inhibition that

occurs when GABA. Commonly used benzodiazepines include triazolam, temazepam, flurazepam, quazepam, lorazepam, oxazepam, and alprazolam. Major alterations in half-life and effect have been noted with the agents that require oxidation in the presence of protease inhibitors, so if a benzodiazepine is to be used, then we recommend that it either be temazepam, lorazepam, or oxazepam in this patient population. Other alternatives include the typical benzodiazepine-like agents such as zolpidem, zaleplon, and eszopiclone. The reader is referred to a comprehensive review of these agents for up to date concerns over drug–drug interactions (67). All these agents are Schedule IV under the Drug Enforcement Administration, which is reflective of the fact that they do have some potential to be habit forming over time in susceptible individuals.

Antidepressants are frequently used in the treatment of insomnia, but none are FDA approved for this indication. The most commonly used agents include sedating tricyclic antidepressants, mirtazapine, and trazodone. However, in contrast to the benzodiazepines, they have less abuse potential in vulnerable patient populations. Tricyclics must be used with caution as they can cause sedation, orthostasis, weight gain, dry mouth, constipation, and cardiac dysrhythmia; although some data exist to suggest that very low dose doxepin can avoid these side effects while improving both sleep onset insomnia and sleep maintenance insomnia. Other alternative antidepressants include mirtazapine and trazodone. Among the antipsychotics that are frequently used off-label for sleep, quetiapine and olanzapine appear to be common choices. Care must be taken in the selection of these choices, as atypical antipsychotics can exacerbate and cause a metabolic syndrome. No atypical antipsychotic has placebo-controlled data to support their use in treating primary insomnia. However, for those patients who are refractory to other measures and who understand the associated risks, they can clinically be useful per our experience (67,68).

Psychosis

Nearly 10% of patients with HIV infection have a diagnosed psychosis of one type or another (68). There are several potential causes for psychosis and the initial evaluation for psychosis includes the same medical workup as that for delirium and dementia (69). Some are preexisting conditions unrelated to the HIV infection, whereas others are thought to result from delirium and CNS involvement of the HIV infection. Others may result from drug use inclusive of rare iatrogenic causes such as that which occurs with efavirenz (70). Many patients with HIV-associated psychosis also manifest symptoms of cognitive decline, such as HMCMD or HAD. In fact, psychotic symptoms may precede the onset of dementing illness (71). There is also a high association between psychosis and HIV-related mood disorders.

Treatment of psychosis in the context of HIV-disease, whether or not there is concurrent CNS involvement, requires timely intervention. This is best accomplished with neuroleptics. However, patients with HIV infection are more sensitive to side effects such as extrapyramidal reactions and neuroleptic malignant syndrome. This is particularly true with high-

potency typical neuroleptics, whereas confusion and seizures are more frequent with low-potency neuroleptics. The atypical antipsychotics (risperidone, paliperidone, olanzapine, quetiapine, aripiprazole, and ziprasidone) have also been shown to control HIV-related psychosis without having the same treatment emergent side effects (72). Quetiapine has been shown to have the least antiparkinsonian effects (73), and should be considered for patients with symptomatic HIV-related CNS disease given the associated subcortical damage related to HIV infection. Risperidone is an effective alternative and has been reported to be well tolerated in low doses (74). Low doses should be used in any regimen involving protease inhibitors because of potentially heightened risk of extrapyramidal reactions (75) and alterations in consciousness that have been reported with such combinations (76,77).

One major area of concern for the use of atypical antipsychotic agents in patients with HIV infection receiving HAART is in the development or exacerbation of metabolic syndrome (72). In such instances where there is a major concern for potentially exacerbating metabolic syndrome, the practitioner can choose to prescribe those with a lower incidence of metabolic effects, such as aripiprazole or ziprasidone. Another concern with the use of atypical antipsychotics is the possibility of cytochrome P450 interactions, especially with protease inhibitors. Although not well studied, the possible use of paliperidone, which has the lowest affinity, should be considered in this patient population (78).

Anxiety

Anxiety disorders affect some 17% to 36% of patients with HIV infection with adjustment disorder with anxious mood, generalized anxiety disorder, and panic disorder (79). Persistent and chronic anxiety following notification of seropositive status affects about 20% of patients and, in time, may evolve into a fully developed PTSD. This may be problematic as avoidant behaviors secondary to untreated HIV-related anxiety may diminish treatment compliance and interfere with medical management of HIV disease.

In the differential diagnoses of anxiety, one should always be concerned about the common association with depression, and a careful assessment to rule out depressive illness is critical. Anxiety may also arise from multiple medical conditions, especially in patients with pain, respiratory compromise due to pneumonia, and delirium as well as substance-induced anxiety. As with other HIV-related psychiatric disorders, a comprehensive medical evaluation is essential (69), including an extensive review of medications. Antiretroviral medications, like efavirenz, have been associated with anxiety, irritability, restlessness, agitation, and insomnia (68).

Treatment with psychotherapy, self-hypnosis, and biofeedback is very effective in anxiety disorders (68). Moreover, all psychotherapies are useful for the development of adaptive behaviors that allow the individual to reduce anxiety while improving coping capacity. Combining pharmacotherapy with a benzodiazepine during psychotherapy may be necessary for acute reduction of symptoms. This is best accomplished with

the use of intermediate-acting benzodiazepines without active metabolites such as oxazepam or lorazepam. Similarly, with chronic refractory anxiety, lorazepam is a better choice because of its ease of use and low neurotoxicity (68,76).

In the management of anxiety in individuals with co-occurring substance abuse, antidepressants and antiepileptic agents are preferred to benzodiazepines (68). All SSRIs and venlafaxine have been reported to be effective and should be considered initial first-line therapies. Also, the combination of a benzodiazepine with an antidepressant or with buspirone can be helpful, but the risk of addiction remains a concern. Use of gabapentin, tiagabine, or pregabalin either alone or in combination with antidepressants has been reported to be safe and effective (72). In cases where painful neuropathy is causing or exacerbating anxiety, the antiepileptic agents should be tried initially with the hopes of improving both disease states.

In cognitively impaired and patients with HAD, benzodiazepines should be avoided as it may further compromise cognitive function and may uncover or exacerbate disinhibition, frontal lobe dysfunction, confusion, and delirium. While the use of antihistamines is sometimes recommended in managing anxiety, our clinical experience suggests otherwise. Anxious patients, especially those with cognitive compromise, do not do well with antihistamines. The use of trazodone in low doses (25 to 50 mg t.i.d.) is preferable (68).

Pain in HIV Patients

HIV patients experience pain commonly, and prevalence of pain within 2 weeks has been estimated to be greater than 60% based on one outpatient survey. Patients answering this survey were noted to have multiple sources of pain and on average experienced 2.5 different pains in the preceding 2 weeks. Average pain scores were rated as 5.4 out of 10, and worst mean pain rated as 7.4 out of 10 indicative of moderately severe pain. The pain levels were noted to interfere with functional status across a variety of measures. Other factors influencing pain included the number of current HIV-related symptoms, treatment for HIV-related infections, and the absence of antiretroviral medications. Female gender, non-Caucasian race, and number of HIV-related physical symptoms were significantly associated with pain intensity, indicating perhaps a different pain experience in these vulnerable groups (80).

The most common source of HIV-linked pain is HIV-associated painful neuropathy, which appears to affect up to 30% of patients with HIV over the course of their disease (39). The causes of this painful neuropathy appear myriad and manifold, but typically involves both direct neurotoxic effects of HIV as well as potential effects from antiretroviral medications—especially the NRTIs (e.g., stavudine). In addition to these causes, patients may have additive neuropathy from such reasons as diabetes mellitus, nutritional deficiencies, or the late results of syphilis. Hyperalgesia and paresthesias are common manifestations of HIV-associated neuropathy, and diminished ankle-jerk reflexes are also frequently noted. Electromyographic data show abnormal sensory and motor

conduction supportive of a dying-back axonopathy. Neuropathy is virtually always progressive (39).

Tricyclic antidepressants have the most data with regards to non-HIV neuropathic pain management, but they must be used cautiously in HIV-seropositive patients due to anticholinergic effects and decreased tolerance. There is also data to suggest that tricyclics may be ineffective for HIV-related painful neuropathy (81). Alternative agents for treating HIV-related neuropathic pain include anticonvulsants (gabapentin or pregabalin), newer generation antidepressants (venlafaxine or duloxetine), or lidocaine topical applications (patches). Unfortunately, none of these agents has been subjected to rigorous testing in a double-blind, placebo-controlled trial in HIV-seropositive patients or in those whose pain is due to HIV-associated painful neuropathy (82).

Even though HIV-seropositive patients are at increased risk of adverse drug reactions, use of opiates can be safe and effective if comorbidities and potential drug–drug interactions are considered at the time of prescribing. There has historically been concern over chronic use of opiates in persistent nonmalignant cancer pain, but multiple evidence-based trials and position statements by pain societies including the American Academy of Pain Medicine support the chronic use of opiates in managing persistent pain due to a variety of etiologies. Multiple randomized high-quality trials of opiates have demonstrated efficacy for diverse pain conditions including musculoskeletal pain, osteoarthritis, low-back pain, painful diabetic neuropathy, and postherpetic neuralgia. To date, no adequate trial has been conducted using opiates to control the pain of HIV-associated neuropathy, but clinical experience supports their judicious use. Long-term data remains suboptimal, and further studies are needed to better understand the role of opiates in long-term management of pain, regardless of etiology.

Tolerance to the respiratory depressant effect of opiates develops quickly in patients, so this can generally be avoided by slow and careful titration. Chronic opiate therapy may also suppress endocrine function in hypothalamic, pituitary, gonadal, and adrenal hormones that leads to fatigue, depression, and diminished libido (83). When evaluating depression in patients using chronic opiates and HIV, attention to endocrine markers becomes more important in the differential diagnosis. Addiction to opiates when used for established medical indications is rare. Opioid abuse may become a concern, however, especially among those with earlier addiction histories. Published guidelines and statements from state medical boards and pain organizations are available to assist physicians in the assessment of responsible opioid use.

Substance Use/Abuse and Treatment

Injection drug users are less likely to receive ART than any other population. Factors associated with poor access to treatment include active drug use, younger age, and female gender, suboptimal health care, not being in a drug treatment program, recent incarceration, and lack of health care provider expertise. Yet these individuals should be considered and can be treated effectively. Nursing outreach interventions over

3 months including home visits have demonstrated improvements in making and keeping appointments, integration of care among HIV, substance abuse and mental health providers and improved access, adherence, and retention of patients in CART (84).

Another study examining the effects of an intensive outpatient cocaine treatment program over 9 months found that risky behavior among participants was correlated with high-intake problem severity and psychological symptomatology. Over the course of treatment, the amount of risky behavior was found to decrease significantly among those participating actively in the treatment program. The decrease in risky behavior was linked to decreased substance abuse, but it did not appear affected by demographic variables or type or duration of treatment in this study (85).

Other potential data-driven intervention models include brief peer-delivered educational interventions, which have demonstrated effectiveness in reducing crack cocaine use, IDU, and the number of IDU sex partners. Methadone maintenance treatment (MMT) programs remain an essential part of the treatment of dually diagnosed patients. Increased numbers of patients in MMT show IVDU abstinence. MMT has been demonstrated to dramatically reduce both illicit opiate use as well as criminal activity. More recent data support that MMT also reduces incarceration rates, which would likely diminish the risk factor of sharing needles while incarcerated and lower exposure to high-risk practices (86). In addition, opiate treatment-resistant dually diagnosed patients show better long-term survivability in MMT programs than their nondually diagnosed counterparts (87).

Non-MMT programs centering around group activity and support also demonstrate significant roles for the treatment of this complex population, and involvement in either MMT or non-MMT programs is associated with improved ART adherence (88). Buprenorphine programs are likewise associated with improved CART adherence, although they are widely underused in HIV-seropositive populations in the United States. France appears to be most experienced with buprenorphine programs in HIV-positive populations, and data support their effectiveness in this population (89) even though both methadone and buprenorphine have significant drug-drug interactions with HAART medications.

Methadone is primarily metabolized via cytochrome P450 3A4 and this cytochrome is also responsible for the metabolism of multiple HAART medications—most notably, the protease inhibitors. Consequently, drug-drug interactions and potential complications involving methadone/buprenorphine prescribed concurrently with HAART include changes in pharmacokinetics as well as other effects such as a prolonged QTc interval. Ritonavir produces strong 3A4 inhibition initially but has also been documented to induce 3A4 when administered chronically. Therefore, it is clear that drug-drug interactions are difficult to predict over time and require careful monitoring. For instance, initiation of a ritonavir or other protease-containing ART regimen in a patient on stable MMT may result in opiate toxicity and overdose due to early cytochrome inhibition. Conversely, lopinavir is a potent inducer

of methadone metabolism with one study finds that the combined effects of lopinavir/ritonavir administered to MMT patients include significant reductions in the methadone area under the concentration–time curve and reductions in the maximum serum concentration in the setting of increased methadone oral clearance (90). Consequently, the authors also noted increased rates of opiate withdrawal in this population, highlighting the need for careful monitoring of patients during either MMT initiation or HAART initiation. Buprenorphine is also metabolized by 3A4, and concurrent ritonavir acutely inhibits its metabolism producing higher levels as with methadone. However, conflicting data also demonstrate relative safety in using buprenorphine in the setting of protease inhibitors and nonnucleoside reverse transcriptase inhibitors (NNRTIs) as well (91).

SUMMARY

HIV-1 infection is a major health and social issue of our time, with drug abuse, unprotected sexual intercourse, and transfusion of contaminated products being well-determined risk factors. As the prevalence of HIV-1 infection continues to increase, advances in treatments permit the prognosis to improve. Neuropsychiatric complications are now accurately diagnosed more often and our understanding of their etiologies and effective treatment regimens continues to improve. Signs of neuropsychiatric disorders are now detected earlier, allowing prompt and aggressive management of these potentially devastating complications of the HIV-1 infection. The overall prognosis for these patients at the moment of seroconversion continues to improve, along with the quality of their lives. The contribution of neuropsychiatry is of great importance as we pay attention to the neurobehavioral aspects of HIV-1 disease in these individuals.

Russell K. Portenoy

When acute, tolerable and appropriate to injury, pain is biologically essential, signaling the need to identify the source of injury, seek help, and rest while healing occurs. When the severity of acute pain is high enough to initiate maladaptive stress responses, however, or its signaling imperatives have passed, treatment to relieve the pain or mitigate its effects is necessary to promote healing, well-being, and functional restoration.

When pain persists, it is never biologically adaptive. Indeed, chronic pain should be recognized as a heterogeneous and complex entity that should be considered a potentially serious illness in its own right (1). Chronic pain is associated with mood disturbance, sleep disorder, loss of function and impaired quality of life, and caregiver burden. It also is a public health problem of immense magnitude. In the United States, a recent evaluation by an expert committee noted that the estimated prevalence of chronic pain—at least 30% of adults and 20% of children in the United States—creates a societal burden that is greater than that of diabetes, heart disease and cancer combined, including direct costs of at least \$100 billion per year attributed to pain-related health care utilization and lost productivity (1).

The assessment and management of acute and chronic pain are within the purview of all clinicians. The ability to apply basic principles of pain management, and to refer appropriately, should represent skills that are broadly acquired and kept up to date. Pain medicine also is a subspecialty, and although the numbers of specialists are relatively small—just a few thousand in the United States—patients with complex chronic pain problems should ideally have access to professionals with specialist competencies, if needed.

There is a complex relationship between pain management and the clinical issues surrounding the problems of drug abuse, addiction, and diversion. The key role played by opioid drugs, which are both essential medical treatments and a major source of abuse, has justified exploration of this relationship. The interface between pain and drug abuse is broad in scope, potentially including issues that extend from basic science to public policy. For clinicians, the focus is on the role of potentially abusable drugs, especially the opioids, and on the challenges in providing effective pain management to patient populations with the comorbidity of a substance use disorder.

Historically, there has been an unfortunate lack of communication between specialists in pain management and specialists in addiction medicine. In recent years, this has been recognized as a problem in need of redress and a new level of

discourse has begun. This discourse broadly promotes *balance* for both the clinical and public health perspectives. A balanced approach to the clinical use of abusable substances applies to all the relevant communities—health professionals, regulators, law enforcers, policymakers, and the public. It acknowledges that all patients must have access to prescription drugs to treat legitimate medical needs, and strongly affirms that those who are charged with protecting the public health through regulation or law enforcement must pursue their agendas in a way that does not obstruct appropriate medical care. It also emphasizes, however, that there is a clear obligation on the part of both health professionals and patients to understand the need to assess, minimize, and manage all known risks, including the potential for abuse, addiction, and diversion.

The goals of this chapter are (a) to provide an overview of the principles of pain assessment and pain management, with a focus on opioid pharmacotherapy and (b) to explore some of the specific issues that arise when treating patients for pain in the context of a substance use disorder.

PRINCIPLES OF PAIN ASSESSMENT

Assessment is the essential prerequisite to the safe and effective treatment of acute or chronic pain. Although it is often straightforward in the setting of an acute traumatic event, a comprehensive assessment should be entertained even in this setting to ensure that the plan of care is safe, likely to provide benefit, and capable of addressing the impact of the pain and comorbid conditions. When pain becomes chronic and the plan of care anticipates a longer, and perhaps indefinite, time frame, the need for a more detailed pain assessment is clear and all the elements of this assessment become more challenging.

The information obtained through pain assessment derives from an appropriate history, physical examination, review of records, and often confirmatory laboratory and radiographic procedures. The most important part of the history is to provide sufficient information to characterize the pain complaint and determine the impact of the pain on multiple functional domains (Table 51.1).

The rest of the history also is important, particularly exploration of medical and psychiatric pathology. The chronic pain patient with a serious medical disorder may have pain attributable to the disease, related to its treatment, or unrelated to either. The patient should be asked about the severity and extent of

TABLE 51.1 Key pain-related information obtained in a routine pain assessment

<ul style="list-style-type: none"> ■ <i>Nature of the pain complaint, including</i> <ul style="list-style-type: none"> ■ Temporal features, including onset (abrupt or gradual), course (improving, progressing, stable), and daily pattern (diurnal variation, episodes of severe pain) ■ Location, including primary site or sites, referral, and whether it is deep or superficial ■ Severity, usually queried in terms of a score on a “0” to “10” numeric scale for pain “on average” and pain “at its worst” ■ Quality, often prompted by cues such as “aching,” “burning,” or “throbbing”; and factors that provoke or relieve the pain ■ <i>Prior and current evaluation of the pain, including</i> <ul style="list-style-type: none"> ■ Where it has been treated and by whom; ■ What laboratory, radiographic, or electrodiagnostic studies have been carried out; and whether prior records are available ■ <i>Prior and current treatments for the pain and their outcomes</i> ■ <i>Current impact of the pain, including effects on</i> <ul style="list-style-type: none"> ■ Physical function, such as the ability to perform activities of daily living and instrumental activities of daily living (e.g., shopping, cleaning), engage in exercise or other physical activities, enjoy restorative sleep ■ Psychological function, such as the effect on mood, coping, and adaptation ■ Social and familial functioning, including the impact on relationships with significant others (including marital and family relationships, and, if appropriate, sexual functioning) and other social interactions ■ Financial status and health system aspects, including financial resources, need for disability payments, and medical insurance status
--

disease, past and current treatments, and the goals of care going forward. Comorbid medical problems also must be recorded.

All chronic pain patients should be queried about other symptoms, including chronic fatigue, insomnia, and appetite changes. Psychological symptoms, such as anxiety or depressed mood, also should be ascertained.

Past and present psychiatric history is extremely relevant and requires focused questioning. Questions should explore the lifetime history of anxiety or depressive disorders, and a question about the occurrence of preadolescent abuse should be considered, particularly in the case of chronic pain associated with disability and other psychological or psychiatric concerns.

The comorbidity of substance use should be explored in all patients with chronic pain, including those with medical illness. Specific questions about the current and earlier use of tobacco and alcohol, illicit drugs, and the nonmedical use of prescription drugs should be asked. If an opioid or another potentially abusable drug has been given for a medical purpose, it is appropriate to ask whether there have been any concerns, either on the part of the patient or family, or on the part of the prescriber, concerning the way in which these drugs have been used by the patient. If a history of substance abuse is elicited, the interview should clarify the specific behaviors, both at the present time and in the past, in an effort to clarify the diagnosis or determine the need for further evaluation or referral.

Information about medical disorders in the family typically is elicited as part of the routine history. With the chronic pain patient, however, this history should be expanded and include questions about chronic pain and psychiatric disorders, including problematic use of alcohol or drugs.

The physical examination of patients with pain attempts to characterize the factors that contribute to the pain diagnosis and ascertain the status of comorbidities. A review of the existing medical records, and often additional laboratory or imaging procedures, is necessary to confirm and expand the understanding.

Framework for Interpreting the Nature of the Pain

A useful framework that may assist in the interpretation of information obtained about the nature of the pain focuses on a set of key considerations. These include the distinction between acute and chronic pain and the utility of syndromic, etiologic, and pathophysiologic diagnosis.

Acute Pain versus Chronic Pain

Acute pain may be defined as pain that has been, or is anticipated to be, experienced for a relatively short period, typically no more than days to weeks. The most common types of acute

pains are linked to recognizable tissue injury following trauma, including surgical trauma. Less common types are related to medical conditions or to primary pain diagnoses such as headache. Acute pains can be monophasic (e.g., following surgery) or recurrent. They may be recognized as a syndrome even in the absence of tissue injury (e.g., migraine), or be expected as part of an underlying pathology producing cumulative damage (e.g., sickle cell disease).

Chronic pain (also called persistent pain) may be defined by a temporal criterion alone, which is conventionally either 3 months or 6 months. Alternatively, chronic pain may be defined using other clinical criteria, specifically: *pain that persists beyond the healing of the inciting lesion, occurs in the context of a lesion that is not likely to heal, or is transitory but frequently recurrent.*

The phenomenology of acute and chronic pain differs in many ways beyond duration. Acute pain usually is caused by an event or disorder with a known anticipated time course. It is usually well localized and has a familiar aching, throbbing, or stabbing quality. These qualities are not absolute, however, and pain related to some visceral processes (e.g., bowel obstruction) and some neuropathic processes (e.g., painful polyneuropathy) typically have other characteristics (see Etiology and Pathophysiology). Irrespective of the underlying cause, acute pain may be associated with sympathetic responses, such as tachycardia, hypertension, tachypnea, and sweating, and the emotional response of anxiety. These emotional and autonomic concomitants of acute pain may be absent, however, especially if the pain is expected or the intensity is not intense.

In contrast to acute pain, chronic pain usually is less well localized, has both intensity and qualities that vary, and typically is not associated with any type of sympathetic response. If a mood change occurs, it typically is in the spectrum of depression.

Acute pain related to some type of tissue injury or damage usually is perceived to be reflective of a “normal” response to a noxious stimulus, a response that is the human output of the neural process of “nociception” investigated in the laboratory. From this perspective, pain is a perception of the sensation of a noxious stimulus, which itself is subserved by the biologic processes of nociception; as a perception, pain is always subject to influence by both thoughts and emotions linked to past experience and current psychosocial status.

Chronic pain is not biologically adaptive and presumably requires some type of pathologic change in nociception. It is assumed that chronic pain, like other illnesses, always is subject to powerful influence by cognitive and psychological processes that can either promote pain relief, coping, and function or contribute to distress and impairment.

The experience of chronic pain does not eliminate the risk of concurrent acute pain. Indeed, episodes of acute severe pain are common among those with persistent pain. When this occurs in the context of long-term opioid treatment, the term *breakthrough pain* is applied. Breakthrough pain occurs in populations with cancer and noncancer pains; its prevalence among opioid-treated chronic pain patients in community settings is at least one third (2,3). The association of breakthrough pain

with adverse physical and psychosocial outcomes, and the recent advent of opioid drugs specifically indicated for cancer-related breakthrough, justifies the effort to separately assess these episodes and consider treatment that targets them specifically.

Etiology and Pathophysiology

One of the goals of the pain assessment is to identify the etiology of the pain—the lesion or the disorder that is responsible for activating or sustaining nociception. In many situations, such as acute postoperative pain, the etiology is obvious. In some chronic pain disorders, such as pain related to osteoarthritis or osteoporosis, the etiology also seems clear in relation to a specific site of chronic tissue injury. Etiology is uncertain in many other disorders, such as chronic headache, fibromyalgia, chronic back pain, and many types of neuropathic pain.

The potential value in an etiologic diagnosis lies in the ability to offer disease-modifying therapy to some patients. If an etiology can be identified and is treatable, and treatment has both a favorable therapeutic index and consistency with the goals of care, primary disease-modifying therapy should be entertained as a part of a pain management strategy. For example, joint replacement therapy, if feasible and appropriate, is a highly effective intervention for chronic pain related to advanced osteoarthritis. An etiologic diagnosis also may allow primary therapy for other aims (e.g., prevention of a complication, such as pathologic fracture) and may help clarify prognosis in some cases.

The term *pathophysiology* refers to the mechanisms that sustain the pain. These mechanisms cannot be determined in humans with clinical pain, and the information provided by the pain assessment can only be used to infer the existence of a category of mechanisms. Although this is undoubtedly a gross simplification of extremely complex processes underlying pain perception, labeling by inferred pathophysiology has become clinically accepted for pain syndromes other than headache because it suggests assessment and treatment strategies that have proved clinically useful.

In general, most pain syndromes are believed to be sustained by tissue injury and/or changes in sensory processing. Pains other than common types of headache are described as *nociceptive*, *neuropathic*, or *mixed*. Occasionally, pain syndromes are believed to have a predominating psychological pathogenesis, and rarely, pain syndromes occur that are unclassifiable (best termed *idiopathic pain*).

Nociceptive pain, which is subdivided into *somatic* and *visceral* subtypes, is defined as pain that appears to be commensurate with the degree of ongoing activation of nerves by tissue injury and related processes. Nociceptive pain typically is inferred to exist when tissue damage is identified and appears to be a sufficient explanation for the pain. If the damage occurs in somatic structures, such as joint, muscle, or soft tissue, it results in somatic pain; if the damage occurs in viscera, it results in visceral pain. Pains classified as nociceptive are believed to be responsive to peripherally directed interventions that reduce the source of injury.

In terms of phenomenology, somatic pain usually has a familiar quality, such as aching or throbbing. It is well-localized,

worsened with movement, and may be associated with signs of inflammation. Visceral pain varies with the organ involved. When due to obstruction of hollow viscus, the pain usually is poorly localized, referred to specific cutaneous sites, gnawing or aching in quality, and often associated with nausea. Visceral pain related to involvement of connective tissue, such as the liver capsule or muscle, is more well localized and typically sharp and aching in quality.

Neuropathic pain may be defined as pain related to disease or dysfunction of the nervous system, or as pain that is inferred to be sustained by aberrant sensory processes induced in either the peripheral nervous system, the central nervous system, or both. There are important subtypes, including pain related to compression or entrapment of nerve (e.g., median neuropathy from carpal tunnel syndrome or radiculopathy from a herniated nucleus pulposus), pain related to neuroma formation after transection of a peripheral nerve (e.g., stump pain), pain related to toxic or metabolic injury to all nerves (e.g., painful peripheral neuropathy), and pain related to central nervous system processes (such as pain due to spinal cord injury or poststroke central pain). The diagnosis may be suggested by the associated neurologic disorder, the phenomenology of the pain itself, or associated features that define a discrete syndrome.

The phenomenology of neuropathic pain is heterogeneous. Some patients describe the pain as a familiar aching, but others describe dysesthesias (abnormal uncomfortable sensations, which are perceived as unfamiliar), which may include pain descriptors such as burning, tingling, squeezing, or electrical. There may or may not be specific abnormalities on examination, such as allodynia (pain with light touch), hyperalgesia (relatively increased pain to a noxious stimulus), and hyperpathia (exaggerated pain response, often with spread, after-sensation, and emotional overreaction). Patients with neuropathic pain also may have coexisting sources of nociceptive pain, the phenomenology of which may further complicate the patient's description of the pain.

The diagnosis of neuropathic pain may suggest the use of selected types of analgesics, including numerous drugs used primarily as antidepressants or anticonvulsants (4). Numerous studies also have established that opioids are efficacious (4), and for this reason, inferences about pain pathophysiology (nociceptive vs. neuropathic) should not be the deciding factor whether or not to try an opioid for chronic pain.

Pain Syndromes

Syndrome identification is extremely useful in pain assessment because it may provide information about underlying organic processes, suggest an efficient evaluation, guide the selection of treatments, and indicate prognosis. The International Association for the Study of Pain has developed a taxonomy of pain, the goal of which is to establish criteria for the diagnosis of specific pain syndromes (5).

Although the term *chronic pain syndrome* does not appear in a taxonomy of pain, the literature may apply it to patients with chronic pain associated with a high level of disability and psychiatric comorbidity. These associated manifestations have long suggested the potential value of a multidisciplinary

approach to management that emphasizes both comfort and functional restoration. Indeed, the clinical challenge posed by the management of the patient with pain and disability was a prime driver of the development of pain medicine as a subspecialty. Although most patients with acute pain and, presumably, most with chronic pain do not have the type of overriding disability that is implied by the label, it is important to acknowledge the needs of this subgroup. Whereas most patients with pain can be managed adequately by a single clinician who expertly administers one or more treatments, patients with a complex chronic pain illness may benefit most from the involvement of specialists in various disciplines, who together implement a multimodality approach intended to address pain and its consequences, and comorbid conditions. A specialist in addiction medicine may be an appropriate member of a multidisciplinary pain management team.

PAIN AND SUBSTANCE ABUSE

The clinical interface between pain and substance abuse can be best illuminated by a focus on the use of potentially abusable drugs used in the management of acute and chronic pain. The most important of these drugs are the opioids. Opioid therapy is the mainstay approach for the treatment of severe acute pain and chronic pain related to active cancer or another advanced medical illness. Although yet controversial, opioid therapy for the treatment of chronic noncancer pain is well established in some countries and rapidly growing in the United States and others. The safe and effective use of opioid drugs requires competencies in pain assessment and management in all patient populations, and these skills must be most highly refined when these drugs are used to manage pain in populations with substance abuse histories.

Terminology and Characteristics of Relevant Phenomena

Many of the terms used to describe opioid-related phenomena, such as tolerance, are difficult to translate to the clinical setting. An understanding of terminology is a foundation to the development of clinical strategies that promote safe and appropriate prescribing. The effort to bring together the perspectives of specialists in pain management and addiction medicine to refine the meanings of key terms has been a notable advance (6).

Tolerance

Tolerance is a pharmacologic property of opioid drugs defined by the need for increasing doses to maintain effects (7). Tolerance can be induced reliably in animal models with little exposure to a drug and occurs to different opioid effects at varied rates and extents. Although there are subtypes based on the impact of learning and pharmacokinetic changes, it is the occurrence of the so-called analgesic pharmacodynamic tolerance—loss of analgesic effects associated with biologic processes induced in cells by the binding of the drug to its receptors—that characterizes opioid tolerance and raises clinical concerns.

If pharmacodynamic tolerance to analgesic effects were to occur regularly, it would be a major impediment to the clinical effectiveness. Alternatively, if the development of tolerance to the positive psychic effects of opioids, and the consequent need to increase doses to regain these effects, routinely drove aberrant use, this too would compromise the long-term utility of these drugs. The latter process has been perceived as a key step in the pathogenesis of addiction (8).

There is no question that tolerance can occur to diverse opioid effects, including analgesia, and that tolerance can be induced with little drug exposure. Clinical observation suggests that tolerance to some effects, such as somnolence and nausea, develops quickly. This is widely perceived to be a clinically favorable outcome, increasing the safety of the drugs and allowing the dose escalation necessary to attain analgesia. In contrast, tolerance to analgesic effects seems to be an uncommon driver of dose escalation to maintain analgesia. Although some patients with pain do report diminishing analgesic effects in the absence of any other reason for changes in pain—the scenario that suggests the occurrence of analgesic tolerance—most patients demonstrate relatively stable dose requirements for prolonged periods. In the cancer population, for example, the need for dose escalation typically occurs only in the setting of a progressive lesion; for example, patients who self-administer morphine for several weeks to control pain from chemotherapy-induced mucositis do not increase the dose after an initial rapid titration (9). Surveys of patients with nonmalignant pain treated with systemic or neuraxial opioids for prolonged periods also demonstrate variable dose requirements over time, with stability in most patients who have no obvious disease progression (10). These observations suggest that analgesic pharmacodynamic tolerance is a pharmacologic phenomenon that can be reliably demonstrated in animal models, presumably occurs to some degree during opioid administration for pain, but has a variable presentation and relatively little impact in the routine management of most patients receiving long-term opioid therapy (7).

The importance of tolerance in the context of abuse and addiction also is uncertain. Although traditionally included in the definition of addiction (11), a newer conceptualization no longer makes reference to it (6). The phenomenon of tolerance may be important for some patients in the development of an addictive pattern of drug use, but overall it appears to be neither necessary nor sufficient for the appearance of addiction.

Physical Dependence

Like tolerance, *physical dependence* is a pharmacologic property of opioid drugs. It is defined solely by the occurrence of an abstinence syndrome (withdrawal) following abrupt dose reduction or administration of an antagonist. Because some degree of physical dependence can be produced with very little opioid exposure, and neither the dose nor duration of administration required to produce clinically significant physical dependence in humans is known, most practitioners assume that the potential for an abstinence syndrome exists after an opioid has been administered repeatedly for only a few days.

Physical dependence has been perceived as an impediment to the discontinuation of an ineffective or problematic therapy, suggesting to some clinicians that the decision to try an opioid for more than a short time means that therapy will be difficult or impossible to stop. The belief that a trial of long-term opioid therapy is something of a “life sentence” presumably leads some clinicians to consider an opioid trial as a last resort.

Physical dependence also has been considered another key element in the pathogenesis of addiction (8). In this view, the need to reduce the adverse effects of withdrawal drives drug-seeking behavior. Like tolerance, physical dependence traditionally has been included in the definition of addiction (11).

Paradoxically, extensive clinical experience suggests that physical dependence actually is a rare concern in practice. Abstinence phenomena seldom present significant challenges to the safe discontinuation of an ineffective or problematic therapy, as long as dose reduction and concurrent therapies are well managed. This has been amply demonstrated by the success of opioid detoxification by multidisciplinary pain programs and the routine cessation of opioid therapy in cancer patients who become fully analgesic following a pain-relieving procedure.

Similarly, physical dependence may or may not be apparent among those who abuse opioid drugs. As a result, it is best to define addiction in a way that fully distinguishes it from physical dependence (6). In short, physical dependence presumably occurs in all opioid-treated patients after a short time, but very few become addicted, and the occurrence of physical dependence, as determined by abstinence phenomena, may or may not be prominent among those who become addicted. Just like tolerance, the capacity to experience uncomfortable withdrawal may be a factor in the development of an addictive pattern of drug use in some cases, but it appears to be neither necessary nor sufficient for the development of the disease of addiction.

Use of the term *addiction* as a synonym for physical dependence appears to be entrenched in the U.S. medical culture. This unfortunate practice reinforces the stigma associated with opioid therapy and should be rejected. The term addiction should only be applied to a specific syndrome characterized by a highly maladaptive pattern of drug use. If the clinician wishes to characterize the potential for withdrawal, the term *physical dependence* must be used. Labeling the patient as *dependent* also should be discouraged, because its imprecision fosters confusion between physical dependence and addiction. For the same reason, use of the term habituation should be eschewed; in the clinical setting, this term is often used indiscriminately to refer to tolerance, physical dependence, or the development of craving.

Addiction

The development of a definition for addiction jointly endorsed by professional societies for pain and addiction in the United States represents an important piece of the effort to improve communication across disciplines (6). According to the statement endorsed by the American Pain Society (APS),

American Academy of Pain Medicine (AAPM), and American Society of Addiction Medicine:

[a]ddiction is a primary, chronic, neurobiologic disease, with genetic, psychosocial, and environmental factors influencing its development and manifestations. It is characterized by behaviors that include one or more of the following: impaired control over drug use, compulsive use, continued use despite harm, and craving.

This definition reinforces the conclusion that a diagnosis of addiction requires an assessment of drug-related behaviors to establish the existence of a seriously maladaptive pattern of drug use. Craving may involve rumination about the drug and an intense desire to secure its supply. Compulsive use may be indicated by escalating consumption of the drug without medical justification or sanction by a clinician. Continued use despite harm could involve outcomes that are problematic for physical or psychosocial well-being, work or other role functioning, or relationships with health professionals. Although an addictive pattern of opioid use may involve phenomena recognized as likely tolerance or physical dependence, neither of these biologic processes is necessary for a diagnosis.

Abuse, Misuse, and Other Terms

Other terms commonly used in the setting of opioid treatment also have challenged precise definition. *Drug abuse* may be considered any type of drug use that is outside accepted societal and cultural norms. This definition is practical, but nonetheless implies that there is broad consensus about the nature of normative behavior. This is not always true, particularly during periods of changing perceptions (e.g., with respect to marijuana use) or when clinicians and patients do not share cultural backgrounds. Nonetheless, it is generally accepted that drug abuse includes any use of an illicit drug and any use of a legal drug in a manner that is contrary to clinician instructions, or to regulations or laws. Importantly, patients with the disease of addiction may or may not be actively abusing drugs, and most drug abuse is undertaken by individuals who do not otherwise meet criteria for a diagnosis of addiction.

Drug diversion should be considered apart from abuse or addiction. Diversion or the transfer of a licit drug into an illegal marketplace is considered a criminal act and the individuals responsible may or may not be personally using the drug in question. Indeed, physicians in the United States who have been prosecuted for drug trafficking typically have not been accused of abusing the drugs they prescribed.

In the clinical setting, drug-related behaviors that are egregious enough to be labeled drug abuse may be positioned on a continuum of problematic *nonadherence behaviors*. Nonadherence behaviors, which also have been called *aberrant drug-related behaviors* and sometimes *red-flag behaviors*, are varied and may be difficult to interpret (Table 51.2). Although it is widely agreed that a very serious nonadherence behavior, such as forging prescriptions, represents both drug abuse and a probable sign of addiction, a less severe behavior, such as repeated requests for early prescription refills, is more challenging

to characterize. Many clinicians use the term *misuse* as a way to distinguish these less egregious nonadherence behaviors.

To date, there has been no standardization of this language into a more precise diagnostic terminology that is broadly applicable across both non-medical and medical settings. The labeling of drug abuse and addiction (substance abuse disorder and substance dependence disorder in the psychiatric parlance adopted in the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders [DSM]* (11)) clearly is simpler when drug use does not involve a drug that has been prescribed for a legitimate medical purpose.

Interpreting Nonadherence Behaviors in the Medical Context

All patients who are given an opioid or other controlled prescription drug for medical purposes must be routinely evaluated for drug-related behaviors throughout the course of treatment. In the ambulatory setting, nonadherence is particularly challenging. In some cases, it takes the form of undertreatment. This problem is seldom discussed but may be a significant issue, particularly when treating pain associated with a serious medical illness. The decision to take less medication than prescribed may be related to cost, fear of side effects or addiction, family concerns, or other factors. Education and support of the patient and family may require specific targeting of these concerns.

When nonadherence takes the form of excessive opioid use, the behaviors can be labeled as misuse or abuse, or perhaps addiction, depending on the nature of the problem. The type of assessment necessary to assess these drug-related behaviors is a core clinical competency for addiction specialists, essential for establishing a diagnosis and evaluating a treatment plan, but is relatively novel for pain specialists and other clinicians. This is an area of practice that must be improved. There is a broad consensus in the United States that clinicians who prescribe opioids or other controlled prescription drugs to manage medical disorders must possess basic skills in assessing drug-related behaviors in terms of the risks associated with abuse, addiction, and diversion. Those who do not, or who encounter patients who pose a high level of challenge in assuring adherence, should not prescribe without help.

The complexity inherent in evaluating nonadherence behaviors may be lessened by applying a "differential diagnosis." In some cases, the behaviors are sufficiently extreme (e.g., injection of an oral formulation) to immediately suggest the diagnosis of addiction (Table 51.2). In other cases, the behaviors are less egregious and could reflect other diagnoses, such as impulsive behavior driven by unrelieved pain (a phenomenon broadly labeled "*pseudoaddiction*"), a psychiatric disorder other than addiction, or a mild encephalopathy with confusion about drug intake. Occasionally, aberrant behaviors indicate criminal intent (i.e., intent to divert).

The phenomenon of *pseudoaddiction* illustrates the complexity of this differential diagnosis. Pseudoaddiction was originally described anecdotally in a cancer patient who demonstrated behaviors consistent with drug craving that

TABLE 51.2 Aberrant drug-related behaviors

Behaviors Probably More Suggestive of Addiction	
	Selling prescription drugs
	Prescription forgery
	Stealing or “borrowing” drugs from others
	Injecting oral formulations
	Obtaining prescription drugs from nonmedical sources
	Concurrent abuse of alcohol or illicit drugs
	Multiple dose escalations or other noncompliance with therapy despite warnings
	Multiple episodes of prescription “loss”
	Repeatedly seeking prescriptions from other clinicians or from emergency rooms without informing prescriber or after warnings to desist
	Evidence of deterioration in the ability to function at work, in the family, or in society that appear to be related to drug use
	Repeated resistance to changes in therapy despite clear evidence of adverse physical or psychological effects from the drug
Behaviors Probably Less Suggestive of Addiction	
	Aggressive complaining about the need for more drug
	Drug hoarding during periods of reduced symptoms
	Requesting specific drugs
	Openly acquiring similar drugs from other medical sources
	Unsanctioned dose escalation or other noncompliance with therapy on one or two occasions
	Unapproved use of the drug to treat another symptom
	Reporting psychic effects not intended by the clinician
	Mildly impaired cognition or subtle signs of impaired function

disappeared when the opioid regimen was increased (12). The term became accepted because of broad clinical experience affirming that aberrant behavior can be driven by desperation caused by uncontrolled pain. The degree of “aberrancy” is relevant, however, and it is essential to recognize that pseudoaddiction can coexist with other drivers of aberrant use, including addiction itself. Indeed, it is a common observation that the stress associated with pain may drive relapse among those with the known diagnosis of addiction. The diagnosis of pseudoaddiction should not be used to explain illicit acts or a clearly maladaptive pattern of compulsive drug use.

Given the differential diagnosis of aberrant drug-related behavior and the extraordinary heterogeneity of the population with painful disorders, the clinician who discerns an episode of nonadherence must determine if the problem is likely to be transitory—perhaps an impulsive action related to a pain flare, to worsening of a comorbid psychiatric disorder, or to some severe situational stressor—or is likely to be more serious and abiding. This may require more time and observation after additional structure has been introduced into the

planned therapy (e.g., urine drug screening, frequent visits, or other strategies; see Structuring Therapy to Reduce Risk).

The diagnostic challenges are most significant in the ambulatory setting during long-term treatment of chronic pain, particularly when the severity of the nonadherence behavior is limited. For example, the patient with unrelieved pain who deliberately takes extra doses of an opioid and fails to contact the physician until an early refill is needed has engaged in aberrant drug-related behavior. The diagnosis is uncertain initially, and the future plan of care would clearly be different if the behavior reflected incipient addiction, pseudoaddiction, or, possibly, both phenomena. Interpretation of the behavior also may not be possible the first time that it occurs. A decision to continue the therapy usually would be justified and closer monitoring of drug-related behaviors would hopefully ensue. Other data, such as the results of urine drug screening, may be obtained and strongly influence the interpretation of the initial event and future behaviors. A diagnosis of the aberrant behavior should be withheld until observations are sufficient to provide a rationale.

The potential for mislabeling nonadherence behaviors as addiction is particularly great in the patient with a remote or current history of substance abuse. Although opioids may be clearly indicated, any evidence of aberrant drug-related behavior may generate great concern that relapse has occurred. This concern is well placed if the aberrant behaviors are egregious (e.g., prescription forgery), but the more common scenario involves less serious behaviors that are far more difficult to interpret. Pain complaints may be voluble and disproportionate to the degree of evident pathology. The patient may appear to require unusually high doses or may request specific drugs. Interactions with the medical staff may be perceived to have a manipulative quality in which the patient appears to be unusually knowledgeable about opioid treatment or presents a posture of negotiation about therapy. It is extremely important that the clinicians caring for these patients recognize that these behaviors may or may not reflect abuse or addiction. Pseudoad addiction may be common, set in motion by both a lack of trust that limits the aggressiveness with which pain is approached and the appropriate concerns raised by an analysis of risk and benefit during treatment with a potentially abusable drug. The challenge is to understand that risk management is part of the therapeutic plan of care; avoid assumptions while continuing to assess behaviors appropriately; and if worrisome drug-related behaviors occur, clarify the differential diagnosis in a manner that is justified by the data available. In the absence of data, both clinicians and patients are best served by clear documentation that information is not sufficient to interpret the behavior.

PRINCIPLES OF OPIOID THERAPY

The safe and effective prescribing of opioid drugs for acute or chronic pain requires skills in optimizing favorable pharmacologic outcomes (reducing pain and minimizing side effects) and reducing the risks associated with misuse, abuse, addiction, and diversion. These skills must be translated into a set of pragmatic decisions: Who should be selected for opioid therapy, how should the drug be selected and administered, and how should the treatment be structured to minimize the risks of abuse?

Selection of Patients for Opioid Therapy

There is a long-standing international consensus that opioid therapy is the mainstay treatment for patients with acute severe pain and patients with chronic pain related to active cancer or another type of advanced medical illness. Selection of an opioid to treat pain in these settings should be viewed as the “default” position; the decision to do otherwise should have a clear rationale.

In contrast to this view, there is no consensus about the role of opioid therapy to treat other types of chronic pain. The populations with chronic pain are very heterogeneous, represent many types of disorders and very diverse comorbidities, and largely encompass patients receiving care in community settings by clinicians who are not pain specialists. These populations include the increasing number of patients with pain caused by stable or indolent medical illness (including those

who are cancer survivors with chronic pain) or a primary pain-related diagnosis (e.g., chronic headache and fibromyalgia).

The decision to select a patient with chronic noncancer pain cannot be based on the existing evidence of effectiveness. Although there have been many clinical trials of opioid therapy for noncancer pain, and these trials have been collated into systematic reviews (13), the existing evidence can provide little insight other than generally supporting the conclusion that opioids are efficacious for all types of pain and that some patients appear to benefit during long-term therapy (and a substantial minority stop treatment over time). There is no evidence of long-term effectiveness and no evaluation of comparative effectiveness, either comparing opioid regimens or comparing opioids with other treatment approaches for pain (14).

Given the lack of evidence, an expert panel charged to create evidence-based guidelines for opioid treatment by the APS and the AAPM were forced to rely mostly on expert opinion (15). Although most of the recommendations offered in this guideline were strong, they were almost all based on low-quality evidence.

The APS–AAPM panel endorsed the view that a trial of opioid therapy with the intent to continue it long-term if beneficial can be considered for any patient with chronic noncancer pain but the decision to offer this therapy requires a detailed assessment designed to determine whether the benefits would be likely to outweigh the risks. It is reasonable to consider four questions in reaching this conclusion:

- *What is conventional practice for this type of patient and this type of pain?*
- *Are there other therapies that have equivalent or better therapeutic indices and might be considered instead?*
- *Are there relatively high risks of adverse pharmacologic effects as a result of medical comorbidities or concurrent treatments?*
- *Is the patient likely to be a responsible drug user, or is the risk of problematic drug-related behavior high?*

The answers to these questions do not exclude any patient from treatment but should help position the treatment against other options and, equally important, help the clinician decide whether treatment might be undertaken only with the help of a consultant or perhaps only through referral to a clinician with more experience or more resources.

Importantly, the initiation of an opioid therapy with the intention to continue it indefinitely if the outcomes be favorable should be conceptualized as a *trial*, even if it is taking place after the patient has been receiving an opioid for some time but without commitment to long-term therapy. Patients should understand that this therapeutic trial will attempt to optimize outcomes and monitor the effectiveness of treatment and drug-related behavior. Like all trials, the outcomes may support the conclusion to continue treatment, change treatment, or stop treatment.

Optimizing the Outcomes of Opioid Pharmacotherapy

Based on receptor interactions, opioid analgesics can be classified as pure agonists or agonist–antagonists (Table 51.3).

TABLE 51.3 Characteristics of Commonly Used Opioid Analgesics

	Equianalgesic doses^a (mgs)	Half-life (hours)	Peak effect (hours)	Duration (hours)	Toxicity	Comments
Morphine-like Agonists						
Morphine	10 IM 20–60 PO ^b	2–3 2–3	0.5–1 1.5–2	3–6 4–7	Constipation, nausea, sedation, hypogonadism most common; respiratory depression rare in practice	Standard comparison for opioids; available in rectal formulation
Modified-release morphine	20–60 PO ^b	—	3–4	8–24	—	Several formulations, including an abuse deterrent form
Hydromorphone	1.5 IM 7.5 PO	2–3 2–3	0.5–1 1–2	3–4 3–6	Same as morphine	Available in rectal formulation
Modified-release hydromorphone	7.5 PO	—	3–4	24	Same as hydromorphone	—
Oxycodone	20 PO	2–3	1–2	3–6	Same as morphine	Combined with aspirin or acetaminophen, for moderate pain; available orally without coanalgesic for severe pain
Modified-release oxycodone	20 PO	2–3	3–4	8–12	Same as oxycodone	Available in an abuse deterrent form
Fentanyl	100 µg	7–14	Minutes	Minutes with acute and 4–6 hours with chronic dosing	Same as morphine	IV sometimes used for acute pain; commonly used as an anesthetic
Fentanyl transdermal system	See package insert	—	—	48–72	Same as morphine	Transdermal system commonly used to treat chronic pain; possibly less constipation than oral morphine; not widely abused by those with a history of substance abuse

(Continued)

TABLE 51.3 Opioid analgesics (Continued)

	Equianalgesic doses ^a	Half-life (hours)	Peak effect (hours)	Duration (hours)	Toxicity	Comments
Fentanyl-containing rapid-onset formulations	Start with lowest doses	—	Varies by product; all within 30 minutes	1	—	Formulations available in the United States and Europe include an oral transmucosal lozenge, an effervescent tablet, a buccal patch, a sublingual tablet, and a nasal spray
Oxymorphone	1 IM 15 PO	3–6 3–6	0.5–1 1–2	3–6 3–6	Same as morphine	Available in rectal formulation
Modified-release oxymorphone	15 PR	2–3	3–4	8–12	Same as oxymorphone	—
Meperidine	75 IM	2–3	0.5–1	3–4	Same as morphine + central nervous system (CNS) excitation; contraindicated in those on monoamine oxidase (MAO) inhibitors	Not preferred because of potential toxicity
Heroin	300 PO 5 IM	2–3 0.5	1–2 0.5–1	3–6 4–5	— Same as morphine	Not preferred because of potential toxicity Analgesic action because of metabolite, predominantly morphine; not available in the United States
Levorphanol	2 IM 4 PO	11–16	0.5–1 1–2	3–6 3–6	Same as morphine	With long half-life, accumulation could occur after beginning or increasing dose, but seldom a problem
Methadone	10 IM 20 PO	12–>150	0.5–1.5 1–2	4–8	Same as morphine plus QTc prolongation	Risk of delayed toxicity as a result of accumulation; concern about cardiac effects and unanticipated high potency in some settings; requires knowledge for safe use as an analgesic
Codeine	130 IM 200 PO	2–3	1.5–2	3–6	Same as morphine	Usually combined with nonopioid

Propoxyphene napsylate	—	12	1.5–2	3–6	Same as morphine plus seizures and cardiac toxicity with overdose	Not preferred because of toxic metabolite; often combined with nonopioid
Propoxyphene hydrochloride	—	12	1.5–2	3–6	Same as napsylate	Same as napsylate
Hydrocodone	—	2–4	0.5–1	3–4	Same as morphine	Available only as acetaminophen and ibuprofen combination
Dihydrocodeine	—	2–4	1–2	3–4	Same as morphine	Only available combined with acetaminophen or aspirin
Partial Agonists						
Buprenorphine	0.4 IM 0.8 SL	20–73	0.5–1 2–3	4–6 6–12	Same as morphine, except less risk of respiratory depression or endocrine effects	Can produce withdrawal in opioid-dependent patients; has ceiling for analgesia but the clinical relevance of this is uncertain; sublingual tablet (with and without naloxone) are available in the United States and indicated for office-based agonist therapy of addiction, but, are used for pain infrequently; low-dose transdermal patch is available in some countries and is widely used for chronic pain
Mixed Agonist–Antagonists						
Pentazocine	60 IM 180 PO	2–3 2–3	0.5–1 1–2	3–6 3–6	Same profile of effects as buprenorphine, except for greater risk of psychotomimetic effects	Produces withdrawal in opioid-dependent patients; oral formulation combined with naloxone or nonopioid available in the United States; ceiling doses and side-effect profile limit role in chronic pain
Nalbuphine	10 IM	4–6	0.5–1	3–6	Same as buprenorphine	Produces withdrawal in opioid-dependent patients
Butorphanol	2 IM 2 intranasal	2–3	0.5–1	3–4	Same profile of effects as nalbuphine	Produces withdrawal in opioid-dependent patients; no oral formulation

(Continued)

TABLE 51.3 Opioid analgesics (Continued)

	Equianalgesic doses ^a	Half-life (hours)	Peak effect (hours)	Duration (hours)	Toxicity	Comments
Dezocine	10 IM ^c	1.2–7.4	0.5–1	3–4	Same profile of effects as nalbuphine	Produces withdrawal in opioid-dependent patients; no oral formulation
Centrally Acting Drugs with Opioid Actions						
Tramadol	—	6–7	1–2	4–6	Similar to morphine	Analgesic action related to monoamine (norepinephrine and serotonin) reuptake blockade and opioid effect; maximum dose is usually 600 mg/day because of concern about toxicity, including seizures and serotonin syndrome
Tapentadol	—	4	1–2	4–6	Similar to morphine but may have fewer adverse GI effects	Analgesic action related to monoamine (norepinephrine) reuptake blockade and opioid effect; maximum dose is usually 400 mg/day because of concern about toxicity, including seizures and serotonin syndrome

^aDose that provides analgesia equivalent to 10 mg IM morphine. These ratios are useful guides when switching drugs or routes of administration. When switching drugs, reduce the equianalgesic dose of the new drug by 25% to 50% to account for incomplete cross-tolerance. The only exception to this is methadone, which appears to manifest a greater degree of incomplete cross-tolerance than other opioids; when switching to methadone, reduce the equianalgesic dose by 90%.

^bExtensive survey data suggest that the relative potency of IM:PO morphine of 1:6 changes to 1:2–3 with chronic dosing.

^cApproximate equianalgesic dose suggested from meta-analysis of available comparative studies.

The agonist–antagonist drugs include a mixed agonist–antagonist subclass (including butorphanol, nalbuphine, pentazocine, and dezocine) and a partial agonist subclass (including buprenorphine). The agonist–antagonists have a ceiling effect for analgesia and for respiratory depression, can reverse the effects of pure agonists in patients who are physically dependent, and are less preferred by individuals who abuse opioid drugs. Two other centrally acting analgesics, tramadol and tapentadol, have opioid activity mediated by the mu-receptor and often are categorized with the opioid agonists. These drugs have a mixed analgesic mechanism involving both mu-agonism and monoaminergic reuptake blockade.

Opioid Selection

The treatment of acute pain may be accomplished with any of the opioid drugs. In the ambulatory setting, the most common approach to the treatment of moderate or severe pain in the patient with very limited or no prior opioid exposure involves the administration of a short-acting oral opioid, which may be combined with either acetaminophen or aspirin. In the United States, these drugs include hydrocodone, codeine, dihydrocodeine, oxycodone, tramadol, and tapentadol. Oral meperidine and propoxyphene also are used but are not preferred because of the potential for adverse effects. Although meperidine has lesser contractile effects on smooth muscle in preclinical models, this characteristic has no established benefits in the clinical setting; the drug is not preferred for either acute or chronic pain because of the potential for toxicity due to accumulation of an active metabolite, normeperidine, which may produce dysphoria, tremulousness, hyperreflexia, and seizures. Propoxyphene also has a toxic metabolite and produces a similar spectrum of potential toxicities, as well as serious cardiac toxicity with overdose.

In the inpatient setting, acute pain is usually managed with a pure mu-agonist such as morphine or hydromorphone, which is usually administered intravenously. The only certain advantage of this route is a faster onset of effect, the advantages of which often are worth pursuing as long as drug administration is in a monitored environment.

The agonist–antagonist opioids also can be used to treat acute pain. These drugs have less abuse potential than the pure agonist drugs, but the lack of oral formulations and the pharmacologic profile (e.g., ceiling effect) has limited their utility. Intranasal butorphanol has gained some acceptance in headache management, and the parenteral mix agonist–antagonists are sometimes used in monitored settings, such as emergency departments.

The partial agonist buprenorphine is available as a transdermal patch in some countries and has gained wide acceptance in the management of pain in the opioid-naive patient. In the United States, the sublingual tablets of buprenorphine that are approved for the treatment of addiction have been used off-label for pain, but experience is very limited. Some clinicians believe that buprenorphine may be especially useful for pain when the patient has a past or current history of drug abuse, but this potential advantage has yet to be established empirically.

In the most common scenario for the treatment of acute pain in the opioid-naive ambulatory patient, a combination product containing an opioid, for example, hydrocodone, and a nonopioid, for example, acetaminophen, is used. The dose may be increased as needed until the maximum safe dose of the nonopioid coanalgesic is reached. For acetaminophen, this is usually considered to be 2.7 to 4 g/day, and even lower (e.g., <2 g/day) in patients with known liver disease or heavy alcohol use.

Patients who have chronic pain and who are opioid-naive also usually receive a short-acting opioid as a first trial. Experienced clinicians do offer some of these patients a long-acting drug from the start, but this strategy does not appear to be common. Usually, the decision to continue opioid treatment for the long term is accompanied by a switch to a drug with a long duration of effect. The opioids conventionally used in the United States in this situation include morphine, hydromorphone, fentanyl, oxycodone (used as a single entity), oxymorphone, levorphanol, and methadone.

All of the long-acting pure mu-agonist drugs should be viewed as alternatives in practice. Although morphine is the most commonly used drug for severe pain on a global level, there is now a large clinical experience that establishes very substantial individual variation in the response to different opioids. A patient may experience markedly different side effects when changed from one opioid to another and the balance between analgesia and side effects cannot be predicted based on the experience with a different drug. This variation is the basis for the so-called *opioid rotation*, the practice of switching opioids when side effects interfere with effective therapy (16).

There are a few drug-specific characteristics that may influence the decision to try one or another of the pure mu-agonist opioids. The specific role of morphine, for example, has evolved with recognition of its active metabolites. Morphine 6-glucuronide (M-6-G) binds to the mu-receptor and presumably contributes to both analgesia and side effects observed during morphine therapy; morphine 3-glucuronide (M-3-G), which is produced at higher concentrations than M-6-G and is not an opioid, may cause toxicity such as myoclonus and agitation. Both these metabolites accumulate in patients with renal insufficiency. Patients with renal insufficiency should be administered morphine cautiously, and those with unstable renal function might be better served by an opioid without active metabolites, such as fentanyl (17).

Fentanyl is available in a transdermal formulation and transmucosal formulations (indicated for cancer-related breakthrough pain; see Route of Opioid Administration). Transdermal fentanyl is very well accepted and may be preferred due to the ability to avoid additional pills, a dosing frequency of every 2 to 3 days, or the possibility of a lower rate of constipation than observed with oral drugs (18).

Most of the long-acting pure mu-agonist drugs used for chronic pain have relatively short elimination half-lives but have prolonged effects because of a delivery system that slowly releases the drug in the gut. The time required to approach steady state with these drugs is determined largely by the half-life of release and absorption, rather than elimination. The modified

release oral opioids containing morphine, oxycodone, hydro-morphone, or oxymorphone, for example, usually require 2 to 3 days to be at steady state, far longer than would be explained by the elimination half-life of the specific drugs delivered.

The potential benefits associated with the long-acting, modified release formulations—more convenience and better adherence to therapy—also may be accomplished by using a drug with a long half-life. Two drugs currently available in the United States, namely levorphanol and methadone, have considerably longer half-lives and may be used as long-acting drugs for chronic pain management. Five to six half-lives must pass before steady state is approached after dosing is begun or altered. With levorphanol, which has a half-life of 11 to 16 hours, this period extends to several days; if the treatment is carefully monitored for this period, further accumulation is unlikely. The long and variable half-life of methadone does complicate therapy, however, and is one of the characteristics of this drug that must be understood to ensure its safe use as an analgesic.

The use of methadone in the treatment of pain has been growing steadily during the past decade, driven by its low cost, high efficacy in some clinical situations, and perceived value in reducing the risk of abuse in patients predisposed to addiction. This increasing use, which was initially welcomed by pain specialists as a means to improve access to effective pain therapy, has been associated with reports of negative outcomes—including mortality—in some populations (19). Recognition that the use of methadone may be associated with a relatively high level of risk has led to re-examination of its pharmacology in relation to analgesia and other effects.

Methadone has a half-life that typically is about 24 hours but ranges from less than 15 hours to more than 150 hours (20); there is no way to predict the outliers from clinical presentation. The time required to approach steady state is 5 days or less in most patients but can extend to a few weeks in some. Without knowing for certain how much time is required after dosing is initiated or the dose is increased before the plasma concentration stops rising, a relatively long period of monitoring is required following each dose adjustment to avoid unanticipated delayed toxicity. This need for monitoring is most critical in patients predisposed to opioid side effects, including those with advanced age or major organ dysfunction.

This potential for prolonged accumulation of drug due to half-life is not the only source of risk associated with methadone. When administered to a patient already receiving a pure mu-agonist opioid, the potency of the methadone is related to the dose of the prior drug and can be much higher than expected. The potency almost always is more than would be anticipated from review of the classic equianalgesic dose tables used to guide opioid switching (16). This unanticipated high potency is believed to be related to the *d*-isomer, which represents 50% of the commercially available racemic mixture in the United States. This isomer blocks the *N*-methyl-D-aspartate receptor, and as a result, may yield independent analgesic effects and partially reverse opioid tolerance. Thus, when methadone racemate is given to patients receiving another opioid, the opioid-mediated analgesic effects produced

by the *l*-isomer are augmented by the *d*-isomer's effects on tolerance. Because there is presumably more tolerance at higher doses, methadone becomes more potent with higher doses of the prior opioid. To accommodate the potential for increased potency, a switch to methadone from another opioid is most safely accomplished by reducing the calculated equianalgesic dose by 75% to 90% (16). Failure to take this potential potency into account will lead to early overdoses.

It is now appreciated that methadone is among a large group of drugs that can prolong the QTc interval (21,22), presumably placing patients at risk for the development of a life-threatening cardiac arrhythmia, torsades de pointe. Although the risk of severe prolongation (above 500 msec) appears very low and there is no consensus concerning ECG monitoring, it is reasonable to obtain a baseline ECG in patients who may be predisposed to a prolonged QTc interval, such as those with heart disease or concurrent treatment with cardioactive drugs. An ECG also is prudent when the dose reaches an arbitrary levels, for example, above 100 mg/day, and periodically thereafter if the dose continues to be escalated.

Clinicians who prescribe methadone as an analgesic must be clear about the differences between this use and its administration for opioid addiction. In the United States, any clinician may prescribe methadone for pain, but a special license is required to use the drug in maintenance therapy for addiction. In contrast to the once-daily administration that is adequate for treating addiction, the use of methadone as an analgesic requires multiple daily doses—typically three or four—in most patients. Patients who are receiving methadone maintenance for the treatment of addiction can receive methadone as an analgesic as well, but this requires a separate prescription.

Route of Opioid Administration

For chronic therapy, the oral and transdermal routes for opioid delivery are well accepted. The advent of oral modified release formulations allowed more convenient dosing, either once daily or twice daily, and the transdermal route offered 48- to 72-hour dosing interval. These formulations also may improve treatment adherence, with theoretical benefits on pain control. They are not preferred when rapid dose titration is needed for severe pain. The transdermal route may be favored by some patients to reduce the pill burden or gain from the potential for lesser constipatory effects; it is relatively contraindicated when the patient is likely to experience spikes of fever, which may alter the delivery characteristics of the patch and lead to periods of increased drug absorption. The use of the transdermal system also is limited by the difficulties involved in delivering high doses and the need for an alternative route to provide supplemental doses for breakthrough pain.

The rectal route occasionally is used for prolonged therapy, particularly at the end of life. Rectal administration of modified release oral formulations has proved useful anecdotally.

The parenteral route typically is used for the treatment of acute severe pain in a monitored setting. The rationale for intravenous bolus therapy, including intravenous patient-

controlled analgesia, is the ability to provide pain relief quickly following a dose and titrate more effectively, unencumbered by the delay associated with oral absorption. Subcutaneous bolus injection also is widely used, particularly in the setting of pain related to advanced illness. In contrast, intramuscular injection is rarely appropriate, given the pain it causes, the risk of hematoma, and the occurrence of variable absorption from different muscles.

Several parenteral drug delivery options exist for the patient in need of long-term treatment but lacking in the ability to swallow or absorb opioid drugs. The usual context is pain related to medical illness. Although repeated subcutaneous injection can be used, continuous infusion techniques are generally preferred because they reduce the need for nursing support, eliminate the potential for bolus effects (side effects at peak concentration or pain breakthrough at the end of the dosing interval), and can be implemented in the home with relative ease. Any opioid available in an injectable formulation can be used for continuous infusion. Long-term intravenous administration is possible if the patient has an indwelling venous access device; long-term subcutaneous infusion can be accomplished using a 25-gauge butterfly needle that can be placed at any convenient site and left under the skin for a week before changing.

A variety of techniques for intraspinal opioid delivery (known as neuraxial analgesia) have been adapted to long-term treatment, and there is emerging evidence that properly selected patients can benefit greatly from this approach (23). The clearest indication is intolerable somnolence or confusion in a patient who is not experiencing adequate analgesia during systemic opioid treatment of a pain syndrome located below the level of mid chest. Continuous epidural infusion, which can be accomplished through either a percutaneous or implanted epidural catheter, is usually preferred if the patient has advanced medical illness and a life expectancy measured in just a few months. Otherwise, subarachnoid infusion using a totally implanted system should be considered. In a population with cancer pain, a controlled trial comparing neuraxial infusion and comprehensive medical management demonstrated that the spinal opioid treatment improved pain, side effects, quality of life, and even survival (24).

The potential for intraspinal infusion has increased further with the use of drug combinations. An opioid, such as morphine or hydromorphone, is usually combined with a local anesthetic, such as bupivacaine. Clonidine is often added, and other drugs may be considered for refractory pain, including other opioids, baclofen, midazolam, and ziconotide. Ziconotide is a unique calcium-channel blocker available only for neuraxial infusion and has been shown to be effective for cancer pain in controlled trials (25). As new drugs are tested for intraspinal therapy, the indications for the approach are likely to increase.

The decision to pursue a trial of neuraxial infusion is occasionally influenced by a history of substance abuse. Patients with severe pain problems, who pose a challenge in risk management, might be considered for a technique capable of providing an effective opioid regimen without patient access to the drug. Based on clinical experience, this strategy may be

beneficial for the patient in recovery, but demonstrably prone to relapse. Given the need for close monitoring and follow-up after pump implantation, a patient with active addiction, or a serious comorbid psychiatric disorder, generally would not be considered appropriate.

During the past decade, there has been extensive effort applied to the development of transmucosal opioid delivery systems. This effort has been driven by the recognition that breakthrough pain may be a serious problem for a substantial proportion of opioid-treated chronic pain patients (2,3) and that conventional management with a short-acting oral opioid fails to address the problem adequately. The transmucosal formulations incorporate a lipophilic drug, such as fentanyl, into a delivery system that can yield more rapid absorption than oral dosing, and thereby produces an onset of analgesia that more closely matches the time course of a typical breakthrough pain (26). The first system available, oral transmucosal fentanyl citrate (OTFC) placed the drug into a candy matrix that is sucked, allowing partial absorption through the buccal mucosa. An effervescent fentanyl buccal tablet and a fentanyl impregnated film also are available in the United States, and other systems available in Europe, including intranasal and sublingual formulations, are undergoing development for the U.S. market. There have been no comparative trials among the rapid-onset formulations and very little evaluation of any of these formulations relative to the conventional oral formulations used for breakthrough pain. Nonetheless, all are efficacious for breakthrough pain, and all yield analgesia more promptly than oral drugs. Given the demonstrated time-action relationship of these drugs, it is reasonable to consider a trial of one or another if breakthrough pain has a very quick time course or if a conventional oral agent fails to provide adequate relief.

Although the development of the rapid-onset opioid formulations may address an unmet clinical need for a more effective treatment for breakthrough pain, they have also raised concerns about potential adverse effects, including the risk of abuse, precipitation or relapse of addiction, and unintentional overdose. In the United States, these concerns have been highlighted by the degree to which the available formulations, which are indicated for cancer-related breakthrough pain, are being used off-label for noncancer pain. Although there are yet no empirical data supporting the view that these drugs are especially problematic in terms of abuse, addiction or diversion, the U.S. government has taken a proactive course and required the so-called “risk evaluation and mitigation strategies” (REMS) for each agent. The REMS programs are intended to improve safety and enhance monitoring of adverse outcomes. Although it is still too early to determine the impact of these or other REMS programs, the mandate demonstrates both the growing level of concern about prescription drug abuse and a strong regulatory response to this concern.

Dosing Guidelines

The success of opioid therapy derives less from the selection of the drug and route than from the clinical strategies used in initiating and altering the dose. In the setting of acute pain,

dosing usually involves a conventional starting dose provided on an “as needed” basis, irrespective of the specifics of the drug, route, or treatment setting. Although side effects such as nausea or somnolence are common during the initial period of drug administration, the overall balance between analgesia and side effects usually is favorable from the start. If not, the treatment should be changed promptly. If the problem is a side effect that typically can be easily managed, such as nausea, the change may involve coadministration of a drug to treat this. If the problematic side effect is difficult to manage, the opioid should be changed. If the problem is not a side effect, but rather a lack of efficacy after several doses, consideration should be given to an increase in the dose, conventionally by an amount in the range of 33% to 100%.

The management of acute severe pain in the relatively opioid-naïve patient using either an oral or parenteral agent is highly successful. The simplicity and effectiveness of the strategy explains its widespread acceptance by health professionals. In contrast, the effort to optimize the outcomes during long-term therapy requires a far greater set of competencies, including skills in pharmacotherapy and risk management (15). Guidelines intended to optimize the pharmacologic outcomes have been developed for chronic cancer-related pain (27,28) and represent the starting point for long-term therapy in all populations and settings.

Dose “By the Clock” For continuous or frequently recurring pain, “fixed schedule” (around-the-clock) dosing is usually preferred and long-acting drugs are used conventionally. Coadministration of a short-acting opioid, offered on an “as-needed” basis (known as a “rescue” dose or “escape” dose), may be used to manage breakthrough pains. Rescue dosing is widely considered to be a standard of care during management of pain related to active cancer but should not be considered routine in other populations. Like the decision to initiate a therapeutic trial of an opioid regimen with the intention to continue it long-term if outcomes are favorable, the decision to coadminister a short-acting drug for breakthrough pain should be taken only after an analysis of potential risks and benefits.

Although there is no evidence that the around-the-clock administration of a long-acting opioid confers any benefit over the use of short-acting opioids during the treatment of chronic pain (29), it is nonetheless taken as axiomatic that regular dosing with long-acting drugs is better because of the potential for improved convenience and adherence, and reduced pain fluctuation associated with bolus effects. On theoretical grounds, it also might be beneficial to use a long-acting drug (without access to a short-acting drug for breakthrough pain) in the effort to reduce the likelihood that the patient predisposed to addiction would experience a flare of the latter disorder induced by rapid changes in drug concentration.

For all of these putative benefits, experienced clinicians generally endorse the use of around-the-clock administration of a long-acting drug for chronic pain. The message provided to patients is that it is better in terms of both relief and side effects to prevent pain than to treat it after it occurs.

Given this widespread perception, it is a remarkable observation that a large proportion of opioid-treated patients receive prescriptions for short-acting medication for prolonged periods of time. These drugs are usually prescribed on an as-needed basis. The reasons for this are unknown but presumably include the failure on the part of some clinicians to properly conceptualize long-term treatment as grounded in a commitment to continue indefinitely. To the extent that this is so, it represents an unmet need for clinician education and support. As noted, current guidelines indicate that the clinician should, at some point, proceed from short-term therapy to a trial of long-term therapy, during which outcomes are evaluated to decide explicitly whether the patient is a candidate for ongoing opioid management of a chronic pain problem (15).

It also is likely, however, that some proportion of long-term as-needed therapy actually follows from the clinical observation that the benefits exceed any problems. Some patients prefer long-term access to a short-acting drug as needed because they value the sense of control over the therapy and the ability to adjust the dose on a daily basis. Other perceive benefit in better control of side effects. For example, the elderly patient with chronic pain from osteoarthritis who benefits from opioid therapy but struggles with constipation may learn that a reduction in dose for 1 or 2 days favorably influences bowel function; this outcome may have more value than the potential improvements in pain control associated with regular dosing of a long-acting drug. The use of a short-acting drug also may be useful in those with widely fluctuating pains, for whom the ability to rapidly titrate the dose higher, and reduce the dose quickly, overrides other concerns. Although the around-the-clock administration of a long-acting drug should be strongly considered whenever the transition to long-term therapy is made, flexibility based on a good assessment is appropriate.

Individualize the Dose In the setting of acute pain management, the dose may need to be adjusted promptly to optimize effects. The typical patient has little or no opioid exposure, and the overall outcomes associated with a conventional dose can quickly be determined. For example, the ambulatory patient might be treated with an opioid–nonopioid combination product, or with tramadol or tapentadol, at the lowest dose available. The inpatient might be treated with intravenous patient-controlled analgesia using a standard protocol (e.g., morphine 1 mg every 6 minutes as needed, or equivalent) or with intravenous injection (e.g., morphine 5 mg intravenously every two hours as needed). If the starting dose is not effective, it should be increased.

If the patient with acute pain has substantial prior opioid exposure, either as a result of long-term opioid therapy for pain or methadone maintenance, the initial dose of the drug for acute pain typically needs adjustment. Based on clinical experience, there are strategies to identify the proper dose quickly. One approach involves the calculation of the dose delivered over 3 to 4 hours (i.e., one eighth to one sixth the total daily dose), which is then converted to a dose of the drug used

for acute pain based on standard equianalgesic data; this dose is then reduced by 25% to 50% to account for variation and incomplete cross-tolerance (16). The result of the first dose is monitored and the dose is adjusted upward with the subsequent permitted dose, usually 3 or 4 hours later. An alternative approach is to give a conventional starting dose for an opioid-naive patient, with a plan to repeat it (with or without a 50% increase) after a long enough period to observe the peak effect of the first dose (e.g., 20 to 30 minutes if using morphine). Additional dose escalations may be needed if the dose remains ineffective. These repeated doses can be given at short intervals until the patient reports that a dose has yielded effect. The subsequent regimen uses this dose, administered every three hours as needed.

Individualization of the dose during long-term opioid therapy is far more challenging and, again, is the key to the overall success of the therapy. The goal is to identify a dose through repeated titration that is associated with a favorable balance between analgesia and side effects. Once a pure mu-opioid agonist drug and route of administration are selected, the dose should be incremented until adequate analgesia occurs or intolerable and unmanageable side effects supervene. If a favorable dose is found, it should be continued, but should pain reappear during the course of therapy, retitration should be considered in an effort to recapture the favorable balance between analgesia and side effects.

There are several approaches to dose escalation at the start of therapy, or later should pain worsen after a period of stability. The size of the increase is usually selected as either the total quantity of rescue drug consumed during the previous day (or if this is changing, the average of the past 2 to 3 days), or as 33% to 50% of the current total daily dose. The increment can be larger (75% to 100% of the total daily dose) if pain is severe and the patient is medically stable, or smaller if the patient is already experiencing opioid toxicity or is predisposed to adverse effects because of advanced age or coexisting major organ dysfunction. Caution is also reasonable if the patient has a limited prior opioid exposure.

Dose titration typically identifies a dose that yields a favorable balance between analgesia and side effects for a stable period. Many patients appear to find the same dose effective for many months or years. This phenomenon belies the inevitability of tolerance as a problem in the long-term administration of opioid drugs.

Although doses typically stabilize for prolonged periods during long-term management, dose escalation is usually required at intervals to maintain analgesia. Patients who ultimately require relatively high opioid doses typically evolve through a series of “retitrations” driven by reappearance of moderate or severe pain after a period of stable, effective therapy. In the patient with pain as a consequence of medical illness, the need for a dose increase can usually be explained by some overt change in clinical status, such as worsening of a pain-producing structural lesion. This implies that the reappearance of pain after a period of stability may call for reevaluation of the underlying pain-producing disease. Pain may worsen in the absence of a progressive lesion, however, and

the assessment at this time also should address the potential of other biomedical factors (e.g., change in the underlying pathophysiology of the pain) or factors related to an emerging psychosocial or psychiatric problem.

Although dose escalation after a period of stability to regain benefit that has been lost should always be considered, this action should not be viewed as automatic. Depending on the assessment, it may be appropriately combined with other interventions (a treatment that targets a factor assessed as driving the pain, a treatment that is independently coanalgesic, or both) or eschewed all together in lieu of an alternative strategy.
