During the steady increase in the use of opioid therapy to manage persistent pain, it has been commonly accepted that the pure mu-agonists do not have a ceiling effect for analgesia and the maximal dose is immaterial as long as the patient attains a favorable balance between analgesia and side effects. Although this is true from a pharmacologic perspective, the guideline to titrate the dose without regard to the total dose must be qualified. Few patients with any type of chronic pain require relatively high doses of an opioid. Although the dose that is considered “high” is entirely arbitrary, data from the pharmaceutical industry in the United States indicate that a large majority of patients receive a total daily dose less than the equivalent of 200 mg of morphine, and it is reasonable on this basis to consider doses that exceed this level to be high. The need for a high dose is not, in itself, a problem—indeed, pain specialists commonly treat patients with doses above this and some patients ultimately stabilize on doses equivalent to several grams of morphine daily while demonstrating good pain control, minimal side effects, and responsible drug use. Nonetheless, the reality that high doses escalation by itself should never be made in isolation to judge the effectiveness and safety of an opioid regimen. Nonetheless, the reality that high doses are seldom needed obligates the clinician to be particularly careful when the dose requires escalation to high levels. The clinician should reassess the nature of the pain and comorbidities (including the potential for substance use disorder), the rationale for therapy, the availability of alternative treatments, and the outcomes associated with dose escalation (15). This reassessment should be well documented and repeated as necessary.

The concerns raised about the use of relatively high opioid doses have increased with elucidation of the physiology of *opioid-induced hyperalgesia* (30). This term refers to a neurophysiologic phenomenon characterized by an opioid-induced lowering of pain threshold and increase in pain response to noxious stimuli. Clearly demonstrated in preclinical models, the empirical data in patients are very limited. Case reports suggest that opioid treatment can result in the so-called “paradoxical pain” but that the phenomenon is rare and heterogeneous. One subtype is characterized by generalized pain and allodynia associated with tremulousness, confusion, and myoclonus, which occur in the setting of escalating doses of systemic or neuraxial opioid; this subtype is not naloxone reversible and appears to be fundamentally different than the opioid-induced hyperalgesia that is observed

in animal models. Other patients may have a type of opioid-induced hyperalgesia that is mediated by the opioid receptor, but at this time, the extent to which this type of phenomenon influences outcomes during opioid therapy is entirely unknown. There are insufficient data to conclude that opioid-induced hyperalgesia represent anything more than a rare adverse event. In the absence of relevant symptoms and signs, such as escalating pain as the dose is increased, or signs of delirium, it is not appropriate to limit or withhold opioid treatment in an effort to prevent or reverse opioid-induced hyperalgesia.

Be Aware of Relative Potencies Potency refers to the dose required to produce a given effect. It is entirely distinct from efficacy, which may be defined as the anticipated effect produced by a given dose, or effectiveness, which is the extent to which the drug has a favorable therapeutic index in the clinical setting. Potency is an issue in opioid prescribing only when there is a planned switch from one drug to another—opioid rotation. The dose of the second drug must be selected based on its potency relative to the drug it is replacing; the dose should be high enough to ensure no flare of pain or abstinence phenomena, but low enough to minimize the risk of toxicity.

Studies of relative potency began five decades ago with the development of a scientific methodology. Using morphine as a standard, relative potencies have been determined for most pure agonist drugs. This information was used to construct an equianalgesic dose table (Table 51.3), which summarizes the results of relative potency studies and provides a guide for the practice of opioid rotation. A recent evidence-based guideline for opioid rotation emphasize that the equianalgesic table is only a starting point for a guideline (16). The first step in this guideline involves calculation of the equianalgesic dose using the values in the standard table. This calculated equianalgesic dose typically is reduced by 25% to 50% in recognition of individual variation and incomplete cross-tolerance between drugs. There are, however, two important exceptions to this: First, a switch to methadone should be accompanied by a 75% to 90% reduction in the calculated equianalgesic dose as a result of the potential for an unanticipated high potency as discussed previously, and second, a switch to the transdermal fentanyl patch should have no immediate dose reduction because the equianalgesic dose ratios that were built into the initial commercialization of this product were conservative.

The evidence-based guideline further suggests a second step in opioid rotation (16). After calculation of the equianalgesic dose and immediate dose reduction in most cases, a second decision is needed about an additional change, specifically either an increase or a decrease by 15% to 25%. An increase should be considered if pain is severe, and a decrease should be considered if the patient is medically frail, the doses are relatively high, or significant opioid toxicity is present. Although there are no empirical data demonstrating the safety and effectiveness of this two-step strategy, the approach is proposed as a flexible method that is likely to transition a

patient from one opioid drug to another with relatively low risk of adverse consequences associated with either overdosing or underdosing.

If a so-called rescue medication is coadministered for breakthrough pain, the conventional dose selected is 5% to 15% of the total daily dose, and the dosing interval in the ambulatory population is usually 1 to 2 hours, as needed. If the rescue drug is changed to another, the same calculations using relative potency estimates can be done to select an appropriate starting dose. As noted, the key exception to this guideline is posed by the rapid-onset fentanyl formulations. Controlled studies have not confirmed that the dose administered on a scheduled basis predicts the effective size of the rescue (31) and guidelines for the use of these formulations should include a low starting dose in all cases (e.g. 200 to 400 μg of the OTFC), followed by dose titration.

Treat Side Effects Treatment of opioid-induced side effects is an integral part of opioid therapy (27,32). Management of side effects enhances comfort and allows continued upward dose titration of the opioid drug, if necessary. Although respiratory depression fosters the greatest concern, tolerance to this adverse effect develops quickly and it is rarely a problem. The most common and persistent side effect during long-term treatment is constipation. Although less prevalent, persistent sedation or mental clouding also may occur and limit dose escalation.

Although the evidence is very limited (33), there is a large experience supporting the use of laxative therapy for opioid-induced constipation. Treatment is needed by a high proportion of those who receive opioids in the context of serious medical illness, most of whom have other factors contributing to constipation; a smaller proportion of patients without these factors require ongoing treatment. The conventional approach involves either the administration of a stool softener, docusate, in combination with a contact cathartic, such as bisacodyl or senna, or the administration of an osmotically active agent. The latter products include poorly absorbed sugars, specifically lactulose or sorbitol, or propylene glycol. The treatment of opioid-induced constipation that is refractory to these therapies may involve trials of drugs that have been used anecdotally, such as a prokinetic agent (metaclopramide), an acetylcholinesterase inhibitor (e.g., donepezil), lubiprostone, misoprostol or colchicine. More specifically, refractory constipation can be treated with an opioid antagonist. Methylnaltrexone is now approved in the United States as a parenteral opioid antagonist specifically indicated for refractory constipation; the studies suggest that more than one half of treated patients respond with a bowel movement, most within an hour of dosing (34). There also is limited experience with oral naloxone for severe opioid-induced constipation.

Patients who experience persistent somnolence or mental clouding during opioid therapy may improve with elimination of nonessential centrally acting drugs or opioid rotation. Another strategy is to treat the symptom using a psychostimulant, such as methylphenidate or modafinil.

There have been very few studies of this approach but extensive clinical experience has been favorable (32). The potential side effects of the psychostimulants, including anxiety, tremulousness, anorexia, and insomnia, must be considered, however, particularly if dose escalation is required to gain benefit. Equally important, the psychostimulants are potentially abusable drugs and the decision to implement a trial, and the approach to monitoring treatment over time, requires consideration of the potential for abuse and diversion, similar to the opioid itself.

Other side effects are common with short-term administration but seldom compromise long-term therapy. These include nausea, itch, dry mouth, and urinary retention. Like other side effects, the management may consider opioid rotation or specific treatment of the symptom.

In recent years, there has been increasing concern about side effects related to the neuroendocrine effects of opioid drugs, specifically drug-induced hypogonadism. Most opioid-treated men have hypothalamic hypogonadism, and although the prevalence of this complication in women is uncertain, the levels of sex hormones in women receiving opioid drugs are relatively low compared to those who are not (35,36). Hypogonadism may be associated with sexual dysfunction and infertility, mood disturbance, fatigue, and osteoporosis. Although the impact of these potential outcomes in the diverse populations with chronic pain is unknown, pain specialists now generally advocate for measurement of testosterone and free testosterone in opioid-treated men with symptoms that may suggest hypogonadism. There is no consensus about the approach to take with opioid-treated women, but it is reasonable to consider hormonal therapy in premenopausal women who become symptomatically hypogonadal during opioid treatment.

Recently, concern also has focused on the potential for opioids to cause sleep-disordered breathing (37). The data are limited but a form of central sleep apnea associated with changes in sleep architecture should be considered a potential risk during long-term therapy. A survey of chronic pain patients suggested that the prevalence of this adverse effect is very high when assessed with polysomnography and that the risk of serious sleep apnea is highest among those patients treated with methadone and those who are receiving concurrent treatment with a benzodiazepine (38). Given concerns about the increase in mortality among opioid-treated pain patients (39), the potential for this effect should be taken seriously. Patients with untreated sleep apnea syndrome, and those at risk by virtue of obesity, short neck, snoring, or daytime somnolence that predates treatment, should be treated cautiously. It is best to avoid benzodiazepines in these at-risk patients and to consider referral for a sleep study and treatment of a sleep disorder, if present.

Monitoring Outcomes

Regardless of the pain syndrome or setting of care, opioid therapy must be monitored in terms of analgesic effects, side effects, impact on functioning, and drug-related behaviors. In the setting of chronic pain management, changes in ther-

apy should be considered if an initial favorable balance between analgesia or side effects change for the worse, physical or psychosocial functioning decline, or nonadherence behaviors occur. A simple framework for monitoring has been summarized using the mnemonic, the “Four A’s” (Table 51.4). Documentation of outcomes in the medical record should periodically describe the assessment of each element. This may be facilitated by use of a chart tool, such as the Pain Assessment and Documentation Tool (40).

Risk Assessment and Management

Monitoring for aberrant drug-related behavior should be considered a best practice during treatment with any potentially abusable drug in any clinical situation. Opioid therapy in all treatment contexts always carries a risk associated with its abuse liability. In some situations, such as acute pain management in monitored settings or the treatment of chronic pain in those with advanced medical illness, the risks may be very low or the management of these risks may be relatively simple. In other situations, such as the treatment of a chronic pain problem in the patient with a recent history of polysubstance abuse, the risks are very high. Irrespective of the level of risk, the most efficient and appropriate framework is a *universal precautions* approach. This approach, which has been emphasized in the setting of chronic pain management (41), should be broadly generalized. It empowers clinicians to act in patients’ best interests by putting the emphasis on assessment and encouraging rational clinical decisions and appropriate documentation.

Laws and Regulations Governing Controlled Prescription Drugs

In the United States, there are three levels to the regulations and laws that govern the use of controlled prescription drugs: (a) international laws and treaties, (b) federal laws and regulations, and (c) state laws and regulations. A basic knowledge of the framework provides the background for clinical risk management; a more detailed understanding of specific regulations and laws is necessary to practice.

The International Narcotics Control Board was established in 1968 as an independent body charged with the implementation of the United Nations drug conventions. It attempts to ensure that adequate supplies of controlled drugs are available for medical and scientific uses while minimizing diversion to illicit purposes. The board monitors international trade in drugs and government control systems. It has no direct interaction with clinicians.

In the United States, the Drug Enforcement Administration (DEA) and the Food and Drug Administration (FDA) work together to regulate drugs. The DEA was created in 1970 as part of the Controlled Substances Act (CSA), which embodies so-called Title II and Title III of the Comprehensive Drug Abuse Prevention and Control Act. The goal of this legislation was to create a closed system for monitoring and providing access to abusable drugs with legitimate medical purpose. The CSA created different “schedules” of drugs

TABLE 51.4 The four A's approach to monitoring long-term opioid therapy

Analgesia
<ul style="list-style-type: none"> ■ Assess pain intensity over time, preferably in terms of a documented measurement, using either of the following scales: <ul style="list-style-type: none"> ■ A 0–10 numeric scale, one for average pain during the past week and one for worst pain during the past week ■ Percent relief scale, using the period prior to long-term opioid treatment as a baseline
Adverse Effects
<ul style="list-style-type: none"> ■ Document symptoms that are side effects, e.g., constipation, mental clouding, or sedation ■ Document monitoring for other side effects, such as hypogonadism and sleep-disordered breathing
Activities
<ul style="list-style-type: none"> ■ Document impact of treatment on at least several functional domains, potentially including <ul style="list-style-type: none"> ■ Physical activities ■ Role functioning ■ Mood ■ Coping ■ Social interactions and family interactions ■ Sexual functioning ■ Impact of other symptoms such as insomnia and fatigue
Aberrant Drug-Related Behavior
<ul style="list-style-type: none"> ■ Document assessment of drug-related behavior, with the scope and specific elements defined by the level of structure applied to the therapy; potential assessments include <ul style="list-style-type: none"> ■ Global assessment ■ Adherence to instruction, including prescription, required consultations, and acquisition of medical reports ■ Results of urine drug screening ■ Reports of drug-related impairment at work or other activities

based on the risk of abuse and diversion, medical use, and safety. Schedule I drugs, such as heroin and marijuana, are believed to have a high potential for abuse, a lack of accepted safety, and no current federally accepted medical use. Schedule II drugs such as morphine, fentanyl, hydromorphone, levorphanol, methadone, oxycodone, oxymorphone, methylphenidate, dextroamphetamine, and dronabinol are believed to have a high potential for abuse but have currently accepted for medical uses. Drugs classified into schedules III through V, such as hydrocodone and codeine, are medically useful and have progressively less abuse potential.

The DEA is a law enforcement agency and relies on the criminal justice system to enforce the CSA. Although most of its activity is focused on reducing the flow of illicit drugs, it is responsible for investigating and stopping the trafficking of controlled prescription drugs. The filter through which it evaluates clinician behavior is framed by two key elements that must characterize every prescription for a controlled drug: (a) it must be provided in *the usual course of professional practice* and (b) it must be *for a legitimate medical purpose*.

The two key elements of a legal prescription under the CSA are similar to the criteria used by medical boards,

which are charged with ensuring that medical practice is appropriate to the standard of care. Although this commonality between criteria used to judge physician prescribing behavior under criminal statute and criteria used to judge physician behavior under civil medical practice laws raises concern about fairness (similar behaviors can be addressed as a criminal or a civil violation without clear criteria for distinguishing them), it does simplify understanding of the legal and regulatory framework for prescribing. It is essential that the documentation in the medical record demonstrates that the person who receives a prescription for a controlled drug is a patient in a doctor–patient relationship and has a medical indication for the drug, and that the prescription is given and monitored in a manner consistent with medical care.

In contrast to the DEA, the FDA is not primarily a law enforcement agency. It is a regulatory body that determines whether a drug is legal for prescribing and dispensing. Historically, the FDA has limited its purview to the assessment of safety and efficacy. With the passage of the 2007 FDA Amendments Act, however, the agency has been required to improve the safety of controlled prescription drugs through proactive approaches that reduce the risk of unintentional

overdose, drug abuse, and addiction. These approaches, known collectively as REMS, are presently evolving. Newly approved opioid drugs now have individual REMS, all of which focus on education of physicians, pharmacists, and patients, and some of which include enhanced monitoring through registries or the use of specialty pharmacies. In the near future, it is likely that REMS will be applied uniformly to some classes of controlled prescription drugs, such as modified release opioids and rapid-onset formulations for breakthrough pain. The FDA has indicated its commitment to maintain access to these drugs for the patients who need them, but there is concern that REMS may increase the reluctance of prescribers to offer Schedule II opioids. This remains to be determined.

In the United States, each state works with the federal government to oversee the movement of controlled prescription drugs and minimize abuse and diversion. Each state also has sole responsibility for maintaining standards of health care practice through licensure of professionals. Law enforcement is conducted through numerous agencies, and medical practice and licensure are governed through state medical boards. Both the existence of medically inappropriate language in state laws and regulations and the empirical demonstration of knowledge gaps among the members of state boards have been recognized as potential barriers to appropriate medical use of opioid drugs (42). In an effort to improve this situation, the Federation of State Medical Boards, a national organization, has drafted a model policy for the medical use of controlled substances (“Model Policy for the Use of Controlled Substances for the Treatment of Pain”), which has now been adopted, at least in part, by most states (43).

Structuring Therapy to Reduce Risk

From the perspective of universal precautions, all patients who are prescribed an opioid should undergo an assessment designed to stratify the risk of abuse, addiction, and diversion. If prescribing is initiated, the plan of care should include strategies for adherence monitoring appropriate for the level of risk.

Risk stratification relies on clinical assessment, potentially supplemented by one of the present numerous questionnaires. Clinical assessment alone typically is used in the setting of acute pain management. Prescribing may be occurring in a monitored environment and is planned for a short time. The most important concern is whether the patient has a personal history of alcohol or drug abuse, and if so, whether the nature of this history is likely to increase the risk that that patient will engage in aberrant behaviors during the relatively brief period of prescribing.

When a decision about potential long-term therapy is being entertained, the challenge of the assessment and its implications is greater. From the clinical perspective, it is widely accepted that the risk of abuse or addiction is increased in those with (a) a personal history of drug abuse, (b) a family history of drug abuse, or (c) a history of major psychiatric pathology. Although it is obvious that each factor may be complex, positive findings in any of these three domains

should raise concerns, particularly if supported by ancillary information. This information may include a past experience of physical or sexual abuse, regular contact with high-risk individuals or environments, prior criminal behavior, or heavy smoking.

During the past decade, multiple tools have been developed to assist the clinician in predicting which patients are at higher risk for developing abuse behaviors during long-term therapy. None of these tools has been adequately validated (44). The tool that has been best validated is the Screener and Opioid Assessment for Patients with Pain (44,45); less well validated, but briefer instruments—the Opioid Risk Tool, the Diagnosis, Intractability, Risk and Efficacy Inventory, and the Cut Down, Annoyed, Guilty, Eye-Opener Tool, Adjusted to Include Drugs—also are in use. Numerous other questionnaires vary in length, validation, specific outcomes assessed, and clinical utility (46). At present, the decision to incorporate a tool in practice is a matter of clinical judgment.

Based on the clinical assessment or information obtained using a questionnaire, each patient who is prescribed a controlled drug can be categorized in terms of the risk for non-adherence behavior. Patients with no past or current history of alcohol or drug abuse, no family history of these disorders, and no major psychopathology may be considered low risk; others may be considered to be at higher risk. As described previously, the assessed level of risk is one element that must be considered in the initial decision to initiate a trial of opioid therapy with the intention of long-term treatment if outcomes are favorable. If the patient is perceived to be a candidate, the level of risk also should be considered in the decision to obtain consultation for assistance in therapy, or possibly referring the patient to a more experienced clinician or structured program.

If the decision is made to prescribe, treatment must be structured in a manner that allows monitoring and control commensurate with the assessed risk. If the patient has acute pain and is treated in a monitored environment, there may be few additional elements of monitoring necessary. In the ambulatory setting, however, even short-term therapy for acute pain must consider risk and structure therapy appropriately.

If the patient has chronic pain, the decision to undertake opioid treatment with the intention to continue treatment indefinitely should begin with a trial, during which nonadherence behavior and other outcomes can be assessed. This overall approach to chronic therapy—risk stratification followed by the structuring of therapy during an initial treatment trial, after which the plan of care for longer-term management can be defined—is appropriate for all types of patients with persistent pain, including those with pain related to serious illness.

There are no guidelines for the initial structuring of therapy in a manner that matches risk with an appropriate degree of monitoring and control. Many of the strategies are well known by those who work with patients who have the disease of addiction, but their adaptation to the context of opioid prescribing for pain is a matter of clinical judgment. Some

approaches are straightforward, such as the requirement for all medical records before prescribing is begun; requirement that contact be maintained with other physicians, counselors or sponsors, or drug treatment program; requirement for consultation with a mental health professional with expertise in the addictions; prescription of small quantities; and frequent visits to the office.

Urine drug screening is a widely accepted approach for adherence monitoring (47,48), but there is debate about the most appropriate method for implementing this strategy in practice. Although there is agreement that high-risk patients should be screened at the start of treatment, and periodically thereafter, some experienced clinicians advocate universal testing repeatedly during therapy. All clinicians who treat patients with long-term opioid therapy should develop a system for urine drug screening, decide proactively on an approach, and learn how to interpret the findings.

The so-called “opioid agreement” is another controversial tool in the structuring of treatment (49). Although a document that is reviewed by the patient and the clinician at the start of opioid therapy may be used effectively as an educational device, it also could contribute to the stigmatization of opioid therapy, undermine goals by stating requirements (e.g., no driving) that are inconsistent with common practice, or encourage the patient to dissemble by threatening negative consequences that may be out of proportion to the behaviors that occur. If the document gives a clinician a false sense of security, it could unintentionally reduce the vigilance necessary in monitoring treatment. Finally, an agreement that includes specific promises theoretically could be used adversely in a medicolegal dispute.

Given the controversy, each clinician must decide whether the use of an agreement is appropriate and likely to be beneficial. If one is selected, it is best to conceptualize it as a tool to enhance patient understanding and expectations about the therapy and provide very specific instructions. A model for this type of agreement has been created by the American Academy of Pain Medicine (50).

Monitoring Therapy and Addressing Nonadherence

Monitoring outcomes using the framework of the “Four A’s” (Table 51.4) will ensure that drug-related behaviors are included among the key outcomes evaluated. The intensity and type of monitoring will determine the information available. For the patient who is assessed as low risk, monitoring of drug-related behaviors may take the form of simple questions about adherence, the answers to which may be documented. For patients at higher levels of assessed risk, these questions may be complemented by the results of urine drug screening, which evaluates for the presence of the prescribed drug and the absence of nonprescribed drugs; pill counts; information from the pharmacy; or reports from other clinicians, sponsors, or programs.

The occurrence of nonadherence behavior of any type should be documented and initiate a thoughtful response. The following elements should be considered:

1. Clarify the nature and severity of the behavior with all existing information; plan to acquire additional information if needed.
2. Evaluate the *differential diagnosis* of the behavior. The following diagnoses are not mutually exclusive: (a) addiction, either de novo (iatrogenic addiction) or relapse; (b) pseudoaddiction; (c) other psychiatric disorder associated with impulsive drug-related behavior, such as an anxiety disorder or a personality disorder; (d) encephalopathy (e.g., an early dementia or a confusional state) associated with disinhibition, automatic behavior, or memory disturbance; (e) family issues driving aberrant drug-related behavior; and (f) criminal intent.
3. Decide whether the plan of care must address a new concern, regardless of the next steps for pain. For example, if a de novo diagnosis of addiction is suspected, the plan of care should include proposed management of this newly diagnosed and serious disorder. The patient should be told of the suspected diagnosis, and, if necessary, referred for further assessment and treatment. Any other new medical or psychiatric diagnosis, or suspected diagnosis, should be documented and addressed, again irrespective of the parallel plan for pain management.
4. Decide whether the behavioral problems warrant an end to the therapeutic relationship. The ethical foundation of medicine requires that the decision to continue or discontinue any specific therapy be separated from the decision to continue the therapeutic relationship. Discharge of the patient from the medical practice should only occur if the patient’s behavior, such as a criminal act or repeated lying, so undermines the therapeutic relationship that ongoing care is not possible. If this is the case, the patient should be informed in writing, given the names and locations of other sources of medical care, and told that emergency care is still available (this can be delegated to a local hospital-based emergency department). If the patient is taking medications that would be unsafe to stop abruptly, he or she should either be referred to a program that provides detoxification or be given a prescription for a tapering dose of the drug. The tapering of an opioid usually can be accomplished quickly by reducing the dose by 50% every 3 days, with an end when the dose reaches that equivalent to about 30 to 60 mg of oral morphine per day.
5. Whether or not the decision is to promptly discharge the patient from the medical practice, a strong suspicion of diversion should lead to a prompt discontinuation of prescribing. Prescription of a controlled substance to someone who is likely to be diverting the drug is prohibited in the United States under the federal CSA. A high index of suspicion that diversion is occurring should be followed by no further prescribing, or if this would place the patient in imminent risk of serious medical compromise, prescribing for no more than a few days with instructions to taper the dose.
6. With the exception of the patient who is likely to be engaged in criminal activity, the clinician is not legally obligated to discontinue prescribing if aberrant drug-related behavior

occurs. Nonetheless, continued prescribing despite clear evidence that serious nonadherence is occurring would not be consistent with good clinical practice. If aberrant drug-related behavior is encountered, the clinician must decide if the type of behavior or its underlying diagnosis (e.g., relapse of an addictive disorder) creates so much risk or burden that the treatment must be discontinued, even as the offer of continued management of pain or other medical problems is made. This has been called an *exit strategy*. If, however, the clinician perceives a high likelihood that the nonadherence behavior will stop and monitoring can be improved, then opioid treatment should be continued.

7. If the decision is made to continue prescribing, the treatment should be promptly re-structured to accomplish three goals: First, prescriber control over the therapy must be regained and the new structure should help the patient maintain control over impulsive use. Second, the new structure for prescribing should enhance the ability to monitor the therapy. Third, the goals of good pain control and maintenance or improvement of function should be retained. The restructuring of the therapy to regain control and enhance monitoring should consider all of the strategies that are used when long-term treatment is initiated for the first time (see Structuring Therapy to Reduce Risk). This may include a written agreement, frequent visits, small quantities prescribed, urine drug screening, and required consultations, perhaps with a specialist in addiction medicine or pain medicine.
8. The documentation surrounding the response to aberrant drug-related behavior should be comprehensive and demonstrate both the rationale for clinical actions and the actions themselves.

Other Issues in the Treatment of the Substance Abuser with Pain

Based on clinical experience, some of the salient differences among subsets of those with substance use disorders can be explored in terms of their impact on the principles discussed above.

Patients with a Remote History of Substance Abuse

Patients with a remote history of alcohol or drug abuse should be stratified as relatively high risk irrespective of the context and setting of opioid prescribing. These patients require more intensive monitoring because of both a presumed increased risk of abuse and addiction and the potential for undertreatment pain. Undertreatment may be related to clinician or patient factors, or both. The stigma associated with a substance abuse history may lead medical or nursing staff to assume that pain reports reflect drug-seeking and should be addressed by the withholding of treatment. Conversely, patients may fear that treatment with an opioid or other abusable drug may lead to relapse, and for this reason, they withhold complaints or underdose. The optimal management of the patient with pain and remote history of addiction must incorporate careful, ongoing assessment and education of the staff and the patient.

Patients in Methadone Maintenance Programs

Patients enrolled in methadone maintenance programs vary in the extent to which craving is controlled and drug abuse behaviors are occurring. Chronic pain is highly prevalent in this population but access to pain therapy is limited (51). Should a patient receiving methadone for addiction seek pain care, the assessment should clarify the nature and effectiveness of the program (the patient should specifically consent in writing to information sharing with the program, and the clinician who manages the pain should determine the results of recent urine drug screening and related information maintained by the program); this assessment should judge the strength of the recovery and the extent to which the patient has access to supports that may help to sustain it. Opioid therapy should be considered for long-term therapy only if there is evidence that the patient's recovery has been established sufficiently to justify a trial and other pain management strategies are unavailable or have proven to be ineffective.

Generally, patients who are considered for opioid therapy should be continued on their daily dose of methadone. This applies to all treatment settings. Occasionally, the patient undergoing methadone treatment for addiction responds so well to long-term opioid therapy for pain that the specific treatment for addiction can be withdrawn (52). This decision should be taken only if there is evidence over time to support it, and only after careful discussion with the patient and clinicians at the methadone treatment program.

If acute or chronic pain is considered for opioid therapy, the methadone-treated population is likely to be at high risk of undertreatment. Negative stereotyping by medical staff may increase the reluctance to prescribe, and the opioid dose selected may be less likely to work because of opioid tolerance related to the concurrent methadone administration. If persistent pain reports are interpreted as a manipulative attempt to obtain opioids for purposes other than analgesia, the therapeutic relationship may become conflicted and the clinician's goals for analgesia may be superseded by the desire to prevent drug abuse. This concern is legitimate if the patient develops a return of aberrant drug-taking behaviors, but if "drug seeking" reflects only the need for pain relief, undertreatment will result from the failure to respond.

The methadone-treated patient can be treated with methadone or another opioid for pain. If methadone is used, dosing for pain usually requires drug administration every 6 to 8 hours, and like other opioids, this regimen can be coadministered with a once-daily dose of methadone given by the program. As described previously, documentation in the medical record must be meticulous in the United States, describing the opioid treatment (including methadone, if given) as treatment for pain and not addiction. The specific dose of the opioid used for pain may be substantially higher than anticipated, although this does not occur in all cases (53). When initiating treatment with opioid, it is best to begin with standard doses and titrate these doses rapidly should the outcomes be unhelpful.

Patients Receiving Opioid-Agonist Therapy with Buprenorphine

Buprenorphine offers another option for opioid agonist therapy of addiction and is increasing in use. It is now being used as an analgesic in many countries. The assessment, assumption of high risk, careful selection of patients for consideration of opioid therapy, need to structure therapy in a manner to mitigate risk, and requirement for careful documentation during pain therapy all parallel the approach taken with methadone-maintained patients.

The pharmacology of buprenorphine is characterized by high-affinity binding to the mu-receptor, a half-life longer than a day, and partial agonism. The high affinity raises concern that the buprenorphine-treated patient may not respond to administration of a pure mu-agonist drug, at least at typical doses. There is very little experience with the coadministration of another pure mu-agonist drug to the buprenorphine-treated patient, either for acute pain or for chronic pain (54). Although it is possible that the patient who experiences severe pain during buprenorphine treatment for addiction could be managed by increasing and dividing the dose of buprenorphine, there also is very little experience with this approach. Based on anecdotal experience, acute pain should be treated initially with mu-agonist opioid doses that are conventional for the setting, but if the response is poor, the dose should be rapidly titrated. In most cases, the buprenorphine should be continued at the prior dose while this is carried out. For chronic pain, the same principles would apply, with the expectation that there is a dose of a pure mu-agonist that may provide added pain relief. Research is needed to clarify the outcomes associated with the management of acute and chronic pain in buprenorphine-treated patients.

Active Drug Abusers

Patients with active alcohol or drug abuse are presumed to be at high risk for nonadherence. In the monitored setting, acute pain can be managed using conventional means, such as intravenous patient-controlled analgesia, but staff must be prepared to manage the type of problems that may be associated with drug abuse, including the development of withdrawal phenomena, comorbid psychiatric disease, and responses to opioid drugs for pain that may be difficult to interpret.

In the ambulatory setting, the use of a controlled prescription drug in the context of current abuse is very challenging. Prescribing is not acceptable if diversion is expected, and even if it is not the case, the abusing patient may be perceived as incapable of honest reporting and this, too, would contraindicate therapy.

All cases deserve careful assessment, however, and there may be scenarios in which a trial of opioid treatment might be considered. For example, the patient who is actively abusing alcohol or marijuana and is entering a treatment program with close monitoring may be assessed as more likely to proceed into recovery if pain is controlled. Given the heterogeneity of the population abusing drugs, the question that must

be addressed is whether the specifics of the situation warrant the risk of an appropriately structured treatment trial.

CONCLUSION

Although an exploration of the issues at the interface between pain and substance abuse focuses on the opioid drugs, decision making in the clinical setting must be informed by a broader knowledge of the varied modalities used to manage acute and chronic pain. Recent texts describe the breadth of therapies—pharmacologic and nonpharmacologic—that can be employed in the management of pain (55) and the influence of a patient's substance use history on the selection and implementation of these therapies (56). The optimal treatment of acute or chronic pain, irrespective of the pain diagnosis and the unique characteristics of the patient, always must consider the risks and benefits of an opioid-based treatment trial against the risks and benefits of other potential strategies. This analysis requires familiarity with other analgesic approaches, an understanding of conventional practice, and good judgment that takes into account the feasibility and goals that surround the plan of care.

The relatively straightforward decision to use a conventional intravenous opioid regimen for any patient who is opioid-naïve and experiencing acute severe pain in the inpatient setting has little in common with the complexity of the decisions involved in the treatment of other populations. This complexity is most apparent in the development of a plan for the patient with opioid addiction who has developed a serious chronic pain disorder. Clinicians who assume responsibility for the management of pain often must coordinate consultations and cotreatment by a group of professionals who can provide insight into the options for pain management, the nature of the associated medical and psychiatric disorders, and the strategies that can be used to reduce the risk of therapeutic nonadherence, undertreatment, or drug abuse. The principles that underlie the safe and effective use of opioid drugs provide the foundation for the development of broader strategies for pain management that promise compassionate and competent care for every patient with pain.

Substance Use Disorders in Individuals with Co-occurring Psychiatric Disorders

Sylvia J. Dennison

INTRODUCTION

Use of, and withdrawal from, alcohol and other substances of abuse can cause, mimic, or mask psychiatric symptoms. The overlap of signs and symptoms makes it difficult to accurately diagnose all conditions present. However, failing to diagnose any co-occurring disorders (COD) increases the likelihood that the individual's treatment needs will not be met, worsening the patient's prognosis.

For some time, individuals with both psychiatric and substance problems have been called "dually diagnosed." This term is now felt to be confusing, appearing to imply, as it does, that only two conditions exist. Currently, individuals who concomitantly suffer from one or more psychiatric and one or more substance-related problems are said to have COD. The population of individuals with COD poses a particular challenge to the treating professional. A working understanding of psychiatric conditions and the motivation for substance use are important, as is the impact various substances of abuse have on psychiatric conditions. It is not enough for the treatment provider to deal with only one problem. If the treating professional is not proficient in the approach to one or the other problems, it is incumbent upon him to see to it that the COD client gets the additional care he needs.

HISTORY

That psychiatric and substance use disorders commonly co-occur is now well recognized, as are the facts that such co-occurrence is predictive of high utilization of services and poor treatment adherence. Prior to this recognition, fractionation of care was the norm, with mental health providers refusing to treat substance abusers, substance abuse treatment providers refusing to work with those with mental illnesses, and both camps often missing the presence of one or the other disorders.

Once it became clear there was a population for whom addiction alone was not the problem, the issue of cause and effect became a subject of debate. Arguments arose regarding which came first. Was the person depressed because he was drinking heavily, or did he drink heavily because he was depressed? Was she psychotic because she was a daily marijuana user, or did she choose to smoke the drug because, as she

claimed, it calmed her nerves and helped her rest? Was he anxious because he chronically abused benzodiazepines and felt the rebound effect, or did he use the benzodiazepines because of his chronic state of anxiety?

Traditional providers of addiction treatment saw the problem as substance abuse and any other unacceptable behaviors as simply excuses to justify continued drug use. The more psychologically minded developed the theory that the addicted individual used his drug(s) of choice as a means of treating uncomfortable or unacceptable impulses (1), the so-called self-medication hypothesis of addictive disorders (2).

Regardless of the cause(s) of ongoing substance use, many mental health treatment providers refused to treat any other psychopathology until the substance use disorder had been addressed and the individual abstinent, sometimes for many months. Unfortunately, such an approach condemned the individual with an untreated mental illness to a high likelihood of early relapse and an overall poorer outcome (1,3).

This fragmented approach to treatment left many, if not most, COD patients without treatment of any sort. For those who did seek treatment, early dropout was common. By the late 1980s, it was increasingly recognized that a new, coordinated approach to care was essential for meeting the needs of persons with COD. In response, the concept of "No wrong door" was introduced (4). No matter where the COD patient presented, providers were admonished to be ready to intervene on his behalf to make treatment immediately available. This approach meant that the alcohol-dependent client with depression must be given access to mental health care at the earliest possible time just as the bipolar client with cocaine dependence must receive immediate help for his stimulant habit.

The cost, morbidity, and mortality of COD prompted the U.S. government, in 2003, to create the Co-Occurring Center for Excellence (COCE) through the Substance Abuse and Mental Health Services Administration (SAMHSA). Its purpose was to function as a resource for the dissemination of information regarding evidence-based approaches to this population as well as to foster the adoption of such practices (5). Over its 5-year course, the COCE served as a clearinghouse for information, data collection, and grants for research on COD. Though its mission is over, this is still a valuable resource. COCE can be accessed at <http://coce.samhsa.gov>.

A consensus panel, also convened by SAMSHA, provided a definition of COD, a definition that will be used throughout this review. That is, that people with COD are

... individuals who have at least one psychiatric disorder as well as an alcohol or drug disorder. While these disorders may interact differently in any person (e.g., an episode of depression may trigger a relapse into alcohol abuse, or cocaine use may exacerbate schizophrenic symptoms) at least one disorder of each type can be diagnosed independently of the other. (6)

EPIDEMIOLOGY

Simply suffering from a mental illness greatly increases the likelihood that the individual will have a comorbid substance use disorder. According to the SAMHSA (7), in 2002 there were over 17.5 million American adults with serious mental illnesses, of whom nearly a quarter had a comorbid substance use disorder. Despite the numbers involved, more than half of those with COD received no treatment for either disorder and only 11.8% received treatment for both.

Further reports from SAMSHA (8) suggest that the cost of treatment of mental health and substance abuse will top \$239 billion by 2014. This is a fivefold increase over costs from 1986 (\$42 billion) and double that of 2003 (\$121 billion). Importantly, these data reflect only the direct costs of treatment, not the additional costs of substance-related illnesses, decreased productivity, police intervention, and incarceration (Table 52.1).

Recognizing that preventing the emergence of COD is preferable to treating established illness, research has focused on the issue of which disorder came first. Unfortunately, the data are often contradictory. Some studies showed early onset of substance misuse in adolescence predicts the later development of some types of psychiatric disorders (9). Others found that childhood or other early psychiatric symptoms predict the later emergence of substance use disorders (10,11). Yet another (12) suggested either could precede or follow the other depending on the exact psychiatric diagnosis and the specific substance of abuse, all of which make the development of prevention strategies very difficult.

Just as there may be a difference in the timing of onset of symptoms of substance use problems and of psychiatric symptoms, there is a difference in the frequency with which the various psychiatric disorders are associated with substance use problems. For example, any affective disorder ap-

pears to be frequently associated with substance use disorders with slightly more than 40% of cases of unipolar depression associated with alcohol problems (13). Bipolar disorder is associated with any substance use disorder in more than 40% of cases (14) and an additional 17% of unipolar respondents associated with a nonalcohol substance use disorder (13). Further, the presence of a substance use disorder increases the frequency of depressive episodes in individuals with either type of disorder (15) as well as that of suicide in depressed individuals (16).

According to the Surgeon General's Report (17), as many as 65% of persons with at least one mental disorder "... also have a lifetime history of a least one substance use disorder." A major source of data for that declaration comes from the Epidemiological Catchment Area study (18), considered one of the most comprehensive studies of COD and a rich source of information for nearly 20 years. A replication study is under way to update the information, and analysis of those data is now under way. It is likely that replication data will provide the same invaluable service as provided by its predecessor. However, for now the original study is the source of much of the data shown here. In this study, Regier et al. (18) found that among individuals with schizophrenia, from 25% in community samples to 66% of individuals in specialized samples such as Veterans Affairs, community mental health, and inpatient samples are estimated to have comorbid substance use disorders. The anxiety disorders, on the other hand, have a much more variable rate of comorbidity, depending on the specific diagnosis. Nevertheless, substance use disorders co-occur at a much higher rate among individuals with anxiety disorders than among the general population (19), with the possible exception of social phobia (20).

The co-occurrence of psychiatric and substance use disorders has social, economic, and prognostic implications. When substance misuse and mental illness co-occur, the risk is great that, in general, the individual will not do as well as if he had not developed such a comorbid problem. Poverty and homelessness (21) are more frequent, as are the risks of being both victim and perpetrator of violent assault (22–24). It is important to note that while most violent crimes are not committed by the mentally ill, those that are perpetrated by members of this population are more likely to be committed by those with COD. Furthermore, among the mentally ill, substance use also increases the risk of both accidental and homicide deaths (25). Yet another issue that has taken on extreme importance is that of greater risk taking among COD clients in terms of sexual behaviors and needle sharing. Such behaviors have resulted in an increased risk for HIV and similar medical conditions in this population (26,27) (Table 52.2).

Comorbidity, in short, is associated with a greater number of social and health consequences than either disorder alone. Thus, although substance misuse per se is a source of significant social and medical morbidity and mortality, in the case of the mentally ill, the problems become magnified many times over.

TABLE 52.1 Direct cost of treating COD (in billions of dollars)

1986	42
2003	121
2014 (projected)	239

TABLE

52.2

Consequences of co-occurring disorders

Increased likelihood of poverty
Increased likelihood of homelessness
Increased likelihood of being the victim of abuse
Increased likelihood of being a perpetrator of violence
Increased likelihood of engaging in high-risk behaviors
Increased risk of death via homicide, suicide, and accidental means

EVALUATION OF THE PATIENT WITH CO-OCCURRING DISORDERS

That it is extremely important to detect the presence of co-occurring conditions early in the evaluation process cannot be overstated. Identification of such conditions subsequent to initial hospitalization for psychiatric disorders results in more hospitalizations and poorer long-term outcome (28).

Having said this, it is also clear assessing the COD client is more complicated than assessing patients with either condition as, again, substance use and psychiatric disorders can mimic, mask, or exacerbate the symptoms of each other. It is obvious that a psychiatric workup is necessary if such has not already been done. Helpful information includes the patient's past diagnoses, if the patient is aware of what they may have been, past hospitalizations for psychiatric reasons, what prompted the psychiatric admission, response to treatment, family history of psychiatric problems, what medications he has had in the past and how he reacted to each. Furthermore, the interviewer should ask about suicidal ideation, both current and past, as well as attempts.

It is also useful to determine if the psychiatric symptoms predated the onset of the individual's substance misuse. Note should be made as to whether or not the patient's psychiatric condition improves, disappears, or worsens when the patient isn't using the substance(s). Unfortunately, it is often impossible to determine either of the above. If the patient uses substances daily and has no substantial periods of clean time, it will not be possible to know if his symptoms improve with abstinence. Likewise, if the patient has been using substances for many years, memory may not prove accurate as to whether the substance misuse or the psychiatric symptoms came first.

Although assuring the safety of the patient must always be a consideration in dealing with the chemically dependent, it is of paramount importance when dealing with the COD individual who poses a greater risk for dangerous behaviors. Patients in the immediate poststimulant dysphoric state or who are acutely under the influence of depressants such as alcohol are at an increased risk of self-harm, regardless of whether or not they have a comorbid psychiatric condition. Both acute and chronic use of substances of abuse, however,

vastly magnify the risk of suicide in individuals with depression and other chronic, severe mental illnesses, including schizophrenia and bipolar illness. Thus, at intake and at frequent intervals throughout the treatment process, the patient's risk of suicide must be assessed.

The treatment provider must be prepared to make judgments about the safety of using medications in patients who may be acutely under the influence of a substance in order to adequately treat this complicated population. For this reason, a brief review of some common medication–street substance interactions follows in the next section. An excellent and much more comprehensive review of drug–drug interactions can be found in Ciraulo et al. (29).

Typical assessment questions must be asked of the COD patient—age at onset of use, what is used, quantity, and how the substance is administered, that is, orally, intranasally, intravenously, rectally, etc. The method called a time line followback may be helpful to jog the patient's memory as to episodes of use. In this technique the patient uses a calendar to remind himself of specific dates or events during which he was actively using. In addition, just as in a non-COD population, collateral information should be obtained if at all available. Oral screening tools used to assess for alcohol and other substance abuse may be less helpful in the COD population, though there is still a place for the Michigan Alcohol Screening Test (MAST) and Drug Abuse Screening Test (DAST) with this population. Use of these tools is described elsewhere and will not be discussed here. It must be borne in mind, though, that the COD population is more likely to experience social isolation, and be unemployed and homeless, rendering some typical questions moot.

While the user may identify himself as having a problem with a specific substance, it is important to ask about substances used with the drug of choice. For example, while readily admitting that he is addicted to cocaine, the same patient may neglect to mention, as feeling it is irrelevant, that he is also ingesting a fifth of hard liquor during cocaine binges. This knowledge is necessary in order to avoid missing such needs as safe withdrawal from alcohol and to screen for further physical damage that may result from such concomitant use.

Understanding the user's motivation for substance use can also be helpful in developing an overall treatment plan. The individual suffering from panic disorder and agoraphobia in middle school, for example, may find that alcohol, at least temporarily, will help relieve her anxiety symptoms (30). Fear of the return or worsening of anxiety symptoms in abstinence may impede her progress toward abstinence. Likewise, nicotine has been shown to lessen the cognitive problems associated with schizophrenia (31), a fact that the psychotic user may be exploiting, either consciously or unconsciously.

As noted previously, it has been postulated that the person with COD is self-medicating with his drug of choice, something argued for a couple of decades. Regardless of the motivation for use, the facts above citing the potential benefits of the substances abused make it important to ask the user what it is he wants to feel as a result of use of his drug(s) of choice. It is possible that the only answer will be “to get high.” However, it is also possible that there is truly a benefit

TABLE 52.3 Psychiatric evaluation of the COD patient

Psychiatric symptoms		
	Age of onset	Pre/postsubstance use disorder

	Using prescription medications at times?	

that the user is seeking. Such information can be invaluable in establishing treatment goals.

Use and abuse of common substances such as caffeine and tobacco should be explored in any addicted population. However, it takes on even greater importance with COD clients. Caffeine may significantly worsen symptoms of anxiety and panic (32). Nicotine, on the other hand, may increase the metabolism of a variety of psychoactive medications, resulting in a need for ever greater doses in order to treat psychiatric symptoms (29). The latter is particularly important in hospitals and other facilities that forbid smoking, as the abrupt withdrawal of nicotine can result in a rapid rise in psychiatric medications and the emergence of uncomfortable side effects.

Prescription and over-the-counter drug abuse should also be asked about. If the individual is getting early refills on any prescription, even those not typically thought of as intoxicants, efforts should be made to determine the reason. Clonidine, for example, may be abused to help mitigate the effects of opiate withdrawal. However, at high enough doses, this alpha-adrenergic antihypertensive can result in a “drug store high,” a mild sedation in its own right (33). Likewise, highly anticholinergic agents such as benztropine, used, among other things, to counter the side effects of some antipsychotic medications, are well recognized for their significant abuse potential (34). Further, readily available over-the-counter medications containing dextromethorphan can induce a common, and potentially lethal, high, especially in alcohol abusers.

As with any substance-dependent individual, the COD patient should have intake and random drug screens performed. It is also essential, though, that the clinician be familiar with what the toxicologic tests available in his facility are actually testing for. For example, some emergency rooms and laboratories do not include PCP or LSD in their routine screens, yet these substances are often around (8). Further, buprenorphine is surfacing as a recreational drug and also may not be on routine tests. Thus, it is helpful to be familiar with what one is really asking for in a “routine screen.”

Medical screening is highly important in this population. As noted earlier, COD patients, especially those with psychotic disorders, are more likely to engage in high-risk behaviors than the non-COD population. Thus, the incidence of HIV, hepatitis C, and other health problems is quite high (35) (Table 52.3).

TREATMENT

Historically, three basic approaches to treatment of COD patients were used: sequential, parallel, and integrated models. In the sequential model, first one and then the other condition was treated. The idea was that one condition had to be under control before the second could be adequately addressed. Of course, determining which condition to treat first presented a significant problem. In addition, addiction-treatment programs have not typically been designed to meet the needs of the mentally ill, while mental health providers were reticent to treat intoxicated patients and ill-equipped to handle them (36).

In the parallel model, both conditions were addressed simultaneously, but in different programs with different staff. Poor communication between staff and the potential for the patient to receive mixed messages posed substantial risk, however. Further, treatment philosophies often clashed and goals were often markedly different between addiction and mental health treatment programs.

Finally, in the integrated model, both conditions are treated simultaneously by providers knowledgeable about both conditions. This is the approach most strongly supported by providers and by evidence-based studies (37).

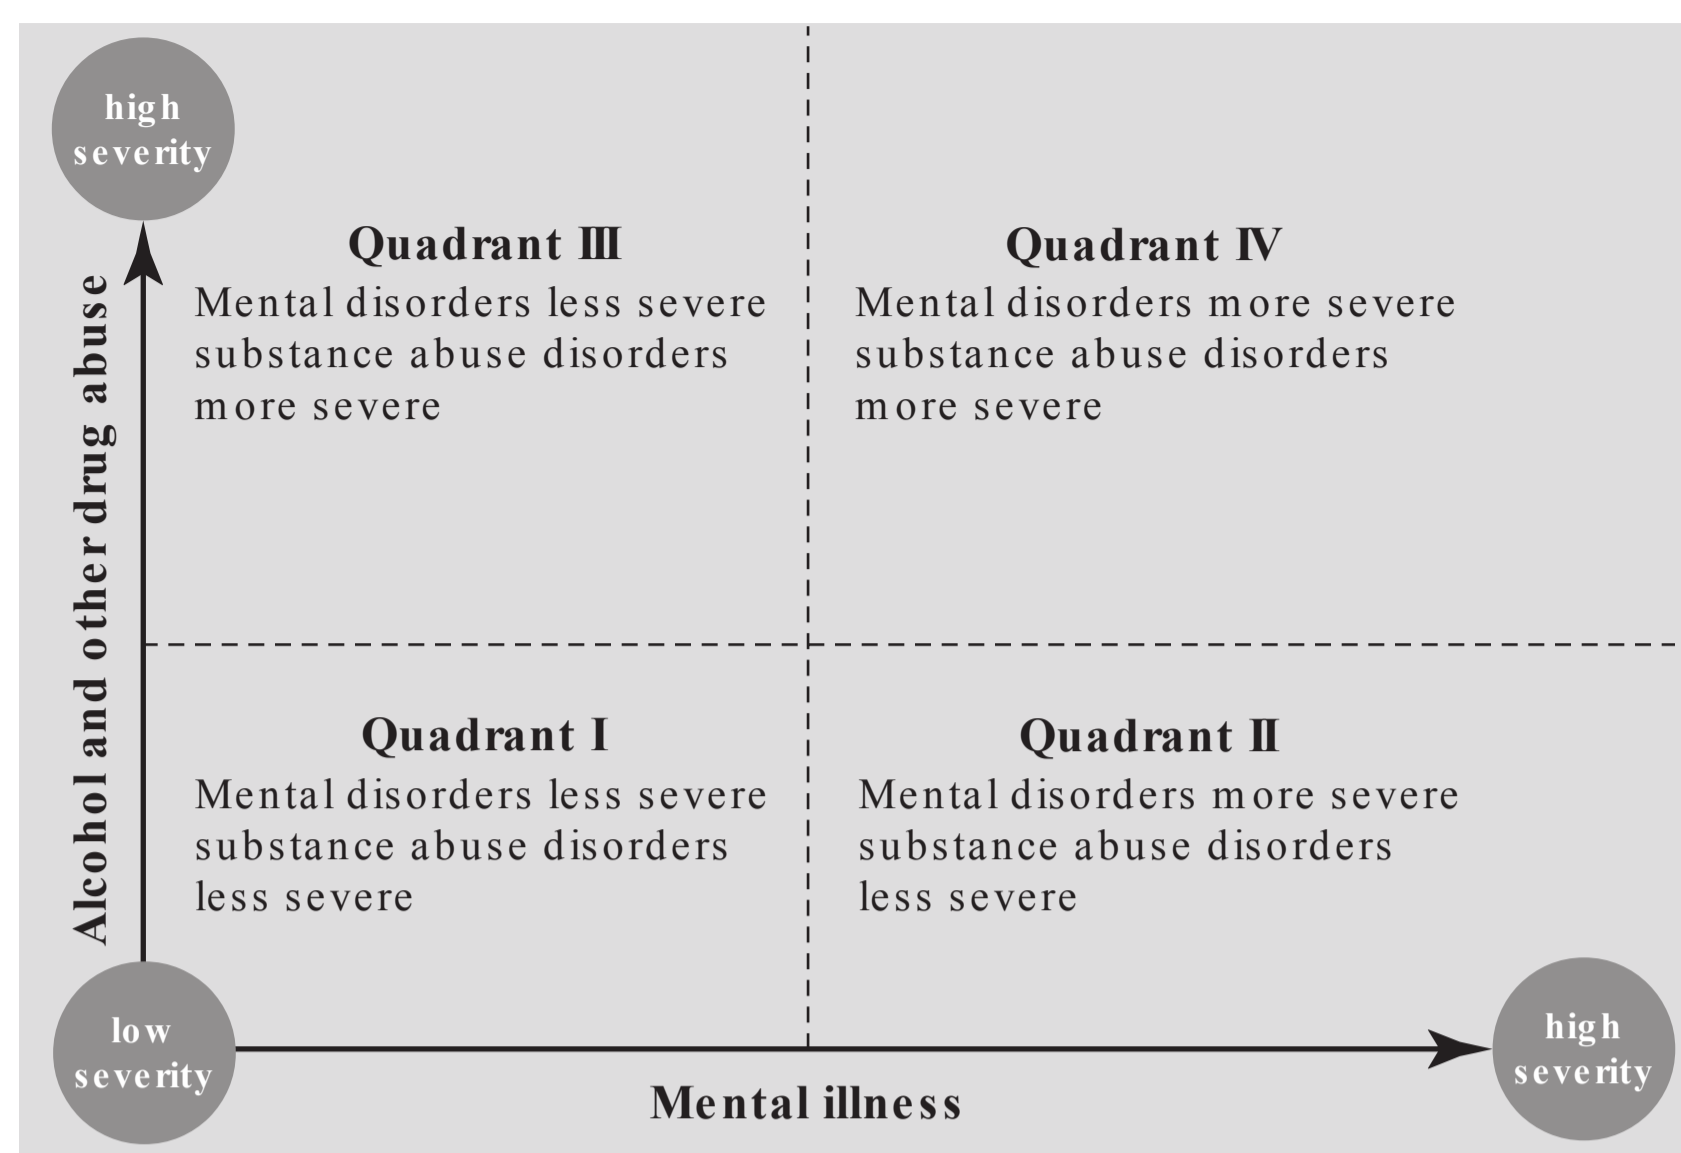

To address some of the deficiencies inherent in existing programs, there has been a major initiative at the national level to educate mental health and addiction-treatment providers in each other’s specialties. Cross-training is promoted at national, state, and local levels. Special certification programs have been developed to standardize and measure necessary levels of knowledge and skills, and to promote quality programming for treating individuals with COD. Where once treatment programs consisted, in many respects, of promoting the principles of Alcoholics Anonymous and other 12-step, self-help programs, it is now accepted that working with the dually disordered is a much more complex task than this. The treatment provider must help the patient gain an understanding of the patient’s substance use disorder, of the patient’s mental illness, and of the impact one has on the other. Further, research suggests that family, legal, and vocational services be included in “integrated treatment.”

A way of conceptualizing the severity of the needs of any given patient has been developed, the four quadrants of COD. Most states use this model for assessing which patients have the greatest needs. The practitioner working with patients with COD should be familiar with this concept. However, it is not as meaningful for the individual or small group of practitioners as it is for larger systems of care. Thus, a great deal of time will not be spent reviewing this beyond the brief description below.

In the quadrant model, the mental illness and the substance use disorder are viewed individually in terms of severity of symptoms, and then grouped together to determine the level of care the individual needs. Less severe mental disorder and substance use disorder are quadrant I, severe mental illness and less severe substance use disorder quadrant II, less severe mental disorder with more severe substance use disorder quadrant III, and severe levels of both substance and psychiatric disorders quadrant IV. Clearly, the latter is viewed as requiring the highest level of care and may include housing, legal intervention, treatment for each disorder, and coordination among a number of entities in order to meet the individual’s needs. The reader is referred to the Center for Substance Abuse Treatment (CSAT) publication *Treatment Improvement Protocol* (TIP) number 42 (37) for a comprehensive review of how this is used in dealing with COD (Fig. 52.1).

Comprehensive treatment for COD individuals demands that programming provide integrated mental health and addiction treatment and includes flexibility, repetition, long-term support, and medication where necessary (38). Increasing

Figure 52.1. Quadrant model for patient care. Adapted from Center for Substance Abuse Treatment. *Substance Abuse Treatment for Persons with Co-occurring Disorders. Treatment Improvement Protocol (TIP) Series 42. DHHS Publication No. (SMA) 05-3922.* Rockville, MD: Substance Abuse and Mental Health Services Administration; 2005.

evidence suggests that individuals with COD are more likely to seek treatment in mental health programs with addiction-treatment components (39) and less likely to receive the breadth of treatment recommended for treating COD clients in addiction treatment-based programs (40). Further, provision of on-site mental health care results in better psychological functioning and decreased substance use (41).

Medication(s) When Necessary

There is no question that some psychiatric conditions can be treated with psychotherapy, behavioral interventions, and other psychotherapeutic techniques. There has been considerable concern among addiction-treatment providers that jumping in quickly with a pill to treat a patient's discomfort sends a wrong message. That is, it signals that only a substance, not personal learned strengths and skills, can help the individual through hard times. The problem with the latter reasoning, though, is that the addicted person with a co-occurring psychiatric condition who presents for treatment typically hasn't learned the alternate means of dealing with his hallucinations or depression, or he wouldn't be there in the first place. Furthermore, psychotherapeutic interventions take time to be learned and rehearsed and, while effective for some psychiatric conditions, are not as beneficial for others. In addition, the dually disordered are at a high risk of dropout and relapse. Waiting for lengthy interventions to take effect may ensure the patient's early withdrawal from treatment long before a positive response can occur. Finally, at least for the severely mentally ill, medication is typically a first, not a last, choice. Early and vigorous intervention with medication, where indicated, using nonaddictive agents may help the patient stay in treatment and gain confidence that he can learn the techniques he needs for dealing with his substance use and psychiatric disorders.

That having been said, when dealing with the COD individual, as with any other person with a substance use disorder, when medication is deemed necessary, every effort should be

made to use medications that (a) do not induce euphoria, (b) do not cause dependence, (c) are effective in the individual who is actively using substance(s) of abuse, and (d) are safe when used by the active user (Table 52.4).

Psychiatric Conditions, Medications, and Substances of Abuse

The following is not an exhaustive review of all possible medications to treat the various psychiatric conditions, but an effort to give the reader an overview of the types of information available regarding medications that have proven safe and effective in relieving psychiatric symptoms in patients with psychiatric disorders who continue to actively use substances of abuse. It cannot be overstated that the clinician must be vigilant about the possibility that a problem will arise with the medicated individual who is also abusing other substances. It is always possible the individual is using more substances than the treatment provider is aware of, increasing the possibility of a negative consequence.

Depression, Antidepressants, and Mood Stabilizers

Depression and mania can be improved by active treatment with medication even when the patient continues to abuse alcohol, opiates, nicotine, and perhaps marijuana. To date, no

TABLE

52.4

Principles for use of psychotropic medications with COD patients

Does not induce euphoria even at doses beyond that prescribed

Does not cause dependence

Effective in actively using substance abuser

Safe in the actively using substance abuser

medication has been shown to be unequivocally superior in improving such symptoms among individuals abusing psychostimulants.

Tricyclic antidepressants (TCAs) and selective serotonin reuptake inhibitors (SSRIs) decrease depressive symptoms in unipolar depression in actively drinking alcoholics (42,43). The clinician is advised to make TCAs available in very limited supplies, however, to a member of this population, because of the potential for a lethal interaction with alcohol. Concomitant abuse of benzodiazepines, alcohol, cocaine, and marijuana is common among opiate-dependent individuals. This fact, and that much of the research available regarding opiate addicts, comes from methadone-maintenance patients, making it necessary to view data on this population with caution. Nevertheless, there is evidence that simply stabilizing opiate-dependent individuals on methadone improves depressive symptoms. Tricyclics and SSRIs also improve depression in individuals actively using opiates. It should be noted, however, that abuse of TCAs by methadone-maintenance patients is a well-known phenomenon in clinics; thus, such drugs should be used only with close supervision and with only small quantities available. Sertraline may cause an initial rise in methadone levels, which will normalize after a brief interval. There is some evidence that SSRI medication may cause a slight improvement in depressive symptoms in individuals actively abusing marijuana. Thus, erring on the side of the patient and offering to treat these symptoms with medication may be reasonable.

Lithium is relatively ineffective in treating substance-dependent individuals with mania. Furthermore, there is an increased risk of toxicity with this medication if the individual is using alcohol or marijuana. Thus, this mood stabilizer should be avoided in COD clients with bipolar disorder or cyclothymia (29). Divalproex improves manic symptoms in actively drinking alcoholics with this disorder, although close observation of liver functions is essential. In one study, gabapentin decreased alcohol abuse in bipolar patients with alcohol problems (44). However, abuse of this medication is becoming increasingly recognized (45). Quetiapine appears to decrease both manic symptoms and cocaine cravings in dually disordered patients with bipolar disorder and substance use problems. It too appears to be abused by individuals in some populations, however (46). Carbamazepine must be introduced and used with caution among individuals on methadone, because it lowers this opiate's levels, leading to withdrawal (29). Tiagabine may decrease cocaine use in some individuals and has been effectively used for the treatment of bipolar disorder (47). Topiramate is sometimes used as a mood stabilizer and appears to decrease alcohol consumption in some alcohol-dependent individuals, producing interesting possibilities for the use of this agent in COD patients (48).

Psychoses and Antipsychotic Medications

Actively treating psychosis improves retention in both addiction and mental health treatment. Despite concern about the possible interaction between antipsychotics and alcohol, there is little in the literature to support this worry. This may, of course, reflect the long-held habit of withholding antipsychotic

medications when individuals with psychoses began to imbibe. Thus, it is reasonable to use this medication with caution in the COD patient. High doses of typical antipsychotic medications in conjunction with cocaine appear to increase the risk of dystonic reactions and perhaps neuroleptic malignant syndrome. Whether or not this applies to other psychostimulants is not known. Risperidone, olanzapine, and clozapine improve symptoms and retention among schizophrenic psychostimulant abusers. Clozaril also appears to decrease substance use in general in COD populations (49). Nicotine acts in competition with some antipsychotic medications (such drugs as haloperidol, fluphenazine, olanzapine, and clozapine), effectively lowering the levels of these agents. It is important for the treatment provider to keep this in mind in the event that a patient is abruptly forced to discontinue his routine dose of nicotine or to have it drastically reduced. The patient's level of neuroleptic medication may become suddenly far greater than it had been, resulting in greatly increased side effects and discomfort.

Anxiety Disorders

Treating anxiety symptoms in individuals actively using alcohol, psychostimulants, and opiates improves retention in treatment and provides some degree of symptom relief. Benzodiazepines are among the top three most-abused prescription drugs in the United States and may be abused by nearly half of individuals seeking treatment for substance misuse. These facts, and that there is some evidence of a disinhibiting effect of some benzodiazepines when used by alcohol-dependent individuals, serve as relative, not absolute, contraindications to their use in this population. Alprazolam, in particular, has been suggested as having this effect. If this class of medication is used, it is advisable to use such agents with caution, in acute situation rather than as a maintenance strategy, under close supervision, and briefly, if at all possible. Furthermore, longer-acting agents should be used. TCAs, SSRIs, and venlafaxine are helpful in relieving anxiety symptoms in individuals with coexisting alcohol and anxiety problems. The existence of so many non-dependence-inducing, effective medications begs the question of necessity of using potentially addictive agents for the treatment of anxiety disorders for any but very short-term problems. Venlafaxine undergoes extensive hepatic metabolism, and close observation of liver functions is advised in individuals abusing alcohol. Many cases of fatal reactions have been reported of opiate-dependent individuals using and abusing benzodiazepines. Consequently, use of this class of agents for individuals with this problem is not advised. Rather, a trial of an SSRI, as in depression, is preferable. Buspirone appears to be effective in reducing symptoms of generalized anxiety disorders in actively drinking alcoholics (50). However, it is also extensively metabolized in the liver, making close monitoring essential.

Use of Disulfiram and Anti-Craving Medications in COD Populations

The use of disulfiram in any population is sometimes controversial, but among those with severe mental illnesses, much more so. Manufacturers themselves warn about the possible

emergence of psychosis as a result of the use of this drug. However, with close monitoring for a worsening of psychiatric symptoms, this medication has proven beneficial in reducing alcohol consumption in some populations (51). It appears that acamprosate may be safe and effective for helping reduce alcohol consumption in individuals with mental illnesses, though definitive studies are lacking. Naltrexone may also be safe and effective in reducing alcohol consumption in this population (52). If there is any suspicion of covert use of opiates, however, this medication should be avoided.

SPECIAL CONSIDERATIONS: TOBACCO USE IN CO-OCCURRING DISORDERS

That ongoing tobacco use is associated with increased risk of relapse in substance abusers has become increasingly accepted over the last two decades. However, it also appears that ongoing tobacco use is associated with increased likelihood of early dropout from treatment (53). Historically, individuals with COD, especially those with psychotic disorders, were not expected, or even encouraged, to stop smoking. Infamously, cigarettes were used to bribe inpatients for good behaviors. For example, compliance with rules could result in the individual being rewarded with a cigarette at hourly intervals. There was a popularly held, and fully discredited, belief that there was something about schizophrenia that somehow protected against the development of cancer, so there was no need to treat nicotine dependence.

It is now quite clear that smoking cessation in COD patients is something that should be strongly promoted. However, it must be borne in mind that nicotine has some very positive effects on symptoms of psychiatric disorders, making it an even more attractive drug than it would otherwise be. The COD patient may require a great deal more support, repetition, and help with motivation than might otherwise be the case. Treatment of individuals with co-occurring disorders should include nicotine cessation training as an integral part of any programming, both to aid in retention and to improve overall patient health.

CONCLUSION

Individuals with both substance use and psychiatric disorders constitute a substantial and difficult-to-treat subsection of the addiction population. Addressing only the substance use predicts a lack of improvement in the psychiatric condition and early relapse to alcohol and other drug use. Addressing only the psychiatric condition likewise is unlikely to result in a decrease in substance use. Early and vigorous treatment for each condition should be initiated, including use of medications where indicated. In the latter case, care must be taken that medications used should be proved safe in the individual actively abusing alcohol and other substances, effective in treating the psychiatric condition when the individual is actively using, and nonaddictive where at all possible.

Much remains to be done to demonstrate that one therapeutic modality is clearly superior to another for the treatment-

specific comorbid conditions, though studies are under way. It is clear, however, that concomitant treatment of all conditions present—medical, psychiatric, and substance related—must occur if there is any likelihood of improvement in any condition. It is also clear that this complicated and diverse population will present challenges for the treatment community for some time to come.

INTRODUCTION

The World Health Organization reports that drug interactions are a major source of morbidity and mortality. Drug interactions can occur with the coadministration of therapeutic medications with alcohol, with other prescriptions drugs, with an illegal or illicit substance, or with other pharmacologic interventions that are used in the treatment of substance use disorders (SUDs). Unfortunately, *in vitro* findings regarding effects of medications and other substances on enzyme function and/or cell-based assays are sometimes not predictive of the clinical manifestation(s) that may be observed when substances are simultaneously consumed in humans. This lack of predictive value underscores the fact that there is a need to conduct drug interaction studies in humans whenever possible. This chapter will summarize many clinically significant drug interactions and underscore the need for clinical staff to consider possible drug interactions depending on the clinical presentation in order to improve clinical outcomes.

Mortality data published by the Drug Abuse Warning Network (DAWN) have shown that the majority of nonsuicidal deaths occur in multidrug users. Those data contributed to the idea that accidental deaths are more likely to occur when drug interactions alter pharmacokinetic (PK) and/or pharmacodynamic (PD) properties of coadministered drugs to produce detrimental effects. The sections in this chapter will describe the current knowledge of the many critical and common drug interactions as they occur in humans. First, we will review drug interactions between opioid therapies used to treat opioid dependence and other medications with a focus on viral therapeutics, since human immunodeficiency virus (HIV) and other co-occurring infectious diseases have a disproportionate effect on drug users. Interactions between opioids, prescription analgesics, and other medications will also be reviewed since there has been, in recent years, a steady increase in emergency department visits involving prescription medications, according to the DAWN surveys. The limited literature on the use of stimulants with other drugs and alcohol will be reviewed. Finally, interactions between tobacco products and other medications will be briefly reviewed, particularly as they relate to those who suffer from other SUDs or concurrent mental illness.

BRIEF OVERVIEW OF MECHANISMS FOR DRUG INTERACTIONS

Drug interactions can occur through several mechanisms, and one or more of these mechanisms may be responsible for observed clinical manifestations. The mechanisms for drug interactions include effects of drugs on hepatic metabolism by cytochrome P450 (CYP) enzymes; on glucuronidation; on the function of the efflux transporter, P-glycoprotein (P-gp); and on absorption of drugs. PD interactions are also important. Some drugs, when taken in combination, can exhibit synergism that might increase drug effects resulting in toxicity.

Drugs can exert effects on hepatic metabolism by the alteration of CYP enzyme functioning. For example, the U.S. Food and Drug Administration (FDA) has classified CYP 3A4 inhibitors as strong, moderate, or weak, based on their effects on CYP 3A4 substrate metabolism (Table 53.1). Increased systemic exposure to buprenorphine, a CYP 3A4 substrate, is noted following concomitant administration with ketoconazole, a strong CYP 3A4 inhibitor. While *in vitro* assays can demonstrate inhibition of CYP 450 enzymes, we often learn of inducing properties of a drug through clinical observation. For instance, the HIV antiretroviral (ARV) medication, nevirapin, is known to inhibit CYP 3A4; however, it has been associated with reductions in the plasma concentrations of methadone, possibly due to induction of other CYP 450 enzymes involved in its clearance (1).

Glucuronidation is a mechanism by which many drugs are eliminated by rendering metabolites water soluble so that they can then be excreted. For example, methadone can inhibit zidovudine (AZT) glucuronidation, resulting in increased concentrations of that drug, which may, in turn, be associated with AZT toxicity (2). Drug interactions can also be associated with specific drug effects on the P-gp efflux transporter. For example, cocaine has been shown to induce the efflux pump, P-gp (3), which could potentially result in lower concentrations of drugs that are substrates of P-gp.

Other mechanisms of drug interactions include production of active metabolites resulting from coconsumed drugs and degradation of drugs in the gastrointestinal (GI) tract as a result of decreased GI mobility induced by another drug taken concomitantly. It has been shown that simultaneous cocaine and alcohol consumption results in the formation of

TABLE 53.1 Classification of CYP3A4 inhibitors

Strong CYP3A inhibitors	Moderate CYP3A inhibitors	Weak CYP3A inhibitors
Cause ≥ 5 -fold increase in AUC ^a of sensitive CYP3A substrate	Cause ≥ 2 but < 5 -fold increase in AUC of sensitive CYP3A substrate	Cause ≥ 1.25 but < 2 -fold increase in AUC of sensitive CYP3A substrate
Atazanavir, clarithromycin, indinavir, itraconazole, ketoconazole, nefazodone, nelfinavir, ritonavir, darunavir/ritonavir, lopinavir/ritonavir, saquinavir/ritonavir, telithromycin	Aprepitant, diltiazem, erythromycin, fluconazole, fosamprenavir, grapefruit juice, verapamil	Cimetidine

^aAUC, area under the curve.

cocaethylene, a cocaine-like compound that can contribute to toxicities associated with the abuse of these substances (4). Altered absorption can also be associated with clinically significant drug interactions, as in the case of methadone slowing GI mobility, which in turn can expose pH-sensitive drugs to an environment that can result in their degradation. For example, if stavudine, a pH-sensitive drug, is exposed for a longer period to the acidic environment of the stomach, increased degradation and subsequent subtherapeutic stavudine concentrations occur. This renders stavudine less beneficial in patients with co-occurring opioid dependence and HIV disease who receive methadone maintenance and stavudine as part of their HIV treatment regimen (5).

PD interactions can result when two or more drugs with similar pharmacologic effects are coadministered. For example, when buprenorphine and benzodiazepines (e.g., alprazolam) have been injected together, deaths have resulted that are thought to be related to depression of the central nervous system (CNS) with a resulting decrease in respiration (6). When given alone, buprenorphine has been shown to have a ceiling effect at which higher doses do not produce further opioid agonist effects (7); however, its injection with benzodiazepines may result in a potentially life-threatening drug interaction (8).

It can be difficult to determine what mechanism(s) are responsible for adverse drug interactions. Controlled studies in humans that include simultaneous administration of medications and measurement of plasma drug concentrations are important for understanding PK and PD drug interactions; these interactions are important in the treatment of medical and mental disorders.

DRUG INTERACTIONS BETWEEN OPIOIDS USED FOR TREATMENT OF OPIOID DEPENDENCE AND OTHER MEDICATIONS

Currently approved medications for the treatment of opioid dependence include methadone, buprenorphine, and L-acetyl-methadol (LAAM). However, LAAM is not currently available, and methadone is the most widely used medication for the treatment of opioid addiction. Buprenorphine is in-

creasingly being used to treat opioid dependence, and its availability by prescription should result in more widespread use for treatment of opioid addiction.

Each of these opioids is metabolized by CYP 3A4 (9), although methadone metabolism is contributed to by CYP 2B6 and 2D6 (10) and a small fraction of buprenorphine metabolism occurs via CYP 2C8 (11). CYP 3A4 is responsible for the metabolism of a wide variety of drugs. Some drugs (which may or may not be substrates of CYP 3A4) may alter the function of CYP 3A4 either by inducing the enzyme and thereby increasing the metabolism of drugs that are substrates of this enzyme or by inhibiting the enzyme, resulting in increased exposure to a drug that would normally be metabolized by CYP 3A4. Those with opioid dependence often have co-occurring illnesses—both medical and psychiatric—which require medication therapy. Some of these medications may alter the function of CYP 3A4, resulting in adverse drug interactions.

The potential for adverse drug interactions in methadone-maintained patients has been recognized for many years when opiate withdrawal symptoms were observed in those prescribed rifampin for the treatment of tuberculosis (11), and similarly, phenytoin (12) and/or carbamazepine were prescribed for the treatment of seizure disorders. This interaction of carbamazepine and methadone was noted when carbamazepine was studied as a pharmacotherapy for the treatment of cocaine dependence in methadone-maintained individuals and was found to be associated with opiate withdrawal and decreased the methadone trough (13). In the ensuing years, other adverse drug interactions, mainly between opioid therapies and medications prescribed for illnesses that occur at high frequency in opioid-dependent patients, have been observed (e.g., ARV therapies such as zidovudine [AZT], whose metabolism may be inhibited by methadone inhibition of glucuronidation, leading to AZT toxicity; or induction of methadone metabolism by efavirenz, leading to opiate withdrawal; or increased buprenorphine and norbuprenorphine concentrations in those receiving the protease inhibitor (PI) combination of atazanavir/ritonavir, which has been associated with cognitive dysfunction in some; or opioid toxicity observed in methadone-treated patients receiving the antibiotic

ciprofloxacin). However, the availability of other medications to treat opioid dependence, albeit with little known of potential drug interactions with those therapeutics, led to a question of whether it might be possible to “match” patients with opioid dependence to medication regimens that would be associated with fewer drug interactions, thus improving clinical outcomes in those with co-occurring conditions.

DRUG INTERACTIONS BETWEEN OPIOIDS AND ANTIRETROVIRAL MEDICATIONS

Opioid-dependent patients frequently engage in high-risk behaviors that make them more susceptible to some infectious diseases. This possibility is conferred through engaging in high-risk behaviors such as sharing of injection equipment (syringes, needles, cotton, etc.) that may be contaminated with infectious agents and/or by high-risk sexual behaviors.

The treatment of choice for opioid dependence in the individual who is opioid addicted and who also has HIV disease

is opioid therapy; methadone has been the most frequently utilized medication for the treatment of opioid addiction in this population. To a far lesser extent, LAAM was utilized in this population until it became unavailable, and more recently, buprenorphine is being utilized in opioid-dependence treatment in those with HIV/AIDS. Drug interactions between methadone or buprenorphine and HIV medications are summarized in Table 53.2.

The first medication to be FDA approved as a treatment for HIV/AIDS was zidovudine (AZT). This nucleoside reverse transcriptase inhibitor (NRTI) was used as a single agent to treat HIV disease prior to the use of multidrug therapy (highly active antiretroviral therapy [HAART] in those with HIV/AIDS). When methadone-maintained patients with HIV were prescribed AZT, some developed symptoms that appeared to be consistent with opioid withdrawal including muscle/joint pain, insomnia, anxiety, and depression. Examination of the methadone trough in these patients showed therapeutic concentrations. This led to a PK study in which both methadone and AZT concentrations

TABLE 53.2 Drug interactions between methadone or buprenorphine and HIV medications

NRTIs	Methadone	Buprenorphine
AZT	↑ AZT concentrations; possible AZT toxicity	No clinically significant interaction
Didanosine (ddI) (buffered tablets)	Significant ↓ ddI concentrations	Not studied
ddI (enteric-coated), lamivudine, tenofovir	No clinically significant interaction	No clinically significant interaction
Stavudine	Significant ↓ stavudine concentrations	Not studied
Abacavir	Withdrawal noted in some receiving amprenavir plus abacavir	Not studied
NNRTIs		
Nevirapine, efavirenz	Opioid withdrawal may occur	No clinically significant effect
Etravirine	No clinically significant interaction	Not studied
Delavirdine	↑ Methadone (and LAAM) concentrations; no cognitive impairment	↑ Buprenorphine concentrations; no cognitive impairment
PI		
Saquinavir	No clinically significant interaction	Not studied
Nelfinavir	↓ Methadone concentrations; few adverse events reported	No interaction
Amprenavir	↓ Methadone concentrations and withdrawal in some receiving abacavir and amprenavir	Under study
Lopinavir/ritonavir	↓ Methadone concentrations and withdrawal in some	No clinically significant interaction
Atazanavir/ritonavir	No clinically significant interaction	Significant ↑ in buprenorphine and norbuprenorphine; cognitive impairment possible
Ritonavir	No clinically significant interaction	No interaction

LAAM, L-acetyl-methadol.

were examined in those with heroin addiction and AIDS. Methadone treatment was associated with a 41% increase in AZT exposure. In some patients, this was sufficient to result in AZT toxicity, which can resemble opiate withdrawal (2). The possible explanations for these findings included that of slowed GI transit associated with methadone treatment resulting in increased absorption of AZT and/or the possibility that methadone inhibited glucuronidation (the principal means of AZT metabolism). A second study examined the effect of other opioid-dependence pharmacotherapies on AZT metabolism. This study showed that, unlike methadone, both LAAM and buprenorphine nonsignificantly lowered AZT concentrations over an 8-hour dosing interval, while naltrexone, an opioid antagonist medication, had no effect on AZT concentrations (14). The results from this study indicated that methadone interactions with specific medications might not be reflective of interactions that could occur with other opioids. This led to further investigations to determine the presence of drug interactions between HIV medications and opioids used in opioid-dependence treatment (methadone, LAAM, and buprenorphine).

Current pharmacotherapy treatment of HIV disease includes a combination of medications from at least two classes. The backbone of HAART consists of either a PI, often boosted by low-dose ritonavir—a PI that inhibits CYP 3A4 enzyme activity and therefore can delay metabolism of PIs that are substrates of CYP 3A4—or a nonnucleoside reverse transcriptase inhibitor (NNRTI). In addition, two NNRTIs are added to complete the regimen. Some of these medications have significant effects on CYP 3A4 including induction by some drugs and inhibition by others.

Further investigation of drug interactions between methadone and ARV medications revealed that other medications with CYP 3A4-inducing properties were also associated with opiate withdrawal when administered concomitantly with methadone. For example, one of the first medications in a line of potent ARV therapeutics, nevirapine, was associated with significant opiate withdrawal in methadone-maintained patients (15). Similarly, another NNRTI, efavirenz, was also associated with significant opiate withdrawal in patients with HIV disease who were also receiving methadone-maintenance therapy (16). The first combination PI, lopinavir/ritonavir, was also associated with onset of opiate withdrawal in methadone-maintained patients, particularly in those with the methadone trough levels that were in the lower end of the therapeutic range (17).

Should medications used to treat HIV alter methadone metabolism, there are two principal adverse events of concern. The first is that of the onset of opiate withdrawal symptoms. If opioid-maintained individuals with HIV disease experience opiate withdrawal with HAART, they may not adhere to the prescribed HIV treatment regimen. Poor adherence to HIV therapeutics has been linked to ongoing drug abuse (18). Poor adherence can also result in development of viral resistance and failure of the HIV therapeutic regimen, underscoring the need for those providing methadone-maintenance therapies to be aware of the potential for adverse drug

interactions in their patients with HIV/AIDS who are receiving HAART. Another possibility is that of opioid toxicity, which can potentially result in cognitive impairment or respiratory depression. While there have been clinical episodes of opioid toxicity thought to be precipitated by the use of methadone with an ARV medication that inhibits methadone metabolism, to date, only one drug interaction study has been conducted in human volunteers that shows significant increases in methadone concentrations and LAAM concentrations when administered with an ARV (again, an NNRTI drug) known to inhibit CYP 3A4, delavirdine (19). No significant opioid toxicity was observed in this study, but delavirdine was dosed only for 7 days in this drug-interaction study. With ongoing treatment as in clinical care, the potential for developing opioid toxicity should be considered. Results from drug interaction studies in humans showing significant interactions with methadone have resulted in the U.S. FDA decision that full approval of any HIV medication would require a drug interaction study to be conducted between methadone and the drug under FDA consideration.

One of the significant findings from drug interaction studies that have been conducted thus far between opioids and HIV medications is the lack of clinically significant effects of PK drug interactions detected between buprenorphine and ARV medications. Unlike what has been reported for methadone, buprenorphine/naloxone-treated individuals have not reported withdrawal symptoms or symptoms of opioid intoxication, even when a significant shift in buprenorphine exposure occurs. For example, when methadone-maintained patients with HIV disease are administered HAART containing efavirenz, a potent inducer of CYP 450 enzymes including 3A4 and 2B6, significant opiate withdrawal has been observed (20); rapid methadone dose increases are often required to relieve these withdrawal symptoms. Despite the fact that concentrations of buprenorphine and of norbuprenorphine, its active metabolite formed as a result of metabolism by CYP 3A4, are substantially reduced following efavirenz administration, withdrawal symptoms were not observed in a clinical study (21). One possible explanation for the lack of opiate withdrawal associated with declines in buprenorphine exposure is that the combined effect of buprenorphine and norbuprenorphine is sufficient to prevent opiate withdrawal; methadone, conversely, has no active metabolites. When methadone metabolism is induced, no active metabolites are formed, opioid blood levels drop, and the patient then experiences withdrawal. Another possible explanation is that the high affinity of buprenorphine for the μ -opioid receptor (7) might prevent opiate withdrawal even in the presence of low plasma concentrations. Two other ARV medications shown to be associated with opiate withdrawal symptoms in methadone-maintained patients, nevirapine and lopinavir/ritonavir, have both been shown not to produce opiate withdrawal in buprenorphine-treated patients (21,22).

One caveat to the otherwise benign profile of drug interactions between buprenorphine and ARV medications thus far is the effect of atazanavir and atazanavir/ritonavir, a

frequently utilized PI combination in those with HIV/AIDS (23). Atazanavir is an inhibitor of CYP 3A4 and an inhibitor of glucuronidation, both pathways for buprenorphine clearance. Concomitant administration of atazanavir and buprenorphine produces significant increases in buprenorphine and norbuprenorphine plasma concentrations. While a drug interaction study with buprenorphine and atazanavir showed no evidence of cognitive impairment, several participants did experience increased sedation (23). There is a report in the literature of cognitive impairment having developed in several patients with HIV/AIDS being treated with atazanavir/ritonavir who began buprenorphine/naloxone treatment for opioid dependence (24). These findings indicate that patients receiving these medications in combination should be monitored clinically for symptoms of opioid excess. This interaction has not been observed with methadone; therefore, methadone might be a better treatment for opioid dependence in those who will be treated with atazanavir/ritonavir. However, the preponderance of drug interaction study data indicates that buprenorphine offers advantages over methadone in the treatment of opioid dependence in those with HIV/AIDS due to a relative lack of adverse drug interactions and the ability to dose both buprenorphine and ARV medications at standard clinical dosages without concern for subtherapeutic concentrations or toxicities.

DRUG INTERACTIONS BETWEEN OPIOIDS AND MEDICATIONS USED TO TREAT OTHER INFECTIOUS DISEASES

Hepatitis C Medications: Interferon

Hepatitis C virus infection (HCV) is a common co-occurring infection in opioid-dependent individuals; at particularly high risk are those who are injection drug users and who have engaged in high-risk injection practices (25). Many of those with co-occurring HCV will require treatment for this infec-

tion. The current standard of care for treatment of HCV is a combination of interferon and ribavirin. Thus far, two drug interaction studies have been conducted exploring the potential for adverse drug interactions between opioid therapies and HCV medications.

Methadone has been studied in combination with interferon and no significant drug interaction was identified (26). The impetus for this study was complaints of adverse symptoms in methadone-maintained patients receiving treatment for HCV. However, the administration of interferon and ribavirin is itself known to be associated with a variety of adverse events (e.g., nausea, anorexia, myalgias, depression, and insomnia), some of which may be mistaken for opiate withdrawal symptoms. There is no additional contribution to the medication side effects that can occur with medications used in the treatment of HCV due to drug interactions with methadone. Buprenorphine has yet to be studied in this population.

Tuberculosis Medications: Rifampin

The adverse drug interaction between methadone and rifampin, a mainstay of tuberculosis treatment, has long been known. Rifampin is an inducer of CYP 3A4, which has been associated with opiate withdrawal in methadone-maintained patients. Rifabutin appears not to produce this adverse drug interaction to the same degree as rifampin (27) and is recommended as a substitute for rifampin in this population. The interaction between buprenorphine and rifampin is currently under study. Several study participants to date have experienced opiate withdrawal requiring early study termination underscoring the potency of rifampin as a CYP 3A4 inducer (28). A second study to determine whether the alternative medication, rifabutin, is associated with adverse drug interactions in buprenorphine-treated patients is currently under way. Isoniazid is an inhibitor of CYP 3A4 (29) and has not been reported to produce significant adverse drug interactions in combination with methadone.

TABLE 53.3 Interactions between methadone or buprenorphine and other antivirals or antibiotics

Hepatitis C Antivirals	Methadone	Buprenorphine
Interferon	No clinically significant interaction	Not studied
Ribavirin	Not studied	Not studied
Tuberculosis Antibiotics		
Rifampin	Opioid withdrawal may occur	Opioid withdrawal may occur
Rifabutin	No clinically significant interaction	Not studied
Other Antibiotics		
Fluconazole, Variconazole, Ciprofloxacin, Clarithromycin	↑ methadone plasma concentrations	Not studied

Antibiotics

Opioid dependence, particularly that associated with injection drug use, is associated with a variety of infectious processes that often require antibiotic treatment. Frequent complications of injection drug use include skin infections such as abscesses, cellulitis, endocarditis, and sepsis. There are limited reports of adverse drug interactions between methadone and antibiotic medications. However, ciprofloxacin, a widely used antibiotic effective for a large number of infections, has been associated with opioid toxicity when administered to methadone-maintained patients (30). Some antifungal medications including fluconazole and voriconazole are potent inhibitors of CYP 3A4 and may also be associated with increases in opioid exposure. Increases in opioid exposure may be better tolerated in those receiving treatment with buprenorphine as compared to methadone or LAAM. The reason for this is that buprenorphine is a partial agonist associated with a ceiling effect in terms of its opioid agonist effects (7). Increasing doses of buprenorphine do not produce proportional opioid agonist effects, meaning that respiratory depression, a common cause of morbidity and mortality with toxic doses of full μ -opioid agonists, is less likely to occur in those treated with buprenorphine. Interactions between methadone and buprenorphine with HCV or tuberculosis medications and other antibiotics are listed in Table 53.3.

DRUG INTERACTIONS BETWEEN OPIOIDS AND BENZODIAZEPINES

Benzodiazepine (BZD) use is prevalent in the population of those with SUDs and, specifically, in those with opioid dependence. Epidemiologic studies have suggested that co-occurring psychiatric disorders such as depression, anxiety, sleep disorders, and polysubstance abuse contribute to the high rate of BZD use among opioid-dependent individuals.

Methadone and buprenorphine could have PK interactions with BZDs since they share CYP enzyme metabolic pathways. Many BZDs are weak competitors for CYP 3A4; methadone is metabolized by a variety of CYP isoforms (31). Buprenorphine is metabolized by CYP 3A4, but is also a weak inhibitor of this enzyme (32). There are few clinical studies that have investigated PK interactions between BZDs administered concomitantly with methadone (33,34), but none have directly studied PK interactions between BZDs and buprenorphine. Human clinical studies are needed to investigate the simultaneous use of opioids and BZDs at therapeutic doses in order to determine the possible clinical consequences resulting from PK interactions between these medications.

Currently, PD interactions are the major concern in those who ingest both methadone or buprenorphine and BZDs. It is of clinical importance to note that methadone and BZDs are administered orally when used therapeutically, while buprenorphine tablets are administered sublingually. Buprenorphine, an opioid partial agonist, has been shown to have a ceiling effect at which higher doses do not produce further opioid agonist effects (7); however, when abused in combination with BZDs

intravenously, significant morbidity and mortality has been reported (6,8). A synergism between opioids and BZDs to produce respiratory depression may result from common intracellular transduction pathways between opioids and the GABA_A receptor system, resulting in increased chloride ion conduction and decreased membrane excitability (35). Methadone alone has been shown to produce respiratory depression in humans; this effect may be potentiated by coadministration of BZDs. The degree of respiratory depression observed with methadone and BZD administration has been reported to be greater than that observed when BZDs are simultaneously administered with buprenorphine (36,37). In contrast, buprenorphine and BZDs when administered by the injected route may produce severe adverse events as a result of rapid attainment of high (toxic) plasma concentrations of the drugs. This may result in a synergism between the two medications and consequent depression of the CNS as well as a potentially lethal decrease in respiration (6).

ADVERSE EFFECTS RELATED TO DRUG INTERACTIONS

Adverse effects related to drug interactions can be quite harmful to patients requiring opioid therapy for treatment of opioid dependence. For those who experience opiate withdrawal symptoms related to induction of opioid metabolism, it is quite possible that nonadherence to prescribed regimens will occur, which could result in poor clinical outcomes, worsening of disease, and increased substance abuse. In situations in which a drug interaction results in inhibition of opioid metabolism, it is possible that adverse events could include cognitive impairment, decreased respiration, and possible adverse effects on cardiac conduction.

In recent years, increasing attention has focused on the effect of LAAM and methadone on cardiac QT interval. LAAM was removed from the market in Europe and was black-box-labeled in the United States following a series of deaths linked to the occurrence of cardiac dysrhythmias including Torsades de Pointes. Both LAAM and methadone have been shown to block hERG (human ether-a-go-go) potassium channels, which can be associated with slowed electrical conduction in the heart, in some cases producing arrhythmia. In some, this has been observed to be correlated with the use of higher doses of methadone (>100 mg daily).

Another potential manifestation of this adverse event can occur when patients who are opioid maintained are treated with medications that induce metabolism of the opioid. For example, some patients being treated with methadone will require an increase in methadone dose to prevent withdrawal when treated with medications that induce its metabolism. A case report of such a patient discussed the onset of Torsades de Pointes in the patient receiving treatment with lopinavir/ritonavir who had their methadone dose increased due to the onset of opiate withdrawal. When the lopinavir/ritonavir was stopped, the methadone dose was not decreased, leading to the development of excessive methadone plasma concentrations and cardiac arrhythmia (38). It is important to consider

this potential sequence of events that can lead to a serious adverse drug interaction in patients with co-occurring conditions requiring treatment with medications that may induce methadone metabolism. In contrast to these findings, buprenorphine has not, to date, been associated with cardiac QT interval prolongation (39).

DRUG INTERACTIONS BETWEEN PRESCRIPTION OPIOID ANALGESICS AND OTHER MEDICATIONS

Morphine exerts its analgesic effects through agonism at μ -opioid receptors. It is metabolized chiefly through glucuronidation by two enzymes: UDP-glucuronosyltransferase (UGT) 2B7, which produces the 6-conjugate (M6G), and UGT 1A3, which produces the 3-conjugate (M3G) (40). The M3G metabolite possesses neuroexcitatory effects, while M6G is responsible for the analgesic effects (41). Both genetic variability of the UGT enzymes 2B7 and 1A3 and drugs that inhibit or induce UGT enzymes could affect the M3G–M6G ratio. However, patient response to morphine analgesia is not well understood because the UGT enzyme system is not as well studied as the CYP 450 enzyme system (42). Inhibitors of UGT enzymes that might decrease the formation of both metabolites include tricyclic antidepressants such as amitriptyline, nortriptyline, and clomipramine (43). Morphine's glucuronidation may be competitively inhibited by morphine itself (44) as well as by the coadministration of chloramphenicol or diazepam (45). Some *in vitro* studies have shown that morphine might be a P-gp substrate (46). Therefore, the inhibition of P-gp would be permissive of morphine entrance through the blood–brain barrier, potentially enhancing its CNS effects including analgesia. Whether this potentiation occurs is still unclear; however, drugs that are P-gp inhibitors that could theoretically enhance CNS morphine effects would include the immunosuppressant, cyclosporine; the calcium channel blocker, diltiazem; and the antifungal medication, itraconazole (47).

Hydromorphone and oxycodone are morphine analogues that are both metabolized by UGT enzymes (48). Hydromorphone is the CYP 2D6–produced metabolite of hydrocodone, and like morphine, it is minimally metabolized by CYP enzymes. To date, there is no published literature regarding PK alteration and changes in clinical efficacy of hydromorphone when UGT enzymes are inhibited or induced (44).

Opioid analgesics such as methadone, oxycodone, and hydrocodone share the same CYP 2D6 pathway for metabolism with numerous other drugs. When multiple substrates of CYP 2D6 are ingested concurrently, altered drug levels may occur, but are difficult to predict. In one known example, methadone has been reported to inhibit CYP 2D6 and may alter the PK of the antidepressant desipramine, a substrate of CYP 2D6 (49). Methadone has been reported to be associated with increased desipramine levels (50). Other tricyclic antidepressants (imipramine), antipsychotics (risperidone and other phenothiazines), analgesics (codeine), antiarrhythmics (flecainide), and some beta-blockers are also substrates of CYP 2D6 and may have the potential for adverse drug inter-

actions based on increased plasma concentrations if given with methadone (49). Dextromethorphan, a substrate of CYP 2D6, has been associated with delirium in a patient receiving methadone (51). This adverse event abated with cessation of dextromethorphan and was attributed to the effect of methadone on dextromethorphan clearance.

Buprenorphine is chiefly metabolized by CYP 3A4. Opioid toxicity or opioid withdrawal is expected as a consequence of drug–drug interactions with 3A4 inhibitors (azole antifungals, macrolide antibiotics, and nefazodone) and inducers (rifampin and some antiepileptics). However, the ability to predict those interactions is difficult (52), and thus far few drug–drug PK interactions have been associated with adverse events in those receiving buprenorphine and other medications concurrently.

DRUG INTERACTIONS BETWEEN STIMULANTS AND OTHER MEDICATIONS

Psychostimulants produce euphoria, mood elevation, sharpened sensory perception, increased energy, and in some, extraversion. Adverse effects typically predominate when high doses are ingested or as a result of drug interactions when stimulants are ingested with other medications. As sympathomimetic agents, psychostimulants produce cardiovascular effects, including hypertension and increased cardiac output. Interactions may occur with the coadministration of psychotropic and cardiovascular medications. The increase in CNS and cardiovascular stimulation that might occur could be related to serotonergic syndrome, which is a constellation of symptoms that includes neuromuscular hyperactivity, autonomic hyperactivity, and altered mental status (53). Psychostimulants might interact adversely with antidepressants as a result of excess serotonin activity, particularly monoamine oxidase inhibitors (MAOI) or selective serotonin reuptake inhibitors (SSRI), and produce symptoms of serotonin toxicity. Fatal case reports have confirmed evidence of the relationship between serotonin syndrome and coadministration of MAOIs, SSRIs, and illegal stimulants (54).

Amphetamines and MDMA (3,4-methylenedioxymethamphetamine, also known by the street name, Ecstasy) are metabolized primarily by CYP 2D6, showing nonlinear kinetics with unpredictable effects. Drugs that inhibit CYP 2D6 may increase the serum concentration of amphetamine and MDMA, leading to risk of toxicity (55). Inhibitors of CYP 2D6 include several SSRIs (e.g., paroxetine and fluoxetine), ARV medications (e.g., ritonavir), and antiarrhythmics (e.g., quinidine).

Cocaine- and methamphetamine-addicted individuals are usually multidrug users, and their conditions are often complicated by co-occurring mental disorders. The opioid-dependent population has been shown to use cocaine at high rates. Among opioid-dependent individuals, up to 50% use cocaine while being treated for opioid dependence (56). Those patients may require multidrug therapy and close monitoring for drug interactions since opioid-cocaine dependence has been associated with poor clinical outcomes in opioid-dependence treatment (57).

Cocaine has recently been shown to diminish buprenorphine concentrations (58). The underlying PK interaction between those drugs is not obvious since each had been reported to be metabolized by different pathways. Lower buprenorphine plasma concentrations may result from induction of buprenorphine metabolism through an effect of cocaine on CYP 3A4 (59) or through an ability of cocaine to induce the efflux pump, P-gp (3). Another possible explanation is that cocaine metabolites are known to be vasoconstrictors, which might reduce buprenorphine absorption sublingually (60). Cocaine use appears to have a similar, but less dramatic, effect on methadone concentrations. This reduced effect may be related to the fact that methadone is metabolized by several CYP 450 enzymes; therefore, the effect of cocaine on CYP 3A4 function regarding methadone metabolism is diminished in the presence of otherwise normal metabolic processing by the liver relative to effects observed for buprenorphine, which is primarily metabolized by CYP 3A4. Methamphetamine has not been associated with adverse drug interactions in combination with either methadone or buprenorphine to date.

A randomized trial of buprenorphine for the treatment of concurrent opiate and cocaine dependence showed that buprenorphine was well tolerated at dose ranges between 2 and 16 mg. Most adverse events appeared to be related to concurrent illnesses common in this population or to opiate withdrawal rather than to direct side effects of the pharmacologic interventions (61).

Disulfiram (also known by the trade name Antabuse) is an FDA-approved treatment for alcohol dependence and has shown promise as a treatment for cocaine dependence as well. Initially, disulfiram was evaluated in patients with co-occurring cocaine and alcohol dependence (62). Study participants in the disulfiram arm of the study used less cocaine; however, it was not clear if the reduction of stimulant use was due to the reduction in alcohol intake or a direct action of disulfiram to reduce cocaine use. A more recent study evaluated disulfiram as treatment for cocaine dependence in a population of primary cocaine users without alcohol dependence. This randomized, placebo-controlled study that included cognitive-behavioral therapy or interpersonal psychotherapy showed that disulfiram exerted a direct effect in reducing cocaine use rather than a secondary effect in reducing concurrent alcohol use (63). The observed effect of disulfiram was postulated to be associated with reduced cocaine consumption resulting from its ability to inhibit the function of aldehyde dehydrogenases. Aldehyde dehydrogenase inhibition is responsible for the disulfiram-alcohol interaction as well as the inhibition of dopamine beta-hydroxylase and of the aldehyde dehydrogenase-mediated metabolism of serotonin to 5-hydroxyindoleacetic acid; the latter two may be associated with reduction in positive effects of cocaine use. When receiving disulfiram treatment, study participants have reported reduction in cocaine-associated subjective effects such as “high” and “rush”; cardiovascular toxicity was not observed (64). Furthermore, the safety of disulfiram for the treatment of alcohol and cocaine dependence was studied in randomized clinical trials that showed that disulfiram generally has an acceptable side-effect and drug-interaction profile (65).

DRUG INTERACTIONS BETWEEN ALCOHOL AND OTHER MEDICATIONS

Alcohol is a potent CNS depressant that may interact with many drugs; it affects multiple systems within the brain, but mainly it acts as an agonist at GABA receptors. When used concurrently with other depressants such as benzodiazepines (BZDs) and opioids, increased sedation and serious depression of respiratory and/or cardiac function can result.

Alcohol is primarily absorbed through the stomach and the small intestine and largely metabolized by the liver. Hepatic alcohol metabolism occurs via alcohol dehydrogenase, catalase, and the microsomal CYP 450 pathway, which leads to the oxidation of alcohol to acetaldehyde. Drugs that share the same CYP P450 metabolic pathway as alcohol may interact in several ways, including reduction in hepatic metabolism of other drugs resulting from acute alcohol ingestion, increased drug clearance in the presence of chronic alcohol intake, and reduced elimination of drugs resulting from alcoholic liver disease.

Benzodiazepines

Alcohol may have significant interactions with BZDs, medications that are commonly prescribed for anxiety and insomnia. BZDs (e.g., diazepam, lorazepam, alprazolam, clonazepam, and temazepam) are generally considered safe when used alone; however, they can be dangerous if taken with alcohol. BZDs and alcohol can act synergistically in that these drugs facilitate inhibition at GABA receptors and alcohol decreases the excitatory effect of glutamate at *N*-methyl *D*-aspartate (NMDA) receptors. This mechanism may help to explain fatal overdose in the presence of opioids and/or BZD and alcohol (66). BZDs may enhance the adverse psychomotor effect of ethanol since it has been reported that BZD concentrations are elevated following a single dose of alcohol and BZD (67). PK changes are expected with both acute and chronic drinkers; however, clinical studies have shown that following a 10 mg (intravenous) dose of diazepam or 1 mg (oral) dose of alprazolam, chronic alcoholics had significantly lower concentrations of the BZDs than healthy nonalcoholics, suggesting that PK alterations may be more prominent in alcoholics with chronic consumption of large amounts of alcohol and who may be more likely to have impaired liver function (68).

All BZDs are expected to result in additive CNS depression with alcohol; however, not all BZDs have similar clinical effects when ingested with alcohol. The concurrent use of BZDs and alcohol is an important issue in patient care, since alcohol and BZDs show cross-tolerance, and abuse of BZDs is frequently observed among alcohol abusers (69). Abuse of BZDs should be monitored, and substance-related disorders resulting from BZD abuse should be treated in these patients. In general, alcohol-abusing patients are not good candidates for BZD therapy and are at higher risk for adverse drug interactions if these drugs are co-abused.

Bupropion

The antidepressant and smoking cessation medication bupropion is metabolized to hydroxybupropion, which is an inhibitor of and substrate for CYP 2D6. Patients with a history of alcohol use metabolize bupropion faster with consequent production of active metabolites; therefore, the use of bupropion and alcohol may increase the risk of lowering the seizure threshold (especially during alcohol withdrawal), which is a known adverse event associated with bupropion use in persons with alcohol dependence. Bupropion treatment of depression or nicotine dependence should be carefully considered in a patient with an alcohol use disorder or known misuse of alcohol.

Methadone

A PD interaction has been reported to occur between alcohol and methadone. Although a direct effect on PK of methadone has not been found, severe adverse events including deaths have occurred in patients who co-ingest these substances (70). Interestingly, no drug interaction of clinical significance has been detected between methadone and disulfiram (71). These findings underline the need to treat co-occurring alcohol disorders in opioid-addicted patients receiving opioid agonist therapy. Clinical reports of adverse events related to alcohol ingestion in buprenorphine-treated patients have not been published to date.

Cocaine

Cocaine metabolism is mainly accomplished through hydrolysis by esterases in the serum and liver. In the presence of alcohol, cocaine undergoes transesterification, resulting in production of cocaethylene, an active metabolite that is structurally similar to cocaine. Cocaethylene is less potent than an equivalent cocaine dose with respect to neurochemical, pharmacologic, and behavioral properties (4); however, when cocaine and alcohol are used together, some studies have suggested that cocaethylene may have the potential to increase cocaine-associated toxicities (72,73). A placebo-controlled, double-blinded study reported that the behavioral and physiologic effects of intranasal cocaethylene in humans are similar to those of cocaine (74). Like cocaine, cocaethylene produces euphoria and increases both heart rate and systolic blood pressure; the slower elimination of cocaethylene could result in its accumulation, with increased potential for toxicity with binge use of cocaine and alcohol. Data from some human studies have shown much higher concentrations of cocaethylene, even exceeding those of cocaine following fatal overdose (72,73).

Methylphenidate

Methylphenidate (MPH) is normally metabolized to an inactive substance, ritalinic acid (75). Coadministration with ethanol produces an active metabolite, ethylphenidate, obtained via metabolism by carboxylesterases in the liver.

Coadministration of MPH with ethanol is also believed to elevate MPH plasma concentrations, decrease clearance, and increase half-life of the drug (75,76), underscoring a potential for toxicity with co-abuse of these drugs.

DRUG INTERACTIONS BETWEEN CIGARETTE SMOKE OR NICOTINE AND OTHER MEDICATIONS

Cigarette smoke is known to contain, in addition to nicotine, thousands of different ingredients (e.g., polycyclic aromatic hydrocarbons, *N*-nitrosamines, and aromatic amines) (77). Those compounds, especially aromatic hydrocarbons, through tobacco combustion may induce CYP 1A1, 1A2, and 2E1 with consequent change of metabolism and elimination of other drugs that are taken at the same time (78).

Induction of CYP 1A2 by cigarette smoking is responsible for many clinically relevant drug interactions, making therapeutic outcomes unpredictable and possibly leading to toxicities. Several classes of drugs that are metabolized by CYP 1A2 include atypical antipsychotics, SSRIs, BZDs, and beta-blockers (78,79). In addition to toxicity related to PK interactions, smoking may also be associated with other adverse events such as increased risk of cardiovascular and cerebrovascular disease. Some of these risks could potentially be exacerbated by drug interactions (78).

A major concern with cigarette smoking with regard to drug interactions is that those affected by other comorbid conditions, for example, schizophrenia and/or alcohol use disorders, have higher rates of cigarette smoking than the general population (80). Smoking is the most prevalent of the SUDs in patients suffering from schizophrenia (81). Between 72% and 90% of those with schizophrenia are smokers compared with 24% of the general population (82). In the alcohol-dependent population, over 80% are tobacco smokers (83), and an epidemiologic study has revealed that smokers have a 4% to 10% increased risk of developing an alcohol use disorder (84). As a result of cigarette smoking with its associated induction of CYP 1A2, increased metabolism and/or decreased plasma concentrations may be observed for many antipsychotics (olanzapine, clozapine, fluphenazine, haloperidol, and chlorpromazine) and other adjunctive therapies for schizophrenia including antidepressants (imipramine, clomipramine, and fluvoxamine), and BZDs (alprazolam, lorazepam, oxazepam, and diazepam) (85). The possibility of alcohol abuse in those with co-occurring mental illness and those who smoke cigarettes may place these individuals at risk for adverse drug–drug interactions as their clinical condition is likely to require that they be treated with several medications.

The potential drug interactions that might occur in cigarette smokers are numerous. Patients who smoke and require other concomitant medications may need higher medication doses than nonsmokers. Clinicians should monitor medication responses and dose accordingly being aware of the potential for drug–drug interactions. If an individual on medications is able to quit smoking, additional monitoring of medication responses and adverse events should be

undertaken, given the possible changes associated with the cessation of chronic nicotine exposure. It is also possible that doses of some medications may need to be reduced following smoking cessation.

CONCLUSION

Drug interactions between presently ingested substances, both licit and/or illicit, are a leading cause of morbidity and mortality. This chapter gives a broad overview of drug interactions among illicit substances (i.e., cocaine), legal drugs (i.e., alcohol and tobacco), prescription medications (i.e., ARV and analgesics), and other pharmacotherapies to treat SUDs (e.g., methadone, buprenorphine, and disulfiram). Patients requiring medications to treat SUDs often have co-occurring medical (e.g., HIV/AIDS) and mental (e.g., schizophrenia) illnesses that will require additional medication treatment. These clinical realities place patients with SUDs at greater risk for potentially toxic drug interactions. Furthermore, the clinical management of patients with polysubstance (i.e., opioid/cocaine/alcohol) abuse is common and complex, and can have unpredictable outcomes.

Much remains to be learned about medication interactions between drugs ingested by those with SUDs. Most medications in combination with illicit substances have not been directly studied in humans. *In vitro* studies and preclinical findings indicating the likelihood of drug interactions are not always predictive of what will occur in humans. The ongoing study of frequently prescribed medications and illicit substances alone and in combination will help to inform clinical care and to increase safety of medication treatments in this vulnerable and high-risk population.

INTRODUCTION

The problem of substance abuse has been a source of concern to health professionals, community leaders, and law enforcement agencies over the past several decades. Considerable effort and resources have been spent attempting to understand the etiology of substance use and abuse and to identify effective prevention and treatment strategies. Research concerning the onset and developmental progression of substance abuse indicates that most youth initiate substance use by experimenting with alcohol and cigarette smoking during adolescence. For a subset of these youth, experimentation escalates to frequent and regular use, and for some, the use and abuse of more serious illicit drugs can ultimately lead to drug dependence and substance abuse disorder. Furthermore, substance abuse can lead to a variety of negative health, legal, social, and pharmacologic outcomes in young adulthood (1).

Preventive interventions and related initiatives to reduce substance abuse have been the focus of a great deal of research. A wide variety of activities have been used to achieve the goal of reduced drug abuse, particularly among adolescents. These prevention activities range from educational and skills training activities that take place within schools, families, and communities to mass media public service announcements (PSAs), policy initiatives such as requiring health warning labels on cigarettes and alcohol, changes in school rules (i.e., “zero-tolerance” policies), and laws and regulations including increased cigarette taxes and minimum purchasing age requirements (2). However, the bulk of the drug abuse prevention research in the United States in the past 25 to 30 years has concentrated on school-based prevention programs. Because the general pattern of substance use initiation and escalation is well documented, many prevention programs aim to prevent early-stage substance use or delay the onset of use among adolescents. Typically, these programs are provided to middle school or junior high school students and target the use of tobacco, alcohol, and marijuana because these are the most widely used substances in the United States and because preventing them may reduce the risk for the abuse of other illicit drugs and their associated negative outcomes. Research shows that the most effective approaches to the prevention

of adolescent drug abuse are derived from psychosocial theories (3) and focus primarily on the psychosocial risk and protective factors that promote the initiation and early stages of substance use (4).

PREVALENCE AND CURRENT TRENDS

National survey data show that prevalence rates of alcohol, tobacco, and illicit drug use among adolescents peaked in the late 1970s and early 1980s. More recently, we have seen a gradual decline in prevalence rates for several substances among adolescents, although there have been increases observed in others. Data from the 2008 Monitoring the Future Study (5) found that among high school seniors, almost half (45%) report ever using cigarettes, and one out of five high school seniors reported being current smokers. This represents a large improvement from the late 1970s, when twice as many high school seniors (two of every five) were current smokers. Rates of alcohol and marijuana use have also decreased since the late 1970s although not as much as cigarette smoking. In the past 10 years, prevalence rates for alcohol and marijuana use have gradually declined for high school seniors; however, both substances are still widely used. Alcohol use is the most prevalent substance use behavior among teens, and marijuana is the most prevalent illicit drug used. In 2008, more than half (55%) of 12th graders reported having been drunk at least once in their life, and one in four reported binge drinking (five or more drinks in a row) in the past 2 weeks. About 47% of high school seniors reported ever using marijuana in 2008, and 32% reported use in the past year. After marijuana, the most commonly abused drugs among high school seniors were amphetamines (11%), inhalants (10%), sedatives and tranquilizers (9% each), hallucinogens (9%), and Ecstasy (MDMA) at 6% lifetime prevalence. The misuse of over-the-counter (OTC) medications is also a growing problem among young people. The active ingredient in many cough suppressants, dextromethorphan (DXM), can produce hallucinations or dissociative, “out-of-body” experiences when taken in very large doses. Approximately 6% of 12th graders reported ever using an OTC cough and cold medication to get high in the past year (6).

THE IMPORTANCE OF PREVENTION

Although there have been significant advances in the effectiveness of drug abuse treatment in recent years, many treatment modalities are expensive, labor intensive, and plagued by high rates of recidivism. Clinicians are confronted by a disorder that often proves to be refractory to change. Patients frequently remain in pathogenic environments in which social networks continue to support substance abuse and the availability of drugs is ubiquitous. Prevention is important because it offers a logical alternative to treatment. Many experts believe it is easier and less expensive to prevent substance abuse than it is to treat such an insidious disorder once it has developed. However, from a historical perspective, most initial efforts to develop effective substance abuse prevention programs achieved only a limited degree of success. Many failed completely because they were based on erroneous assumptions about the causes of drug abuse. The first major breakthrough came at the end of the 1970s in the area of school-based smoking prevention. That work stimulated a great deal of prevention research and led to the development of several promising prevention approaches. Since the 1980s, empiric evidence from a growing number of carefully designed and methodologically sophisticated research studies indicates that prevention works, and recent research suggests that substance use prevention is also cost-effective (7).

THE SCHOOL AS THE SITE OF PREVENTION EFFORTS

The development and testing of approaches for preventing adolescent substance abuse have largely focused on middle/junior high school students. Schools have served as the primary setting for prevention efforts in large part because they offer the most efficient access to large numbers of adolescents. Furthermore, in addition to their traditional educational mission, schools often take steps to address a variety of social and health problems among students, particularly those that present a significant barrier to the achievement of educational objectives. The U.S. Department of Education, for example, has included “drug-free schools” as one of its goals for improving the quality of education in this country. Many states mandate schools to provide their students with programs in health education and/or tobacco, alcohol, and drug education as well as teenage pregnancy and AIDS education.

CHAPTER OVERVIEW

This chapter provides a summary of developments in school-based substance abuse prevention over the past three decades. It begins with a discussion of what is currently known about the etiology and developmental progression of substance use and the implications for prevention. Traditional and contemporary prevention approaches are described and the evidence for their effectiveness is summarized. A major focus of this chapter is on the current generation of theory-based substance

abuse prevention approaches and the results of research testing their short- and long-term effectiveness. The final section summarizes conclusions to be drawn from this body of research, directions for future research, and implications for public health policy.

ETIOLOGY AND IMPLICATIONS FOR PREVENTION

To provide a context for understanding existing substance abuse prevention efforts and for developing a prescription for the most effective preventive interventions possible, it is necessary to be familiar with the factors associated with the initiation and maintenance of tobacco, alcohol, and drug abuse. Furthermore, it is important to identify when the onset and escalation of substance use typically occur to determine the most appropriate point of intervention. An understanding of the developmental course of substance abuse is also central, in terms of both the progression from nonuse to experimentation to abuse and the general sequence of using specific psychoactive substances or classes of substances.

Etiologic Determinants

A variety of risk factors for early-stage substance use have been identified, as well as several protective factors that offset the effects of risk (4). Furthermore, a number of theoretical models have been developed or applied to phenomenon of alcohol and drug use among youth (3). A large body of literature demonstrates that substance abuse results from the complex interaction of a number of different factors, including cognitive, attitudinal, social, personality, pharmacologic, biologic, and developmental factors (8,9).

Social Factors

Social factors are the most powerful influences promoting the initiation of tobacco, alcohol, and drug abuse. These include the behavior and attitudes regarding substance use among significant others such as parents, older siblings, and friends (10). Studies reveal that parents’ use of alcohol, tobacco, marijuana, and other illicit drugs, and parental attitudes that are not explicitly against use, often translate into higher levels of use among children and adolescents. Poor family relationships and inadequate parenting practices (i.e., lack of parental monitoring) have been identified as risk factors for youth substance use. Other social influences include popular media portrayals showing substance use as an important part of popularity, sophistication, success, sex appeal, and good times (11). Both the modeling of substance use behavior by media personalities and the positive messages about substance use in popular music, movies, and other media are powerful sources of influence that promote and support substance use (12).

Cognitive and Attitudinal Factors

Individuals who are unaware of the adverse consequences of tobacco, alcohol, and drug use, as well as those who have positive attitudes toward substance use, are more likely to

become substance users than those with either more knowledge or more negative attitudes toward substance use (13). In addition, individuals who believe that substance use is “normal” and that most people smoke, drink, or use drugs are more likely to be substance users. Positive expectations about the effects of substance use are also predictive of substance use behavior (14).

Personality Factors

Substance use is associated with a number of psychological characteristics. Substance users have lower mood, self-esteem, assertiveness, personal control, and self-efficacy than nonusers, and are more anxious, impulsive, and rebellious than nonusers (7). The clinical literature also suggests that individuals with a specific psychiatric condition or symptoms (e.g., anxiety and depression) may use particular substances as a way of alleviating these feelings. For example, through experimentation with different substances, highly anxious individuals may find that alcohol or other depressants help them to feel less anxious, and they might use those substances as a way of regulating their feelings of anxiety. This has been referred to in the literature as the self-medication hypothesis (15).

Pharmacologic Factors

The pharmacology of commonly abused substances varies, although animal research has shown that several drugs of abuse (cocaine, amphetamine, morphine, nicotine, and alcohol), each with different molecular mechanisms of action, affect the brain in the same way by increasing strength at excitatory synapses on midbrain dopamine neurons (16). Furthermore, virtually all of these substances produce effects that are highly reinforcing and dependency producing. For tobacco, alcohol, and most illicit drugs, tolerance develops quickly, leading to increased dosages and an increased frequency of use. Once a pattern of dependent use has been established, termination of use produces dysphoric feelings and physical withdrawal symptoms.

Behavioral Factors

Substance use is highly associated with a variety of health-compromising or problem behaviors. Individuals who use one substance are more likely to use others. Indeed, substance abuse among young people is often considered to be part of a general syndrome reflecting a particular value orientation (17). Youth who smoke, drink, or use drugs tend to get lower grades in school, are not generally involved in adult-sanctioned activities such as sports and clubs, and are more likely than nonusers to become involved in antisocial or delinquent behavior, aggressiveness, and premature sexual activity (18,19). Furthermore, it is believed that these problem behaviors have the same or highly similar causes, which have significant implications for prevention. Notably, it may be possible to develop a single preventive intervention capable of having an impact on several associated behaviors at the same time.

Initiation and Developmental Course

Since the 1960s, some degree of experimentation with substance use has become commonplace in contemporary American society. This is particularly true with respect to alcohol, tobacco, and marijuana, which are the most widely used and abused substances in society. For most individuals, experimentation with tobacco, alcohol, and marijuana typically takes place during the adolescent years. First use and intermittent experimentation generally occur almost exclusively within the context of social situations. After a period of experimentation and regular use, some individuals develop patterns of use characterized by both psychological and physiologic dependence. The initial social and psychological motivations for using drugs eventually yield to one driven increasingly by pharmacologic factors.

Substance Use Progression

Research indicates that experimentation with one substance frequently leads to experimentation with others in a logical and generally predictable progression (20). Most individuals begin by using alcohol and tobacco, progressing later to the use of marijuana. This developmental progression corresponds closely to the prevalence of these substances in our society, with alcohol being the most widely used, followed by tobacco and then marijuana. Some individuals may also use inhalants early in this sequence because of the wide availability. For some individuals this progression may eventuate in the use of depressants, stimulants, hallucinogens, and other drugs. However, many individuals either may discontinue use after a short period of experimentation or may not progress from the use of one substance to the use of others. The likelihood of progressing from one point in the developmental sequence to another can best be understood in probabilistic terms, with an individual's risk of moving to greater involvement with drugs increasing at each additional step in the developmental progression.

Knowledge of the developmental progression of substance use is important because it has implications for the focus and timing of preventive interventions. Interventions targeted at the use of substances occurring toward the beginning of this progression have the potential of not only preventing the use of those substances, but also of reducing or eliminating the risk of using other more serious substances further along the progression.

Adolescence and Substance Abuse Risk

Adolescence is frequently characterized as a period of great physical and psychological change (21). During adolescence, individuals typically experiment with a wide range of behaviors and lifestyle patterns. This occurs as part of the natural process of separating from parents, developing a sense of autonomy and independence, establishing a personal identity, and acquiring the skills necessary for functioning effectively in an adult world. However, many of the developmental

changes that are necessary prerequisites for becoming healthy adults increase an adolescent's risk of smoking, drinking, or using drugs. Adolescents who are impatient to assume adult roles may smoke, drink, or use drugs as a way of appearing more grown-up and laying claim to adult status. Adolescents may also engage in substance use because it provides them with a means of establishing solidarity with a particular peer group, rebelling against parental authority, or establishing their own individual identity.

As the result of normal cognitive development, adolescents shift from a "concrete operational" mode of thinking, which is characteristically rigid, literal, and grounded in the "here and now," to a "formal operational" mode of thinking, which is more relative, abstract, and hypothetical (22). It has been suggested that these changes in the manner in which adolescents think may serve to undermine previously acquired knowledge relating to the potential risks of smoking, drinking, or using drugs. For example, the "formal operational" thinking of the adolescent facilitates the discovery of inconsistencies or logical flaws in arguments being advanced by adults concerning the health risks associated with substance use. Similarly, cognitive development during early adolescence may enable young people to formulate counterarguments to antidrug messages, which may, in turn, permit rationalizations for ignoring potential risks, particularly if substance use is perceived to have social or personal benefits.

Conformity needs and conformity behavior increase rapidly during preadolescence and early adolescence, and decline steadily from middle to late adolescence. However, an individual's susceptibility to conformity pressure may vary greatly, depending on values and a variety of psychological factors, as well as the relative importance of peer acceptance. Finally, because adolescents characteristically have a sense of immortality and invulnerability, they tend to minimize the risks associated with substance use and overestimate their ability to avoid personally destructive patterns of use.

PREVENTION STRATEGIES

In view of the adverse health, social, and legal consequences of substance abuse and the difficulty of achieving sustained abstinence once addictive patterns of use have developed, it is apparent that the most promising approach to the problem of substance abuse is prevention. Prevention efforts have taken place on several different levels and have taken many forms. Prevention has been conceptualized in terms of supply and demand reduction models and as primary, secondary, and tertiary prevention. Each encompasses a different aspect of prevention, and has substantially different operational implications.

Supply and Demand Reduction

Supply reduction efforts are based on the fundamental assumption that substance use can be controlled by simply controlling the supply or availability of drugs. This has been

the driving force behind the activities of law enforcement agencies, particularly with respect to the interdiction of drugs by governmental agencies such as the Drug Enforcement Administration (DEA), the Federal Bureau of Investigation (FBI), and local police departments. Demand reduction efforts, on the other hand, are conceptualized as those that attempt to dissuade, discourage, or deter individuals from using drugs or reducing the desire to use drugs. Demand reduction includes prevention, education, and treatment programs.

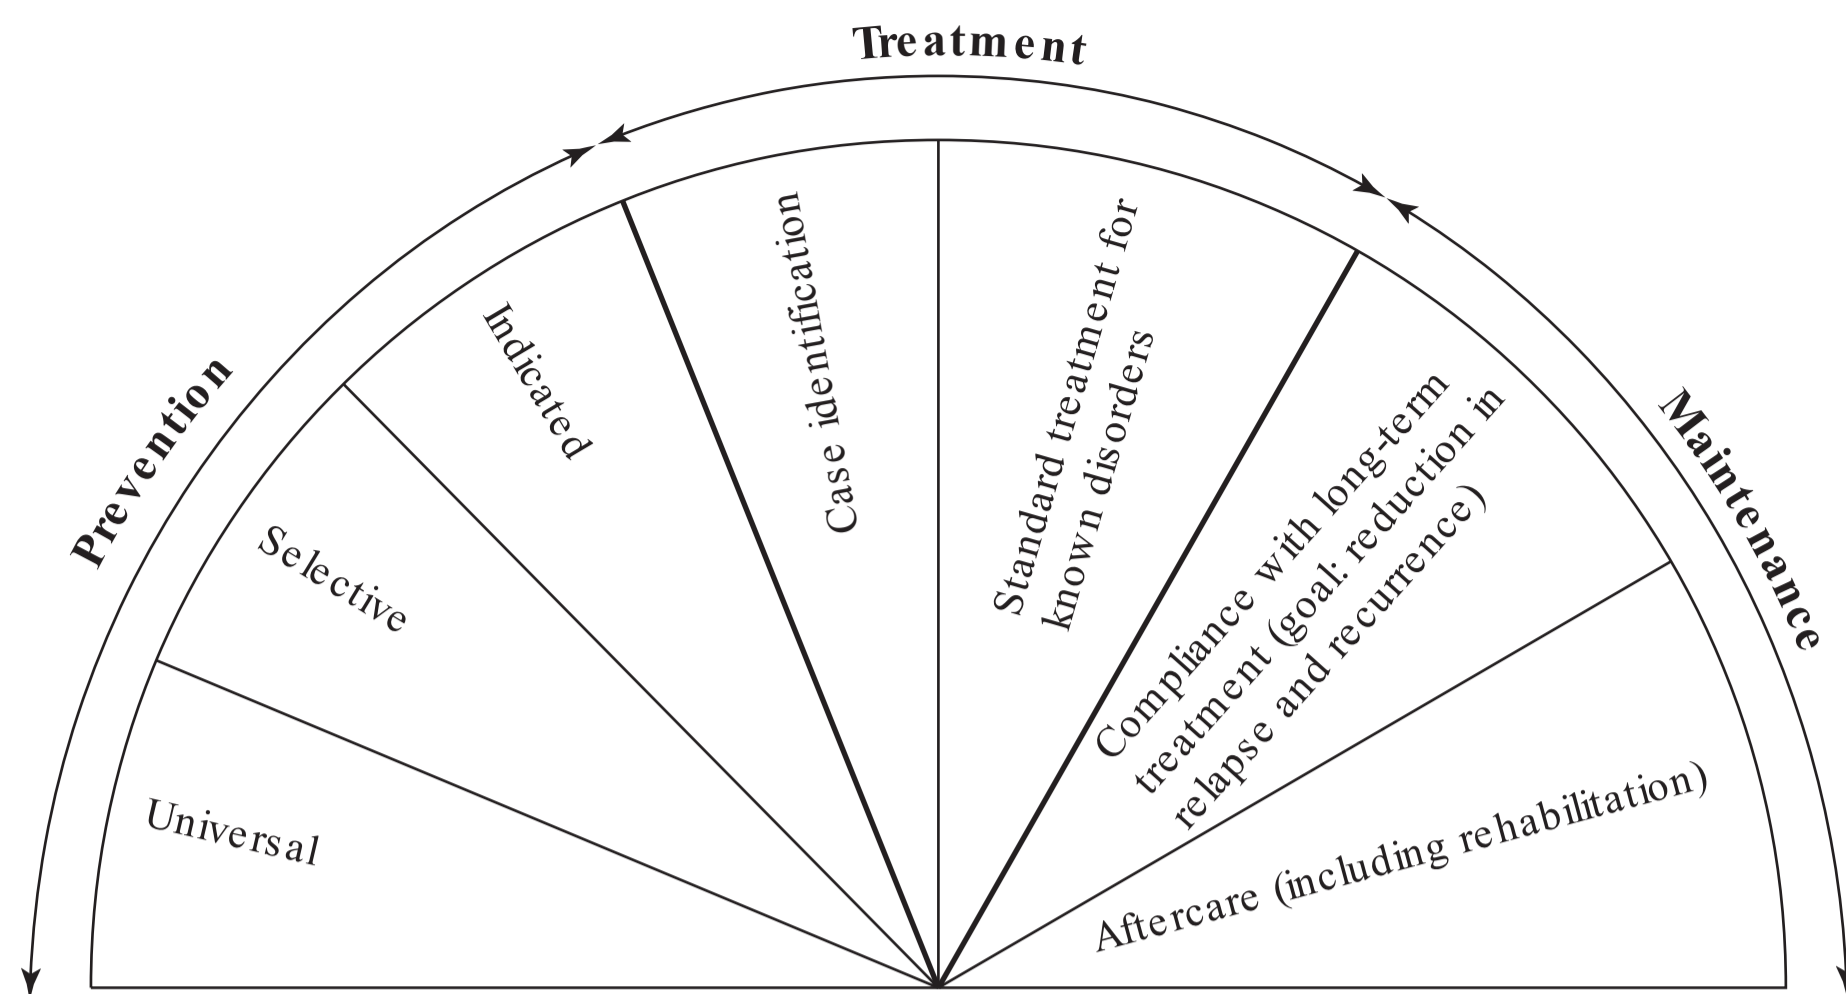

Types of Prevention

Consistent with usage in the field of public health, primary prevention interventions are designed to reach individuals before they have developed a specific disorder or disease. As such, they target a general population of individuals who, for the most part, have not yet begun using tobacco, alcohol, or other drugs. The goal of these approaches is to prevent substance use and abuse by intervening upon individual and/or environmental factors viewed as promoting or supporting this type of health-compromising behavior. Secondary prevention involves screening and early intervention. Tertiary prevention involves preventing the progression of a well-established disorder to the point of disability. However, one criticism of this classification system is that it is difficult to distinguish between tertiary prevention and treatment in that both involve care for persons with an established disorder.

In a 1994 report on preventive intervention research, the Institute of Medicine (23) proposed a new framework for classifying intervention programs as part of a continuum of care that includes prevention, treatment, and maintenance (Fig. 54.1). While originally proposed as a system to classify interventions for mental disorders, the framework has been widely adopted and the terminology is now applied to other types of interventions. In this framework, prevention is reserved only for interventions that occur prior to the initial onset of a disorder. Prevention is further divided into three types: universal, selective, and indicated preventive interventions. These categories define prevention according to the groups to whom the interventions are directed, rather than the stage of illness progression.

Universal prevention programs focus on the general population and aim to deter or delay the onset of a condition or risk behavior. While the level of risk for developing the condition may vary among individuals, universal programs recognize that all members of a population share some level of risk and can benefit from prevention programs that provide information and skills to help individuals avoid the outcome or condition. Selective prevention programs target selected high-risk groups or subsets of the general population believed to be at high risk because of membership in a particular group. Risk groups for selective interventions may be based on biologic, social, psychological, or other risk factors. Selective interventions for drug abuse prevention, for example, might recruit groups such

Figure 54.1. Institute of Medicine continuum of care model. (Reprinted with permission from Institute of Medicine. *Reducing Risks for Mental Disorders: Frontiers for Preventive Intervention Research*. Washington, DC: National Academy Press; 1994.)

as children of drug users, pregnant women, or residents of high-risk neighborhoods. An individual's level of risk is presumed to be higher than average because of their membership in the selected group. Indicated prevention programs are designed for those already engaging in the behavior, or showing early danger signs, or engaging in related high-risk behaviors. Indicated programs for drug abuse prevention, for example, would be appropriate for individuals that recently initiated substance use, with the goal of reducing their chances of a further escalation in use that can develop into a drug abuse problem. Thus, while recruitment and participation in a selective intervention is based on subgroup membership, recruitment and participation in an indicated intervention is based on early warning signs demonstrated by an individual.

Substance abuse prevention efforts can be divided into five general strategies:

- Information dissemination approaches
- Affective education approaches
- Alternatives approaches
- Social resistance skills approaches
- Broader competence enhancement approaches, which emphasize personal and social skills training

Table 54.1 summarizes these prevention strategies, which are discussed in the following sections.

Information Dissemination

Ubiquitous on the prevention landscape are programs that rely on the dissemination of factual information. The hallmark of these programs is the primary focus on providing factual information such as the pharmacology and the adverse consequences of use. Information dissemination approaches to substance abuse prevention are based on a rational model of human behavior. Substance abuse is seen as being the result of insufficient knowledge of the adverse consequences of using psychoactive drugs. Thus, the prescription for preventing substance abuse is to educate adolescents about the dangers of

smoking, drinking, or using drugs. It is assumed that exposure to factual information about the dangers of using drugs will lead to changes in attitudes, which, in turn, will lead to non-substance use behavior. Within the context of the information dissemination approach, individuals are seen as being essentially rationale individuals that are likely to avoid the harms of substance use once they become aware of factual information about these harms.

Information dissemination programs have taken the form of public information campaigns and school-based tobacco, alcohol, and drug education programs. Public information campaigns have involved the use of pamphlets, leaflets, posters, and PSAs to increase public awareness of the problem of tobacco, alcohol, or drug abuse and alter societal norms concerning use. School programs have involved classroom curricula, assembly programs featuring guest speakers (frequently policemen or health professionals), and educational films.

Many informational approaches have been designed to deter substance use by emphasizing, even dramatizing, the risks associated with substance use. The underlying assumption of fear-arousal approaches is that evoking fear is more effective than a simple exposition of the facts. These approaches go beyond a dispassionate presentation of information by providing a clear and unambiguous message that substance use is dangerous. In addition, traditional prevention programs have sometimes focused on the immorality of substance use. Program providers not only teach the objective facts, but also “preach” to students about the evils of smoking, drinking, or using drugs, and exhort them not to engage in those behaviors.

Examination of the empiric evidence concerning the effectiveness of the different approaches to tobacco, alcohol, and drug abuse prevention indicates quite clearly that while informational approaches may in some cases increase knowledge and change attitudes regarding substance use, these approaches fail when it comes to the most important outcome: reducing or preventing alcohol, tobacco, and other drug use. Increasing knowledge has little or no impact on substance

TABLE 54.1 Overview of major school-based prevention approaches

Approach	Focus	Methods
Information dissemination	Increase knowledge of drugs, their effects, and the consequences of use; promote antidrug use attitudes	Didactic instruction, discussion, audio/video presentations, displays of substances, posters, pamphlets, school assembly programs
Affective education	Increase self-esteem, responsible decision making, interpersonal growth; generally include little or no information about drugs	Didactic instruction, discussion, experiential activities, group problem-solving exercises
Alternatives	Increase self-esteem, self-reliance; provide variable alternatives to drug use; reduce boredom and sense of alienation	Organization of youth centers, recreational activities; participation in community service projects; vocational training
Resistance skills	Increase awareness of social influence to smoke, drink, or use drugs; develop skills for resisting substance use influences; increase knowledge of immediate negative consequences; establish nonsubstance use norms	Class discussion; resistance skills training; behavioral rehearsal; extended practice via behavioral “homework”; use of same-age or older peer leaders
Competence enhancement	Increase decision making, personal behavior change, anxiety reduction, and communication, social, and assertive skills; apply generic skills to resist substance use influences	Class discussion; cognitive-behavioral skills training (instruction, demonstration, practice, feedback, reinforcement)

use or on intentions to engage in tobacco, alcohol, or drug use in the near future (24). As such, the evaluation studies refute the basic assumption of the information dissemination model: that increased knowledge alone is sufficient for behavior change. Furthermore, research in health communications has found that fear appeals used as part of informational approaches are generally not effective in changing behavior, although these approaches as well may contribute to change in attitudes about drug use. It is also clear that appeals to the immorality of substance use are unlikely to be persuasive to students at highest risk for substance use.

Considering the complex etiology of substance abuse, it is not surprising that approaches that rely on the provision of factual information are ineffective. Information dissemination approaches are inadequate because they are too narrow in their focus and are based on an incomplete understanding of the factors promoting substance use and abuse. Although knowledge about the negative consequences of substance use is important, it is only one of many factors considered to play a role in the initiation of substance use among adolescents.

Affective Education

Substance abuse prevention efforts have also used affective education approaches, which are based on a different set of assumptions than information dissemination approaches. Less emphasis is placed on factual information about the adverse consequences of substance abuse, and more emphasis is

placed on students’ personal and social development. Affective education approaches focus on increasing self-understanding and acceptance through activities such as values clarifications and responsible decision making; improving interpersonal relations by fostering effective communication, peer counseling, and assertiveness; and increasing students’ abilities to fulfill their basic needs through existing social institutions. A common component of many affective education programs is the inclusion of norm-setting messages concerning responsible substance use.

The results of evaluation studies testing the effectiveness of affective education approaches have been as discouraging as evaluations of informational approaches. Although affective education approaches have, in some instances, been able to demonstrate an impact on one or more of the correlates of substance use, they have not produced an impact on substance use behavior (25). While some of the components of affective education that focus on personal skills (e.g., communication and assertiveness) may be helpful as part of a larger prevention strategy, they are not effective in changing drug use behavior when emphasized on their own.

Alternatives

One method of preventing substance abuse that has been a part of both community-based and school-based interventions has been to restructure part of the adolescent’s environment to provide them with alternatives to substance use and activities associated with substance use. Several different alternatives approaches have been developed. The original

model for alternatives typically involved the establishment of youth centers providing a particular activity or set of activities in the community (e.g., hobbies, team sports, and community service). It was assumed that if adolescents could be provided with real-life experiences that would be as appealing as substance use, their involvement in these activities would actually take the place of involvement with substance use. Another type of alternatives approach is Outward Bound and similar programs. These activities are organized in the hope that they would alter the affective-cognitive state of an individual and that they would change the way individuals felt about themselves and others and how they saw the world. This approach focuses on healthy activities frequently designed to promote teamwork, self-confidence, and self-esteem.

While these approaches may seem worthwhile, few alternatives approaches have been evaluated properly, and those that have been evaluated are ineffective in preventing substance use behavior. Most alternative activities have limited theoretical or conceptual connection to substance abuse prevention. Although some activities related to academics, religion, or physical fitness training may be associated with nonsubstance use (26), these are unlikely to be attractive activities for high-risk young people. Furthermore, certain alternative activities may expose young people to environments or settings where substance use is normative, such as some social, entertainment, and vocational activities, and therefore may increase the risk for substance use. Like affective education, some components of alternative activities that help young people develop specific skills may be helpful as part of a larger prevention strategy, but by themselves these approaches are not effective in changing drug use behavior.

Toward Theory-Based Interventions: Psychological Inoculation

The pioneering prevention research of Evans and his colleagues at the University of Houston toward the end of the 1970s triggered a major departure from traditional approaches to tobacco, alcohol, and drug abuse prevention. Unlike previous approaches that focused on information dissemination and/or fear arousal, the strategy developed initially by Evans and his colleagues (27) focused on the social and psychological factors believed to be involved in the initiation of cigarette smoking.

Evans's work was strongly influenced by persuasive communications theory as formulated by McGuire (28) and a concept called "psychological inoculation." Psychological inoculation is analogous to that of inoculation used in infectious disease prevention. Persuasive communications designed to alter attitudes, beliefs, and behavior are conceptualized as the psychosocial analogue of "germs." To prevent "infection" it is necessary to expose the individual to a weak dose of those "germs" in a way that facilitates the development of "antibodies" and thereby increases resistance to any future exposure to persuasive messages in their more virulent form.

The application of the concept of psychological inoculation as a smoking prevention strategy is fairly straightforward.

Smoking is conceptualized as being the result of social influences (persuasive messages) to smoke from peers and the media that are either direct (offers to smoke from other adolescents or cigarette advertising) or indirect (exposure to high-status role models who smoke). If adolescents are faced with peer pressure to try cigarettes, for example, they can be forewarned and prepared by providing them with the necessary skills for countering such pressure. They can be trained on what to say in specific situations to diffuse or negate attempts at peer pressure, and they can be taught to form counterarguments in situations when they see older youth posturing and acting "tough" by smoking.

The intervention initially developed by Evans consisted of a series of films designed to increase students' awareness of the various social pressures to smoke that they would be likely to encounter as they progressed through the critical junior high school period. Also included in these films were demonstrations of specific techniques that could be used to effectively resist various pressures to smoke. The prevention strategy developed by Evans also included two other important components: periodic assessment of smoking with feedback to students and information about the immediate physiologic effects of smoking. Smoking was assessed by questionnaire on a biweekly basis, and saliva samples were collected as an objective measure of smoking status. The rate of smoking in each classroom (which was considerably lower than most adolescents thought) was publicly announced to correct the misperception that cigarette smoking is a highly normative behavior (i.e., that everybody is doing it).

In the first major test of this prevention strategy, Evans compared students receiving assessment/feedback with those receiving monitoring/feedback plus inoculation against a control group (29). The students in the two treatment conditions exhibited smoking onset rates that were about 50% lower than that observed in the control group. The overall reduction in smoking onset was dramatic in view of the history of failed prevention efforts that preceded this study. The success of the study conducted by Evans triggered an explosion of prevention research and offered the first real evidence that preventive interventions could produce effects on substance use behavior.

Resistance Skills Training

Several variations in the prevention model originally developed by Evans have been tested over the years. Similar to Evans's model, these interventions were designed to increase students' awareness of the various social influences to engage in substance use. A distinctive feature of these prevention models is that they place more emphasis on teaching students specific skills for effectively resisting both peer and media pressures to smoke, drink, or use drugs. These resistance skills training programs (also referred to as "social influence" or "refusal skills training" approaches) are based on a conceptual model stressing the fundamental importance of social factors in promoting the initiation of substance use among adolescents. These influences come from the family (parents and

older siblings), peers, and the mass media. Adolescents may be predisposed toward substance use because substance use behavior is modeled by parents or older siblings, or because of the transmission of positive messages and attitudes concerning substance use. Similarly, individuals who have friends who smoke, drink, or use drugs are more likely to become substance users themselves as a result of issues relating to modeling and the need for peer acceptance (as well as the greater availability of substances). Finally, on the larger societal level, high-status role models in the mass media may promote substance use by increasing perceived positive norms and expectations with respect to substance use. As Bandura (30) indicated, all social influences are themselves a product of the interaction between individual learning histories and forces in both the community and the larger society. Through social learning processes, a young person may expect various positive outcomes from substance use, such as increased alertness, relief from anxiety, or enhanced social status. While expectations of reward can be learned from direct experience with substance use, positive expectancies are initially typically learned by observing the expectations, attitudes, and behaviors regarding substance use of significant others like parents, siblings, peers, and media personalities.

Research on resistance skills training approaches initially focused primarily on preventing the onset of cigarette smoking, that is, preventing the transition from nonsmoking to smoking. Eventually, the onset of alcohol and illicit drug use was targeted as well. Most studies have targeted junior high school students, generally beginning with seventh graders. Fewer studies include elementary school students, partly because substance use rates are very low, and it is difficult to demonstrate behavioral effects in this age group. Social resistance skills programs generally teach students how to recognize situations in which they will have a high likelihood of experiencing peer pressure to smoke, drink, or use drugs so that these high-risk situations can be avoided. In addition, students are taught how to handle situations in which they might experience peer pressure to engage in substance use. Typically, this includes teaching students not only what to say (i.e., the specific content of a refusal message), but also how to deliver it in the most effective way possible. Material has also generally been included in these programs to combat the perception that substance use is widespread because adolescents typically overestimate the prevalence of smoking, drinking, and using certain drugs. These beliefs can be challenged by simply providing students with the prevalence rates of substance use among their age mates in terms of national survey data or conducting classroom or schoolwide surveys, which can be organized and directed by students participating in the program. Resistance skills training programs also typically include a component designed to increase students' awareness of the techniques used by advertisers to promote the sale of tobacco products or alcoholic beverages and to teach techniques for formulating counterarguments to the messages used by advertisers.

Perhaps the best known application of the social resistance skills training model is Project DARE (Drug Abuse Re-

sistance Education), which is being used in approximately 60% of the classrooms in America. A unique aspect of DARE, and one that undoubtedly has contributed to its adoption by many schools, is that it is conducted by police officers. Although DARE has been remarkably successful with respect to being adopted by a large number of schools and in promoting an awareness of drug abuse, the results of DARE are disappointing. Although DARE has been repeatedly evaluated, many outcome studies have been of limited scientific value because of weak research designs (e.g., posttest only), poor sampling and data collection procedures, inadequate measurement strategies, and problems in data analysis approaches (31). Several evaluation studies of DARE using more scientifically rigorous designs (i.e., large samples, random assignment, and longitudinal follow-up) show that DARE has little or no impact on drug use behaviors, particularly beyond the initial posttest assessment (32–34).

While DARE is not effective in changing behavior, several studies have documented that well-designed and rigorously implemented social resistance skills programs can prevent substance use in adolescence. In a comprehensive meta-analysis of school-based smoking prevention programs, 23 randomized controlled trials (RCTs) were identified that met rigorous inclusion criteria for research design and execution quality, and 13 of these were categorized as social resistance programs (24). The main outcome variable was prevalence of nonsmoking at follow-up among those students not smoking at the baseline assessment. Of 13 RCTs of social resistance programs rated as most valid in terms of research design, 9 were found to produce positive intervention effects on smoking prevalence; four RCTs showed no effects on smoking behavior. In general, the positive behavioral effects of social resistance smoking prevention programs were relatively short term. A separate review of the smoking prevention literature compared studies comparing social influence programs to no intervention control group conditions. Findings indicated that mean differences in smoking across conditions ranged from 5% to 60% with durations of 1 to 4 years (35). The authors concluded that the most effective school-based smoking prevention programs are those with sustained application, booster sessions over several years, and reinforcement in the community including the involvement of parents and/or the mass media, and those that are part of a comprehensive school health promotion program.

In general, results from long-term follow-up studies of school-based social influence approaches indicate that these prevention effects are typically not maintained. While this has led some to conclude that school-based prevention approaches may not be powerful enough to produce lasting prevention effects, others have argued that the apparent failure of studies testing resistance skills training approaches to produce long-term prevention effects may have to do with factors related to either the type of intervention tested in these studies or the way these interventions were implemented. Resnicow and Botvin (36) argue that the absence of long-term prevention effects in these studies should not be taken as an indictment of school-based prevention; instead, the lack of

effects in several long-term follow-up studies may have occurred because (a) the length of the intervention may have been too short (i.e., the prevention approach was effective, but the initial prevention “dosage” was too low to produce a long-term effect), (b) booster sessions were either inadequate or not included (i.e., the prevention approach was effective, but it eroded over time because of the absence or inadequacy of ongoing intervention), (c) the intervention was not implemented with enough fidelity to the intervention model (i.e., the correct prevention approach was used, but it was implemented incompletely, improperly, or both), and/or (d) the intervention was based on faulty assumptions, was incomplete, or was otherwise deficient (i.e., the prevention approach was ineffective). Indeed, it now appears that these factors played a role in the negative findings of long-term follow-up studies with prevention approaches based on the resistance skills training model. School-based prevention programs that are powerful enough to have a durable impact on adolescent substance use need to focus on a broad and comprehensive set of skills-building activities, have a strong initial dosage and include at least two additional years of (booster) intervention, and be implemented in a manner that is faithful to the underlying intervention model.

Competence Enhancement

Since the end of the 1970s and up to the present, considerable research has also been conducted with a prevention approach that teaches general personal and social skills either alone (37) or in combination with components of the social resistance skills model (38). These competence enhancement approaches are more comprehensive than either traditional cognitive–affective approaches or the more recent resistance skills model. In addition to recognizing the importance of social learning processes such as modeling, imitation, and reinforcement, competence-enhancement approaches posit that youth with poor personal and social skills are not only more susceptible to influences that promote drug use, but also motivated to use drugs as an alternative to more adaptive coping strategies (38). They are based on social learning theory (30) and problem behavior theory (17). Substance abuse is conceptualized as a socially learned and functional behavior, resulting from the interplay of social and personal factors. Substance use behavior is learned through modeling and reinforcement and is influenced by cognition, attitudes, and beliefs.

Personal and social skills training prevention approaches typically teach two or more of the following:

- General problem-solving and decision-making skills
- General cognitive skills for resisting interpersonal or media influences
- Skills for increasing self-control and self-esteem
- Adaptive coping strategies for relieving stress and anxiety through the use of cognitive coping skills or behavioral relaxation techniques
- General social skills
- General assertive skills

These skills are taught using a combination of instruction, demonstration, feedback, reinforcement, behavioral rehearsal (practice during class), and extended practice through behavioral homework assignments. The intent of these programs is to teach the kind of generic skills for coping with life that will have a relatively broad application. This is in contrast to the resistance skills training approaches, which are designed to teach skills with a problem-specific focus. Personal and social skills training programs emphasize the application of general skills to situations directly related to substance use and abuse (e.g., the application of general assertive skills to situations involving peer pressure to smoke, drink, or use drugs). These same skills can be used for dealing with many of the challenges confronting adolescents in their everyday lives, including, but not limited to, smoking, drinking, and drug abuse.

Although prevention approaches that emphasize the development of general personal and social skills have a broader focus compared to approaches designed to teach skills for resisting social influences to use drugs, the most effective prevention approaches appear to combine the features of both. Indeed, evidence suggests that broad-based competence enhancement approaches may not be effective unless they also contain some resistance skills training material. A prevention approach with both components will help teach students to apply generic personal and social skills to situations related specifically to preventing substance abuse and may also serve to increase antidrug norms.

Evaluation studies testing a combined social influence and competence enhancement skills training approach have demonstrated significant behavioral effects on alcohol, tobacco, and other drug use. A series of evaluation studies has been conducted over the past 30 years examining the effectiveness of the Life Skills Training (LST) program, a universal school-based prevention approach that teaches general personal and social skills training combined with drug-refusal skills and normative education. Studies range from small-scale efficacy studies to large-scale randomized trials. These studies consistently show that the LST approach produces positive behavioral effects on alcohol, tobacco, and other drug use.

The focus of the initial evaluation research of the LST program was on cigarette smoking and involved predominantly white middle-class populations. Several early small-scale efficacy studies demonstrated that this prevention approach effectively reduces cigarette smoking among youth receiving the program, as compared to a control group that does not. Additional studies examined its effectiveness with different delivery formats, different program providers, and different substances; these studies found that the prevention approach was made more effective by the inclusion of booster sessions after the initial year of intervention; that it is equally effective when taught by teachers, peer leaders, and health educators; and that it produced behavioral effects on alcohol and marijuana. These initial studies were among the first school-based prevention studies to show consistent behavioral effects on adolescent substance use (see Ref. (39) for a review).

More recent evaluation research on the LST approach has focused on the intervention's long-term effects on drug use, effects on more serious levels of drug involvement including illicit drug use, and its impact on hypothesized mediating variables, and has increasingly focused on effects when used with inner-city minority populations. The evaluation designs have become increasingly sophisticated with time, including two large-scale multisite randomized prevention trials with long-term follow-up. The first of these randomized controlled prevention trials focused on a predominantly white, suburban sample of youth. Beginning in 1985, this prevention trial examined the short- and long-term effects of the LST approach among close to 6000 students from 56 junior high schools in New York State. Students in the prevention condition received the intervention in the seventh grade and booster sessions during the eighth and ninth grades. Significant prevention effects were found among intervention participants at the end of the ninth grade in terms of cigarette smoking, marijuana use, and immoderate alcohol use (40), as well as at the end of the 12th grade (41). In the latter follow-up study, there were significantly fewer smokers, heavy drinkers, marijuana users, and polydrug users among students who received the prevention program relative to controls. The strongest prevention effects were produced for the students who received the most complete implementation of the prevention program. A related study using data from a confidential and random subsample of these students ($N = 447$) found that there were lower levels of overall illicit drug use and lower levels of use for hallucinogens, heroin, and other narcotics in the intervention group relative to controls (42).

A large-scale prevention trial tested the LST approach among inner-city minority youth in New York City. The sample was predominantly African American (61%) and Hispanic (22%) and consisted of students ($N = 3621$) in 29 urban middle schools. Results at the posttest and 1-year follow-up indicated that those who received the prevention program reported less smoking, drinking, drunkenness, inhalant use, and polydrug use relative to those in the control group who did not receive the intervention (43). Additional studies using data from this large-scale trial focused on prevention effects of the intervention program in terms of cigarette smoking onset and binge drinking. The first of these studies examined the effectiveness of the prevention program in reducing the initiation and escalation of smoking in a subsample of girls from the larger study (44). One-year follow-up data indicated that girls who participated in the intervention condition were significantly less likely to initiate smoking relative to controls, and 30% fewer participants escalated to monthly smoking relative to students in the control group. A second study showed that this intervention approach had protective effects in terms of binge drinking (five or more drinks per drinking occasion) among inner-city, middle school boys and girls (45). In this study, the proportion of binge drinkers was more than 50% lower in those who received the prevention program relative to the control group at both 1- and 2-year follow-up assessments. Finally, a study of a subset of students from the larger sample examined the effectiveness of the prevention

program among youth at high risk for substance use initiation and found that those students who had poor grades in school and friends that engaged in substance use were less likely to engage in smoking, drinking, inhalant use, or polydrug use than were similarly matched controls that did not receive the intervention (46). Taken together, the results from several large-scale randomized prevention trials provide strong evidence of the effectiveness of the competence enhancement plus resistance skills prevention approach, with both suburban white youth and inner-city minority youth. A major strength of the evaluation studies conducted with the broader personal and social skills training approaches such as LST is that they also have a demonstrated impact on variables hypothesized to mediate the effect of the prevention programs in a direction consistent with nonsubstance use. These include significant changes in knowledge and attitudes, assertiveness, locus of control, social anxiety, self-satisfaction, decision making, and problem solving.

Together, the results of these studies provide compelling evidence supporting the efficacy of broad-spectrum prevention strategies focusing on general personal and social skills development combined with drug-specific social resistance skills. Thus, this prevention approach has been demonstrated to produce reductions in substance use (relative to controls), as well as changes in several hypothesized mediating variables in a direction consistent with reduced substance abuse risk.

SUMMARY AND CONCLUSION

A number of substance abuse prevention approaches have been developed and tested over the years. The most common approaches to tobacco, alcohol, and drug abuse prevention are those that focus on providing factual information about the adverse consequences of using these substances, with some approaches including a mix of scare tactics and moral messages. Other commonly used approaches to substance abuse prevention have used affective education and alternatives approaches. The existing evaluation literature shows rather conclusively that these are not effective prevention strategies when the standard of effectiveness concerns the ability to influence substance use behavior. On the other hand, research shows that the most effective prevention approaches are based on an understanding of the etiology of substance abuse supported by a sound theoretical model. Contemporary school-based substance abuse prevention programs that focus on social resistance and competence enhancement skills are effective in large part because their assumptions about the causes of substance use are consistent with more recently conducted etiologic research.

The large body of research on school-based prevention contains a number of findings regarding the key components and characteristics of effective substance use prevention programs (47,48). Programs should be based on a comprehensive theoretical framework that addresses multiple risk and protective factors. Program content should be developmentally appropriate and include information relevant to the target age group and the important life transitions they face. The

material should include skills training exercises to help young people recognize and resist pressures to use drugs, as well as comprehensive skills training to enhance personal and social competence skills, and other skills to build resilience and help participants navigate developmental tasks. Programs should provide accurate information regarding rates of drug use to reduce the perception that it is common and normative. They should be delivered using interactive methods—including facilitated discussion, structured small group activities, and role-playing scenarios—to stimulate participation and promote the acquisition of skills. Interventions must be culturally sensitive and incorporate relevant language and audiovisual content familiar to the target audience. They should include adequate dosage to introduce and reinforce the material, including booster sessions in subsequent years. Program providers should participate in comprehensive interactive training sessions to generate enthusiasm, increase implementation fidelity, and give providers a chance to learn and practice new instructional techniques. Published meta-analytic studies indicate that competence enhancement and social influence approaches are more effective than traditional didactic approaches and that attitude and behavior change is most substantial in high intensity, multicomponent programs implemented with booster sessions after the initial intervention. To be effective, school-based interventions need to be more comprehensive, have a stronger initial dosage, include at least two additional years of (booster) intervention, and be implemented in a manner that is faithful to the underlying intervention model. Generally social resistance prevention programs are effective with a broad range of adolescents including high- and low-risk individuals and urban, suburban, and rural students. These studies indicate that the inclusion of additional intervention components produces stronger prevention effects than the school-based intervention alone. Peer-led programs have been found to frequently be more effective than adult-led programs (25), particularly when peer leaders assist adult program providers and have specific and well-defined roles.

Over the past two to three decades, there have been a number of significant developments in the field of substance abuse prevention. Yet despite the promise offered by these approaches, future research is needed to further refine current prevention models and to develop new ones. Given the urgency and importance of dealing with the problem of substance abuse, it seems prudent to proceed on two simultaneous tracks: one involving further prevention research and the other involving the dissemination of the most promising existing prevention approaches. This is particularly important in view of the fact that the most widely utilized prevention approaches continue to be those that have already been found either to be ineffective or to lack any scientifically defensible evidence of their efficacy.

The problem of substance abuse is still very prevalent. However, for the first time in the history of its prevention, evidence now exists from a number of rigorously designed evaluation studies that specific school-based and community-based prevention models are effective. It is now incumbent

upon health care professionals, educators, community leaders, and policy makers to move expeditiously toward wide dissemination and use of these approaches. It is equally important for private and governmental agencies to provide adequate funding for the important research necessary to further refine existing prevention models and to increase our understanding of the causes of substance abuse.

Harm Reduction: New Drug Policies and Practices

OVERVIEW

In this chapter, we review the conceptual basis and scientific evidence for harm reduction (HR) drug policies and document their applications in practice worldwide. We begin with the public health model for many HR methods that are some of its signature applications (i.e., syringe exchange, safe injecting sites, overdose [OD] prevention). We then discuss HR approaches to drug treatment (especially opioid substitution methods) and introduce some of the more innovative HR drug policies (such as heroin maintenance and medical marijuana). A section on China is included as a current case study in the development of a national HR program. We conclude by examining how these prevention and intervention strategies affect individual and public health outcomes, such as the HIV epidemic, and the more general HR goals of human rights, improvements in global security, and the protection of public health and safety in civil societies.

THE PROBLEM

The production, distribution, and sale of illicit drugs are among the world's leading industries. Approximately 200 million people (4.8% of the world's population) use illicit drugs each year (75% of that cannabis)—an economy estimated at \$400 to \$500 billion annually by the World Bank, U.S. Drug Enforcement Agency (DEA), United Nations International Drug Control Program (UNDCP), and Interpol (1) (Table 55.1). This unprecedented scale and worldwide nature of today's international drug markets has profound social, public health, and political implications, confronting us with a potent new version of a very old problem—the globalization of drugs.

Our apparent inability to contain illicit drugs and their harms challenges old ways of thinking about drugs and forces us to reconsider the fundamental ideas and policies we employ for their control. Additionally, with its many links to the HIV/AIDS pandemic, drug use is now one of the most urgent public health problems facing the world (1). The HR model is an outgrowth of these contemporary realities (2). Well before AIDS, the Dutch undertook HR as “normalization” of drug policies to increase users' contact with social, treatment, health, and other community services. The realization that people shared needles, spreading the human immunodeficiency virus (HIV) and other infectious diseases (e.g., hepatitis C), created

powerful new reasons for establishing new public health goals for drug policy. In the 1980s, public health officials in the United Kingdom declared: “HIV is a greater threat to public and individual health than drug misuse” (3) (a sentiment echoed in Australia, Canada, Switzerland, and many other countries) (4). By 2009, some 74 countries explicitly supported HR as a basis of their national drug policies.

REFRAMING THE ISSUE

HR concepts and measures share two underlying assumptions:

1. It is better (for both society and the individual) to reduce the risks and harms of drug use, rather than to focus solely on the utopian goal of making people (or the world) “drug free.”
2. Drug control policies based primarily on the criminalization of drug use and drug users should be replaced with policies that produce demonstrable reductions in the adverse consequences of continued drug use worldwide.

HR concepts and policies address the harms of drug policies as well as those of drugs themselves, offering pragmatic public health-oriented alternatives to the unachievable goals of drug prohibition—“a drug-free society” (5)—through a new model and set of pragmatic approaches intended to address the following significant challenges:

How can we reduce the likelihood of people who use drugs contracting and spreading blood-borne infections (HIV, hepatitis), and other infectious diseases (e.g. tuberculosis), suffering fatal overdoses, and developing other drug use-related medical problems?

How can we reduce the likelihood that people who use drugs will engage in criminal and other undesirable behaviors?

How can we increase the likelihood that people who use drugs will be good citizens, act responsibly toward others in their communities, take care of their families, complete their education or training, and become legally employed?

How can we develop drug policies that are both effective (at reducing adverse outcomes) and humane, while improving quality and access to effective prevention, treatment, and rehabilitation services? and

TABLE 55.1 Extent of drug use (annual prevalence^a) estimates 2005/2006 (or latest year available)

	Cannabis	Amphetamine-type stimulants		Cocaine	Opiates	Heroin
		Amphetamines	Ecstasy			
(Million people)	158.8	24.9	8.6	14.3	15.6	11.1
In % of global population aged 15–64	3.8	0.6	0.2	0.3	0.4	0.3

^aAnnual prevalence is a measure of the number/percentage of people who consumed an illicit drug at least once in the 12-month period preceding the assessment.

How can we minimize the harms associated with prohibition drug policies and the criminalization of drug users?

DRUG USE, PUBLIC HEALTH, AND HUMAN RIGHTS

The HR model grows from the clinical and preventive medicine framework of public health (6), whose goals include reducing morbidity and mortality in populations by using the tools of primary, secondary, and tertiary prevention. In HR, rather than focusing on the reduction of drug use per se, primary prevention seeks to reduce the harms of drugs and drug control policies (i.e., rates of addiction and other hazards of drug use, including infectious diseases, and OD deaths) and the risks of illicit drug markets (with their violence and corruption). Secondary prevention aims to limit the prevalence and severity of these individual psychologic harms and medical disorders associated with continued drug use and addiction (i.e., effective treatment and rehabilitation, HIV programs). Tertiary prevention involves limiting collateral medical and social consequences of drug use, drug markets, and addiction for individuals, families, and communities—once drug use has become a prevalent and chronic condition.

This is a shift of viewpoint: one where drug use and drug problems are not seen as based on a model of individual psychologic, moral, or legal deficiencies. Rather, HR recognizes that many of the most destructive consequences and refractory problems of illicit drug use are not only attributable to the ingestion of drugs but are the result of the methods of use (e.g., injection leading to HIV, HCV) or uncontrolled dependence on drugs of unknown purity and potency (OD and poisoning). Others are linked to the failure of the drug policies employed to control them—especially harsh enforcement of their prohibition and criminalization of drug users. Combined with the irrepressible global demand for mood-altering drugs, this must inevitably increase their value, foster aggressive trafficking, and spread drug use. Criminalization also undermines drug users' ability to protect themselves, their families and communities, setting the stage for collateral public health and

social damages (e.g., epidemics of blood-borne diseases, violent drug wars in communities, and mass incarceration (7).

Drug use and drug policies are also a matter of human rights: abuses committed in the name of drug policy violate international conventions ratified by the member states of the United Nations. Human rights considerations focus on protecting people who use drugs from discrimination, individuals rights violations, and disproportionate punishment—including arrest and incarceration for positive urine tests or possession of drugs for personal use, deprivation of due process (e.g., internment in forced labor camps with no right of appeal), and police abuses such as extortion of monies from drug users threatened with arrest, the use of withdrawal symptoms to coerce confessions, or use of medical records to subject patients to repeated stop-and-frisk procedures. Additionally, human rights advocates support “positive obligations” to promote the health of people who use drugs, arguing against bans on methadone treatment, needle exchange, or provision of medical care. Jurisprudence, rather than peer-reviewed scientific studies, is often cited in support of these positions. Regional human rights courts and leading human rights officials have affirmed with increasing force that drug users do not forfeit their human rights just because they use illicit drugs and questioned the legality of punitive drug control practices (8).

THREE CAVEATS

Analysis of HR efforts and their outcomes must be qualified by three important caveats:

1. Drug prohibition policies remain the context for all HR efforts: In most countries HR programs and policies must coexist in tension with (and are usually dominated by) the “War on Drugs” and the international drug prohibition regime. The rise of HIV infection rates has created competing discourses based on international public health and human rights, but these do not have the force of law. HR programs therefore continue to struggle with largely hostile mechanisms of drug law enforcement and criminalization.

2. The limits of research and science: Illicit drug use and behavior are shaped by so many societal influences that it is extremely difficult and sometimes impossible to isolate and determine the precise impact of specific measures on drug-related behavior. Data collection and analysis regarding generally hidden and highly stigmatized illicit behavior are inherently difficult (making the subject very difficult to study), and governments vary in how they collect and categorize data on illicit drug use and related public health and criminal justice information—making cross-national comparisons problematic.
3. The importance of different cultural contexts: Most societies in which HR policies (e.g., syringe availability or substitution treatment) were first implemented are advanced industrialized social democracies. Some HR programs now exist in most countries of the former Soviet Union and multiple countries in East and Southeast Asia; for example, methadone treatment is currently operative in more than 65 countries but not in Russia or India. Naturally these programs vary sharply in their scale, quality, and auspice (private, church, government). Even in countries of the developing world, HR models and practices may also be quite different—for example, do they support community outreach or prefer stationary, clinic-based approaches; do they acknowledge or reject a role for people who use drugs in the formation and operation of programs and policies?

HARM REDUCTION IN THE UNITED STATES

While there are exceptions, most American politicians and public officials have publicly rejected many HR premises and ignored the evidence supporting HR, even as drug policy in the United States remains officially blind to abundant evidence of its own failures. While Europeans and Australians established and expanded such programs in the 1980s (often in response to the all-too-apparent American catastrophe of HIV among injection drug users [IDUs]), the United States resisted needle syringe programmes (NSPs) arguing that syringe distribution encourages illicit drug use and “sends the wrong message.” Bitter confrontations blocked public and governmental action during the crucial early phase of the U.S. HIV/AIDS epidemic. It is now estimated that more than 4300 HIV infections (and perhaps as many as 9000 to 10,000 infections, depending on estimates of NSPs effectiveness) could have been prevented between 1987 and 1995, had an effective program of needle exchange been implemented and approximately 20,000 IDUs are still being infected with HIV in the United States each year (9).

In 1988, Congressional amendments first banned the use of federal funds for needle and syringe programs (because they could “promote drug use”). Until 2008, the very term “harm reduction” was banned from government vocabulary and from federal grant applications. HR policies (e.g., medical marijuana) have been attacked by U.S. government officials as “surrender in the War on Drugs” and stepping-stones to “drug legalization” (10). President Barack Obama’s campaign

pledged support for needle exchange, and in 2009, officials agreed to rein in federal officers threatening California’s medical marijuana program (with over 250,000 registrants). As of this writing (2010), the federal ban on funding of needle exchange has been lifted, but federal health officials remain unwilling to endorse HR more broadly.

HARM REDUCTION AS PREVENTION: NEW MODELS AND SERVICES FOR ACTIVE DRUG USERS

Syringe Exchange Programs

Early in the HIV/AIDS epidemic, the sharing of syringes was clearly linked to HIV transmission. By 1995, about half of the new HIV infections in the United States (now estimated by the CDC as 55,000 per year (9,10)) were attributed directly or indirectly to drug use. The institution of NSPs was the first well-organized and explicit HR program in the United States (11) and in many European and Asian countries and had a marked impact—by 2007, less than one third of newly reported AIDS cases in the United States and Western Europe were among IDUs or their sexual partners. However, in many countries NSPs still meet with strong opposition and are not implemented at levels adequate to affect the spread of blood-borne pathogens.

The positive effects of NSPs on syringe sharing and a wide range of other behaviors linked to HIV/AIDS risk were well documented in the United States, Great Britain, the Netherlands, and Australia by the early 1990s. Both previous and more recent reviews NSPs (12) found more than half of the programs were associated with reductions in syringe sharing. In Connecticut, the sharing of needles among IDUs dropped by 40% after that state changed its paraphernalia laws in 1992 to allow for purchase, possession, and sale of up to 10 syringes without a prescription. The results of this change were a decrease in IDUs marginalization (11,13), better access to social and legal services and drug treatment, as well as increased referrals to medical care (e.g., for tuberculosis [TB] and HIV). A few showed an increase in HIV (e.g., in Montreal and Vancouver among populations involved in very high-risk cocaine injecting), but study designs precluded adequate comparisons to non-NSP users (13,14).

Referral to drug treatment is a major accomplishment of SEPs in practice. Since 1991, a Tacoma, Washington NSP has been the largest single source of recruitment to methadone-maintenance programs in the region. Of the first 569 clients in New Haven, Connecticut’s NSP, 188 (33%) requested drug treatment, and 107 (57%) of those clients were placed in treatment programs. In the United Kingdom, where almost 60% of new NSP clients have no contact with other treatment or HIV prevention services, many clients are subsequently referred to such services. NSPs are well suited for disseminating information on HIV/AIDS risks and users take such information seriously; the claim that drug injectors will not alter their behavior to reduce the risks of contracting HIV and other infections has consistently been refuted. In cities that implemented SEPs in the mid-1980s, there is evidence of lower HIV

prevalence among IDUs than in cities that did not offer SEPs until later in the HIV/AIDS epidemic. In Australia and the United Kingdom, where NSPs were instituted in the mid-1980s, HIV seroprevalence in drug injectors has remained lower than in most other countries (15).

Needle and Syringe Programs in the United States

Despite very favorable early reports on the public health impact of NSPs worldwide and endorsements by national commissions (i.e., *the National Commission on Acquired Immune Deficiency Syndrome, the Centers for Disease Control and Prevention, the General Accounting Office, the National Academy of Sciences' Institute of Medicine, and the Office of Technology Assessment*) (13–15), implementation of NSPs faced daunting challenges throughout their American history: funding shortages, continued police harassment, and, in some cities, criminal prosecution for activists caught distributing syringes. Many American NSPs operate without the legal sanction of local authorities, and all sanctioned SEPs operate under strict rules—which may include limits on the number of syringes that can be dispensed to individual clients, restrictions on where NSPs can be located and what hours they are open—requirements hindering their ability to achieve maximum effectiveness (16). U.S. federal support for even the evaluation of NSPs did not occur until 1992, the 11th year of the AIDS epidemic. And (until 2009) the United States prohibited the use of federal funds to pay for NSPs either in America or overseas. It is the private sector, charitable foundations, and community volunteers and activists, along with state and local officials, which provide the funds and personnel for many NSPs in the United States. Today only 10% to 15% of U.S. drug injectors have access to NSPs, of which there were 101 (including Puerto Rico). Some local laws prohibit the sale or possession of syringes without a prescription, and all but five states have drug paraphernalia laws that criminalize the possession or distribution of syringes except for “legitimate medical purposes” (16).

In 2000, New York State began a pilot program under which 2500 community pharmacists could sell syringes under a waiver of paraphernalia laws (15); this program has been evaluated and found to produce positive outcomes. Circulation time of used syringes is minimized by encouraging or requiring drug injectors to return used syringes for clean ones and by providing multiple disposal sites for used syringes. But even where over-the-counter sale is permitted, pharmacists may be prohibited or discouraged from selling syringes to anyone they suspect of illicit drug use. Paraphernalia laws also dissuade users from returning syringes to the exchanges, because they could be arrested if police find them in possession of syringes (16).

Needle and Syringe Programs Outside the United States

Unlike the United States, most countries in Western Europe, and many elsewhere, never enacted prescription or paraphernalia laws, and two that did—France (17) and Austria—revoked

A

them during the mid-1980s when HIV/AIDS came on the scene. By the late 1980s, virtually all developed countries allowed legal access to sterile injection equipment through syringe exchanges, over-the-counter sales, or both (Fig. 55.1). Most NSPs abroad are strongly supported by government officials at the national and local levels, most law enforcement officials, and a substantial majority of public opinion. Most public health authorities agree on the importance of reaching as many drug injectors as possible and minimizing the circulation of used syringes through aggressive syringe exchange and distribution efforts. Syringes are available around the clock, from pharmacies (18), vending machines, and even police stations. NSPs are now commonplace throughout the world: they are found in the Netherlands, Britain, Switzerland, and Australia and are present in dozens of cities in Europe.

The first exchanges were established in 1981 in the Netherlands and rapidly expanded in response to the threat of HIV later in the decade. In the United Kingdom, political support for syringe exchange arose in 1986 in response to evidence from Scotland that a shortage of syringes in Edinburgh had facilitated the spread of HIV. More than 200 NSPs now operate in England and two thirds of all drug agencies maintain some syringe distribution or exchange scheme. In Australia, NSPs began in 1986, initially with a pilot program that was illegal. Since 1996, all eight Australian states provide NSPs—distributing 30 million sterile needles and syringes

yearly—about the same number as the United States with 15 times the number of injectors. A British study analyzed data from 103 cities worldwide and found that HIV prevalence increased an average of 8% in cities without needle-syringe exchange programs and declined an average of 18% in cities with NSPs. Applying these results to Australia, the independent evaluators estimated that NSPs have saved (by 2000) 25,000 HIV infections, 21,000 hepatitis C virus (HCV) infections, at least a \$1.6 billion (at 5% annual discount), and (by 2010) 4500 AIDS and 90 HCV deaths (13,19).

NSPs are now commonplace in most large cities in European countries (e.g., Vienna, Madrid, Bologna, Dublin, Oslo) and many smaller European cities. In those major cities where no exchanges have been established, syringes are readily available in pharmacies. NSPs now operate in at least one location in every country of Central and Eastern Europe and Central Asia (except Turkmenistan) as well as in multiple countries of South, Southeast, and East Asia, including Nepal, India, Pakistan, Cambodia, Vietnam, Malaysia, Indonesia, and China (20).

Services at NSPs extend far beyond the distribution of injecting equipment (e.g., alcohol swabs, sharps containers, medicinal ointments, bleach, cookers, cotton, sterile water, and usually condoms) and collection and safe disposal of used paraphernalia. Clients may be shown how to inject less hazardously so as to avoid complications (such as abscesses, septicemia, and endocarditis), and programs often provide access to primary health services and more generic advice on maintaining good health. The ethos is sympathetic to users, and drug injectors are not harassed about their drug use, although they are informed of, and on request referred to, drug-treatment programs and other alternatives (20).

Peer Outreach and Education

Most needle and syringe exchange programs rely on active drug users such as outreach workers and volunteers. Their HIV prevention efforts engage the highest risk groups for OD and new-onset HIV infection—active drug users not in treatment—through street outreach in local drug scenes, drop-in centers, and social service settings. Rather than aiming solely to direct people who use drugs into treatment, they focus most of their energies on minimizing drug-related harms outside formal treatment settings. Some use vans or buses, while others have drop-in centers with support services, but importantly for the most marginal users, they have amenities such as laundries, showers, and food. These organizations typically offer information about safer drug use and safer sex, provide a link between people who use drugs and social and/or medical services, distribute needles and condoms, and prove indispensable in collecting information about recent developments in the drug scene. A growing number of programs are initiated and promoted by current and former drug users and employ users as street outreach workers, program staff, leaders of peer counseling groups, and the like (18,20,21).

NSPs also provide outreach services with mobile vans and pedestrian distributors to homes or street corners. In Zurich and Vienna, sterile syringes can be obtained around the clock via a network of distribution points, a “syringe van,” mobile medical teams, pharmacies, and vending machines (20). In Amsterdam, police stations will provide clean syringes in return for dirty ones. In Liverpool, all pharmacies can sell injecting equipment and, of these, 20 operate free syringe exchanges. In New Zealand, by 1990, 16% of all retail pharmacies were involved in syringe distribution and exchange (19); today that figure is 60%. Automated syringe exchange machines, which deliver a clean syringe when a used one is deposited, can now be found in more than a dozen European and Australian cities (19). These machines are inexpensive and available 24 hours a day. The synergy of NSPs and expanded access to methadone appears to be especially effective in controlling HIV (20), and many countries that averted or controlled epidemics of HIV among IDUs explicitly accepted HR strategies and vigorously implemented both needle-syringe exchange programs and methadone.

OTHER PUBLIC HEALTH STRATEGIES FOR ACTIVE USERS

Overdose Prevention

In many areas of the world, where HIV has been controlled by HR programs, drug OD is the leading cause of death among IDUs. Since the 1990s, a series of OD prevention programs have evolved (21): educational programs using both popular media and underground publications; better emergency medical services and police response systems; and new models for the distribution of injectable narcotic antagonists that reverse OD symptoms (naloxone [Narcan]) as well as cardiopulmonary resuscitation (CPR) training for users’ networks; and formation of groups of victims’ families who work with local authorities to improve response to OD emergencies. These programs are now being piloted and studied in the United Kingdom, Australia, and parts of Europe as well as in U.S. cities including Chicago, Boston, San Francisco, and New York. Naloxone distribution has also been initiated, although on a limited basis, in countries including Tajikistan, China, Kyrgyzstan, Kazakhstan, and Russia. Such programs and many others described below are facilitated by the development of drug user educational organizations and the community involvement of drug users and their advocacy organizations in OD prevention (19–21).

Other Initiatives Supporting Safer Drug Use

HR efforts also seek to reduce the damage resulting from drugs of unknown purity or potency, which is especially important as new drugs (e.g., ecstasy and other club drugs) arrive in a country that has little history of experience with their effects. Some syringe exchanges have taken the initiative and distributed information gained from users about which street drugs are particularly potent or have dangerous adulterants.

This information, however, tends to be erratic, comes only after a hazardous batch of drugs hits the street, and reaches only a small fraction of users. Recognizing this need (and opportunity), Dutch public health authorities identified that one of the greatest dangers associated with the sudden expansion of the “rave scene” (gatherings, often at dance clubs, where young people consume methylenedioxyamphetamine [MDMA] and other stimulants and hallucinogens while dancing to high-energy music) was the sale of adulterated and unexpectedly high-potency drugs. Private organizations, which later gained government support, responded by employing drug analysis units at raves where illicit drugs could be tested prior to consumption. Some cities in Germany (e.g., Berlin and Hanover) maintain silent or unspoken agreements between HR groups and officials, allowing for inconspicuous drug analysis of MDMA and methylenedioxyethylamphetamine (MDE) as well as heroin in the context of “fixer rooms” (see below). Such initiatives resemble the earliest HR attempts in the United States—the Analysis Anonymous drug-testing service in the United States, created by PharmChem Laboratories, Inc. in 1972 to provide a similar service to people who mailed in samples of illicit drugs.

Drug Consumer Groups

Organized and subsidized self-help groups of people who use drugs have played a modest but important role in the formulation and implementation of drug control policies in the Netherlands, Germany, and Australia and have begun to exercise some influence in Switzerland and the United States (22). The Rotterdam “junkie union” began the first Dutch syringe exchange in response to the hepatitis B epidemic. Amsterdam’s junkie union was decisive in initiating free SEPs in 1983 to 1984, after a major pharmacist in the central inner city “copping” area refused to sell needles to people who use drugs. Similar groups in Canberra, Rotterdam, Groningen, Basel, Bern, and Bremen have worked with local public health officials on SEPs and other HR initiatives. Although these groups tend to be short-lived and dependent on one or two highly motivated individuals, they play an important role in articulating the sentiments and perceptions of precisely those citizens who are most affected by local policies. They also offer valuable conduits between local policy makers and underground populations. Most of these groups also produce publications (often comic books or “zines”) targeted at people who use illicit drugs with information on reducing drug-related harms, kicking the habit, and identifying treatment alternatives. Drug user groups also operate throughout Asia and the former Soviet Union, with activities including public protests against limited drug treatment and criminal penalties, information exchanges, and internet posting on daily realities.

Municipal Zoning Policies and Open Drug Scenes (23)

In large part, public opposition to certain forms of drug use relates to their visible presence in the community, that is, to public appearance of intoxicated individuals and to open drug dealing scenes with their associated loitering, violence, and

disorderly conduct. Such open drug scenes are deeply embarrassing to city officials, especially in cities that pride themselves on maintenance of public order, underscoring the need to work collaboratively with local police. Like prostitution, homelessness, and public consumption of alcohol, they challenge community morals, appear disorderly or threatening, and effectively resist all attempts to be suppressed. This is in contrast to alcohol use, which is generally accepted in private spaces (i.e., bars, restaurants, and homes), and public intoxication, which is tolerated under a broad (though declining) range of circumstances, from the office party to public sporting events.

The use of illicit drugs is viewed quite differently when it occurs in public. Although public cannabis use is viewed benignly in many cities, the use and sale of hard drugs is often seen as a sharp challenge to authority. Open drug dealing broadcasts to community residents that law enforcement has been displaced from power. Public consumption—particularly injection—of illicit drugs communicates a clear breakdown of public order and social control. Both attract political attention and create pressure for change that frequently—in the context of prohibition and its enforcement—takes the form of short-term solutions that do little more than conceal drug scenes or shift them to a different locale. In the United States, this spawned the “shooting gallery,” a place where people who use drugs could buy drugs and rent injecting equipment in a locale somewhat insulated from the view of the law, and which played a key role in the explosive growth of HIV in many U.S. cities in the 1980s. European and Australian police and public health officials, aware of this relationship early in the HIV/AIDS epidemic, officially tolerated certain spaces where drug use could be contained and health risk reduced while meeting the social requirements of drug law enforcement.

Under this concept, “open drug scenes” were allowed to develop in a few restricted areas. Early experiences with open scenes were sometimes adverse, as in Zurich’s Platzspitz of the late 1980s and early 1990s, which became notorious as “Needle Park,” but was instructive for later attempts at steering the use of drugs to less publicly offensive locations and for the need to establish many small scenes rather than one central “supermarket.” In Rotterdam, police briefly allowed and supervised an open drug scene next to the central railway station, known as “Platform Zero,” with syringe exchange services and a mobile methadone unit readily available. In Frankfurt, open heroin scenes emerged during the 1970s and 1980s in two adjacent parks, the Gallusanlage and the Taunusanlage, when top police officials decided that their decade-long efforts to suppress the local drug scenes had failed to halt their growth and merely shifted them from one neighborhood to another. Local authorities in Frankfurt established three crisis centers in the vicinity of the drug scenes, stationed a mobile ambulance to provide syringe exchange services and emergency medical assistance, offered first aid courses, and established a separate bus to provide services for drug users in commercial sex work. These initiatives were combined with efforts to lure users away from the exclusive involvement in the drug scene by providing night lodgings, daytime residences, and methadone treatment centers in neighborhoods removed

from the city center. In conjunction with these measures, the open drug scene in the park was shut down in late 1992, and the new policies that grew from that experience are believed to be responsible for significantly reducing the number of homeless people who use drugs, drug-related robberies, and drug-related deaths in the city (23).

“Safe Spaces” for People Who Use Drugs (24)

Low-threshold facilities known as “contact centers,” “street rooms,” “health rooms,” “harm reduction centers,” “supervised consumption facilities,” and “safe injecting rooms,” where active users congregate, are now officially tolerated (and sometimes even government sponsored) in many European cities. Another innovation worth noting is the “apartment dealer” arrangement, adopted informally in Rotterdam, whereby police and prosecutors refrain from arresting and prosecuting apartment dealers—including sellers of heroin and cocaine—as long as they do not cause problems for their neighbors. This arrangement is viewed as part and parcel of broader “safe neighborhood” plans in which police and residents collaborate to keep neighborhoods safe, clean, and free of nuisances. Both toleration and regulation of open drug scenes and safe spaces for people who use drugs represent forms of informal zoning controls similar to those long employed in Europe and Asia to regulate commercial sex work.

Safe injecting facilities challenge norms but are regarded as preferable to the two most likely alternatives: open injection of illicit drugs in public places, which is widely regarded as distasteful and unsettling to most urban residents, or consumption of drugs in unsanctioned “shooting galleries,” which are often dirty, sometimes violent, frequently controlled by drug dealers, and where needle sharing is often the norm. A few “fixing rooms” were quietly tolerated within some drug agencies in England during the 1960s, and during the late 1970s a number of “drug cafes” for heroin users were established in Amsterdam, but they were later shut down when drug dealers effectively displaced social workers from control of the daily course of events. In Switzerland, the first Gassenzimmer (“fixer rooms”) were established by private organizations in Bern and Basel during the late 1980s. By late 1993, eight were in operation, with most under the direct supervision of city officials: two in Bern, two in Basel, one in Lucerne (in City Hall), and three in Zurich. An evaluation of the three Gassenzimmers in Zurich after their first year of operation concluded that they were effective in reducing the transmission of HIV and the risk of OD. Three “injection rooms” have been in place in Frankfurt since 1995. By 2003, over 60 supervised consumption facilities were operating in Europe, and the number of sites and countries involved has continued to expand.

Building on the European experiences, medically supervised safer injection facilities (SIFs) have opened as scientific research pilots in Sydney, Australia (25), and Vancouver, Canada (26). In 2001, local health authorities in Sydney, Australia, opened a “medically supervised injecting centre” (MISC), after a long debate successfully gained community support (25). The MISC is linked to a well-established full service Harm Reduction (HR) program (the Kirketon Road

Centre) located in the Kings Cross area of the city—well known for its open drug and sex scene—the site now sees about 200 drug injectors per day i.e. > 70,000/year and “aims to reduce harm associated with illicit drug use by supervising injecting episodes that might otherwise occur in less safe circumstances such as public places or alone and has documented its capacity to “reduce the risk of morbidity and mortality associated with drug ODs and transmission of blood-borne infections” and getting active users more “engaged with the health and social welfare system.” The trial of the Sydney MISC has now been successfully concluded and the program is set to become a regular part of the states public health service apparatus.

In Canada, a supervised injection facility known as “In-site” was opened in Vancouver in 2003 (Fig. 55.2), although its continued operation is under threat from Canada’s current federal government. The federal government has (so far) unsuccessfully appealed a 2008 constitutional decision (25) that confirmed the facility’s right to operate. These are places where drug users can meet, pick up injection equipment and condoms, and obtain simple medical care, advice, help with domestic problems, access a public washroom or laundry, and sometimes a place to sleep. Most facilities allow users to remain anonymous, many have qualified medical staff present, and some provide a “fixer room” where drug injectors can consume illicit drugs in a relatively hygienic environment.

Both of these programs have been subjected to very close oversight and rigorous evaluations. The results published in leading peer-reviewed medical and public health journals (25,26) have demonstrated a range of positive impacts—including reduction in HIV risk behavior, successful intervention in the event of OD, and improved public order around the site. Drug users attending a supervised site have the opportunity for regular contact with health care professionals and addiction counselors that leads to increased admissions to addiction treatment. Drug-related crime did not increase around the SIF. Of note, following the opening of the Vancouver site, no detrimental impact was found on IDUs enrolled in a preexisting cohort study in terms of prolonging their use of drugs or increasing relapse for those who had stopped. Modeling the impact of the Vancouver site based on published studies suggests that 2 to 12 OD deaths and over 100 HIV infections are prevented annually through the operation of the supervised injecting site, leading to health care savings of \$2 million per year (25).

ADDICTION TREATMENT AS HARM REDUCTION

HR views problematic drug use (including self destructive chronic use and valid diagnoses of addiction) as only one possible outcome of even significant levels of drug use. Vaillant and Zinberg (26) have noted that the majority of drug users (of tobacco, opiates, and alcohol) do not develop serious problems from that use—modulating its level and generally reducing and terminating use over time. They argue further that most who do develop problems manage to resolve them without formal treatment, especially many cigarette smokers and heavy alcohol drinkers—although this appears to be less so of heavy stimulant use. However, many illicit drug users living under punitive prohibition regimes also face serious psychologic, social, and medical problems (as well as serious legal difficulties) that are attributable to the criminalization of their addictions, for example, the destabilizing effects of recurrent criminal justice involvement (especially multiple arrests and prison recidivism) on their ability to reestablish stable homes and family ties. Accordingly, much treatment of addiction often represents “tertiary prevention,” occurring many years after initiation of use, and compounded by its neglect and mistreatment, as well as the adverse effects of criminalization of users, their families, and their communities. In many countries, long involuntary internment for drug dependence is a common practice (1–8).

In the HR model, the pathologies of addiction and challenges of drug treatment are seen as inseparable from prohibitionist drug policies, and these policies’ collateral damages must be addressed in all treatment and HR programs (27). The recent advent of HR-oriented drug treatment (28) also acknowledges a different set of goals than those of conventional treatment (i.e., total abstinence) and may even include the wishes of the clients to continue some forms of safer drug use at lower levels (i.e., “controlled drug use”) and certainly not to make continued drug use a basis of termination of treatment. “Low-threshold” treatment models may also address

users other real and perceived needs (e.g., for health care, housing, and legal assistance) as pathways to engaging clients, placing only minimal demands regarding cessation of all drugs. A pillar of HR approaches to drug treatment for many years has been for the medical prescriptions of “substitution” medications, especially of opiates, on a long-term basis as “maintenance treatment,” which has now become an integral part of HR policy and practice worldwide.

Drug Substitution and Maintenance Treatment

Drug substitution, drug replacement therapies, and maintenance treatment are an essential part of HR strategies in many countries (see also Chapters 28 and 29 on methadone and buprenorphine treatment). But substitution treatments have a long and complex history (28,29). Despite strong medical and public health evidence for their effectiveness, these approaches still encounter opposition in many societies that consider them to violate the goal of a “drug-free society.” A crucial factor is the right of physicians to prescribe maintenance drugs for their addicted patients. Drug maintenance was first pioneered in Great Britain (where doctors have long had the authority to gradually detoxify or maintain addicts by prescribing their drugs of choice). When AIDS struck in the mid-1980s, Britain was able to rapidly increase prescription of maintenance medications—mostly oral methadone (which was increased 10-fold) accompanied by other HR efforts, including opening over 100 needle and syringe exchanges within medical and public health services. This and similar HR approaches have effectively contained the HIV epidemic in the United Kingdom, Australia, and New Zealand—where HIV rates among drug injectors have remained at low levels for 20 years or more.

But in the United States, where morphine was prescribed to more than 10,000 chronic dependent users from 1900 to 1925, the drug maintenance approach was soon overwhelmed by the militant temperance movement and by federal and state drug enforcement agents hostile to opiate maintenance. By 1925, organized medicine and the U.S. courts had rejected drug maintenance, largely silenced its proponents, and led American medicine to all but abandon not only the maintenance treatment but also the entire field of addiction medicine—conceding the problem to law enforcement (28,29). It was not until the early 1960s, with the pioneering work of Drs. Vincent Dole and Marie Nyswander (see chapter 28) that the concept of addiction treatment using the prescription of maintenance drugs was reintroduced in the United States (30,31).

Methadone

There are hundreds of studies of the effects and outcomes of methadone maintenance treatment (MMT) (see Chapter 28). Positive outcomes include the complete elimination of or large reductions in daily heroin use and injecting, reductions in criminal behavior and arrests, reductions in death rates, and increased employment (32–34). The public health significance of MMT soon became apparent as the rate of HIV infection among those in MMT was found to be inversely pro-

portional to the time in treatment. Thus, although 20% to 30% of New York City's injectors were HIV positive by 1995, those in MMT since 1978 were virtually free of the virus.

Despite this result and the overwhelmingly positive findings for MMT (most of them initially from American studies), the United States has fallen far behind other Western nations when it comes to its effective utilization. For three decades methadone was the most tightly regulated drug in the U.S. pharmacopoeia (35) and could only be dispensed in licensed "programs," subject to strict federal and state regulations governing matters typically left to the discretion of physicians. This has had a chilling effect on the normalization and accessibility of MMT programs (MMTPS) in America.

Although it is acknowledged that many patients do not totally cease drug use while receiving MMT, most programs have not integrated HR interventions that recognize that reality, for example, are providing access to sterile syringes, OD prevention, or education on safer drug use. Recently some US MMT programs do provide access to sterile syringes via needle and syringe programs and pharmacies, and provide safe syringe disposal on-site. But in the United States, many more remain "patient unfriendly," expelling clients who use drugs illegally or who otherwise violate program requirements (e.g., failure to attend "counseling sessions"). In addition, the large public MMTPs with hundreds of patients (a scale dictated by regulatory and cost considerations) are no one's favorite neighbor, and the NIMBY (Not In My Back Yard) phenomenon serves to further constrict access to care. Accordingly, the United States has failed to expand MMT to the scale required to effectively respond to the needs of the estimated 1 million heroin-dependent individuals, plus 2 to 3 million additional opioid-dependent Americans who have received prescribed opiate analgesics, which they may, in some cases, misuse or sell (30,34).

Furthermore, the therapeutic efficacy of many MMTPs in the United States has eroded as standards of clinical practice have deteriorated (31). There is widespread ignorance of the proper use of this treatment and often hostility toward methadone among many of those working in MMTPs. Problems include administration of inadequate doses and a misguided orientation toward abstinence, not just from illegal drugs but also from methadone itself, as a universal treatment goal. The failure to relax counterproductive regulatory constraints and the continued punitive posture of some local drug enforcement authorities regarding MMT have taken a once successful modality of addiction treatment and driven it to the margins of American medical and public health practice (30–34).

Despite methadone's proven clinical effectiveness over millions of patient-years of positive experience using this treatment, punitive prohibitionist attitudes and policies have had a huge adverse impact on public health by restricting access to this treatment, in the United States and elsewhere (30). One striking example of this failure is AIDS, where the epidemic continues to infect over 20,000 injecting drug users and their sex partners each year in the United States (34). Only 20% of the 1 million heroin-dependent individuals, and an even smaller portion of the growing prescription opioid-dependent population, receive maintenance treatment. In many American states, methadone

regulations conflict with sound medical and public health practices regarding dosage ceilings (often self-imposed by the programs), prohibition of take-home medication, and arbitrary restrictions on the number of methadone clinics allowed within a certain area (e.g., Tennessee allows no more than one clinic within a 100-mile radius). As of 2009, five states—Idaho, Mississippi, Montana, North Dakota, and South Dakota—still had no methadone-maintenance programs. In California and elsewhere, privatization and limitations on the duration of publicly funded treatment have raised barriers to MMT.

There have been many efforts to correct these problems in the United States, but they continue largely unabated today (35). In 1996, the Institute of Medicine issued a series of studies and a report calling for the expansion and modification of methadone treatment, and in 1997, a National Institutes of Health (NIH) Consensus Conference reasserted the conceptualization of opiate addiction as a medical disorder. It called for "effective medical treatment of opiate addiction" through the reduction of "misperceptions and stigma," improved medical training, assurance of greater access to methadone, and the reduction of "unnecessary regulations" that restrict the availability and quality of methadone treatment. In 2000, the Drug Abuse Treatment Act (DATA) was passed by Congress, expanding the possibilities of employing new models of opioid-maintenance treatment with buprenorphine—an alternative to methadone. Buprenorphine and a buprenorphine–naloxone combination via community-based physicians became available in the United States in 2003.

Buprenorphine's safety and efficacy are well established (38), but it remains underutilized due to slow uptake of prescribing among office-based physicians. While current buprenorphine treatment guidelines advance a treatment model substantially less intense than that of conventional methadone maintenance, they still go far beyond the level of care and monitoring standard in treating other chronic conditions such as diabetes, depression, or HIV/AIDS. As of 2008, 13,000 physicians had been certified (following completion of the federally required training) to prescribe buprenorphine, yet only an estimated 67% were actually treating patients. Even among addiction treatment specialists, just over half (58%) of those with waivers to prescribe it had done so in the first year after its approval. Important barriers identified by practitioners include the guidelines' recommendations regarding three components of treatment "intensity": in-clinic (observed) induction, frequent visits, and the ability to provide ancillary behavioral health services. Though covered by many insurance providers, buprenorphine itself is priced at several times the (very low) price of methadone and results in outpatient buprenorphine costs (in private practice) now comparable to "full service" methadone clinic treatment (\$3000 to \$5000 per year).

International Developments in Maintenance Treatment

Despite the lags in treatment availability in the United States (where many drug-free treatment advocates remain hostile to medication-assisted treatment), public health and medical

authorities in a number of other countries have greatly expanding access to substitution treatment. They have also altered their intervention strategies to accommodate a greater number and wider spectrum of patients. Much of this expansion has been achieved through the use of primary care practitioners to prescribe opioid-agonist medication within office-based practices. Today in Europe, Canada, and the Asian-Pacific Region, more than 250,000 patients are prescribed opioids by a general practitioner in health clinic settings (38,39), and this model of addiction medicine is gaining popularity and application worldwide. But despite the adoption of buprenorphine for patients in the United States, except for some “medical maintenance” experiments, American pharmacists and doctors in general medical practice still are barred by federal regulations from playing any role in methadone maintenance.

With the growing international awareness of AIDS risks and the potential role of maintenance treatment in limiting its spread, most countries in the developed world initiated or have greatly expanded maintenance treatment. Australia increased its MMT capacity 10-fold between 1985 and 1994. In Germany, methadone was outlawed as late as 1987, but today more than 70,000 patients receive it (the great majority from generalist, community-based practitioners) without other comorbidities being a requirement. In France, in 1995, there were only 52 patients who were maintained on methadone in the entire country; a decade later, approximately 10,000 patients were being treated with methadone, and an additional 80,000 were prescribed buprenorphine through general practitioners (36,38).

In combination with NSPs, opiate substitution treatments have contained and reduced new HIV infections among injecting drug users in many countries. While availability remains minimal in Eastern Europe and Central Asia, several Asian countries—including Iran, China, and Malaysia—have moved beyond pilots and are scaling up services. Outside the United States, some of methadone’s expansion has been achieved within “mainstream” medical practice (39). Thousands of general practitioners in community-based practices throughout Europe, Australia, New Zealand, and Canada are involved in methadone maintenance. In Belgium, Germany, France, Australia, Canada, Ireland, Scotland, and Croatia, this is the principal means of methadone distribution. In the Netherlands and, to a lesser extent, Switzerland, methadone is available in public and private health clinics and other government facilities. In Copenhagen, Amsterdam, and Rome, methadone is available at police stations for drug users who have been arrested.

Low-Threshold Maintenance

Low-threshold maintenance treatment does not “require” ancillary services (such as counseling) nor does it make retention in treatment contingent upon total abstinence from heroin and/or other drugs. Accordingly, it can accommodate a far broader segment of addicts in the community for a longer period of time. These programs frequently provide fewer ancillary services, although referrals are usually offered to relevant sources available to the general population. Many do not demand regular attendance, urine tests, or regular counseling contacts, all

of which are standard requirements in U.S. methadone clinics. Support for low-threshold programs is based on their relatively low cost; the relative ease of establishment on a large scale; their proven success in establishing contact with people who use illicit drugs but are put off by programs with more rigorous requirements; and the fact that, as expected, their patients have been shown to fare better than drug users not enrolled in any programs (39). The Dutch were pioneers in deploying low-threshold “methadone buses”—mobile facilities that carry previously prescribed doses, free of charge, for a list of 100 or more patients who may meet the bus at any one of several predesignated locations daily, an innovation that has been adopted in Barcelona and, in the United States, in Baltimore and Boston. Low-threshold programs also now operate in several cities in Europe and Australia, and in Hong Kong.

Methadone in Correctional Settings (see also Chapter 65)

The injection of heroin within correctional facilities has been documented in many countries and continues to exist, notwithstanding vigorous attempts to deter and detect the importation of drugs and injecting equipment into these facilities. Although episodes of drug injecting inside these facilities generally are far less frequent than in the community, adverse consequences (including HIV infection) are well documented. The use of methadone in jails and prisons—in the United States—has generally been restricted to brief detoxification programs, although there are exceptions. For over 25 years, New York City’s Rikers Island jail has operated a methadone-maintenance program with 3000 annual admissions, and there are now small pilot prison and jail programs in Puerto Rico and New Mexico. However, elsewhere in the United States, there is still no methadone maintenance for the 2 million longer-term state and federal inmates. By contrast, as of January 2008, methadone maintenance has been implemented in prisons in at least 29 countries or territories, with the proportion of all prisoners in care ranging from less than 1% to over 14% (39). In Canada, any methadone maintenance patient who is incarcerated is maintained on methadone throughout their time in custody and many heroin users are started on methadone during a period of federal incarceration. In Eastern Europe and Central Asia, Moldova and Kyrgyzstan now offer methadone maintenance in prison, and the Republic of Georgia has initiated a short course of methadone-to-detoxification program in a pretrial detention facility.

Other Drug Substitution Initiatives

Despite its unparalleled effectiveness, some who receive oral methadone-maintenance treatment either drop out or continue to use illicit drugs in addition to the prescribed medication. Stimulated by the need to control the spread of HIV/AIDS, maintenance treatment is entering a new phase of clinical experimentation. Accordingly, several countries have expanded drug-maintenance programs and practices beyond oral methadone and sublingual buprenorphine to

include prescribed injectable methadone and, most recently, injectable heroin, which many considered revolutionary. But, in fact, this approach has a long history (40,41).

In the United States from 1919 to 1923, several morphine- and heroin-assisted therapy clinics were in operation until their termination by the government (29). British physicians prescribed injectable opiates early in the 20th century and in a controlled trial in the 1970s; a small morphine-maintenance program was initiated in 1983 in the Netherlands and was deemed modestly successful in improving the health and functioning of most of the addicts and in reducing their involvement in criminal activities. Another program, operated by the Municipal Health Department in Amsterdam, prescribed injectable methadone and dextromoramide tartrate (Palfium)—an opioid that can be taken orally—to a group of long-term heavy opioid users, the latter medication did not gain user acceptance and was difficult to administer. In Italy during the late 1970s, a number of physicians dissatisfied with the quality of care for heroin addicts began providing addicts with injectable morphine on an outpatient basis. The Italian government legalized this prescribing experiment in 1980, but approval was abruptly withdrawn a few years later. No comprehensive evaluation of the program was ever conducted, although it is estimated that as many as 4000 patients were participating in 1982. Years earlier, in Canada, in 1972, the LeDain Commission recommended the implementation of a heroin prescription trial for addicts who could not be attracted into conventional forms of opioid addiction treatment.

In Austria, physicians have always been free to prescribe any legally available drug to addicts. In 1993, in addition to widespread availability of oral methadone, approximately a dozen addicts were receiving prescriptions for injectable morphine or methadone, and many others had prescriptions for codeine and other synthetic opioids. One study substituted oral morphine sulfate for methadone and found the morphine preferable for some patients who experienced negative methadone side effects. In Australia, until the mid-1950s, physicians could prescribe maintenance doses of opioids, principally morphine, and did so for a small numbers of white, middle-class patients and to aging Chinese opium smokers. In Queensland, a small injectable methadone program has operated for decades.

More flexible prescribing practices also emerged in Edinburgh in 1988, a few years after authorities realized that the prevalence of HIV infection (more than 50%) among local heroin users was the highest in the United Kingdom. Community-based physicians responded with more liberal prescription of methadone, as well as oral versions of other drugs in common use (e.g., dihydrocodeine, diazepam). This policy, combined with the rapid expansion of needle distribution and exchange, is believed to have played an important role in reducing needle use and sharing, the rate of new HIV infections, and drug-related criminality. Experimentation with oral opioids other than methadone includes the use of long-acting codeine (dihydrocodeine) in Germany (1), and ethylmorphine in the Czech Republic. Even where there is ready access to methadone, however, it is clearly desirable that med-

ical practitioners have the freedom to prescribe different opioids for different patients, depending on circumstances, and that researchers be able to responsibly try to identify more effective treatments without excessive constraints from policy makers.

During the 1970s, numerous proposals to prescribe heroin for addiction treatment were advanced in the United States: as a lure and stepping-stone to oral methadone maintenance; as a supplement to oral methadone; and as a distinct program to attract heroin addicts unwilling to enter methadone or drug-free treatment programs. Each of these proposals was rejected, mostly on political rather than scientific grounds, and to date, none has been implemented in the United States.

Recent Studies of Heroin-Assisted Treatment (41)

In the 1990s, Switzerland and the Netherlands both initiated major studies examining the effectiveness of heroin prescription in the treatment of opioid addiction. The 3-year multisite Swiss study (1994 to 1997) provided injectable opioids to more than 1000 opioid-dependent individuals who had a history of long-term heroin injection and multiple unsuccessful treatment attempts. This naturalistic cohort study produced important feasibility results for prescribed injection opioid maintenance, with on-site nursing supervision of every dose and a rich package of primary care, mental health treatment, and social services. Benefits demonstrated included retention of 69% of the original sample of chronic, previously treatment-resistant patients in treatment throughout the 18-month study period; more than half of the dropouts switched to other treatments or went drug free, and no deaths occurred as a direct consequence of the opioid drugs prescribed. Analysis of 12-month retention rates showed that among the heroin-assisted treatment group, the retention rate was twice that of either methadone maintenance or residential drug-free treatment samples from other studies in Switzerland. The majority of those leaving heroin-assisted treatment switched to abstinence-based therapy (22%) or methadone maintenance (37%). Importantly, self-reported drug use decreased dramatically during the first 18 months of treatment. The proportion of patients reporting no illicit heroin use increased from 18% at entry to 91% at 6 months and 94% at 18 months.

Participants experienced marked improvements in physical and social health (e.g., social functioning, employment, decrease in illegal activities, housing). The overall death rate was 3%; a rate comparable to other reported death rates in cohorts of regular injection heroin users. The proportion of participants with unstable housing fell from 43% on admission to 21% at 18 months. The rate of unemployment fell from 73% to 45%. Arrests and illegal income generation decreased substantially from 69% to 11%, and there was a greater than 50% reduction in criminal offenses registered by the police over the time of the study. A subsequent cost:benefit analysis of the study suggested that, despite the considerable research and treatment costs of the trial, the outcomes were cost-effective at a ratio of almost 2:1. Furthermore, the

study demonstrated the feasibility of implementing and operating a heroin-assisted treatment program without disorder, misconduct, and/or diversion of heroin supply. In 1997 in two referenda, 71% of the Swiss voted in favor of continuing the trial as an ongoing program for more than 1000 patients. In addition, a World Health Organization (WHO) evaluation of the Swiss study issued a call for continued investigation of the effectiveness of heroin-assisted therapy.

Although evaluated favorably by the WHO commission, there were several methodological limitations identified in the Swiss study, whose observational design and lack of a randomized control group may have allowed uncontrolled biases into the study. However, the Geneva arm of the study used a randomized controlled design and had similar findings to the rest of the national study. In addition, the Swiss program provided extensive psychiatric and social services making it less clear to what degree the heroin-assisted therapy versus the psychosocial interventions caused the positive changes in the program participants. Subsequent studies include a more rigorous selection methodology and controlled design with randomization and are finding similar results.

In response to these limitations, the Dutch government commissioned a multisite randomized control trial of heroin-assisted treatment that began in July 1998. In contrast to the Swiss design, the Dutch conducted two randomized clinical trials, one examining injectable heroin and the other heroin smoked off foil, the most common mode of use in the Netherlands. Both trials had similar designs, consistent outcome measures based on well-validated instruments, and a single a priori definition of both response and effect. Because of the wide availability of maintenance treatment in the Netherlands, the Dutch trials were targeted at patients in methadone-maintenance treatment who continued to use illicit drugs. In both the injection and inhalation trial, the Dutch found significantly greater improvements in drug use, physical and mental health, and social function in those receiving heroin prescription in combination with methadone, than in those randomized to continue on oral methadone alone, with 56% of the heroin-assisted group compared with 31% of the control group meeting response criteria. Despite the higher costs of heroin-assisted treatment, the additional benefits produced savings of € 12,793 per patient per year when compared with methadone maintenance. The Dutch results persuasively demonstrate the effectiveness of heroin-assisted treatment for those whose response to methadone maintenance was deemed poor. However, because of their focus on patients currently on methadone and the very different treatment system in place in the Netherlands, there are limitations on the generalizability of their findings to other localities.

The large German clinical trial of heroin-assisted treatment extended the Dutch results through randomly assigning 1015 patients to heroin-assisted treatment or methadone maintenance and to one of two manualized psychosocial treatments. Participants had long-term heroin injection but were not required to currently be in methadone treatment at study enrollment. Treatment retention was greater in heroin-assisted treatment (67.2%) than methadone maintenance

(40%). Heroin-assisted treatment patients were more likely to meet criteria for improved physical and/or mental health (OR = 1.41; CI = 1.05 to 1.89; $p = 0.023$) and reduced illicit drug use (OR = 1.85; CI = 1.43 to 2.40; $p < 0.001$). Heroin has subsequently been approved as a medication for the treatment of addiction in Switzerland, Germany, and the Netherlands and forms an increasingly integrated component of the comprehensive treatment system. Heroin-assisted treatment studies have also been conducted in Spain and the United Kingdom with efforts ongoing to expand access to this treatment option to other countries in Europe.

Therefore, to investigate heroin-assisted therapy suited to their own settings, Germany and Spain have started heroin trials. In 2008 Canada completed a 3-year randomized controlled clinical trial, the North American Opiate Medication Initiative (NAOMI), and is scheduled to begin another, the Study to Assess Longer-term Opioid Medication Effectiveness (SALOME) in 2011 to test the efficacy of hydromorphone as a treatment option.

Recently, the NAOMI trial of heroin-assisted treatment has been completed in Canada (41). The NAOMI study demonstrated the effectiveness of heroin-assisted treatment in a setting with less comprehensive social services than Western Europe, high rates of unstable housing, and pervasive dependence on cocaine. Heroin-assisted treatment patients were more likely to meet predefined criteria for treatment retention (88.7% vs. 54.1%) and treatment response (67% vs. 47.7%) than those on methadone maintenance. In addition, the inclusion of a small group of participants treated with injection hydromorphone on a double-blind basis suggested that this widely available pain medication might be a viable alternative for countries where prescription of injection heroin as addiction treatment may not be politically feasible.

Prescription of Nonopioid Drugs (42)

Methadone is not a treatment for primary addiction to cocaine, amphetamine, alcohol, and other nonopioid drugs, although use of these drugs by heroin addicts in MMT will often decline over time. But opioid-maintenance programs do not directly address the consumption of nonopioid drugs such as amphetamines and cocaine. This is an increasingly important limitation, given the dramatic growth since the late 1970s in cocaine and multidrug consumption, notably the use of “crack” cocaine and “cocktail” combinations of cocaine and heroin known as “speedballs,” and the recent rise in use of amphetamine-type substances worldwide.

In the United Kingdom, where some physicians reason that legal maintenance with prescribed stimulants is preferable to illegal “maintenance” with illicit drugs, the practice of prescribing stimulants, typically in combination with heroin and/or methadone, has persisted for decades (43). An initiative in Britain to prescribe injectable amphetamine during the amphetamine epidemic of 1968 was deemed a failure, but recent attempts to prescribe oral amphetamine appear more successful. A 3-year study of a small oral amphetamine-prescribing program in Portsmouth found that more than

half of the 26 study participants (all daily amphetamine injectors on entry) stopped injecting and that all decreased their sharing of injecting equipment and used less illicit amphetamine. The program was popular among users: it retained 67% of those who entered for at least 15 months, and of those who dropped out, two had stopped amphetamine use. The program also precipitated an increase in the number of primary amphetamine users presenting to treatment services in the area. Treatment services in Exeter, and a larger program in Cornwall, also achieved substantial drops in illicit amphetamine use and injecting with similar programs of oral amphetamine prescription. Using oral and injectable methadone, oral amphetamine, codeine, and benzodiazepine prescription, and a drug team that integrates needle exchange, prenatal and primary care health services, and mental health care, the Cornwall service exemplifies the flexible HR-oriented approach that is the legacy of the British system. In Australia, researchers demonstrated the feasibility of establishing a clinical trial model for amphetamine maintenance for both cocaine and amphetamine users, and are now planning full trials (42).

DRUG POLICY REFORM AS HARM REDUCTION

Although addiction treatment innovations and expanded access, preventive interventions such as SEPs, environmental changes to make drug use safer, and OD prevention programs play a crucial role in reducing the harms associated with drug use under prohibition, it is changes in drug control policy that offer the best chance for minimizing drug-related harm. By reducing the association of drug use with criminal prosecution, a system that drives drug use and people who use drugs to the most dangerous margins of society, the reform of punitive legal policies can produce clear benefits in the realm of public health and social order. Marijuana, the most widely used illicit drug, has been a special target for such law reform.

Marijuana Policies

In the United States in the 1970s, the movement to decriminalize marijuana was driven by the realization that criminal sanctions created greater harm than marijuana use itself. During the 1970s, 11 states decriminalized marijuana, effectively reducing the punishment for possession of small amounts to sanctions other than imprisonment (43). The impact on marijuana consumption and related problems was negligible, but decriminalization did reduce the number of marijuana arrests and prosecutions. California saved an estimated \$1 billion in the decade following the 1976 Moscone Act decriminalizing marijuana. While total drug arrests increased almost every year throughout the 1980s, arrests for marijuana consistently declined, leading many to suggest the drug had been effectively decriminalized. However, in response to harsher drug policies, marijuana arrests have risen in recent years in the United States (more than 800,000 in 2001). In contrast, significant drug law reform has been undertaken in several European countries and Australia in direct response to perceived

public health needs and humanitarian concerns, starting with de facto decriminalization of marijuana. The case of Dutch regulation of cannabis is the most impressive example of this approach, both for its longevity (more than 35 years) and its apparent success.

Dutch Cannabis Policy and the Separation of Markets (44)

The Netherlands decriminalized cannabis at the national level in 1976, when The Baan Commission, a national drug policy working group, said that drug laws should not be more damaging to an individual than the use of the drug itself and argued that the tendency of some cannabis users to move on to illicit opiate use could be reduced by separating the “soft-drug” and “hard-drug” markets. The national Opium Law was revised to increase penalties for heroin and cocaine trafficking and to cut penalties for the sale and consumption of small amounts of cannabis to misdemeanor offenses. Prosecutorial and police guidelines were also revised to de-emphasize enforcement of cannabis laws. The result was the creation of a relatively normalized, essentially non-criminal, and easily accessible cannabis distribution system in most Dutch cities. A clear-cut distinction was made between people who use drugs and traffickers, and between “hard” illegal drugs, with so-called “unacceptable health risks” (e.g., heroin, cocaine), and cannabis products (44).

The Netherlands permits the retail trade of cannabis products in hundreds of local “coffee shops” under very specific conditions, that is, no advertising, no hard drugs, no disturbance of public order, no sale to minors (under 18 years of age), and strict limits on the amount that can be sold to each customer. Enforcement of these guidelines falls to local “Triangle Committees” composed of the mayor, chief of police, and district attorney of each city. Today, the domestic Dutch market is a well-established commercial structure operating in a “gray economy” with legal tolerance and even some taxation. An estimated half-million regular customers are supplied by many small to midsize local producers plus a number of larger importers. So far there has been little evidence of organized crime in the coffee shop operations, and virtually no violence associated with the domestic trade of cannabis in the Netherlands.

This tolerant policy toward the retail trade and use of cannabis for recreational purposes has had a positive effect in the Netherlands. Cannabis consumption among Dutch teenagers has increased somewhat over the decades (as it has in most other countries), but the rate of regular cannabis users in the Netherlands has remained significantly below U.S. levels. Rates of cocaine and heroin consumption among Dutch citizens are similarly modest, although the relatively high quality and low price of the drugs have attracted “drug tourists” from elsewhere in Europe. Dutch authorities express some concern about organized criminal involvement in wholesale production and sale of cannabis, and they contend with complaints from authorities in neighboring Germany, Belgium, and, lately, France, but by and large, the policy is supported by most of the public, politicians, and law enforcement officials. Cases of problematic cannabis use are rare, but

cannabis users (like all Dutch citizens) who do develop problems have ready access to diverse and comprehensive treatment facilities based in the public health sector. Because of international pressures and some local discontent with the rapid growth in coffee shops, the Dutch government has cut back the number of coffee shops (in some cities by as much as 50%) and reduced the amount of cannabis allowed to be purchased at any given time by each customer from 30 to 5 g.

Other governments have also moved toward decriminalization of cannabis. During the 1970s, national drug commissions in many countries recommended cannabis decriminalization. In Australia in 1987 (46), the South Australian government introduced a Cannabis Expiation Notice system that allows individuals apprehended with small quantities of cannabis (up to 100 g) to have their offense discharged, with no record of a criminal conviction, upon payment of a fine. A similar scheme was introduced in the Australian Capital Territory in 1992, and later in two other jurisdictions. Although there has been a small consistent increase in cannabis use since 1985 (prior to the expiation system), an analysis of the first 2 years of the expiation system by the South Australian Office of Crime Statistics found little evidence of any impact on the number or type of people detected using cannabis. Its principal recommendation was that steps be taken to ensure that notice recipients pay their fines promptly to avoid court appearances.

In Switzerland, the Federal High Court decided in 1991 that penalties for dealing cannabis were unduly harsh and needed to be revised, given increasing evidence that the health hazards of cannabis consumption were relatively modest. A number of lower courts in Germany have ruled similarly, finding cannabis prohibition laws in conflict with the German constitution. A German Supreme Court decision in May 1994 removed criminal penalties for possession of small amounts of cannabis, furthering an earlier decision that had given states the option not to prosecute for possession of small amounts of any drug. Although some states (e.g., Bavaria) responded by decreasing the amount necessary to trigger a “large amount” charge, many other state officials announced that they would no longer arrest people for possessing small amounts of any drug. The state of Hessen initiated federal legislation in the Second Chamber (equivalent to the German senate), requesting the legalization of cannabis and its regulation by way of state monopoly. The state of Schleswig-Holstein received consent from the majority of state health ministers to dispense marijuana in pharmacies but withdrew in the face of opposition from the Federal Agency in Berlin. Spain decriminalized private use of cannabis in 1983 but has since tightened its laws. Italy decriminalized possession of “moderate amounts for personal use” of any drug in 1975, toughened penalties in 1990, and then abolished criminal sanctions for illicit drug use altogether in April 1993. Although no government has advocated outright repeal of cannabis prohibition, an increasing number now favors decriminalization.

Most recently, Canada, Australia, and the United Kingdom have taken significant steps toward the decriminalization of cannabis (46). Although Canada’s federal Liberal government introduced successive bills between 2003 and 2005 to

remove the possibility of incarceration for possession or production of small quantities of cannabis, it backed away from calling the measure “decriminalization,” and none of the bills became law. The Conservative Party that won the 2006 Canadian federal election, and that has governed since, remains strongly opposed to decriminalizing cannabis. In 2007, it introduced a bill to increase penalties for some cannabis offenses, including provisions for mandatory minimum prison terms in some situations. That bill died when an election was called, but the re-elected government introduced a nearly identical bill in 2009. At the time of this writing, the bill had been passed by Canada’s House of Commons but not by the Senate, which was undertaking a thorough, and often critical, review of the bill.

Medical Marijuana—A Special Case (47)

Many patients have found marijuana to be a relatively safe, well-tolerated, and rapidly effective way to deal with some medical conditions: reducing nausea in chemotherapy; intraocular pressure in glaucoma; muscle spasms and chronic pain; stimulating appetite; relieving the symptoms of HIV/AIDS; cancer and chemotherapy; multiple sclerosis; and epilepsy. The hostility to this use of marijuana (especially by federal officials in the United States, where the campaign for medical marijuana has been most vigorous) has made it almost impossible to gain support for rigorous research to confirm (or disprove) these widespread beliefs. Polls indicate that a majority of Americans believe marijuana should be medically available, and numerous organizations, including the American Public Health Association and the American Federation of Scientists, have issued resolutions in support of medical marijuana. In 1988, a Drug Enforcement Administration administrative law judge ruled that marijuana should be moved to Schedule II, making it available for medical purposes, but the agency refused to comply. Thus, marijuana remains a Schedule I drug, meaning that in the eyes of the U.S. government, it has no legitimate medical use, and further research on its medical properties has been stifled. Hundreds of individuals received marijuana for medical purposes in the 1980s, but this federal program was discontinued, and all but eight of the original recipients have either died or been cut from the program.

In the meantime, there have been moves to provide marijuana to medical patients through “cannabis buyers’ clubs,” which are illegal but often tolerated by local police. Buyers’ clubs, which supply marijuana to patients who have a doctor’s prescription for marijuana, have sprung up across the country in recent years. Many of the clubs are private, underground operations, but others have achieved national attention. Many of those who grow marijuana for such clubs have been arrested and prosecuted. Additionally, antiparaphernalia laws ban the use, possession, and sale of items used to consume illegal substances. Included in those laws are vaporizers, heating devices that deliver the medically useful components of marijuana without burning the plant material. Because the smoking of any organic substance can deposit tars and other harmful substances in the lungs, vaporizers are extremely useful tools for medical patients.

Nonetheless, an increasing number of doctors and patients view marijuana as a legitimate medicine that can be effective in reducing the nausea associated with cancer chemotherapy, stimulating appetite for AIDS patients suffering from wasting syndrome, and reducing the intraocular pressure of glaucoma. It is also commonly used as an anticonvulsant, muscle relaxant, and mild pain reliever for menstrual cramps and certain types of chronic pain. In May 2001, the U.S. Supreme Court ruled that so-called medical marijuana “buyers’ clubs,” which operate legally under California state law, cannot use a “medical necessity” defense to federal marijuana charges. Such clubs, which offer varying potencies and varieties of marijuana to patients certified to use it under California law, have experienced continual harassment from federal authorities since that ruling, and others have shut down preemptively, effectively depriving thousands of patients of their medicine. But the issue remains open in the United States: in an important ruling in 2003, the U.S. Supreme Court upheld a lower court’s opinion that the federal Drug Enforcement Agency could not continue to threaten doctors who advised their patients that marijuana might be beneficial with loss of licensure.

Despite decades of prosecution of marijuana users in the United States (e.g., 300,000 in prison; 800,000 arrests in 2000), no state ballot initiative dealing only with medical marijuana has ever failed, and an October 2002 *Time* magazine poll showed that 80% of the American public supports legal access to medical marijuana. Since 1996, a majority of voters in Alaska, Arizona, California, Colorado, the District of Columbia, Maine, Nevada, Oregon, and Washington have voted in favor of ballot initiatives to remove criminal penalties for seriously ill people who grow or possess medical marijuana. Hawaii has passed a medical marijuana bill through its state legislature. Nonetheless, the federal government continues to fight against state laws that accept the medical value of marijuana.

Medical Marijuana in Canada (45)

Although Canada’s Controlled Drugs and Substances Act (CDSA), the central law on illegal drugs, prohibits possession, cultivation, trafficking, and importing and exporting of marijuana, the Minister of Health is authorized to grant exemptions from the Act for a medical or scientific purpose, or if it would be otherwise in the public interest. In 1997, a small

Box 55.1 Harm Reduction in China—A National Case Study

China faces the dual challenge of drug use and HIV/AIDS. Proximity to the Golden Triangle and the Golden Crescent contributes to trafficking and ready availability of heroin to residents along drug trafficking routes. Heroin is the main illicit drug used in China, with amphetamine and polydrug use on the rise. Needle sharing has been the major transmission route of HIV in China, since the first indigenous outbreak was identified in 1989 among IDUs in Yunnan Province in southwestern China (48). China reported in 2008 that HIV/AIDS was the nation’s leading infectious disease killer, continuing its spread among IDUs. Nearly half of the new HIV cases in 2007 were transmitted through IDU (49). This recent history serves as the baseline of a case study of China that will teach us much about the outcome of HR efforts in such a large and important society. Recognizing the efficacy of HR strategies, the Chinese government has committed significant resources and energy to addressing these epidemics (50). As a result, they have built HR services at an unprecedented rate, with over 600 methadone programs and 900 needle syringe programs (NSPs).

In 2004, the first eight MMT clinics opened in five provinces (Guangxi, Guizhou, Sichuan, Yunnan, and Zhejiang) (51). By the end of 2006, there were 320 MMT clinics operating in 22 provinces. By the end of 2008, over 600 MMT clinics were operating in China; 178,684 heroin users had cumulatively been served, and 93,773 clients were being served (52). An expansion of NSPs is underway despite their common perception as “condoning and encouraging” drug use. Nonetheless, government officials have agreed that

NSPs should be the work of health professionals and non-government organizations (NGOs), not that of law enforcement agencies. In 2004, China had 93 needle-exchange service points. By 2006, this number had increased to 790, of which 392 were supported by the government. By the end of 2008, there are 897 NSPs operating monthly and serving 360,000 IDUs, on average, each month (52).

The government has also scaled up HIV testing throughout the country; there were 6077 free HIV testing sites in operation by the end of 2008 (52). Expansion of these services has been concentrated in venues with a high prevalence of HIV and thus has become increasingly available to drug users. However, uptake of these services has been disappointingly low. Nearly 70% of HIV-infected adults in China are unaware of their infection status, despite outreach efforts. Barriers, for example, stigma and discrimination, contribute to both low testing rates and low utilization of HIV services, especially among IDUs.

China is a country with such a vast population and highly autonomous provincial governments, a large population of drug users confined in geographically disparate rural areas, and only a recent recognition of the efficacy of HR. Thus, the implementation of HR programs, while massive in quantity, needs to mature in quality. Programs are still unevenly and inconsistently conducted nationwide. Mere access to HR services is insufficient to ensure adequate uptake, adherence, and impact. So scaling up the response to drug use and HIV remains an enormous challenge, if HR services are to be effective and reach a majority of drug users such that their public health impact is assured.

group of Ottawa lawyers and physicians applied unsuccessfully on behalf of an AIDS patient for medical access to cannabis. However, the minister introduced a narrow exemption from the Act for medical cannabis in 1999, and by May 2002, 658 exemptions had been granted under this program. Access to medical marijuana was initially permitted to a small number of applicants in the late 1990s through such a ministerial exemption, and formal regulations followed in 2001, driven by a successful constitutional challenge to the marijuana laws. As of June 2009, 4029 individuals were authorized to possess marijuana under the regulations (45). The Canadian government is now exploring ways to permit both the cultivation and possession of cannabis for therapeutic reasons.

CONCLUSIONS

The HR paradigm has made great progress during the last decade. A public health conception of drug use, the foundation of HR, is now generally far better understood than previously, although often still willfully misinterpreted by its opponents. Nonetheless, in an increasing number of countries and regions of the world, HR is now regarded as mainstream drug policy (e.g., virtually throughout all countries of Western Europe), while zero tolerance supporters are growing ever more isolated and marginalized as their failure and its high cost become evident. This sea change is driven by genuine national concerns, including a new interest in the implications of drug addiction, AIDS, and the huge illicit drug markets for human rights and the potent effects of HIV epidemics on regional and global security (54), fueled by high levels of opium production in Afghanistan (destined for European markets), a growing drug trade in China, and a vicious power struggle over the U.S. drug markets now occurring in Mexico (53).

Several countries have now also explicitly endorsed HR as national drug policy, including the United Kingdom, the Netherlands, Australia, Canada (until a recent change in the federal government), France, Switzerland, Spain, Germany, New Zealand, many countries in Central and Eastern Europe, Iran, and several countries in Asia (Nepal, Vietnam, Indonesia, and China) and South America (Brazil and Argentina). HR has also been endorsed in recent years by an increasing number of United Nations agencies (including WHO and UNAIDS) and by organizations such as the International Red Cross.

Although HR programs continue to spread, their availability and scale are still well below levels required to achieve the public health goals that we should be setting in the drugs area. Thus, zero tolerance and the basic premises of the “War on Drugs” remains the stated drug policy in the United States. And while the US is the most important and most influential opponent to HR, it is not the only country to bitterly oppose these policies. Other countries that oppose HR policies are Russia, Japan, and Sweden, which play vocal roles in setting UN drug policies—with a Russian chosen in 2010 to head the powerful UNODC. In Canada, the federal government had a national drug strategy since the late 1980s that—at least on paper—identified drug use as primarily a health rather than an enforcement issue. But now, it has moved away from this

philosophy with the election of a new government that promises more punitive drug legislation, has aborted the NAOMI heroin trial and tried to reverse Vancouver’s successful supervised injection facility INSITE, although (as of this writing) this has been held off by court rulings.

But the surge in interest in HR around the world in the last two decades has been most powerfully stimulated by the urgent need, first recognized in the early 1980s, to control HIV among people who use drugs. With 25 million deaths to date, 42 million people currently living with HIV infection, and HIV estimated to infect additional millions each year, HIV/AIDS is now the most serious threat to global public health since the Black Death and is widely seen as a threat to national security. In most regions of the world, drug injecting has played a central role in the ignition of HIV outbreaks that rapidly made the transition from small, localized epidemics to extensive, generalized regional ones, buttressed by sexual transmission and amplified by widespread unsterile medical injections and unsafe blood transfusions throughout the developing world (53). Violent drug markets and drug injection are now emerging in sub-Saharan Africa (54) and undoubtedly will open a new chapter in the monstrous epidemic that now grips that region, challenging both the theory and practice of HR in unprecedented ways.

Thus, although the growth in support for new drug policies and programs is gratifying, HIV continues to spread faster than HR programs are being established or expanded to meet the need. The struggles to spread HR in the developing world (with its majority of the world’s population) are especially important, and acceptance of HR in principle is insufficient to avert disaster. For example, although HR programs were introduced early enough in Nepal, they failed to avert an HIV epidemic there because they were not expanded rapidly enough. And the growing popular and professional commitment to HR in many countries is often thwarted by a strong national commitment to traditional control methods and a culture of corruption that surrounds all illicit drug markets: the more intense the repressive drug policies, the more they undermine effective HR.

Nonetheless, there continues to be strong growth in HR institutions worldwide. By 2010, there had been 21 annual meetings of the International Conference on the Reduction of Drug-Related Harm, the leading international meeting on drug policies and innovations in the field. These conferences, attracting a growing body of delegates from an increasing number of countries, have now been held in developing and transitional countries several times. The International Harm Reduction Association (IHRA) was established in 1996 and has grown rapidly. It now has a constitution, elects new members to its Executive Council, has a vigorous publication division (producing a hard copy journal, electronic newsletter, and Web site), and held its 21st annual meeting in Liverpool, where it first met in 1990. Increasingly, the IHRA plays an active advocacy role for HR with other organizations and within the UN system and is expanding its scope beyond illicit drugs to alcohol and tobaccos. The International Harm Reduction Development Program was established in 1995 as part of the Open Society Institute (OSI) and Soros Foundation. It operates in Eastern Europe and Asia to protect the

health and human rights of drug users and has supported the promotion of HR policies and programs in more than 26 countries. The Centre for Harm Reduction (CHR) in Australia was established in 2001 to conduct research and disseminate research findings, provide training, and advocate for HR. Six regional HR networks (including Eurasia, Asia, Latin America, North America, the Caribbean, and Africa) have been established with significant international support. There is even an online peer review academic journal dedicated to the subject (www.HarmReductionJournal.com) devoted to HR studies. These developments represent a growing trend toward the building of HR institutions throughout the world and the normalization of HR practices. Although HR continues to face formidable opposition, it is now clear that this new approach to policy and practice, based on public health and human rights, is becoming the mainstream approach for dealing with the global nature and broad implications of illicit drugs and their many consequences.

Paul F. Engelhart ■ Cindy Taormina

THE VALUE OF WORK IN THE RECOVERY PROCESS

Some of us may be uncomfortable with Thomas Carlyle's poetic assertion that "the whole soul of man is composed into a kind of harmony the instant he sets himself to work" (1). Still, we cannot deny the significant role that work can play, both in the disease progression of alcohol and drug addiction and in the recovery process. Clients in substance abuse treatment programs realize the contribution that employment makes to their recovery. Research indicates that many recovering substance abusers express a need for greater vocational services than they are presently receiving (2).

Personality theorists from the early psychoanalysts to the more recent existential analysts have identified love and work, Freud's *liebe und arbeit*, as two of the most basic principles of human existence. Their absence can destroy a person's life and, just as powerfully, their presence can save it. Involvement in meaningful relationships and contribution to the tasks of society are crucial to the development of a healthy sense of self (3).

While not denying the equally important role that love plays, this chapter focuses on the role that work plays in the recovery process. Though the entry or return to employment can have many benefits, recovering substance abusers may face many problems when returning to the workplace, and therefore there is a need for a coordinated range of services for facilitating their success.

Work may be defined as purposeful effort expended to positively alter one's environment. Traditionally, work has been seen as a central component of one's identity. Standard adult social introductions usually begin with responses to two coupled questions: "What's your name?" and "What do you do for a living?" Young children are repeatedly asked about their future worker identity: "What do you want to be when you grow up?" Older adults can find adjustment to retirement difficult not only because of a reduction in established activities, but also because of a loss of their specific occupational identity.

American culture extols the virtues of work and assigns a stigma to the unemployed. In our society, employment is a sign of maturity and considered necessary for the independence associated with adulthood. Moreover, our society assigns degrees of respect to people based on the type of work they do.

Although there are different theories on how an individual determines a specific worker identity for himself or her-

self, most occupational psychologists agree that vocational identity is attained through a developmental process. If we agree with this perspective, then it is easy to see how a disability like substance abuse could deprive an individual of the experiences necessary for a transformation from a nonworking child into a working adult. Substance abuse is a disability that begins before or during early adulthood or that removes a worker from employment for a significant period during later adulthood.

There are two basic groups of recovering substance abusers in the treatment setting: those who, as a consequence of their abuse or other environmental or family factors, have never worked and those who have worked and been suspended from their jobs or fired as a consequence of substance abuse. The first group is looking to enter the workforce for the first time and the second group is looking to return. Although there are similarities between the two, care must be taken to fully understand the unique dynamics influencing each group's movement toward work.

Recovering substance abusers entering the labor force for the first time may be confronted with poor, inadequate, or unrealistic concepts of what work is and who they are and can be as workers. Individuals who grew up in disadvantaged or unstable homes because of poverty, generational substance abuse, or family conflict may never have worked formally or been raised with close "worker" role models. Employment may be seen by recovering substance abusers as foreign and unknown, creating feelings of inadequacy and fear. Many of their lifestyle patterns and habits are maladaptive and not conducive to work. Adolescents and young adults whose lives have focused on drug or alcohol addiction have not experienced many of the stresses and fears that most people gradually confront in high school educational programs or their first part-time or summer jobs.

In addition to not experiencing these feelings early on, substance abusers may have missed the opportunities to develop effective coping skills and strengths, to make mistakes in less-significant vocational responsibilities, and to learn from these mistakes, integrating healthy social and personal management skills into their sense of self (4,5). They lack concrete experiences in exploring specific occupational fields, as well as the general expectations and unwritten rules associated with employment. As a result, many have false and immature expectations of what to expect from a job or of the necessary elements to build a career. They may also lack awareness of their own values, interests, and abilities.

These individuals arrive at the job market overwhelmed by the enormity of the task of entering the “straight” world and meeting employers’ expectations that they have already completed the more basic vocational development tasks. Still, a position in the labor force is attractive, because it offers to place them into a recognized position in society for the first time in their lives.

Other individuals coming from the mainstream with an intact background may have come to accept their chemical addiction only when their substance abuse destroyed their ability to work. They were removed from the labor market for one or more periods of employment. Paradoxically, they may now question their ability to handle work demands sober and drug free. They face discrimination because of employment gaps and poor previous work references. They may lack a career plan because of the unstable and interrupted patterns of their prior employment. Employment for these people is a sign of their restored health and a return to their place in society.

As a result of the current economic downturn, the current job market is characterized by keen competition and advanced skills requirements for even entry-level jobs. Regrettably, both of these groups of recovering abusers are often further handicapped by a lack of marketable educational and occupational skills. Either they never developed these skills, or they have been absent from the workforce for so long that their developed skills are obsolete. Many of these individuals may also suffer additional discrimination because of a history of legal convictions.

Obviously, recovering men and women have many needs as they seek to enter or return to work and re-establish themselves in the community. Comprehensive, specialized services are needed to help them make this transition.

VOCATIONAL REHABILITATION

Rehabilitation can be simply defined as the series of steps taken by a disabled person to achieve fulfillment in life. The process that specifically addresses an individual’s work fulfillment and remuneration is referred to as vocational rehabilitation. A further distinction in terms is important because of the specific needs of recovering substance abusers. The process for many who are characterized by a late onset of substance abuse, or who have worked before and are returning to competitive employment, may appropriately be termed vocational “rehabilitation.” These individuals are being restored to a former level of functioning. However, for those recovering people who have lived on the fringe of society, never having worked before, vocational “habilitation” provides a more accurate understanding of their need to learn what work is about and to establish for the first time effective work behaviors. Having made this distinction, the term *rehabilitation* is used in this chapter to refer to both concepts.

There are three basic vocational rehabilitation strategies (6). The first and most desirable strategy is to remedy the cause of the person’s disability by restoring or developing functional ability. For example, a recovering person who is

impaired by the lack of current marketable job skills may “cure” this handicap by completing an appropriate occupational skills training program. The second strategy is to enhance the individual’s other vocational/educational attributes so that the person can compensate for the disability. For example, a recovering substance abuser may need to outweigh a lack of past employment by obtaining significant positive references from volunteer positions the individual has held. The third strategy is to adapt the work environment so that the person’s disability is not a functional impairment. This tactic is least feasible because the provision of specialized tools or techniques or making physical changes in a workstation usually does not effectively rectify the consequences of a recovering substance abuser’s disability. However, an example of this strategy might be the alteration of a regular work schedule to allow a recovering person to keep ongoing counseling support appointments.

The ultimate guideline for all rehabilitation and vocational rehabilitation is to provide help so that the recovering individual becomes less dependent on external resources and more independent by making changes in himself or herself. With this as one of our guiding principles, we can now examine the components of an effective vocational rehabilitation program for recovering substance abusers: assessment, counseling and referral, and placement and follow-up.

Assessment

The first and most crucial component of vocational rehabilitation for any disabled group is assessment. The fourth step of the Alcoholics Anonymous recovery program is a “searching and fearless moral inventory” (7). A similar vocational inventory needs to be undertaken by recovering individuals to develop their vocational plans. They must be evaluated in four key areas: Is the recovering substance abuser ready to enter or return to work? If so, for which specific employment position is the individual best suited? If not, what is the client lacking to effectively obtain and maintain a job? And, finally, where and how can these needs be addressed?

The question of readiness for work is multifaceted. As a result, the assessment must be ongoing in terms of evaluating the client initially in relation to work in general and then later in the process in relation to a specific job’s demands. Obviously, a person’s understanding of and attitude toward work must be evaluated. Often, as a consequence of their lack of exposure to healthy worker models and their own absence from the labor force, many substance abusers develop an inaccurate concept of what a job will require or provide. Frequently, recovering substance abusers see employment as a panacea. Obtaining a job, they believe, will solve all their problems, help them stay “straight,” and move them into the mainstream. Their concept of employment is a fantasy: wearing a suit, having a secretary, going to lunch, and getting a paycheck.

Motivation is a crucial ingredient and, unless properly assessed and addressed, will lead to resistance from the client and frustration for the counselor later in the process. If the

client is not able to progress to a point where the client is keeping appointments on time and demonstrating initiative and choice in selecting from available vocational options, then the client's motivation is questionable. Certainly, a criterion for evaluating motivation, as well as overall work readiness, is the client's chemical abuse status. If the individual is neither drug and alcohol free nor stabilized on a prescribed medication like methadone, then the client is unable to be endorsed for employment. Moreover, a vocational/educational assessment battery would have little value if the client was abusing drugs or alcohol when involved in the testing.

If the recovering substance abuser has an accurate understanding of what employment involves, is expressing a desire to work, and showing some evidence of this motivation, the next issue is evaluating the client's ability to work. Specifically is the client physically, psychologically, occupationally, socially, and placement ready (8)?

First, is the client physically ready? Are there any medical problems that would either rule out employment or restrict job options? For example, a client affected by acquired immunodeficiency syndrome (AIDS) may be able to work full-time, part-time, or only on a temporary basis depending on the status and progression of the disease. In some cases, health problems can be remedied. Still, care must be taken to allow adequate time and logical service provision so that the client is not expected to engage in vocational pursuits before stable health has been established. Further physical considerations include issues such as the possession of a stable residence, the availability of childcare if necessary, and realistic travel time to and from a job.

Second, is the client emotionally and psychologically ready? Has the client developed adequate coping skills to handle the frustration, rejection, and criticism associated with looking for, obtaining, and keeping a job? If clinical issues such as denial, transference, or projection are present, have they been adequately addressed? Is the client mature enough to appreciate the short-term benefits of a realistic vocational step as opposed to focusing on the long-term "ideal" job, which may be serving as a fantasized panacea? If further psychological support is necessary, does it preclude further vocational steps or can it be offered in conjunction with the progressive steps toward employment?

Third, is the client occupationally ready? Does the client have a job goal? Appropriate vocational interest assessment can be accomplished through a combination of psychometric testing and individual research. The combination of the two provides an opportunity for a client to be actively involved in the process with greater responsibility for the outcome. Based on John Holland's trait-factor theory of occupational choice, the Career Assessment Inventory, Strong Vocational Interest Inventory, and Self-Directed Search are some of the available standardized interest-testing measures. Other tests such as the Career Occupational Preference System (COPS), the Career Orientation Placement and Evaluation Survey (COPES), and the Barriers to Employment Success Inventory are available to help clients clarify their values and preferences and understand obstacles to their job attainment. Computerized pro-

grams such as the System of Interactive Guidance and Information Plus (SIGI³) and CareerZone help clients obtain an integrated occupational profile of their interests and values. SIGI³ integrates self-assessment with in-depth and current career information and provides users with a realistic view of the best educational and career options. CareerZone provides information on more than 800 occupations from the National Occupational Information Network (O'Net). Up-to-date job postings provide data on the labor market, and the resume builder helps users prepare the tools needed for a successful job search. Many of these tests are available in Spanish and have forms for clients with lower reading levels.

Individualized research can be done in the *Occupational Outlook Handbook* (OOH) and the *Dictionary of Occupational Titles* (DOT), published by the United States Department of Labor. The OOH is a reference work that describes the nature, qualifications, employment outlook, and promotional opportunities for general job groupings. The DOT is a specific classification system for the breakdown of general job groupings with descriptions of the exact efforts, techniques, and tools needed to accomplish the typical work tasks. Both the OOH and the DOT can be accessed online. O'Net is a full-access online version of the occupational network database and can be linked to Career One Stops. It is designed to assist individuals in planning and preparing for the transition to work.

In addition to an interest focus, an occupationally ready client should possess the specific aptitudes, general intelligence, and appropriate math, reading, and writing skills to adequately meet the job demands. General and specific assessment tools are available to help clients with limited awareness of their abilities to determine their strengths as well as to verify perceived abilities. The Differential Aptitude test, the Career Ability Placement Survey (CAPS), the Bennett Mechanical Comprehension Test, and SIGI³ are examples of assessment tools. Work Keys, the assessment system component of KeyTrain, assists users in measuring and improving the common skills required for success in the workplace. An important component of this program is job profiling, the process of determining the basic skills that a person needs to do a specific job successfully.

A client's level of educational skills, particularly in the areas of reading and math, should also be assessed using measures such as the Adult Basic Learning Examination, the Test of Adult Basic Education, and the Wide Range Achievement Test 4. As with the interest tests, versions in Spanish and those for different ages or skill levels are available to obtain a more accurate picture of an individual's functioning. Undiagnosed learning disabilities may be at the root of some clients' development of a substance abuse problem, and therefore, screening should be incorporated into all educational evaluations. Educational remediation services are available through the ProLiteracy, the Learning Disabilities Association of America, local school districts, and specialized diagnostic and tutorial agencies.

If the client possesses the basic aptitudes for an occupation, does the client also possess sufficient relevant experience, academic degrees, training certificates, or licenses to meet

hiring standards and compete in the job market? Does the client have any legal convictions that would be a bar to the desired employment goal? If the client has impairments in any of these areas, referrals for educational remediation, vocational, or legal assistance should be made. A way of responding to the complex needs of a client is the provision of wraparound services. Recent studies have indicated a positive association between wraparound services and treatment outcomes (9). Assistance with childcare, housing, transportation, and medical issues is provided directly or by referral as part of the client's total treatment plan.

A fourth area to evaluate is the client's social readiness. Remembering that a significant percentage of recovering substance abusers have been living in a "subculture" with little or no exposure to a work environment underscores the importance of this assessment. Can the client communicate effectively, speaking as well as listening? Does the client know how to dress appropriately for a specific job environment, neither underdressing nor overdressing, and dressing neither to attract attention nor to make a statement? Has the client evidenced the ability to interact appropriately with coworkers, supervisors, and employment authority figures? Observations of a client's interaction with his or her peers and treatment staff may provide excellent insight into this ability. Does the client possess sufficient self-management and planning skills to ask questions when unclear about instructions and to notify an employer when unable to meet a commitment? A supportive family and involvement in a 12-step program are important factors in determining social readiness.

Finally, the client needs to be evaluated in terms of the ability to job-hunt effectively. Can the client complete a job application or resume? Is the client capable of presenting marketable job qualities and a positive work attitude in an employment interview? Is the client able to address an employer's possible questions about work gaps and conviction history, or possibly past substance abuse, in a way that will relieve the employer's fears about hiring someone with negative elements in his or her background? Special attention must be paid to the level of work readiness skills in the counseling process.

It should be clear that comprehensive vocational assessment of the recovering substance abuser may require a significant commitment of time and resources. It is essential that adequate time be allowed lest undiagnosed deficiencies surface later in the vocational rehabilitation process. Not only could this significantly delay or disrupt the progress that the client is making, but it could also cause the client to become discouraged and lose confidence in his or her abilities, thereby diminishing motivation. Proper assessment should determine the scope, timing, and logical sequence of the client's rehabilitation steps and services delivery.

Counseling and Referral

The basic goal of counseling is accelerated learning. As a result of a proper assessment, a counselor should be able to depict what a client needs to know and clues for helping the client

learn what he or she needs to know. A basic epistemological principle applies, helping a client understand the unknown by examining what the client already knows.

Vocational counseling has four classic elements: developing a positive self-concept, obtaining occupational information, expressing the self in occupational terms, and learning job-seeking skills (10).

The starting point for all counseling is the client, and more specifically, the perception that the client has of himself or herself. A fundamental task for rehabilitation counselors is to help clients remove the stigma of disability that many have internalized. Vocational rehabilitation with recovering substance abusers must address this issue. Many of these clients believe the label that society has assigned them, more convinced of what they cannot do than confident of what they can do. Their histories of failures become a projection for the future, a self-fulfilling prophecy rooted in a negative self-concept or, at best, low self-esteem.

With histories of missed opportunities and nonsuccess, recovering substance abusers need to be reminded by their counselors of the obstacles that they overcame and the progress made in treatment. Vocational rehabilitation counselors can further boost their clients' self-concepts by extracting from their "past" experiences transferable job skills. For example, experience caring for an elderly relative could transfer to nursing aide skills in health facilities.

Recovering substance abusers in vocational counseling will generally present one of four major needs. The first group of clients possess no occupational goals and will therefore need assistance in establishing goals. The second group has inappropriate or unrealistic goals and will need help in developing more achievable goals. The third group has appropriate goals but needs support in planning the steps and obtaining the resources needed to achieve the goals. The fourth group sees no value in working. Values clarification activities must be the foundation of this group's vocational counseling (10).

Counselors need to help clients integrate their self-concepts, interest assessments, values clarifications, aptitude evaluations, and the realities of the job market into a concrete employment goal. Additional assistance may be required by clients to locate the necessary resources and to plan the specific achievable steps to the desired goal. Empowering the client to choose is a central theme in the vocational counseling relationship. Clients will invest energy only in goals that they have had responsibility for selecting. Among the materials available to help clients achieve this integration and empowerment is the *Adkins Life Skills Program: Career Development Series* created at Columbia University's Institute for Life Coping Skills in New York. The institute is currently located in Stamford, Connecticut.

Referrals to resource agencies for aptitude assessment, educational remediation, or occupational skills training may augment a client's strengths and may serve as gradual steps in the transition to employment. However, initially such referrals may also threaten a weakened self-concept. Returning to the classroom can rekindle the feelings of insecurity and

self-doubt that a client experienced in school. Apprehensions about testing, competition, and acknowledgment of mistakes will need to be addressed by the counselor prior to and during a client's attendance at such programs. In light of these considerations it is important that a counselor develop a client's ability to evaluate not only the general efficacy of such a program but also the appropriateness of the program to the client's individual needs. Is a large or small program better for the client? Is a teaching approach with more hands-on lab experience more appropriate to the client's needs or is one with more classroom lecture?

Obtaining employment is a major challenge for even the most mentally, physically, and emotionally capable person. The basic skills necessary to look for and secure a job must be either learned or relearned by the recovering substance abuser. Moreover, because of their disability, specialized techniques and strategies must be used for the job-hunting process to be successful. The importance of counseling support at this juncture cannot be overemphasized.

The seemingly simple task of completing a job application or resume can be overwhelming for clients. If they have never worked before, they may feel intimidated by the extensive questions about past employment and education. Even if they have worked before, many clients have poor memory and limited records of the training and job experiences during their periods of substance abuse. Moreover, some clients report that during the compilation of necessary work data, they become overwhelmed by negative feelings associated with the failures and incomplete undertakings that were consequences of their abuse.

In general, job hunting for clients with employment gaps and other stigmatized background elements is a very frustrating process. Equipping clients to handle the rejections and disappointments of a job search, offering them healthy outlets to vent their feelings, and providing them with coping strategies are necessary components of placement preparation.

Placement and Follow-up

The National Association on Drug Abuse Problems (NADAP) is a private nonprofit organization based in New York City that provides placement assistance to recovering substance abusers. NADAP has found that for many recovering persons it is necessary to augment the individual vocational rehabilitation counseling with specialized group workshops. These workshops have been designed as "groups" because work is public and requires socialization. As members of these groups, clients can be further assessed in terms of their ability to interact appropriately. The workshops also provide clients with opportunities to learn and practice job-related social skills.

The presence of other clients who are also searching for job helps each client realize that they are not alone in their rejections and frustrations. Also, they realize that they are not alone in their ignorance of aspects of the work world and job-hunting skills. They learn from others' mistakes and are encouraged by others' successes. The shared disability of the

members allows for more direct peer critique of individual obstacles and assistance in breaking their goals into short-term concrete steps. The group often, very practically, serves as a networking resource for employment leads.

The skills-building exercises in the NADAP workshops incorporate role playing, videotaping, and the involvement of employer representatives. Through role playing and videotaping, a client is able to see very clearly the strengths and weaknesses of his or her interviewing behaviors. The corporate personnel recruiters who participate in the role-plays provide an excellent "dress rehearsal" for the client's real interview, directly represent employers' expectations of job applicants, and offer clients suggestions on how they can better present their marketable traits and such negative elements in their background as legal convictions, job dismissals, and periods of unemployment.

Appropriately addressing these elements of the application and in an interview is a major task for recovering substance abusers. Guidelines for the presentation of confidential information are also addressed in the workshops. Clients learn through group exercises that the way information is presented is as important as what the information is. First, clients are encouraged not to volunteer negative data unless it is specifically requested (11). Second, they are trained to couple their admittance of past negative experiences with at least one positive step or change that has occurred as a result of their substance abuse treatment.

Depending on the client's individual background and chosen employment direction, the client may require consultations with agencies such as the Legal Action Center and the state Human Rights Office. Through such resources, recovering substance abusers learn their employment rights; eliminate unrealistic employment options; access bonding, licensure, or certification alternatives; and challenge employment discrimination.

Participation in such workshops helps a client develop not only specific skills but also a self-evaluation ability that will help to improve presentations on successive interviews and enhance their job performance. Research has demonstrated that recovering substance abusers who participate in job-hunting groups are more likely to secure and retain employment (12). Faced with discrimination and impairments, clients looking for work have to try different strategies and use as many employment resources as possible: community, city, county, state, and federal agencies, as well as specialized placement services such as NADAP.

NADAP advocates with large and small employers for competitive job opportunities for recovering substance abusers. In 2008, NADAP placed more than 50% of the clients who entered the program who were job-ready (13).

To enhance a client's success in employment, NADAP provides retention and career advancement services. A NADAP staff member is available to clients and their employers to resolve problems that might arise during the initial adjustment to a job. Follow-up, aftercare, and ongoing support issues are important from a vocational rehabilitation, as well as a clinical, perspective.

Support services in the form of group or individual counseling should be available to employed clients. Issues of anxiety, self-confidence, socialization, communication, basic attendance, and punctuality are usually greater determinants of job terminations for recovering substance abusers than lack of adequate skills or inability to learn quickly enough. Clients may need continued opportunities to role-play problem situations on the job and concrete exercises addressing assertive as opposed to aggressive behaviors.

Being a “worker” puts a client in a new role with family and friends. These significant others may be threatened by the client’s progress and attempt to sabotage job retention. Coupled with a new job, budgeting money, scheduling leisure pursuits, and attending to daily living needs may also create new stresses for a client who previously had never worked or had been unemployed for a long time. After securing an entry-level position, clients will need career-planning assistance so that they can develop appropriate long-term goals, strategies, and timetables.

Given adequate rehabilitation time, comprehensive assessment, and appropriate services, recovering substance abusers can succeed in securing employment. The New York State Office of Vocational and Educational Services for Individuals with Disabilities (VESID) provides this proper climate and has established a history of helping disabled individuals achieve employment. Historically, the VESID office rehabilitated consumers with histories of substance abuse at a higher rate than consumers with other disabilities. VESID spent only slightly more money to help a recovering substance abuser secure employment than to rehabilitate most of the other disability groups it serves (14).

A final consideration in analyzing the placement of recovering substance abusers is how these individuals compare with other employees on the job. Two research studies indicate that there are no significant differences between recovering substance abusers and their peers on the job in terms of job retention, absenteeism, punctuality, performance, promotions, dismissals, and resignations (15,16).

Illustrative Cases

Jane

Jane was a 34-year-old woman who had been raised in an alcoholic home and had a history of 11 years of heroin addiction. She had been stabilized on methadone for 18 months after four unsuccessful detoxification attempts. Recently divorced from her husband, she was responsible for supporting herself and her 7-year-old son.

Jane was a high school graduate who had managed a retail business with her husband for 6 years. She had been unemployed for the past 2 years. Motivated by her desire to provide for her son, she entered into vocational rehabilitation counseling at her outpatient clinic. Her counselor referred her to an employment exploration and skills development group and helped her complete some occupational research. As a result of these undertakings, Jane decided that she was interested in pursuing a career in computer programming.

However, she lacked confidence in her academic skills and knew that her goal would require college-level training. She feared that with her existing childcare responsibilities, therapy appointments, and necessary dental treatments, she would not have sufficient time to devote to school. She was concerned that employment would reduce her welfare benefits for herself and her son. She also felt isolated from others because of her “addict” stigma and was afraid of entering into new social situations.

An initial educational assessment revealed basically strong reading and math skills, although weak algebraic ability. As such ability would be needed for computer training, Jane was referred to a part-time evening tutoring program. She also decided to participate in a half-day vocational aptitude assessment program to address some of her other fears.

Jane made progress in her math tutoring and demonstrated the necessary aptitudes and work behaviors to consider a referral to the state office of vocational rehabilitation. This agency agreed to fund Jane for a 1-year computer certificate program at the local community college. This was in keeping with welfare reform regulations and was approved by her local Department of Social Services. Because of her age and childcare responsibilities the college granted her special student status. This gave her priority in registering for courses and allowed her to design a class schedule that ensured that even though she was taking a full course load, she could be home for most of the times when her son was not in school. Daycare for her son was provided at a licensed center through social services.

Initially after starting college, Jane maintained contact with her tutor for assistance with her first math classes. She also continued in primary therapy for support with her single-parenting issues and socialization needs. Jane graduated from college and was able to secure a job with a company that provided her with additional in-house programming training.

John

John was a 24-year-old polydrug abuser. He had dropped out of high school and was living at home, supporting himself on his earnings as a semiprofessional athlete. The death of his girlfriend because of cancer was the catalyst for his involvement in counseling. His bereavement counselor noted John’s need for substance abuse treatment. While attending outpatient treatment, John realized the need for vocational rehabilitation services.

Because John had no consistent work record, specific occupational interest, or sense of his abilities, his vocational counselor referred him to an aptitude assessment and work adjustment program. While there, John received occupational interest testing. The testing revealed John’s preferences for health and computer activities. Additional occupational exploration helped John focus on a position in medical billing. The assessment indicated that he possessed the necessary aptitudes for such work, but his math skills were not sufficient to pass the entrance exam for the appropriate training schools. Moreover, a high school diploma was required to

meet the hiring standards of most of the employers in the medical billing field.

John investigated the three local trade schools offering medical billing training. He decided to attend the longest and most advanced course because of the increased career opportunities it would afford him. John's counselor helped him see that this choice meant more homework than the other programs required and additional efforts on his part because of his math deficiencies. John rose to the challenge and enrolled in a part-time educational program offering preparation for the high school, General Equivalency Diploma (GED), and math tutoring.

As a result, he was able to raise his math skills sufficiently to pass the training program's entrance exam. He applied for and received government-sponsored financial aid to cover most of the tuition costs. Once in training, he transferred the discipline he had developed as an athlete into his new endeavor. John established a specific study schedule and took advantage of every "extra help" session his training instructors offered him. He secured a part-time, evening maintenance job to meet his general expenses and the tuition costs not covered by his financial aid. He continued his outpatient counseling to help him resolve his grief and relationship issues.

On his first attempt prior to the end of his medical billing training, John passed the GED exam. He graduated from training and secured a position as a medical biller for a small group practice. After 2 years he left his first job for a more advanced position at a health clinic. At the new firm he received specialized training on a unique piece of technology and became a troubleshooter and trainer of new staff.

IMPEDIMENTS TO VOCATIONAL REHABILITATION SERVICE DELIVERY

The federal government has joined with state and local governments in endorsing the connection between work and recovery. This is evident in their policy developments and antidiscrimination legislation. This extends to funding provisions for training and job opportunities for recovering substance abusers (17). Certainly the Rehabilitation Act of 1973 serves as a cornerstone for the legal rights and public opportunities available to individuals with disabilities (18).

However, it is naive to believe that this support alone guarantees vocational rehabilitation services to those who need and desire it. There are three major categories of hindrances to effective provision and use of these services by recovering substance abusers: the clients themselves, the programs that treat them, and the society to which they return (19).

Clients who have been addicted to drugs and/or alcohol typically suffer with multiple impairments: poor health, HIV/AIDS or AIDS-related complex (ARC), psychological limitations, educational deficits, vocational development deficiencies, conviction records, family problems, daycare needs, and/or public assistance dependency. These factors affect the nature, pace, scope, and objectives of a client's vocational rehabilitation. As has already been outlined, careful, compre-

hensive assessment and appropriate remediation, compensation, or adaptation require significant commitments of time and energy to overcome these various problems. Some clients are too discouraged and alienated to persist in the process.

Treatment program obstacles can be examined in terms of the themes of philosophy and staffing. Historically, vocational rehabilitation, if considered at all by substance abuse treatment programs, has been seen as an adjunct, ancillary part of the recovery process. This is indicative of the low priority and concern that treatment professionals in general have for this component of treatment (20).

Many believe that the basic premise of most treatment programs is that if a client stops abusing drugs and alcohol, everything will fall into place and all things are possible. This principle is much too simplistic. Regretfully, clients accept this false expectation and find themselves returning to their communities without the knowledge and skills needed to function independently and achieve stability. Vocational rehabilitation is the treatment that helps these individuals develop much of this knowledge and many of these skills.

Unfortunately, a philosophic orientation toward vocational rehabilitation that downplays its contribution to the treatment process has translated into reduced staff resources available for such services. The drug and alcohol treatment field in general suffers from staff shortages and high turnover. The low-pay, insufficient advancement opportunities and the frustrations and burnout associated with serving multidisabled clients have reduced the appeal of positions in substance abuse treatment (21). Faced with this reality, treatment program administrators knowingly or unknowingly diminish the status of vocational rehabilitation services. If they can afford the time, effort, and funds to hire a vocational rehabilitation counselor, it is usually a last priority in their hiring hierarchy, offering lower salaries than most clinical positions, unrealistic caseloads, less than full-time opportunities, or combined responsibilities, for example, general program intake and vocational counseling.

As a consequence of these factors, personnel with limited vocational rehabilitation skills may be hired. Research shows that less trained rehabilitation counselors provide less efficient, less cost-effective, and less successful delivery of vocational rehabilitation services (22). Certainly the multiple disabilities with which many recovering substance abusers suffer require highly trained counseling staff. Without such staff the integrity of the rehabilitation services provided to recovering substance abusers is compromised.

Societal obstacles are probably the most difficult to overcome because of the prevalent ignorance and fear that are at their roots. Recovering substance abusers suffer from the same degrees of employment discrimination as many other disabled individuals and ex-offenders.

The discrimination that recovering substance abusers confront in the employment market is discouraging enough. Regretfully, they are also frequently faced with discrimination and misunderstanding by agencies in the social services system that supposedly exist to help them. This includes the disincentives to competitive employment imposed by public

assistance guidelines as well as insensitive, illogical, and often contradictory eligibility criteria for counseling, educational remediation, training, and job placement assistance.

Is formal entry-level employment with limited or no fringe benefits attractive to a recovering substance abuser if it means surrendering the Medicaid, which covers the cost of his or her treatment as well as the health insurance costs of his or her family? Substance abusers with psychiatric histories are often refused entry into substance abuse treatment programs because these programs do not provide psychiatric counseling and supervision. These same clients are refused entry into psychiatric facilities because of their substance abuse.

A similar, if not more extreme, situation exists for physically disabled substance abusers who are often rejected by substance abuse treatment programs that cannot accommodate some of their special needs and are uneasy about how to treat these clients. Rehabilitation treatment programs for the physically disabled are just beginning to acknowledge that they may have clients with substance abuse problems and often cannot provide adequate substance abuse treatment for them.

Pregnant abusers are also ineligible for many programs because they are not designed to handle the needs of expectant mothers. There are limited treatment programs for women with children. This can force mothers with a substance abuse problem to have to choose between treatment and placing their children in foster care. Even clients who are functioning appropriately on monitored methadone dosages find it difficult to access many of the support services available to other substance abusers because they are not considered “drug free.”

Against such obstacles, even the most motivated client may lose hope that he or she can succeed in his or her employment recovery.

IMPROVING VOCATIONAL REHABILITATION SERVICES

The past four decades of providing vocational rehabilitation services to men and women recovering from drug and alcohol abuse point to three guidelines for improving these services: understanding, expansion, and coordination.

Regretfully, there will probably always be new drugs surfacing that carry with them certain unique vocational impairments. These impairments will need to be examined as they become evident and new rehabilitation strategies and resources will need to be developed to address them. However, we now have an understanding of the depth and scope of the effect that substance abuse has on an individual’s vocational development and of the basic rehabilitation principles to apply. Most recovering substance abusers can make progress if they are allowed to do so in a slow, gradual manner with a full complement of support services. Although it may be too strong to say that relapse is frequently part of the recovery process, we know that it is a reality for many clients. This is true in terms of a client’s vocational development as well. It is not necessarily a neat progression but one that may be char-

acterized by false starts and occasional steps backward. For some, because of the chronic nature of their substance abuse histories and the multiple handicaps they have, competitive or full-time employment may not be a realistic goal. For others, it will be appropriate only as a very long term goal.

In keeping with these characteristics we must adopt more of a mental health model of rehabilitation as opposed to a medical one. We must acknowledge this understanding in the design of vocational programs and in the expectations about working that we communicate to clients.

The second theme for future vocational rehabilitation is expansion. This means adding new services, but it also means expanding existing roles to involve more segments of society in the delivery of vocational rehabilitation services. If we acknowledge the need of recovering substance abusers for gradual movement from not working to working, then we must provide more work adjustment and transitional employment opportunities. These may include noncompetitive sheltered or semisheltered workshops that are available to other disability groups. Supported work programs for recovering substance abusers increase levels of employment and income and reduce arrests and jail time (23,24). New programs alone, however, are insufficient to meet the vocational rehabilitation needs of recovering substance abusers.

Employers in the United States are confronting a shrinking labor force of educated, skilled workers. Certainly the drug crisis is contributing to this deficit. Employers must respond with programs that offer alternatives to substance abuse and nourish the vocational development of recovering individuals who are looking for new positions or for a healthy return to their former jobs. Included must be nondiscriminatory hiring practices, business-sponsored training, transitional and noncompetitive work opportunities, and job maintenance and support services. At the very least, employers must be willing to abide by the current legislation addressing these issues. The Americans with Disabilities Act (ADA) specifically extends antidiscrimination treatment and employment policies to individuals with drug and alcohol problems and to those affected by the AIDS virus. While not protecting current users of illegal drugs, the ADA generally safeguards individuals with a history of substance abuse who have completed or are enrolled in treatment. For example, the ADA dictates that accommodations be made in the work schedule of a recovering individual to allow that person to attend a treatment program, unless such an accommodation would create undue hardship for the employer (25).

Researchers, as well, must become more involved in examining the vocational rehabilitation of recovering substance abusers. They can help to better delineate specific needs of these individuals and enhance the design of effective interventions and strategies.

Finally, for there to be effective vocational rehabilitation of recovering substance abusers, there needs to be increased coordination of relevant services. Drug and alcohol prevention programs need to include career exploration, educational remediation, occupational skills training, and work adjustment experiences into their services. Treatment programs must integrate comprehensive educational/vocational services into

the early, middle, and late stages of their clinical treatment. Staff of these programs should familiarize themselves with existing vocational rehabilitation resources and adapt their program procedures to allow clients to avail themselves of these services. Just as a placement specialist working with a recovering person must be aware of the client's clinical needs and progress, so must a treatment counselor be aware of the client's vocational impairments and efforts at remedying or compensating for them. Treatment staff must be trained in the basic principles of vocational assessment so that while clients are in their care they can at least refer them to appropriate agencies that can prepare them for employment and independent living outside treatment.

In addition to the expected increases in employment, it appears from recent research that vocational rehabilitation programs are one of the psychosocial support services that can be effective in reducing drug use (26). Moreover, employment, specifically, can be an effective reinforcement for abstinence (27,28). Clearly such an outcome justifies the costs associated with integrating these components into substance abuse treatment programs. Both because of what it demands from an individual in recovery and because what it provides for that individual, sustained employment is a significant component of successful treatment (29).

Work dignifies us as human beings. Unless we provide men and women recovering from substance abuse with support and opportunities to achieve this dignity, to earn a place in society, we should not fault them for taxing our welfare system, straining our criminal justice system, and perpetuating a destructive subculture.

INTRODUCTION

This chapter focuses on enhancing knowledge and comprehension of adolescent substance abuse by addressing the following areas: epidemiology, vulnerability and developmental course, comorbidity, assessment, and treatment/outcome. The areas of prevention and early intervention are addressed more thoroughly in the section on Models of Prevention. The goal of the chapter is not a critical analysis of the literature, but rather a discussion of the preponderance or balance of the evidence. Over the last two decades there has been significant growth in number of studies and an advance in the knowledge related to adolescent substance abuse, yet much remains to be learned. In this manner, only original and review articles that specifically relate to this topic and population will be included here, distinguishing itself from the adult literature.

The focus of this chapter is on adolescents, as preadolescent substance abuse is uncommon and there are few studies and/or comprehensive reports on such use. Substance abuse in adolescence continues to present as a major challenge. It is a serious mental health and social problem with its significant association with morbidity and mortality. Substance abuse has progressed from the more antisocial, risk-taking, and marginal groups of the population to the mainstream of society and dramatically to younger populations, reinforcing and expanding the boundaries of at-risk populations for substance abuse. The transitional period of adolescence presents itself as an especially critical and vulnerable time for the onset of substance use disorders (SUDs) (1–4).

EPIDEMIOLOGY

The Monitoring the Future survey has been annually measuring the prevalence rates of substance use in adolescents attending school across the United States in a nationally representative sample for more than three decades. Substance use (alcohol and illicit drugs) in general, across all grade levels 8, 10, and 12, has shown a steady and considerable decline over a decade or more, though with some exceptions. Rates appear to have stabilized in recent years. Marijuana, in contrast, has shown an increased trend in use over the last 2 to 3 years affecting the rate of illicit drug use, whereas illicit drug

use other than marijuana has more or less held steady or declined. This recent rise in marijuana use has been associated with an even longer decline in adolescents' perceived risk of regular marijuana use. Annual prevalence rates for 2009 of any illicit drug use in grades 8, 10, and 12 stand at 15%, 30%, and 37%, respectively, which remain relatively high. It is almost without exception that substance use increases with the next higher grade level or age in adolescents. Inhalant use, on the other hand, shows the reverse prevalence, being most common in 8th graders and heroin use being equally distributed across the grades, though annual prevalence rates remain nominal at less than 1% in any of the three grades. However, narcotic use other than heroin has remained elevated at 9% in grade 12 students for many years. By far, the two most common substances used by adolescents are alcohol and marijuana, with annual rates for senior high school (grade 12) students of 66% and 33% in 2009. However, marijuana has been the most common substance of daily use among adolescents for more than a decade, with rates over 50% higher than for alcohol. The prevalence of daily marijuana use for the past 5 years in senior high school students has ranged from 5.0% to 5.4% as compared to alcohol at 2.5% to 3.1%. Binge drinking has hovered at 25% for the past several years in grade 12 students. Prescription drug misuse among high school seniors remains a concern at approximately 15% per annum. Included in this group are narcotic analgesics (vicodin and oxycontin), stimulants used for treatment of attention-deficit hyperactivity disorder (ADHD) (Adderall and Ritalin), and sedatives/tranquilizers.

Prevalence rates of substance use do not provide one with comparable rates of SUDs in general and especially in adolescents, barring the controversy with respect to the applicability of DSM-IV-TR SUD criteria, developed for adults, to adolescents (5). Substance experimentation among adolescents is highly prevalent, though the vast majority of these adolescents do not develop an SUD, even with some of these adolescents engaging in more regular use for a period of time, though the latter does increase the likelihood of developing an SUD (1,2,5). These patterns of substance use, as it would relate to alcohol and marijuana use seen in adolescents, appear for some to be within normative behavior and part of the maturation process of adolescence, but for others may lead to significant substance abuse (1,6).

Community samples of adolescents have found lifetime rates of SUD to range from approximately 10% to 30% with rates of alcohol use disorders (AUD) and drug use disorders (predominantly cannabis) similar, apart from one study. This wide range in SUD rates may be attributed to differences in methodology and categorization of SUD. Several common themes are identified in these studies in that SUD rates increase with age, appear to be greater in males, and are quite infrequent for ages 13 and younger (7–10).

Prevalence rates have also been examined for higher risk groups of adolescents, specifically those receiving services in the public sectors of alcohol and drug, juvenile justice, school-based services for severely emotionally disturbed youth, child welfare, and mental health. An overall prevalence rate of 24% was found for SUD in the past year (11).

Community studies have also shown that lifetime SUD rates are notably greater than current rates for adolescents, indicating some movement in and out of SUD through adolescence. The U.S. National Survey on Drug Use and Health (12) provides estimates of SUD for youth 12 to 17 years of age as well as for young adults 18 to 25 years of age. The most recent report on the 2008 findings showed an SUD rate of 7.6% that was significantly less from findings in 2004 (8.8%). The highest rate of SUD was found in the young adult group at 20.8%, whereas the greatest proportion with illicit drug use disorders was in the adolescent group at 60.6%, in comparison to 37.4% for young adults. An interesting finding that may be reflective of the survey was that females were somewhat more common than males in the youth group with SUD. This is in contrast to community samples of adolescents and adult findings. However, it would suffice to say that females are definitely in greater proportion in adolescents with SUD than in adults.

In summary, despite the overall decline in substance use and SUD in adolescents, the prevalence remains high and is the greatest with older adolescents. As well, it is important to recognize the historical cyclic pattern of substance use and abuse rates. One can also surmise that cannabis would appear to be the most significant and the most common substance of dependence in adolescents with alcohol being the predominant substance of abuse (13).

DEVELOPMENT AND COURSE OF DISORDER

Adolescence is a time of major risk for the onset of substance abuse. The peak age of onset for both alcohol and drug use disorders is in late adolescence/early adulthood, between the ages of 18 to 20 (1,14). Adolescence, as seen from a developmental perspective, represents a time of convergence of significant neurobiologic, cognitive, behavioral, emotional and social changes with continuity of risk from earlier developmental stages, providing a unique period of heightened vulnerability and susceptibility for SUD (1,3). Brown and colleagues (1) reflect on these interrelated developmental factors, the changes that occur during adolescence, and its influence on individual alcohol use trajectories and risk for problem drinking. Their narrative highlights the increasing

evidence that adolescents are particularly vulnerable to the adverse effects of heavy alcohol use both in the biological and social domains and that the consequences of drinking appear to differ between adolescents and adults. They also identify that problem drinking has the potential to redirect the normative course of adolescent development in a manner that not only increases the risk of alcohol use disorders but also of mental health and social problems.

Schepis and coauthors (3) in their review of the neurobiological processes involved in the etiology of adolescent SUD emphasize the significance of maturational changes of the central nervous system that occur in adolescence; the foremost of these being synaptic pruning, myelination, and neurotransmitter system modification. Adolescents overall appear to have greater neurological bases for risk-taking behavior with attenuated suppressive and regulatory controls on behavior. The authors surmise that the abnormal neurological markers of those at risk for the development of SUD may best correspond to disinhibition and/or negative affect. Adolescents appear more vulnerable to the effects of many substances that are most likely mediated by increased neuroplasticity and the effects of stress. It is likely that substance-induced neurobiological changes enhance drug use behaviors. These attributes reinforce the progression to SUD in adolescents.

An abundance of risk factors have been, and continue to be, identified in the prediction of substance abuse in adolescence/young adulthood. These various risk factors may be conceptualized into four domains: (a) culture and society (e.g., laws and availability of substances); (b) interpersonal (e.g., peers and family including attitudes); (c) psychobehavioral (e.g., early/persistent behavioral problems, poor school performance, rebelliousness, early onset of substance use, personality characteristics such as temperament and affect); and (d) biogenetic (e.g., inherited susceptibility and psychophysiologic vulnerability to the effects of substances) (2,14,15).

It appears that social factors, particularly peer influence, are the strongest determinants of initiation of substance use, whereas psychological factors and self-reinforcing effects of the substance are more closely associated with substance abuse (16).

There is little evidence on distinguishing the relative importance of risk factors and their specificity in the development of adolescent substance abuse. It is the cumulation of risk factors, rather than any one factor, that is predictive of substance abuse. Many of these risk factors overlap with those related to the onset of other adolescent psychiatric disorders (2,16).

Protective factors are those that reduce the likelihood and level of substance use. Multiple protective factors have been identified which include a positive temperament (absence of depression)/self-acceptance, intellectual ability/academic performance, supportive family/home environment, caring relationship with at least one adult, external support system (e.g., religion/church) that encourages prosocial values, and law abidance/avoidance of delinquent peer friendships

(2,16,17). Newcomb and Felix-Ortiz (18) in the analysis of their longitudinal prospective study of drug use in early adolescence found several important relationships for multiple protective and risk factors. Again, it is not one particular protective factor but, rather, the number of protective factors that have the most influence on reducing the likelihood of adolescence substance abuse. For example, those adolescents with five or more protective factors were over 20 times less likely to develop cannabis abuse than the general sample. They also found a moderating effect of protective factors on risk for involvement and most notably that high protective indices had their greatest impact on those at high risk for greater drug involvement. One variable that has been identified above others as protective of substance use, and not *per se* SUD, is having early academic success (19). The strongest predictor of current substance use in late adolescence and young adulthood is past use (20,21). The early onset of substance (alcohol and marijuana/illicit drugs) use in adolescence predicts a considerably greater likelihood of developing later SUD and a more rapid progression to substance dependence, at least for cannabis. These findings are most robust for initiation of substance use by age 15 or younger, thereafter other variables may come into play (12,22–25). Adolescent SUD has been found to be a strong homotypic (refers to a disorder predicting itself over time) predictor of young adult SUD (25). The regular weekly use of cannabis by adolescents appears to be a threshold marker for the risk of cannabis dependence in young adulthood (26).

A widely held concept contends that there are developmental stages in the progression of substance use through adolescence into young adulthood; this concept has been derived, in part, from epidemiologic studies (27). The sequence of stages defines a temporal relationship progressing from legal to illegal and softer to harder drug use, with each stage acting as a potential “gateway” to the initiation of the next stage (27,28). The use of one substance increases the likelihood of initiation of the second substance. For example, very few individuals who have tried cocaine and heroin have not already tried marijuana, the majority having previously used alcohol or cigarettes. However, the use of one substance does not invariably lead to the use of other substances. Many youth will stop at a certain stage and do not progress further or may return to an earlier stage of substance use (27). It is typical to carry over substance use from one stage to the next versus substitution. This carryover effect has clinical relevance in the application of the polysubstance dependence diagnosis for adolescents. The causal effect of the gateway hypothesis is more open to debate and specifically as it relates to cannabis use and other drugs. However, a clear association has been well established for cannabis use and the use of other illicit drugs (29). Further to this, regular or heavy cannabis use has been significantly associated with other illicit drug use and abuse/dependence. The relationship is especially strong during adolescence and declines with age. These findings add support to the potential causal role of cannabis use on the development of other illicit drug use disorders, though the actual causal mechanisms, whether direct or indi-

rect, remain unclear (30,31). Adolescents have shown a greater likelihood of developing drug dependence (cannabis) than adults across levels of use (32).

Substance abuse in adolescence is clearly associated with significant negative consequences in the developmental tasks’ multiple life areas including behavioral, emotional, social, and academic/vocational problems (1,33,34).

In summary, the onset of substance abuse in adolescence with its biopsychosocial determinants is a serious problem, with a direct impact on development and a strong link to future SUD.

COMORBIDITY OF SUD

The association of SUD and mental health disorders is well established. In clinical and treatment studies of adolescent SUD, elevated rates of comorbid mental health disorders have been found across settings from hospitalized/residential to outpatient status with prevalence rates ranging from 55% to 80% (35–38). Prevalence rates of comorbid disorders are significantly greater than community control samples of non-SUD adolescents. Adolescent SUD patients often present with more than one comorbid disorder. Clinical studies, however, may typically suffer from Berkson’s bias where it is probable that an adolescent with a particular disorder such as SUD seeking treatment will have a higher likelihood of a second disorder, thus confounding the ability to generalize results. Only a handful of studies have examined the psychiatric comorbidity of adolescent SUD in general community samples. Two such studies have found similar results of elevated rates of comorbidity as seen in clinical studies. Comorbidity rates were two to three times greater in adolescents with SUD than those without SUD for any anxiety, mood, or disruptive behavior disorders (DBD). In comparison to adult studies, comorbidity rates of psychiatric disorders are similar for lifetime SUD and may be higher for current SUD in adolescents (7,39). These reported higher rates of psychiatric comorbidity in adolescents with SUD are most likely reflective of the greater number of DBD (Axis I) diagnoses available for adolescents that are either not applicable or not routinely assessed in adult SUD populations. There is some evidence to support the idea that comorbidity of mental health disorders increases with progression of substance use diagnosis and is associated with more severe substance use (40,41). In terms of gender relationship to comorbidity, males and females share far greater similarities than any meaningful differences, especially when gender differences seen in the general population of such disorders as conduct disorder (CD) and major depressive disorder (MDD) are considered (35,42).

Prospective studies suggest that early and more frequent substance use through adolescence is associated with, and may predict, later psychiatric disorders in particular depressive disorders in young adulthood (43–45). Analysis of retrospective data for the National Comorbidity Survey Replication found the age of onset of DBD and anxiety disorders to precede the onset of substance dependence (46).

The most common comorbid psychiatric disorder seen in community studies of adolescent SUD are the DBD, in particular CD, with these disorders showing a prevalence range of 25% to 50% and a median of four times greater likelihood of co-occurrence with SUD than without. This is followed by depression with a prevalence range of 20% to 30% and a median of over twice the likelihood of co-occurrence (42). These findings are relatively consistent with clinical studies, though there is a fair degree of variability in prevalence rates between studies, depending on the clinical population sample. SUD, on the other hand, is a common comorbid disorder in clinical studies of youth that present with serious emotional disturbances or mental health disorders (47–50).

In this section of comorbidity, we will take a closer look at selected aspects of the relationship of the more prominent comorbid psychiatric disorders and SUD.

Conduct Disorder

CD and SUD are strongly associated, with CD typically preceding the onset of SUD (51–53). This relationship, however, appears to be reciprocal with each condition heightening the expression of the other. In such a manner, CD may influence the early adolescent development of SUD and the severity of CD has been found to predict the severity of SUD. Early-onset substance use has been associated with later criminality. Furthermore, if substance use or drug dealing is reduced, there is a subsequent decrease in criminality (54). Reebye and colleagues (55) in their clinical study of CD and SUD found the rapid development of substance abuse and substance dependence in adolescents with CD, on average taking about 9 and 18 months, respectively, after initiation of drug use. Gender differences have been found such that adolescent girls with CD progress more rapidly to SUD following first use than boys (56).

Juvenile offenders with comorbid SUD have shown greater additional psychopathology than juvenile offenders without SUD. It is also important to recognize that no relationship with early conduct problems has been found for the onset of SUD in adulthood (57).

Attention-Deficit Hyperactivity Disorder

ADHD has been found to be a common comorbid disorder in clinical studies of adolescents with SUD, with large outpatient clinical studies reporting a range of 17% to 38%; however, similar findings have not been found in community samples (36,37,42,58).

The significance of comorbid ADHD appears to lie with its association with CD in adolescents. The clustering of ADHD, CD, and SUD has been found in several studies of adolescents (58–60). Together, longitudinal prospective studies of ADHD into adolescence, in comparison to normal controls, and a large population-based study examining the relationship of ADHD, CD, and SUD in adolescents provide

consensus that ADHD as a risk factor for SUD is strongly mediated by its association with CD and/or externalizing disorders of oppositional defiant disorder (ODD)/CD. In essence, ADHD when not associated with another DBD is not generally seen as a significant independent risk factor for the development of SUD in adolescence (58–61). The severity of ADHD may have an impact on the risk for development of SUD in adolescence (62,63).

Adolescents with ADHD have shown an earlier age of onset of SUD and a more rapid progression of SUD from abuse to dependence than normal controls; as well, adolescents with SUD and comorbid ADHD have exhibited more severe substance abuse than those without ADHD (59,61). No significant gender differences have been found in the effects of ADHD on SUD in adolescents (58,59). The persistence of ADHD into young adulthood has been shown to be an independent risk factor for the development of SUD (64).

It is important to recognize that both well-designed prospective longitudinal studies and a meta-analysis provide sound evidence that stimulant treatment of children and adolescents with ADHD does not increase the risk of developing an SUD in either adolescence or young adulthood (65–68). There is also some evidence to suggest that stimulant treatment of children with ADHD actually significantly reduces the risk of developing SUD in adolescence by several fold (67,69). However, these protective findings of stimulant treatment of children and adolescents with ADHD appear to wane and become nonsignificant as they continue on into young adulthood (66).

The relationship between ADHD, CD, and SUD remains complex in adolescence and may represent a worse prognosis for the persistence of antisocial behaviors and substance abuse.

Depressive Disorders

Depressive disorders frequently co-occur with adolescent SUD and are the second most common comorbid disorder. The association of depressive and substance use disorders in adolescents is more frequent than one would expect and has been more widely studied than other comorbidities. It is also noteworthy that adolescents with a history of MDD show an elevated rate of SUD than those without a history of depression (12,70). Rao and Chen (71) in a comprehensive review of this topic proposed that common genetic, environmental, and neurobiologic factors may possibly mediate the relationship between depressive and substance use disorders in adolescents, constituting a basis for their linkage. The authors recognized the limitations of the neurobiologic findings and by design, the selectivity of various risk mechanisms examined.

In adolescents with SUD, the onset of MDD most often follows the onset of SUD (secondary MDD). Secondary MDD is considerably more common than MDD preceding the onset of SUD (primary MDD) (72,73). In the majority of cases, irrespective of whether it is primary or secondary, comorbid MDD has not been found to spontaneously remit

with abstinence and/or early treatment (excluding pharmacotherapy) by the third week in adolescents. This finding appears to differentiate adolescent SUD from that found in adults with elevated rates of acute remission (72). As would be expected, comorbid MDD has been found to be more prevalent in girls with adolescent SUD than in boys, with the girls showing an earlier age of onset of depression (73). Adolescents with depressive symptoms and SUD on admission in residential treatment have shown poor substance use outcome (74).

In adolescents with depression, comorbid SUDs are associated with earlier onset of and more severe substance abuse. Comorbid SUD in adolescents with depression appears to have a negative impact on the phenomenology and course of illness with greater behavioral and CD problems, longer duration of depressive episodes, and increased psychosocial (school, family, and legal) impairment (70,71,74–76). Recently, it has also been shown that simply a greater severity of substance use in adolescents with treatment-resistant MDD and without comorbid SUD is associated with increased severity of depression and comorbid ODD and CD. Adolescents with low substance-related impairment at the end of treatment for depression demonstrated the best response (77).

SUD in adolescents has been linked to an increase in suicidal behaviors including ideation, attempts (frequency, recurrence, and seriousness), and completed suicide. However, the risk for suicide is most significant when comorbid with MDD (78–80). A history of recent interpersonal separations and family dysfunction has been found to be more common in adolescents who attempt suicide with depression and comorbid SUD than without. Alcohol abuse has been most often associated with increased risk, though the number of substances used may be a more important predictive factor (81).

The comorbidity of substance use and depressive disorders appears to be interactive and has at least an additive, if not a synergistic effect on the burden of illness of these disorders, carrying a significant morbidity and mortality.

Psychotic and Bipolar Disorders

There is a paucity of studies that report the incidence of comorbid primary psychotic disorders (PPD)/schizophrenia related disorders and bipolar disorders (BD) in the adolescent SUD population. This absence of reporting may be a reflection of the severity of the illnesses, with those adolescents who experience the onset of these disorders being more likely to present to psychiatric services for assessment irrespective of whether they have an SUD or not. In that comorbid PPD and BD are not commonly or reliably reported in the adolescent SUD population, a detailed discussion of their association is beyond the scope of this chapter. Apart from a few general comments, the interested reader is referred to a comprehensive review on the topic of comorbid SUD with PPD and BD in adolescents/young adulthood by Milin and colleagues (82).

A strong association has been found for comorbid SUD with both PPD and BD in clinical studies involving adoles-

cents/young adults as well as first-episode psychosis (FEP) or mania. The presence of comorbid SUD has been associated with a more debilitating course of illness, poorer clinical and treatment outcomes, as well as greater functional impairment in patients with FEP and BD (including preliminary evidence in first episode mania and adolescents) than without comorbid SUD. Comorbid SUD has been linked to an earlier age at onset of schizophrenia and BD with its clinical implication on prognosis. In the majority of cases, SUD typically precedes the onset of psychosis/schizophrenia, whereas the onset of BD often precedes that of SUD. The most common SUD is that of cannabis in FEP and first-episode/early-onset BD.

Cannabis use has been found to be an independent risk factor for the development of psychosis/schizophrenia in young adulthood. The risk for this outcome increases in a dose-dependent manner and is greater with the onset of use in adolescence and especially in vulnerable individuals. Cannabis-induced psychotic disorder has been found to be a cogent marker in the vulnerability for developing PPD. In essence, adolescents and young adults should be counseled that cannabis use may increase their likelihood of developing a PPD (82).

Other Comorbid Disorders

There is considerably less extant literature on the relationship of other comorbid disorders in adolescents with SUD. Elevated rates of anxiety disorders, including social and generalized anxiety disorders and posttraumatic stress disorder (PTSD), have been noted in clinical studies (37,83–86). From these studies, social anxiety disorders (SAD) and PTSD have been identified as the most clinically significant of the anxiety disorders. SAD precedes the onset of SUD and inherently may have an impact in SUD treatment that is oriented toward group therapy. Those with SAD may best be served initially through individual cognitive behavior-oriented SUD treatment.

The importance of PTSD in this population has significant relevance, given the high rate of physical and sexual abuse (57% of girls and 31% of boys) identified in a clinical sample across treatment settings (residential, inpatient, and out/day patient programs) (87). In a cross-sectional community sample of adolescents, a strong association was found for the comorbidity of SUD and PTSD with a significant impact on psychosocial impairment. The findings suggested multiple pathways leading to comorbid SUD and PTSD (86).

No consistent association has been found in adolescents for comorbid SUD and eating disorders (ED). There is some clinical evidence to suggest a possible relationship of SUD with bulimia (88).

ASSESSMENT OF ADOLESCENT SUBSTANCE USE DISORDERS

The importance of screening and assessing SUDs in adolescents is underscored by the recommendation of the inclusion of such screening as a part of mental health assessments of

older children and adolescents (5). Despite the importance of screening adolescents for substance use, most physicians/pediatricians feel uncomfortable screening for drug and alcohol use and even fewer feel comfortable completing a comprehensive assessment or referring adolescents for drug and alcohol treatment (89). Reasons for failure to screen adolescents for substance use and abuse include lack of training and familiarity with screening tools, lack of time to complete the assessment, need to triage competing medical problems, unfamiliarity with treatment options and resources, and issues with confidentiality and disclosure due to parents who will not leave the room (89).

Screening tools are brief self-reports or interviews often used as the initial step in assessing for adolescent substance use and related problems. The outcome of screening may determine the need for further evaluation and a more comprehensive assessment. The next step would entail a comprehensive assessment that examines the nature and severity of substance use and related problems (frequency, quantity, duration, number of substances used and circumstances, etc., problem-related consequences of substance use and treatment needs in multiple life domains (90)). The appropriateness of the instrument is dependent upon the setting for the assessment and the purpose of the assessment (91). Winters and Kaminer (90) identified and reviewed several preferred measures for screening and assessing adolescent SUD in clinical populations. Their selection of instruments was comprised of two screening tools, the CRAFFT and the Personal Experience Screening Questionnaire, and three comprehensive assessment instruments, the Global Appraisal of Individual Needs (GAIN), the Teen Severity Addiction Index, and the Personal Experience Inventory. These instruments were guided by a combination of robust psychometrics and user-friendliness. The features they examined included the strength of psychometric properties, simplicity of scoring, efficient length of administrations, and the degree of user training required. The measures were also found suitable for periodic use in re-evaluation of treatment outcome. The authors recommend that clinicians working with youth should receive training in at least one screening and one comprehensive assessment instrument, ideally during their formal years of education. For a more comprehensive review of available assessment instruments for adolescent substance use disorders, the reader is referred to a recent review of the topic by Winters and colleagues (92).

Urine drug testing is an objective measure to screen for recent drug use in a time-limited manner. However, a positive urine screen is not diagnostic of an SUD and does not provide information on substance-related problems. Echoing the findings from studies investigating the concordance between objective, self-, and collateral reports of substance use in adolescents (93,94), Winters and Kaminer (90) advocate that the use of self-report and collateral information may be the most reliable measure in many instances of assessing adolescent substance use and disorders. Nevertheless, urine drug analysis may be beneficial when screening those who fear the consequences of reported substance use and abuse or those who

are concerned about confidentiality and therefore may not respond validly. As well, it may be helpful in promoting clinical feedback to the adolescent in treatment.

Further to the instruments identified, we would like to provide additional information on three tools that may be clinically useful in screening for adolescent SUD in different settings.

The CRAFFT (95) is a six-item questionnaire designed to be given orally by the clinician during a routine interview of the adolescent patient. Responding yes to two or more of the questions indicates further assessment is required. It has been found to be predictive of SUDs (96). The CRAFFT is suitable for use in primary care settings.

The Adolescent Alcohol and Drug Involvement Scale (AADIS) (97) is a 14-item self-report instrument designed to screen for alcohol and drug abuse in adolescents, and to assess the extent to which substance use is interfering with the adolescent's psychological, social, and family functioning. A significant total score suggests alcohol and/or drug use which may reach DSM-IV criteria for an SUD, thus indicating the need for comprehensive assessment. The AADIS has reasonable psychometric properties, including moderate to good internal consistency (Cronbach's alpha from 0.42 to 0.94) and test-retest reliability ($r = 0.91$) (97). The AADIS is a suitable screening tool for clinical mental health programs and may be used as a repeated measure.

The Global Appraisal of Individual Needs-Short Screener (GAIN-SS) (98) was adapted from the GAIN. It is a brief interview questionnaire that can be self-administered and is designed to identify youth with internalizing, externalizing, substance use, and criminality problems and to triage them to the appropriate level of services and comprehensive assessment in a timely manner. Dennis and fellow researchers (98) report that the GAIN-SS is highly correlated with the GAIN, has high internal consistency, and is able to discriminate between those with and without psychiatric disorders with excellent sensitivity and specificity. The GAIN-SS is highly suitable for screening by clinicians in addiction centers or in the community to help identify comorbid mental health issues in those who present with substance use problems.

The significance of screening and assessing for SUD in adolescents using multiple sources is brought to bear by findings from a study of adolescents seeking mental health treatment (50). The study found an SUD prevalence of approximately 17% on a self-report structured measure, whereas clinicians identified less than half (45%) of these adolescents with SUD. The researchers suggested that the gap between the need and access to SUD treatment services may have contributed to poorer outcomes for youth with comorbid SUD. They also realized the important clinical consideration that clinicians should continue to screen/assess for SUD throughout treatment in that confidence to disclose this behavior may be enhanced with the establishment of a therapeutic relationship with the adolescent patient and family.

In summary, there is convincing evidence that all adolescents presenting for treatment of either substance-use or mental health problems should, at minimum and in an ongoing

manner, receive screening and as warranted more comprehensive assessment for comorbidity of substance use and mental health disorders. Assessment should include diverse sources where possible and cover multiple life domains leading to identifying the appropriate treatment sources to meet the needs of the adolescent.

TREATMENT

Treatment of adolescent SUD starts for all intents and purposes with the process of a biopsychosocial/multidimensional assessment. The American Society of Addiction Medicine Patient Placement Criteria (ASAM-PPC) for the Treatment of Substance-Related Disorders (99) sets forth consensus criteria and guidelines for adolescents with many distinguishing features from that of adults. The six dimensions identified for assessment include (a) intoxication and withdrawal potential, (b) medical conditions and complications, (c) emotional, behavioral, and cognitive condition (includes stages of development) and complications, (d) readiness for change, (e) relapse, continued use, or problem potential, and (f) recovery environment. The third dimension is further expanded into subdomains to underscore the significance of broad functional impairments that are associated with both SUD and mental health problems/psychiatric comorbidity. These subdomains are composed of dangerous/lethality, interference with addiction recovery efforts, social functioning (including educational or vocational responsibilities), ability for self-care, and course of illness. The evaluation of these key clinical domains is intended to help guide the clinician with treatment planning and toward matching the adolescent patients to the appropriate level of care. ASAM-PPC has become a standard in the addiction field in the United States. Unfortunately, only preliminary work has been done in the study and operationalization of the adolescent PPC. The reader can consult Fishman (100) for a further discussion of this topic specific to adolescents.

An area often previously overlooked in adolescents is the presence of substance withdrawal and its impact. Two recent studies support that cannabis withdrawal is common and of clinical significance in adolescents with cannabis dependence (101,102).

The treatment of adolescent SUD may occur at one of several levels of care, across a range of settings reflecting the intensity of treatment and level of supervision/restriction of environment (5). These treatment settings mainly encompass outpatient, partial hospitalization/day treatment, and inpatient or residential care. There continues to be a significant gap between adolescents who need treatment for SUD and those who receive treatment in a specialty facility. It is likely that two major factors play a role in this marked deficit of treatment: they did not seek treatment or they were unable to access treatment for various reasons (12).

As of date, there has been a proposed shift away from large-scale outcomes-based performance measurements as they may be impractical where outcomes may be reflective of

case-mix, and between program differences may be small, for identifying quality of care indicators for adolescent SUD treatment programs (103). In this vein, Brannigan and colleagues (104) identified several key elements of effective adolescent drug treatment through literature review and expert panel consensus. The key elements identified were (a) assessment and treatment matching, (b) comprehensive integrated treatment approach, (c) family involvement, (d) developmentally appropriate program in treatment, (e) engaging and retaining teens in treatment, (f) qualified staff, (g) gender and cultural competence, (h) continuing care, and (i) treatment outcomes. However, no weighting was assigned to these key elements. In a subsequent survey of highly regarded adolescent SUD treatment programs across a range of settings in the United States, most were found to be insufficiently undertaking the key elements of effective adolescent SUD treatment in their programs. The elements with the poorest quality performance were assessment and treatment matching, engaging and retaining teens in treatment, gender and cultural competence, and treatment outcomes. The authors concluded that there is a considerable need to expand the awareness of effective elements in treating adolescent SUD, and that this will heighten program improvement and also serve as a measurement of progress in the field.

In reviews of the literature on adolescent SUD treatment outcomes, it has been deduced that treatment is better than no treatment (5). The largest follow-up study to date of over 1000 adolescent patients, SUD treatment outcomes across different treatment modalities, [outpatient, short-term inpatient, and residential care] showed significant improvements in the domains of substance use, psychological adjustment, school performance, and criminal behavior at one year post treatment than in the year prior to treatment. Also, a longer duration of treatment was associated with reduced rates of substance use and arrested following treatment. This finding is similar to that in adult SUD evaluation research as well as the finding that different treatment modalities appeared to reflect different levels of problem severity (105).

Psychosocial Treatments

Waldron and Turner (106) undertook a comprehensive review and meta-analysis of specific psychosocial outpatient treatment modalities for adolescent SUD with the purpose of establishing evidence-based practice guidelines. They identified three approaches to be considered as well-established interventions: the first two being family-based approaches, Multidimensional Family Therapy (MDFT) and Functional Family Therapy, and the third being group Cognitive Behavioral Therapy (CBT). The authors also found other family models, including Multisystemic Therapy, Brief Strategic Family Therapy, and Behavioral Family Therapy, as most likely efficacious pending further exploration by independent researchers. Both Adolescent Community Reinforcement Approach (ACRA) and other individual CBT models appear promising but require further research. They also concluded that none of the

treatment approaches emerged as being superior over another. Waldron and Turner also identified Winters and colleagues' (107) evaluative study of the Minnesota Model 12-step approach for treatment of adolescent SUD as promising, with favorable substance use outcomes and worthy of further research to establish the effectiveness of this treatment approach. The Minnesota Model has been reported to be the most widely used approach in the United States for the treatment of severe SUD/substance dependence in adolescents which is typically taken within a short-term (28 days/admission to a specialized) inpatient hospital or residential care setting (107). Although, an intensive outpatient program employing the Minnesota model was included as part of Winters and colleagues' (107) study which showed similar treatment outcome findings to short-term residential care.

To date, the largest randomized adolescent SUD treatment comparison study has been the Cannabis Youth Treatment (CYT) Study (36). This multisite study ($N = 600$) was comprised of two interrelated randomized trials of five short-term psychosocial treatment interventions for outpatient adolescents with cannabis use disorders (46% met criteria for a substance dependence diagnosis). All interventions were designed to be developmentally appropriate. The study included an extended period of naturalistic follow-up of more than 8 months posttreatment, with study completion at 12 months postrandomization to treatment. All five CYT interventions, including brief psychotherapy of five sessions in total, were found to be effective, demonstrated by significant improvements in the days of abstinence by an average of 24% and the percent of adolescents in recovery (no substance use or abuse/dependence problems) averaging 24% across the 12-month duration of the study. Clinical outcomes were similar across treatment sites and interventions, with no significant differences between conditions on these outcome measures. Despite the findings of clinical improvements, more than 50% of adolescents went in and out of recovery or relapse one or more times posttreatment. The majority were still reporting substance use or related problems at 12 months. These results lead the authors to suggest a need to consider the potential role of continuing care for a significant segment of adolescents entering outpatient treatment for SUD.

Treatment Outcome Parameters

A substantive concern has been the high rates of attrition reported in adolescent SUD treatment that ranges from 20% to greater than 50% across program types (108,109). This high rate of treatment dropout is greater than that seen in adults and is likely related to the adolescents' typically low motivation for treatment and the absence of perceiving their substance use as a problem. The CYT study (41) reported that only 20% of adolescents who entered treatment viewed their substance use as a problem. There has been no thorough examination of motivation as a moderator of treatment outcome in adolescents. However, along this line of thinking, several psychosocial interventions for adolescent SUD have

specifically incorporated individual motivational enhancement therapy (MET) as part of treatment (106). Recent studies have demonstrated in several modes of treatment that formation of early therapeutic alliance predicts the likelihood that adolescents will stay in treatment and that they will have better clinical outcomes on measures of drug use as well as internalizing and externalizing behaviors (106,110).

Most adolescent SUD treatment programs advocate a primary goal of achieving and maintaining substance abstinence. The maintenance of abstinence has been linked to positive long-term psychosocial functioning in treated youth (111). Reviews of adolescent treatment outcome studies identify relatively low rates of continuous abstinence following treatment with over 50% of adolescents showing relapse of substance use by 3 months posttreatment (108,112). In comparison to adults, the rates and timing of relapse to any substance use posttreatment appear to be similar. However, the most common context for initial relapse differs between adolescents and adults. Adolescents most commonly report a social situation or peer influence such as socializing with pretreatment friends as context for initial relapse, whereas adults most commonly report negative intra- or interpersonal states (108).

Follow-up treatment studies that examine the patterns of substance use suggest fluctuations in use and problems with an overall reduction of clinical symptoms in youth who have received treatment (108). The reduction in substance use and improvement in related problems are appropriate measures of treatment outcome. Predictors of adolescent SUD treatment outcome have been historically categorized into pretreatment, in-treatment, and posttreatment determinants.

Pretreatment factors, in general, represent background and personal characteristics that, upon entering treatment, may be associated with outcome. Multiple pretreatment characteristics have been identified as potential variables that may have an impact on outcome, but study findings and the manner of reporting factors associated with treatment outcomes are inconsistent. However, a few pretreatment determinants are worth consideration, these being severity of substance use, school functioning, and social supports. Demographic characteristics of gender and ethnicity, overall, have not been found to predict outcome.

The in-treatment factors most consistently associated with favorable treatment outcomes are treatment completion, with its correlation to programs that provide comprehensive services and longer time in treatment. Posttreatment factors include a wide range of psychosocial and environmental variables that occur following treatment that may influence outcomes. Posttreatment factors most consistently related to positive outcome include, but are not limited to, participation in aftercare treatment, peer/parental social support, and prosocial activities. Posttreatment factors, as one may have expected, have been found to be the most important determinant of clinical outcomes (5,108,112,113). More recently, the literature on adolescent SUD treatment has emphasized the need for evaluation of both moderators and mediators of specific treatment interventions that may

affect outcome. Moderators are pretreatment characteristics that influence the association between treatment intervention or other independent variables and treatment outcome. Mediators are intervening determinants that may account for the association between a treatment intervention and outcome (106).

A better understanding of the impact of risk and protective factors on substance-related outcomes improves the ability to enhance treatment and relapse prevention programs (113). For example, in an adolescent treatment outcome study, persistent cigarette smokers and smoking initiators during the follow-up period of 1 year were found to be significantly at greater risk for relapse of any substance than those who quit smoking or were nonsmokers. The implications of this study would be to incorporate smoking cessation treatment in the context of adolescent SUD treatment and relapse prevention programs (114).

Several adolescent SUD studies have identified the deleterious impact of psychiatric comorbidity on treatment outcomes across treatment modalities (residential, short-term inpatient/residential care, and outpatient programs). In general, those adolescents with mixed comorbidity of both internalizing and externalizing disorders or with a greater number of comorbid psychiatric disorders showed an increased rate/level of substance relapse/use. Findings from certain studies have supported a more rapid time to relapse of substance use than those adolescents without comorbidity at treatment follow-up of 6 or 12 months (40,115–117). The majority of adolescents with comorbidity in these treatment studies presented with both comorbid internalizing and externalizing disorders. In an adolescent SUD treatment study that investigated the impact of internalizing and externalizing behaviors on clinical outcomes over both short-term (1 year) and long-term (4 and 5.5 years) follow-up, it was found that adolescents with externalizing behaviors had significantly more rapid and higher rates of substance relapse as well as lower treatment retention than those with internalizing behaviors. The authors concluded that these results suggest poorer prognostic treatment outcomes for youth who show core features of delinquency or deviant behavior (92).

Comorbid CD has been implicated in poorer SUD treatment outcomes. Kamon and colleagues (118), in an open study involving a family-based contingency management model including individual CBT provided support for the feasibility and potential for improved retention, substance use outcomes, and reduction of conduct problems in adolescents with SUD (all met criteria for cannabis use disorder), who received this intervention.

Aftercare Treatment

There is a paucity of studies examining the effectiveness of continuing care (CC) in adolescents who have received SUD treatment. Godley and colleagues (119) provided preliminary evidence in their randomized study to support the role

of assertive continuing care (ACC) involving case management and ACRA over referral to CC as usual for adolescents discharged from residential SUD treatment. Adolescents who received ACC were more likely to show greater initiation and retention in CC and improved short-term substance use outcomes in comparison to those referred for CC as usual. Adolescents who receive residential SUD treatment often have the most serious SUD and are at high risk for relapse.

Kaminer and colleagues (120) conducted the first and what would appear to be the *only* published prospective randomized controlled trial (RCT) of active aftercare intervention (five in-person or brief telephone sessions) in outpatient adolescents with AUD. The adolescents were identified for the study as having alcohol use disorders (AUD) and completed outpatient group CBT treatment for SUD with aftercare intervention being delivered in the first 3 months posttreatment. Adolescents who received aftercare were significantly less likely to experience relapse to alcohol use versus those who did not receive aftercare, despite the overall significant increase in relapse occurrence at the end of aftercare compared to the end of treatment. The authors concluded that active aftercare posttreatment was relatively efficacious but that the dose of aftercare may not have been sufficient to maintain treatment gains.

Pharmacotherapy

The role of psychopharmacology in the treatment of adolescent substance abuse has not been adequately investigated. Barriers include the lack of safety and efficacy information for the use of psychotropic medications in younger populations and a general reluctance in the consideration of psychopharmacology to treat adolescent SUD. A review of the literature investigating psychopharmacologic treatment of adolescent SUD, with or without comorbid psychiatric disorders, revealed a paucity of studies (121). However, clinical studies have reported high rates of medication use by adolescents receiving SUD treatment, though on the other hand many treatment studies will omit altogether the reporting of medication use in this population. When pharmacotherapy is used in the treatment of adolescent SUD, it is typically for comorbid psychiatric symptoms or disorders and not directly for the SUD.

Pharmacotherapy for SUD

Open-label studies of buprenorphine treatment for adolescents with opioid addiction (122), naltrexone treatment for adolescents with alcohol dependence (123), and ondansetron treatment for youth with alcohol dependence (124) have shown a reduced frequency of substance use.

Randomized clinical trials of 28 days of buprenorphine treatment (125) and 12 weeks of buprenorphine–naloxone treatment (126) in youth with opioid dependence reported significantly greater treatment retention and greater abstinence than comparison treatments of clonidine for detoxification

and short-term detoxification with buprenorphine–naloxone, respectively.

An RCT ($N = 26$) of acamprosate treatment for 90 days in adolescents with alcohol dependence reported the number of youth continuously abstinent and the number of continuous days abstinent was greater in the acamprosate group than those in the placebo group (127).

All of these studies reported pharmacotherapy in the context of concurrent psychosocial or behavioral therapies for SUD. The exact role of each therapy cannot be determined definitively. Furthermore, due to methodologic differences in research studies, results may not be replicable and are not directly comparable, rendering it difficult to assess the preference of one pharmacotherapy over another. Nevertheless, the research suggests an advantage for those using pharmacotherapy in the treatment of adolescent substance dependence, in conjunction with either psychosocial or behavioral therapy.

In a case series study by Duffy and Milin (101) of withdrawal syndrome in adolescents with cannabis dependence, the authors commented on the clinical utility of using trazodone 50 to 100 mg at bedtime to assist with withdrawal insomnia. Since then, our center has also found quetiapine 50 to 100 mg at bedtime to be helpful for cannabis withdrawal insomnia in outpatients. Research studies are required to investigate whether selective pharmacotherapy may be beneficial in the management of cannabis withdrawal symptoms and enhance rates of discontinuation of cannabis dependence in adolescents.

Pharmacotherapy for Comorbid Disorders

A randomized, controlled pilot study of sertraline in a small number of outpatient adolescents with alcohol dependence and comorbid clinical depression showed that both groups (sertraline and placebo) experienced a reduction in number of drinking days, a reduction in depression scores, and no significance between group differences. These results may have been due, at least in part, to the requirement that all subjects received CBT regardless of group membership, suggesting the potential effectiveness of CBT in treating MDD and alcohol dependence (128).

In a small open trial of fluoxetine in adolescents with comorbid MDD, SUD, and CD who were in residential treatment for SUD, found promising results. Subjects were included in the study if their depression persisted after at least 1 month of residential care and they were abstinent from substance use (129). The findings showed an improvement of depressive symptoms and functioning. Cornelius and colleagues (130) examined the effectiveness of fluoxetine, in an acute open-label trial and 5-year naturalistic follow-up study of a small group of adolescents with comorbid AUD and MDD who also received treatment as usual, individual psychotherapy, over the acute phase of the study. The acute-phase study results showed a significant reduction (improvement) in depression symptoms and alcohol use. In the 5-year follow-up phase of the study, the subjects (who were now young adults) continued to maintain

improvements in depressive symptoms although recurrent episodes were common, and comorbid AUD continued to improve over the course of follow-up.

To date, the largest published RCT of pharmacotherapy in adolescents with comorbidity ($N = 126$) evaluated the efficacy of fluoxetine and individual CBT for SUD in adolescents with MDD, SUD, and CD (131). Riggs and coauthors reported that fluoxetine combined with CBT had demonstrated greater efficacy on one of two depression response measures with a significantly greater reduction in depressive symptoms than placebo and CBT. Both treatment groups demonstrated a higher-than-expected rate of treatment response, which suggested to the researchers that CBT may have contributed to this occurrence with mixed efficacy results. There was an overall decrease in substance use and CD symptoms in both conditions but no between group differences were found. It was also reported that those adolescents who experienced remission of MDD had a greater proportion of negative results on weekly urine drug screens and self-reported days of drug use in the past month, compared to those without remission, irrespective of treatment group assignment. In terms of clinical implications, the authors proposed that the study findings showed that in the context of CBT for SUD, comorbid depression may improve or remit without antidepressant pharmacotherapy. However, if depression does not appear to be improving early in the course of SUD treatment with CBT, then fluoxetine treatment should be considered even if the adolescent is not abstinent, with careful follow-up monitoring of adherence and progress in treatment.

A subsequent RCT in adolescents ($N = 50$) with comorbid MDD and AUD also investigated the efficacy of fluoxetine treatment with all subjects receiving individual manualized CBT for the treatment of MDD and AUD, and manualized MET for SUD. Cornelius and colleagues (132) found no significant treatment outcome differences between the fluoxetine and placebo treatment groups. Both treatment groups showed significant improvements in alcohol use and depressive symptoms over the duration of the study, with having received a course of CBT/MET therapy. The number of heavy drinking days was significantly associated with the lack of remission of self-reported depressive symptoms. The study results lead the researchers to consider various reasons for their findings including limited medication efficacy, small sample size, the efficacy of CBT/MET psychotherapy and to some extent, depressive symptoms may have been alcohol/substance induced. They suggested that psychological intervention should be the first line of treatment in this adolescent comorbid MDD/AUD population with pharmacotherapy afforded to those adolescents who do not respond to psychosocial intervention alone (132). In commentary, the findings of these two RCTs of fluoxetine/placebo and CBT add to the evidence of the effectiveness of individual CBT as a treatment intervention for adolescents with SUD and especially for those adolescents with comorbid MDD.

Only one RCT study of adolescents with BD and comorbid SUD has been conducted. Geller and colleagues (133) in a small RCT ($N = 25$) examined the efficacy of acute lithium treatment in outpatients presenting with bipolar spectrum disorders and comorbid substance dependence with all subjects receiving interpersonal therapy. The lithium treatment group demonstrated a reduced number of positive drug urine screens and an improvement of general psychopathology on a measure of global assessment in comparison to those receiving placebo. However, no between group differences were found on measures of mood or substance dependence symptoms. Nevertheless, the authors concluded that lithium was an effective treatment for both disorders. Though often reported in the literature, this study has numerous limitations and there have been no further published trials to replicate or build on the findings.

In an open-label study, Riggs and colleagues investigated the effectiveness bupropion (134) in a small group of adolescent males with comorbid ADHD, SUD and CD, who were attending a residential SUD treatment program. They reported an improvement in ADHD symptoms and in overall functioning for those adolescents receiving bupropion treatment. However, the effectiveness of bupropion treatment on SUD or CD symptoms could not be evaluated as these variables were well controlled within the residential setting (134). Solhkhah and colleagues (135) also reported positive findings in a retrospective chart review of outpatient adolescents who had presented with comorbid ADHD, mood disorders and SUD and received naturalistic treatment with bupropion sustained release (SR). The adolescents showed improvement of substance use, ADHD symptoms, depressive symptoms and the severity of these disorders at 6 months of treatment. Bupropion SR was well tolerated.

In a community study, adolescents with ADHD and comorbid SUD and CD participated in an RCT ($N = 69$) to evaluate the effectiveness of pemoline treatment (136). The study results demonstrated a significant improvement in the severity of ADHD symptoms for the pemoline group as compared to the placebo group. No significant differences were found between the two groups on measures of substance use or conduct symptoms that did not differ from baseline scores. This study was unique as no concurrent psychosocial SUD treatment was provided. The authors concluded that pemoline was efficacious for ADHD but lacked effect on symptoms of CD and SUD in the absence of specific treatments for SUD supporting the clinical importance of treating comorbid ADHD in the context of concurrent SUD treatment.

A small 6-week crossover ($N = 16$) in adolescents with ADHD and SUD who received treatment with methylphenidate-SODAS, a long-acting formulation, demonstrated a significant reduction in ADHD symptoms and improvement of clinical global functioning versus placebo. There was no significant treatment effect on substance use including no increase in substance use with this long-acting treatment (137).

In a larger RCT ($N = 70$) of atomoxetine for ADHD in adolescents with SUD where all subjects received MET/CBT for SUD, no between group differences were found for ADHD or substance use. However, both groups, atomoxetine plus MET/CBT and placebo plus MET/CBT, showed a significant reduction in ADHD symptoms. The authors concluded that MET/CBT and/or a placebo response contributed to a high treatment response in the placebo group for ADHD, although substance use findings were more equivocal (138).

Riggs and colleagues have recently completed a multisite community-based RCT of OROS methylphenidate an extended release formulation, in adolescents with SUD and comorbid ADHD and the results await publication (139). An important clinical consideration in the selection of these medications for the treatment of comorbid ADHD in adolescents with SUD has been the understanding that they carry low abuse liability.

In summary, over the last decade there have been significant advances in the development of evidence-based psychosocial treatments for adolescent SUD in outpatient settings. These fall within the broad categories of family-based interventions and developmentally appropriate CBT as well as the assimilation of MET as part of these interventions. There is accumulating evidence that supports the benefit of adolescent SUD treatment programs across different settings, including residential, short-term residential/inpatient, partial hospitalization/day treatment and outpatients, as well as some promising findings with respect to aftercare.

It is well defined that treatment of comorbid psychiatric disorders in adolescent SUD remains a priority and a necessity to enhance treatment effectiveness. Pharmacotherapy for the treatment of adolescent SUD remains a work in progress, especially with respect to the direct treatment of substance dependence. At this point, the effectiveness of pharmacotherapy for such common comorbid disorders as MDD and ADHD has not been established in the context of adolescents with active substance dependence. There are mixed findings whether concurrent pharmacotherapy of these comorbid disorders may be beneficial from the onset of treatment in the framework of evidence based psychosocial therapy for adolescents presenting with SUD.

The current clinical implication being that concurrent pharmacotherapy for comorbid disorders may be best served for those adolescents engaged in SUD treatment who show persisting symptoms of MDD or ADHD with significant reduction in substance use/abstinence. Apart from the need for larger treatment studies, there is also the need for extended or maintenance pharmacotherapy trials in adolescents with SUD and comorbid disorders.

CONCLUSION

SUD is a complex and serious problem in the adolescent population with a significant impact on normal development, future SUD and thereby for society in general. Adolescent SUD must be viewed through a developmental lens with adolescence being a period of major risk for the

development of SUD. It is closely interrelated with other mental health disorders and social problems requiring comprehensive assessment and an integrated developmentally appropriate treatment approach in working with the adolescent and their family. Significant advances have occurred in determining evidence based treatments for adolescent SUD. There is a strong case that can be made for the need to provide psychiatric care for adolescents in SUD treatment with psychiatric comorbidity being more the rule rather the exception (37). The intervention needs of comorbid youth may best be served by an integrated treatment approach focusing both on SUD and comorbid psychiatric disorders in order to enhance treatment for these conditions. The implementation of treatment specific for adolescent SUD is paramount to an integrated approach. One must consider both the chronicity of SUD in some adolescent populations and the self-limited nature of substance use and related problems in others (5). Defining the adolescent SUD population better such as in terms of substance dependence and substance abuse versus the general category of SUD or employing a standard measure of substance use severity may assist in the development of more specific evidence-based treatment approaches.

ACKNOWLEDGMENT

The authors would like to gratefully acknowledge the assistance of Natasha Ferrill, BA, for all her hard work in the completion of this book chapter.

Bennett W. Fletcher ■ Wilson M. Compton

Older adults in the United States have experienced a period of rapid cultural change unlike any other in history. This period saw the United States become embroiled in a long and bloody war in Southeast Asia that fueled the rise of a youth culture of acceptance and widespread use of illicit drugs, especially marijuana. Other illicit drugs, notably heroin, also saw epidemic use in the 1960s, but that period and the decades following were characterized by the misuse of many types of illicit drug use, including use of hallucinogens and prescription medications (stimulants, depressants, and synthetic opiates), as well as cocaine and heroin. Many older adults in the United States have had personal experience with use of illicit drugs at some point in their lives. The 2008 National Survey on Drug Use and Health (NSDUH) estimated that 40% to 60% of those between the ages of 45 and 64 had used illicit drugs at some point in their lives (1). Throughout their youth and adult lives, all older adults have lived with an awareness that illicit drug use is a significant societal problem.

Some older adults who began drug use in their earlier years became addicted and continued use over time. Drug abuse in early years affects health and well-being later in life. The chronic misuse of certain drugs, particularly stimulants, is associated with neurodevelopmental abnormalities that can impair cognitive function during early to middle age (2), and that may interact with aging to speed the onset and progression of degenerative brain processes such as dementia and Alzheimer disease (3).

Other older adults who used illicit drugs may have discontinued use for long periods for the sake of family or employment. There is a concern that as their situation changes—with retirement, from social isolation following the departure of children or friends, or with the onset of a chronic illness—some older individuals may return to drug use. Chronic illness has a higher prevalence rate in older populations. Many of these illnesses are treatable, but patients with histories of illicit drug use may be susceptible to relapse, medication misuse, or harmful drug interactions if misuse is ongoing. Individuals who initiated heroin, cocaine, or hallucinogen use before the age of 30 were estimated to be three times more likely to use drugs when 50 or older (4). Projections of drug abuse in 2020 estimate a doubling of the number of adults age 50 or higher who report misuse or abuse of illicit drugs compared to 1999 to 2001 (from 1.6 million to 3.5 million), as a result of both increasing size of the older population and the higher rates of illicit drug use in this segment of the population.

The United States experienced a large increase in the number of babies born between 1946 and 1964. This “Baby Boom” cohort will begin to turn 65 in 2011. In addition, populations in the United States and many industrialized countries are becoming older as a result of increased life expectancies coupled with declining fertility rates (5). The U.S. Census Bureau estimates that in 2010 about 32% of the U.S. population, or 98.6 million residents, will be 50 years of age or older. The proportion will grow to nearly 37%, or about 161.1 million, by 2050.

The misuse and abuse of psychotropic drugs by older adults is a matter of great concern, both for the health of the individual patient and for public health. The prevalence of illicit drug abuse by those 50 and older is projected to increase in the coming years, and this will create problems for those individuals, for their families, and for a health care system that is not presently oriented toward screening, assessing, or providing care for the older drug abuser.

The purpose of this chapter is to provide an overview of the research and clinical implications for drug abuse in the older adult population, defined as adults who are age 50 or above. The topics that we review include the epidemiology of drug abuse and addiction in older adults; the implications of living in a time of widespread illicit drug use for the “baby boomer” generation; the emerging neurobiology research in two areas, aging and addiction, and how these may intersect; the impact of comorbid and chronic illnesses on drug use in the older adult population; and research on the treatment of drug abuse and addiction in the older adult.

EPIDEMIOLOGY OF DRUG ABUSE AND ADDICTION IN OLDER ADULTS

Increasing Prevalence of Illicit Drug Use

Rates of illicit drug use peak in the general population around ages 18 to 25 and decline with increasing age. Rates of illicit drug use among adults aged 65 or older have historically been quite low. However, as the baby boom generation has aged, the prevalence of illicit drug use among older adults has increased. In the 2008 NSDUH, a national household survey conducted annually by the U.S. Substance Abuse and Mental Health Services Administration (SAMHSA), 40% to 60% of those between the ages of 45 and 64 had used illicit drugs at some point in their lives (1).

Some individuals simply continue to use illicit drugs as they grow older. Han, Gfroerer, and Colliver (6) analyzed the NSDUH to explore whether the increase in use of illicit drugs by older adults was from new users (those who initiated drug use after age 50) or from resumption of illicit use after a period of abstinence, or whether use was continued over time. Continuing use was defined as past-year use (use in the 12 months prior to the survey) coupled with use in the 13 to 24 months prior to the survey. For marijuana use, the researchers found that continuing use described about 82% of current marijuana users over 50, and about 17% represented a resumption in prior use following abstinence. Only about 1% were new initiates to marijuana use; about nine tenths of those reporting lifetime illicit drug use initiated use before the age of 30. Together with the growing size of the baby boomer population, it is not surprising that the prevalence of current drug use (use of drugs in the past month) by adults aged 50 to 59 has increased in recent years, to 5% in the 2007 NSDUH, compared with 2.7% in 2002 and about 1% in 2000 (when the survey was called the National Household Survey on Drug Abuse).

Marijuana and nonmedical use of prescription drugs comprise the majority of illicit drug use by older adults, but the average age of injection drug use has also increased over time (7). Based on NSDUH surveys, the mean age of participants who had injected drugs in the past year increased from 21 years in 1979 to 36 years in 2002. From 1979 to 2002, the average age of respondents who had ever used injection drugs increased from 26 to 42 years. Injection drug use by younger adults has trended downward over the same time period. As the baby boom cohort ages, older adults will be more likely to have a lifetime history of injection drug use than younger adults. It is recommended that clinicians should routinely ask patients about present and past drug use in order to prevent public health consequences of blood-borne viruses (7).

The National Comorbidity Survey Replication (NCS-R) is a nationally representative, multistage weighted household survey of English-speaking household respondents interviewed in 2001 to 2003. The NCS-R has been used to examine the cumulative incidence of alcohol and illicit drug use in four age groups—those aged 18 to 29, 30 to 44, 45 to 59, and 60 to 98 years (8). The incidence of illicit drug use in the 45 to 59 year baby boomer cohort, those born during 1943 to 1957, was much more like that of the younger cohorts than of the oldest cohort, those born between 1904 and 1942. Another study of a general household sample of adults, the National Epidemiologic Survey on Alcohol and Related Conditions (NESARC), found similar results. Nonmedical lifetime use of prescription drugs by those aged 45 to 64 was significantly higher than by those 65 or older, but did not differ significantly from prevalence rates in younger ages (9). Depending on the drug category (sedatives, tranquilizers, opioids, or amphetamines), lifetime nonmedical use of prescription drugs in the 45 to 64 age cohort ranged from 3.3% to 4.9% in the general population.

Projected Need for Drug Abuse Treatment by Older Adults

Admissions to substance abuse treatment are counted in the United States by SAMHSA through their Drug and Alcohol Services Information System and reported in the Treatment Episode Data Set (TEDS). TEDS is an annual census of admissions to specialty treatment providers receiving public funding. While it does not include private practice providers or treatment provided by federal agencies such as the Bureau of Prisons or Veterans Administration, it provides useful trend information. The data show an upward trend in admissions to substance abuse treatment for older adults.

Figure 58.1. Changes over time in the percentage of admissions (age 50 years and old) reporting alcohol-only problem, alcohol problem with another drug problem, or drug problem without an alcohol problem. (Data from US Dept Health & Human Services, Substance Abuse and Mental Health Services Administration, Office of Applied Studies. *Treatment Episode Data Set (TEDS) Highlights—2007 National Admissions to Substance Abuse Treatment Services*. OAS Series #S-45, HHS Publication No. (SMA) 09-4360, Rockville, MD; 2009.)

Across all ages, substance abuse treatment admissions have increased over time. Total admissions to treatment reported to TEDS for a drug problem or a combined drug and alcohol problem (excluding admissions for alcohol alone) increased from 932,300 in 1992 to 1,356,802 in 2007 (10). Individuals aged 50 or older have grown from 20,383 (2.2%) admissions in 1992 to 114,561 (8.4%) in 2007 (10). There has also been a shift away from admissions for alcohol alone toward illicit drugs alone or in combination with alcohol (Fig. 58.1). In 1992, admissions for problems with alcohol made up only about 77% of all admissions for people aged 50 and higher. By 2007, over half (55%) of all older admissions were for drugs alone or in combination with alcohol, reflecting the increasing upward trend in older admissions for problems with multiple substances (11).

Estimates of future numbers of older adults using illicit drugs take account of the increasing population and the increased illicit drug use by this aging cohort. Projections suggest that the number of individuals 50 year or older who use illicit drugs will more than double in the 20 years between 2000 and 2020, from an estimated 1.6 million with past-year illicit drug use in the interval 1999 to 2001 to about 3.5 million in 2020 (4). (Note that this does not include the number who might need treatment for alcohol problems.) The number of past-year marijuana users aged 50 or higher is projected to increase by about 355% (from 719,000 to 3.3 million) in this period, and the increase projected for the nonmedical use of prescription psychotherapeutics is about 190%, from 911,000 in 1999 to 2001 to about 2.7 million in 2020.

Some of these aging individuals will develop a substance use disorder, resulting in a projected increase in demand by older adults for substance abuse treatment. Han et al. estimate that there may be 5.7 million older adults who would need treatment for alcohol or illicit drug use in 2020 (12).

EFFECTS OF DRUG USE ON HEALTH

Increased Risk of Physical Problems

Aging can be considered a set of progressive degenerative changes that cumulatively affect an individual's neurologic and physiologic capacities. The normal aging process involves a loss of brain cells, reductions in muscular volume and strength, reduced cardiovascular function, reduced function in body organs, increased vulnerability to infection and chronic illnesses, and increased risk of mental health disorders. How a given individual ages depends on genetic and environmental factors.

Drug abuse and addiction can interact with the aging brain and body to increase the apparent rate of aging by speeding the decline in cognitive and functional capacity and by increasing the vulnerability to both chronic and acute illnesses. Individuals in their 50s who have a substance use disorder may be more similar in their medical morbidity profile to non-drug-using individuals in their 60s in terms of general health, physical and social functioning, bodily pain, and mortality risk (11). Chronic misuse of addictive drugs can have

serious clinical effects. Cocaine, for example, may result in clinical problems in the following areas: cardiac, pulmonary, psychiatric, neurologic, gastrointestinal, and endocrinologic function; other physical problems (head and neck problems, optic neuropathy, thrombosis); as well as infections from intravenous use (13).

Neurotoxicity, Neuroprotective Effects

Normal aging processes interact with the neurobiologic systems implicated in drug abuse. Drugs of abuse act on the dopaminergic, serotonergic, and glutamatergic systems of the brain. It has been demonstrated, for example, that both heroin and cocaine reduce the number of dopaminergic receptors in the brain and that these changes persist for significant periods of time after cessation of drug use (14,15). The dopaminergic, serotonergic, and glutamatergic systems also change as part of normal brain aging (16). Changes associated with aging include decreases in dopamine receptor binding in the striatum and in extrastriatal regions (including the frontal cortex, anterior cingulate gyrus, temporal insula, and thalamus) that can affect motor and cognitive functions. The nature of the interactions between aging and drug misuse is an important area for further research.

Aging increases susceptibility to the neurotoxic effects of some illicit drugs, particularly methamphetamine. Aging may compound the effects of methamphetamine-induced neurotoxicity, which is associated with reductions in dopaminergic function. Chronic cocaine use at younger ages can impair the maturation of white matter—myelinated nerve axons—in the brain's temporal and frontal lobes (2). Neural transmission is related to axon diameter and thickness of the myelin sheath, and white matter is thus implicated in higher neurocognitive processing functions. Although more research is needed, cocaine use may exacerbate the loss of white matter volume, which begins to decline around age 50 as part of the natural aging process. Chronic cocaine use results in frequent and persistent hypoperfusion, or reduced cerebral blood flow. This can damage white matter in the brain, impairing normal brain development. Cocaine use is associated with both hemorrhagic and ischemic stroke. These two types of stroke have approximately equal risk of occurring with "crack" cocaine use, but powder cocaine (cocaine hydrochloride) carries a higher risk for hemorrhagic stroke than ischemic stroke. About three quarters of patients with cocaine-induced stroke have no known vascular risk factors. The possible mechanism of action for stroke includes enhanced platelet aggregation, vasospasm, cerebral vasculitis, and cardioembolism. Cocaine is a vasoconstrictor and also disturbs cerebral autoregulation, which can increase the risk of hypertensive surges and vascular rupture (13).

Interaction of Drug Neurotoxicity and Neurology of Aging

Specific drugs may interact with normal aging to increase health risks. Drug pharmacokinetics (the relationship between the drug dose and its concentration in the body) and

pharmacodynamics (the relationship between the concentration of a drug in the body and the pharmacologic response to it) change as the body ages (17). Individuals older than 65 react differently to a number of drugs (and to alcohol); of particular note are drugs affecting the central nervous system (CNS), particularly benzodiazepines and opioids. Although the mechanisms for these functional changes are not well understood, it is known that some CNS drugs may penetrate the blood–brain barrier more readily with advancing age, neurotransmitters and receptors change with age, glucose metabolism slows as cerebrovascular function declines, and hormone levels change with age.

Increased Risk of Mortality

Illicit drug use increases several premature death risk factors, and these risk factors tend to increase as an individual ages. Direct risks include the immediate consequences of drug use, including poisoning (overdose) and increased risk of an accident while intoxicated, such as falling or having a traffic accident. Indirect risks include those associated with the illicit nature of drug abuse, including criminal activity, physical trauma, arrest, and incarceration. Indirect risks also include contracting substance abuse–related illnesses, including chronic infectious diseases such as the human immunodeficiency virus (HIV) and hepatitis C, through sharing of unsanitary injection equipment. Smoking is prevalent among those who use illicit drugs and is associated with higher rates of many chronic illnesses (such as cardiovascular disease) as well as cancer.

A 14-year follow-up of a household survey of mental health in Baltimore found that those with a drug dependence diagnosis had nearly a threefold increased risk of death compared with nonusers. Using illicit drugs only a few times (that is, less than five times over a lifetime) was not associated with increased mortality, but exceeding this threshold resulted in a twofold increase in mortality risk (18). The authors estimated that individuals with a drug use disorder died on average 22.5 years earlier than those without such a diagnosis. This is comparable to findings on premature death (defined as death before age 65) in a cohort of 581 heroin addicts followed over a 33-year timespan from 1962 to 1964 to 1996 to 1997. The authors estimated that on average, Whites and Hispanics lost about 19 years, and African Americans about 9 years, to premature death (19). At the end of the 33-year follow-up, 282 subjects (48.5%) had died. The mean age at death was 46.9 years. Overdose deaths, liver disease, and fatal accidents or injuries were the three most frequent causes of premature death.

A longitudinal prospective study of a community sample of adolescents and their fathers found that fathers with a substance use disorder (about 44% of the 769 fathers) had a mortality rate about 2.5 times higher than in fathers with no substance use disorder (20). At death, the mean age of the fathers with substance use disorders was 50.7; most deaths were caused by medical problems rather than drug-related causes.

CHRONIC ILLNESSES AND USE OF MEDICATIONS: IATROGENIC ADDICTION OR ABUSIVE MISUSE

Use of Psychotropic Medications by Older Population

Psychotropic medications are commonly prescribed for older adults. It has been estimated that one third of all such psychotropic medications are prescribed for those aged 65 or older (21). Epidemiologic surveys show that increased age is associated with a higher likelihood of prescriptions for antipsychotics, antidepressants, and/or hypnotics. Women are more likely to be prescribed medications than men. These prescriptions are often for multiple indications and for long periods of time. Older adults are at risk for unintentional or “inadvertent” nonmedical use, which can result in adverse health consequences, toxicity, cognitive impairment, falls, and motor vehicle accidents. Prescription medications may also be misused. The inappropriate use of prescription drugs includes sharing medications, using higher doses for longer durations than prescribed, recreational use, and of course, persistent abuse and dependence (22).

Many psychotropic medications prescribed for older adults, including tricyclic antidepressants and benzodiazepine sedatives, can lead to a variety of cognitive impairments, including effects on attention, executive function, language, memory, and perception (23). Cognitive impairment may be reversible once the drug is discontinued (21). Benzodiazepines, either used by prescription or misused without a prescription, may cause drowsiness or cognitive impairment, increasing the possibility of falling (causing hip and thigh fractures) and of vehicle accidents.

Use of Pain Medications

Opioid analgesics are increasingly prescribed for chronic pain, and there is ongoing concern that opioids prescribed for pain management may evolve into misuse or addiction (24). Persistent pain is common among older patients, including among patients who are dependent on opioids (25). Even patients with a history of substance use disorders are more likely to be prescribed opioid medications for pain than in past years (26).

Patients prescribed opioid medications are at higher risk for opioid misuse problems, especially patients with co-occurring depressive and anxiety disorders (27). Pain can be treated successfully using opioid medications, but physicians must balance the risks and benefits of pain medication (28,29).

Pain medicine physicians would benefit from better screening methods, better ways to recognize and intervene if opioid treatment for pain shifts from benefit to harm, and better ways to screen for co-occurring mental disorders such as depression. Passik, Kirsh, and Casper provide a review of instruments that might be useful for screening pain patients (30).

A number of tools have been developed to evaluate the risk of opioid misuse with chronic pain patients. Examples

include the DIRE (Diagnosis, Intractability, Risk, and Efficacy) Score for rating patient suitability for long-term opioid analgesic treatment (31), the Screener and Opioid Assessment of Pain Patients-Revised (SOAPP-R) (32), and the STOPP (Screening Tool of Older Person's Prescriptions) (33). Of these, only the STOPP was developed specifically for older patients. The STOPP is comprehensive and covers potentially inappropriate prescribing for several of the body's systems, including the cardiovascular, central nervous, gastrointestinal, respiratory, musculoskeletal, urogenital, and endocrine systems. Sections that may be of particular interest with regard to potential drug problems include use of analgesic medications, drugs that adversely affect those at risk of falling, and identification of duplicate drug classes.

Medications and Interactions with Illicit Substances

Aging results in a progressive decline in the functional reserve of body organs and physiologic systems. Drug effects, both medical and nonmedical, can be altered by the effects of aging, including delayed renal excretion, delayed gastrointestinal absorption, increased body fat and decreased proportion of body water, and reduced basal metabolic rate (34,35). There is a decline in the functionality of the circulatory, gastrointestinal, and hepatic systems. Older adults are also much more likely to suffer from chronic illnesses such as diabetes, cardiovascular diseases, and hypertension. These diseases may have a greater impact than age per se on the level of impairment in body system functionality.

Physiologic changes associated with aging can alter drug metabolism and drug pharmacokinetics. With aging, the metabolism of many drugs is slowed, increasing their bioavailability compared to physiologically younger individuals (36). This reduced drug tolerance can contribute to accidental drug overdose or adverse drug interactions in older adults. Older adults may also reduce their level of use since the effects of illicit drug and alcohol use persist for longer periods.

Older adults are more likely to suffer from a variety of chronic physical and mental disorders than younger adults, and this likelihood increases with age. A study of a national random sample of 1.2 million Medicare beneficiaries found that 65% had multiple chronic conditions. It is estimated that prescription medications are used by 60% to 78% of older adults. Individuals 65 and older consume about 30% of all prescription medications (37). Although it has been suggested that the most common type of drug misuse is underuse, polypharmacy—prescribing multiple medications—is also common for older patients. Since the likelihood of adverse drug interactions increases with the number of medications prescribed, older adults are more susceptible to adverse drug effects simply because they are prescribed more medications than younger adults. In a sample of 626 Iowa Medicare beneficiaries, over half had received at least one potentially inappropriate medication, including drugs contraindicated for older patients, drug–drug interactions, drug–disease interac-

tions, and therapeutic duplications (38). Those with inappropriate medication use were twice as likely to report having experienced an adverse drug effect in the past year compared with patients who had no inappropriate use. However, determining the optimal prescription of medications for older adults is complex, and the various approaches that have been tested to improve prescribing practices have met with mixed success (39).

The number of prescribed psychotropic medications (antidepressants, antipsychotics, mood stabilizers, and sedative-hypnotics) has trended upward over time. Data from the National Ambulatory Medical Care Surveys show an increase in visits with two or more psychotropic medications from 42.6% in 1996 to 1997 to 59.8% in 2005 to 2006 (40). Individuals aged 45 to 64 were more likely to be prescribed two or more of these types of medications than either younger or older patients, and were also more likely to be prescribed combinations of antidepressants + antipsychotics and antidepressants + sedative-hypnotics. Multiple drug prescriptions over long periods of time and from multiple providers increase the chance of adverse drug interactions. Adverse drug interactions are more likely for older adults because of a higher level of prescribed drugs, more psychotropic drugs prescribed (especially for women), and changing pharmacokinetics, physiology, and neurophysiology in older adults (41). Drug misuse—using medications in ways other than prescribed, sharing medications, using higher doses or using for longer durations than prescribed, and of course, recreational use or abuse—can result in harmful interactions between illicit drugs and prescribed drugs. Drug or alcohol misuse may also impair the patient's ability to adhere to prescribed medications.

Many older adults drink, some in excess of recommended limits. While not a focus of this chapter, it must be noted that alcohol interacts adversely with many prescribed medications. Acute alcohol use can inhibit hepatic enzyme production, prolonging drug bioavailability and increasing potentially adverse side effects. Conversely, the efficacy of many oral medications is reduced when they are consumed with substances (including chronic alcohol use, tobacco, and barbiturates) that induce the production of liver and lower intestine enzymes, which speed medication metabolism (36,42). Alcohol use is contraindicated for a large number of prescribed and over-the-counter medications, including antihistamines; anti-infectives; antineoplastics; autonomic drugs; many cardiovascular drugs; many CNS drugs; electrolytic agents; antitussives; eye, ear, nose, and throat drugs; gastrointestinal drugs; hormones; antidiabetic drugs; and smooth muscle relaxants (43). In addition to altered efficacy, bioavailability, and drug or alcohol metabolism, adverse outcomes can include liver toxicity, gastrointestinal inflammation or bleeding, sedation and delirium, and disulfiram-like reactions (44).

Symptoms of substance abuse in the older patient may include confusion, fatigue, irritability, insomnia, forgetfulness, or emotional instability. These symptoms may be mistaken for conditions common in old age, presenting the potential

TABLE 58.1 Warning signs for prescription drug abuse

Patient behavior	Comment/example
Overreporting symptoms	Drug-seeking behavior to obtain prescriptions for controlled medications ^a
Multiple or vague somatic complaints	Pain of unclear origin, anxiety, insomnia
Insistence on specific medications	More concerned about the drug than the complaint
Refusal of generic equivalents	Trade-name prescription drugs more valuable than generics when diverted
Arguments about pharmacology	Display of sophisticated knowledge of particular drugs
Insistence on controlled prescriptions on first visit	Visit to emergency department rather than primary physician
Flattery or veiled threats followed by prescription request	“You are the only one who can help me”
Symptom complexes that seem to indicate need for multiple controlled drugs	Diagnostic/symptomatic criteria for two or more controlled drug prescriptions are rare
Self-asserted multiple medication sensitivities or high tolerance	“It is the only thing that works ...”
Scams to obtain prescriptions or refills, more potent or higher formulations, or controlled drug alternatives	“Lost” prescriptions or medications; “the dog ate it”; “but you filled it before ...”; prescription alterations or forgeries
Obtaining prescriptions for controlled drugs from two or more physicians	“Doctor shopping” to obtain prescription drugs; calling clinic after hours or when primary physician is unavailable

^aControlled drugs most often implicated in prescription abuse include opioid analgesics, benzodiazepines, stimulants, barbiturates, and sedative-hypnotics.

Data from Ref. (45) and Isaacson et al. (46).

for misdiagnosis and inappropriate prescribing. Patients may play an active role in medication misuse. The prescription medications that are most likely to be intentionally misused or abused by older adults include sedative-hypnotics (benzodiazepines and barbiturates), anxiolytics, and opioid analgesics. These medications are often prescribed for insomnia, anxiety, and chronic pain, which are conditions common in older patients (42). In turn, older patients may seek to take these because of their psychoactive effects (that is, reinforcement and reward). Prescribing clinicians should closely monitor the patient for adverse side effects, inappropriate use, or use of medications for longer periods or in higher dosages than planned. Parran (45) cautions that clinicians should be alert to strategies that drug-dependent patients may use to obtain prescribed medications (Table 58.1). He catalogs a variety of these drug-seeking behaviors; examples include insistence on specific medications (particularly on the first visit); reporting vague symptom complexes involving pain, anxiety,

and insomnia; and overreporting of multiple somatic symptoms. Parran also provides guidance for physicians who encounter a patient engaging in drug-seeking behavior. Clinicians should not underestimate the importance of family members; particularly if they are in caregiver roles, they may be able to provide information about their elders' history and status with regard to substance abuse, addiction, and drug-seeking behavior.

HIV, Aging, and Drug Abuse

HIV, the virus that causes AIDS, is most commonly contracted through sexual contact with an infected individual or through sharing contaminated syringes or other injection drug use components. Until about 1995, adults over the age of 50 comprised about 10% of the cumulative number of AIDS cases, but the number of newly diagnosed HIV infections among older adults has increased in recent years (47).

In 2005, about 19% of newly diagnosed AIDS cases were 50 or older. Given the relatively long latency period of AIDS, it is likely that many individuals live with undetected HIV infection for a number of years, and HIV infection is diagnosed only when symptoms begin to appear in later years. It is also likely that some of the increase in new cases results from higher HIV testing rates, following the revised recommendations of the U.S. Centers for Disease Control and Prevention (CDC) (48). The CDC estimated that in 2006, about 10% individuals with HIV were age 50 or older when they were infected (49).

It is estimated that by 2015 about half of all HIV-seropositive individuals will be 50 or older (50). The HIV exposure category of injection drug use has declined from its peak in the mid-1990s. In the nationally representative HIV Cost and Service Utilization Study (HCSUS), 23% of HIV cases in those over 50 were attributed to injection drug use (51). As the baby boom cohort ages, the number of adults over 50 with an injection drug use history can also be expected to increase (52). Older adults who use illicit drugs appear to be less likely to engage in risky injection drug use behavior than those under age 50, but they appear to be as likely as their younger counterparts to engage in risky sexual behavior (53). However, because of medical advances in the prevention and treatment of HIV infection, older adults who began heroin use in their later years appear to be at lower risk for HIV and other health disorders than those who began using heroin before age 30.

Although individuals with treated HIV are living longer as a result of advances in antiretroviral treatment, the time from HIV infection to the development of AIDS decreases with age, and HIV can accelerate the development of many age-related chronic illnesses. Older patients with HIV are more likely to report symptoms such as weight or hair loss and peripheral neuropathy, but may underreport other symptoms, including headaches, depression, white oral patches, and diarrhea (54). Compared with whites, older nonwhites may underreport HIV symptoms (54). Older patients tend to have better adherence to antiretroviral treatment, but CD4+ T cell restoration and immune recovery are poorer in older patients. Among those with HIV diagnoses, age and injection drug use appear to contribute independently to increased mortality measured as average years of life lost compared to life expectancies among similar individuals in the general population (55).

For a number of reasons, HIV-infected injection drug users are less likely to be prescribed antiretroviral therapy than nondrug users. Some research suggests that while older patients have better adherence to HIV medications than younger patients, ongoing illicit drug use has been associated with lower rates of antiretroviral adherence. Hinkin et al. (56) found that about half of the patients older than 50 achieved 95% adherence to highly active antiretroviral therapy (HAART), compared with only about a quarter of the younger patients. Neurocognitive impairment, which may be related both to aging and to AIDS, reduces the likelihood of good adherence and may be a more important determinant

of adherence than ongoing drug use (57). Many older drug users also have hepatitis C, acquired through injection drug use or other risky behavior in prior years (58). Antiretroviral therapy can interact with methadone medication, and while more study is needed, there is some indication that HAART may increase the risk of hepatic failure and cirrhosis in those coinfecting with HIV and hepatitis (59). Despite concerns about treating HIV-infected drug users, mortality rates in patients on HAART do not appear to be associated with a history of injection drug use (60).

TREATING SUBSTANCE ABUSE IN OLDER ADULTS

The number of individuals 50 and older admitted to drug abuse treatment in 2007 (208,910, or 11.5%) was more than double the number admitted in 1992 (102,705, or 6.6%). Alcohol, long the primary problem at treatment admission among older adults, has been supplanted as the primary problem by drugs alone and by combined drugs and alcohol for those aged 50 and older (Fig. 58.1) (11). Based on a household survey of drug use in the general (noninstitutionalized) population, it was estimated that about 4.4 million individuals 50 years or older would need treatment for drug or alcohol abuse in 2020 (61). A national survey of drug abuse treatment services for older adults found that about 18% of the 13,749 responding facilities were designed for older adults (those aged 65 or more). These tended to be associated with hospitals, especially those with psychiatric inpatient units. The number of these facilities in the states was lower than the need based on the size of the state's older population (62).

Screening and Assessment

Screening for substance use disorders is an important first step in identifying the need for preventive interventions or drug treatment in older adults. Many symptoms of substance abuse and withdrawal (such as mild cognitive impairment, irregular heartbeat, and tremor) are seen in many aging individuals. It is important for medical providers to have a high "index of suspicion" and to understand the symptoms of substance abuse and dependence in order to be able to properly diagnose, treat, and refer the older patient.

There are a number of instruments to screen and assess alcohol and drug use disorders in the general population, but many of these have shortcomings that limit their utility for clinical applications, and few have been validated for use with older adults. The Michigan Alcohol Screening Test—Geriatric Version (MAST-G) (63) and the CAGE (64) are two screening tools that have been tested with older populations. The MAST-G is a 24-item screener for alcohol problems that has good psychometric properties. A shorter, 10-item version (the SMAST-G) is also available (65). Although there is a parallel drug abuse version of the MAST, no version of the Drug Abuse Screening Test (DAST) (66) has been developed for the older individual.

The CAGE is a four-item screener that has been tested in clinical substance abuse treatment patients aged 50 and older (67). The CAGE-AID version (CAGE-Adapted to Include Drugs) (68) has four items: (a) Have you felt you should Cut down on your drinking or drug use? (b) Have people Annoyed you by criticizing your drinking or drug use? (c) Have you ever felt bad or Guilty about your drinking or drug use? and (d) Have you ever had a drink or used drugs first thing in the morning (*Eye-opener*) to steady your nerves or to get rid of a hangover? Its reviewers suggest that the specificity of the instrument may be improved for the older patient by omitting the first, “cut down,” item (67).

The Alcohol, Smoking and Substance Involvement Screening Test (ASSIST) was developed by the World Health Organization to identify substance use problems in primary care settings. The ASSIST compares favorably with a number of drug abuse screening tools in samples from several countries (69), but it has not been validated on adults older than 45 years.

Current standardized criteria for diagnosing substance use disorders were developed and validated using young and middle-aged populations. They may not be appropriate for older or elderly populations because the diagnostic criteria are oriented toward adverse consequences in a younger population (70). Diagnostic criteria based on failure to meet role obligations or adverse social, legal, or interpersonal consequences may miss older adults with substance use disorders. Older and elderly adults are more likely to be socially isolated and are less likely to be employed, married, have minor children, or have legal involvement. The criteria for increased tolerance leading to increased levels of consumption do not consider the pharmacodynamic changes that lower drug tolerance in the elderly (71). Tolerance or withdrawal symptoms may not create problems for individuals who do not have major role obligations and whose performance is therefore not closely observed. Drug and alcohol abuse and dependence rates are often very low in the older population. In the National Comorbidity Survey-Revision (NCS-R), a nationally representative sample of community-dwelling adults, only 1.5% of those aged 45 to 64 had a substance abuse disorder in the year preceding the NCS-R interview, and virtually no one aged 65 and older in this survey met criteria for past-year drug abuse (72). Rates for lifetime drug abuse were 6.0% in the 45 to 64 year age group and near zero for those 65 or older. (Dependence rates were not reported in this study because of a controversial decision to skip collection of dependence criteria unless at least one abuse criterion was reported.) Medical and psychiatric problems are more common consequences of drug misuse in the older adult (73). Thus, for the older patient, clinicians may be advised to pay more attention to quantity and frequency of use than to diagnostic cutoff scores for abuse or dependence (74).

Prevention of Illness

Drug abuse treatment can be considered primary prevention because it reduces the incidence of chronic illnesses associated with misuse of drugs. For example, for those 50 years and

above, smoking cessation interventions are primary prevention: they can increase longevity and, by avoiding the cost of treating chronic illness associated with smoking, can also reduce health care costs over the life of the individual. Models of smoking cessation suggest that it could add over 3 years to life depending on the effectiveness of the smoking cessation intervention (75).

Access to Medical Care

Because of illnesses associated with aging, the older drug abuser often has a connection with a primary care provider. This medical provider can play an important role in screening, diagnosing, and assessing substance use disorders, and in recommending and referring the patient to appropriate treatment. It is also important for physicians to recognize the risk of prescription drug abuse in their elderly patients (76).

Older Offenders

Criminal justice involvement is common among users of illicit drugs, including older adults. About a quarter of older adults admitted to treatment are referred by the criminal justice system (77). Approximately half of the individuals incarcerated in jails, state prisons, or federal correctional institutions meet criteria for drug abuse or dependence (78). In the 2008 National Survey of Drug Use and Health, a survey of the civilian noninstitutionalized population, it was estimated that over 18% of adults on parole/supervised release and about 24% of those on probation were current illicit drug users (1). These rates compare with about 7.5% of the adult population not under criminal justice supervision who were current illicit drug users.

Like the general population, the offender population is aging. From 1992 to 2001, the number of state and federal inmates aged 50 or older increased by over 170%, from 41,586 to 113,358. At least one state (Florida) has established a prison for geriatric inmates. Apart from demographic trends, this increase in the number of older offenders stems from stricter laws mandating long-term determinate sentencing for certain felonies and offender classes such as substance abusers, and the elimination of parole at the federal level and in many states.

It has been estimated that about 70% of older offenders—those aged 50 or older—have a substance use disorder. Alcohol-only disorders are more common among older inmates. Relatively few older inmates have received drug abuse treatment (79). Although some correctional administrators suggest that incarceration speeds the aging process and the general deterioration of health, others suggest that the prevalence of health problems among older inmates is similar to or only somewhat higher than those of the aging adult in the general population. These problems include dementia, cancer, stroke, incontinence, arthritis, ulcers, hypertension, chronic respiratory ailments, chronic gastrointestinal problems, prostate problems, heart disease, and deteriorating kidney functions (80). Higher rates of offender health problems may,

in part, be attributed to the long-term consequences of smoking, drug and alcohol use, and other risky and unhealthy behaviors (81).

Treatment Outcomes

Despite earlier concerns that elderly substance abuse patients might not fare well in treatment (70), many recent studies have found that older patients in treatment for substance use disorders have outcomes that are similar to or better than those of younger patients (82,83). Patients aged 55 or older do have more medical problems than younger patients, but they may have better substance abuse outcomes and comparable or better levels of functioning in mental health, family, and legal domains.

Older adults treated in the private health care system may have more favorable treatment outcomes than younger adults (84). At 5 years posttreatment, 52% of adults over 55 years of age (older adults) in a private managed care program reported total abstinence in the month prior to the interview, compared to 40% of younger adults (those aged 18 to 39). Older adults also had significantly longer periods of total abstinence, averaging nearly 2 years, compared with 1.33 years for younger adults. Older adults tended to stay in treatment longer and to have a social support network that discouraged substance abuse. Older women had somewhat more favorable outcomes than older men (or younger women), but this was explained in part by their better retention in treatment.

The service needs of methadone patients change with age. A clinical sample of methadone maintenance patients over the age of 50 ($N = 140$) was studied to determine their physical and mental health status (85). Over half the sample indicated having a mental health problem in the past year, with the most common being major depressive episode, generalized anxiety disorder, and posttraumatic stress disorder. Physical health problems were found as well; over half the sample indicated their health was fair or poor. Common complaints included arthritis and hypertension. Drug treatment may reduce medical and lifestyle risk factors associated with illicit drug use in the older patient, but older drug treatment patients may still have a higher incidence of chronic illness and other lifestyle risk factors compared to the general population (86).

SUMMARY

An increasing overall population of older Americans combined with an increasing prevalence of drug abuse and addiction in this population suggests the need for greater clinical attention to the drug abuse-related problems of aging. Specific concerns are especially rooted in the interaction of drugs of abuse with an aging body. The normal complexities and consequences of aging are accentuated in the face of drug abuse and addiction. Clinicians will need to increase their vigilance about drug abuse and addiction in their older patients.

African Americans: Alcohol and Substance Abuse

William B. Lawson ■ Jessica Herrera ■ Robert G. Lawson

INTRODUCTION

Alcohol and drugs of abuse are popular and their related disorders are common, as noted in other chapters in this volume. They are a source of substantial health care costs, morbidity, and mortality (1). The neurobiologic factors, psychological factors, and socioeconomic conditions that contribute to their widespread use and destructive capacity are well documented. These issues are true for the African American community, but there are unique factors that exacerbate both their use and outcomes. The problem of health disparities for African Americans is well documented. The Surgeon General's Report noted that African Americans had significantly greater morbidity and mortality for general medical conditions and added mental and substance abuse disorders to that list (1,2). The disparity in the prevalence of substance abuse disorders appeared to be a consequence of socioeconomic factors, lifestyle, and the disparities in care from limited access to information and services (1). In a supplement, *Mental Health: Culture, Race, and Ethnicity*, they reaffirmed these findings for mental and substance abuse disorders for racial and ethnic minorities. These and subsequent reports showed that African Americans often always were more likely to have these disorders, but not consistently so. However, they reliably carried a greater disease burden that was often a consequence of limited access to services (2,3). We will show that the life experiences and culture of the African American community both protect against and exacerbate the risk of substance abuse. However, cultural factors, limited access to services, and a focus on a correctional approach have led to a greater individual and community burden. This burden extends beyond the substance abusers and impacts others through family disintegration, loss of employment, failure in school, domestic violence, child abuse, and other crimes (3). Moreover, mental disorders are often undertreated and unrecognized in the African American community (4). The combination of mental disorders and substance abuse reinforces the consequences and risk of both conditions and worsens the outcome. Substance abuse is known to contribute to general medical disorders (1). Many of the disparities in health in general are to a large part due to substance abuse. Finally, some individuals face a triple whammy: mental disorders, substance abuse, and chronic

disease burden with such disorders as AIDS. These individuals are all too common and greatly strain the service delivery system and community burden.

We will discuss the pervasive impact of substance abuse and show its effect on social forces and health issues that extend beyond the individual and often the African American community. We will also discuss the development of new prevention and treatment approaches that when available show great promise in addressing substance abuse. The result may be a reduction in the health disparities seen in African Americans, and moreover, these treatments not only impact substance abuse, but also provide hope for many of the disorders that disproportionately kill African Americans.

Sociocultural Factors

Clearly, socioeconomic factors are important. Substance abuse costs the country over half a trillion dollars per year in direct costs, including \$181 billion for illicit drugs, \$168 billion for tobacco, and \$185 billion for alcohol (5). African American families are more likely to have incomes below the poverty level, and they are more likely to be uninsured (2). Moreover, they are often the first or second generation able to accumulate wealth. As a result, family wealth is only a fraction of that of their white counterparts (6). Consequently, there is simply not enough resources within the family to address the need for treatment services. Moreover, the stigma attached to treatment, the barriers related to racism, and the tendency to criminalize substance abuse greatly limit the willingness of the public sector to provide treatment resources (3). As a consequence, economic factors alone could contribute to the disparities seen in substance abuse consequences and lack of access to treatment. However, the Surgeon General's Reports showed that disparities in outcome persisted even when income or insurance status was controlled (1,2). Subsequent studies have shown that poverty is important, but the consequences of substance abuse extend beyond what socioeconomic factors would predict (3). Clearly, socioeconomic factors interact with sociocultural and political issues to greatly increase the burden of substance abuse on communities that often have to struggle with the effects of poverty and limited resources.

Epidemiology

African Americans are often stigmatized as being at greater risk of becoming substance abusers (2). The evidence, however, paints a more complex picture. Prevalence of overall substance abuse disorders is indeed greater (7). However, these global statistics often hide findings that show the opposite, depending on age of use, gender, residence, and type of drug. The household survey of youth consistently shows that African American youth are less likely to abuse many types of drugs and alcohol (2). Among teenagers, Caucasians are more likely to drink or use some drugs than African American youth (8). African Americans tended to begin drinking and to use marijuana at an older age than other ethnic groups and are less likely to smoke. As a consequence, African Americans are less likely to suffer from alcohol-related problems. Designer drugs are rare among African American youth (3). The peak age for injected heroin use is higher for African Americans than for Caucasians (9).

Some drugs are used heavily by African American youth. Crack cocaine is used at the same rate as or greater than in other ethnic groups (3). Most importantly, as we will show, the consequences of drug abuse are more devastating. Nevertheless, the later age of onset is worth investigating and suggests preventive factors in the lifestyle of African Americans. Overall these findings show the importance of examining the patterns of usage rather than the volume or quantity of use to better understand ethnic differences.

Preventive and Risk Factors

Multiple factors contribute to the ethnic differences in use patterns. As noted above, socioeconomic factors are important. They are important not only because the cost of a drug may determine its use, but also because income can determine where one resides. Drugs of abuse may be more easily accessible in inner city and marginalized areas. Moreover, residents in many of these areas see themselves as trapped and unable to move due to poverty and other social factors such as redlining (3).

Place of residence also adds to economic and cultural determinants. African Americans who live in the same locations as Caucasians consequently have the same use pattern. Regardless of race, the same access to drugs tend to show the same abuse pattern both in the type of drug used and in the prevalence of abuse.

The type of neighborhood also can determine the risk of exposure to trauma. Traumatic experiences are a risk factor for substance abuse even when they do not lead to post traumatic stress disorder. It is well documented that individuals in inner city neighborhood are more likely to be exposed to traumatic events (10). African Americans are especially at risk, given their residence pattern, which is often not because of choice (3).

Education and positive role models are associated with drug use. Academic achievement and peer drug use have been consistently shown to have protective effects. In a recent study,

they were shown to be significant predictors of alcohol and marijuana use among high-risk African American youth (11). Religiosity and spirituality have been proposed as protective factors (12). One way in which these factors may work in inner city youth may be through preventing posttraumatic stress disease or other complications of trauma exposure (10). Understanding the mechanisms by which religion might influence substance use and the reasons why these mechanisms may vary by race and ethnicity may provide clues to implementing effective prevention programs.

Social Consequences

Drug abuse is known to be associated with family and personal violence. Adults who were abused were often done so by an intoxicated parent leading to increased risk of drug abuse and abusive behavior. The increased risk of child abuse in African American communities can be attributed to the interaction of drug abuse with other risk factors in inner city settings. Drug abuse contributes to behaviors such as personal conflicts, poverty, poor maternal care, and other factors that increase the risk of abusive behavior (2,3).

Dealing drugs of abuse is potentially lucrative. For a low-income individual, the benefits may outweigh the risks and have the added value of giving the dealer status. Such individuals may appear altruistic to the community—as one who has the power and income to distribute resources to improve the life of everyone. However, any wealth accumulated by dealers does not offset the tremendous costs to the community of drugs of abuse. Also the dealer runs the very high risk of being incarcerated or a homicide victim as a result of turf wars (13).

The problem of gang violence is well known as a risk factor for the high rate of adolescent assaults and the extremely high homicide rate in African Americans. Unsafe communities and worsening poverty make such areas unattractive to businesses. Drug abuse is clearly a factor (3). Drug use can lead to violent turf wars, and serve as a justification for violent crimes. Even illicit but less lucrative drugs such as marijuana can contribute to gang formation and criminal activity in African American youth. In fact, alcohol and marijuana are often the most commonly used drugs (14).

One of the other consequences of drug abuse is involvement with the criminal justice system. African American substance abusers are far more likely to be referred to the correctional system than for treatment. Moreover, African Americans arrested for possession are more likely to be incarcerated than their white counterparts. These observations are significant because 40% of those in the correctional system have alcohol use and 20% have substance abuse at the time of offense, with two third actively involved in drugs prior to admission to jail (13). Incarceration means that as many as 14% of African American males can no longer vote as a result of criminal conviction. Those who have served time can be excluded from public assistance, subsidized housing programs, and college financial aid. Many are also barred from employment in certain professions, including education, childcare, and nursing home service provision.

In an effort to remedy the negative consequences of drug abuse, legislatures across the country de-emphasized treatment and addressed drug abuse exclusively as a correctional problem with stringent penalties including mandatory minimum sentences. Crack cocaine users received especially harsh sentences, while distributors of the parent drug, cocaine, were able to escape with less punishment. This legislation had the consequence of further exacerbating the disparity in incarceration seen for African Americans since they and others in poverty settings were far more likely to use crack cocaine (3).

Thus, while African Americans do not reliably use drugs more often than other ethnic groups, drug use itself interacts with other risk factors that contribute to violence and other risky behaviors. African Americans may be in fact at lower risk of drug abuse if all other factors were kept equal (15). A legacy of discrimination, poverty, and social adversity contributes to a drug abuse problem that in turn worsens the impact of drug use on both the individual and the larger society.

Medical Comorbidity

Alcohol- or substance-abusing African Americans compared to other ethnic groups have worse outcomes in mental health, physical health, and social outcomes when socioeconomic factors are controlled (1,2). These agents adversely affect health outcome irrespective of race. African Americans, however, seem to have a worse morbidity and mortality.

African American alcohol-, heroin-, or cocaine-dependent persons are less likely to have primary medical care, but more likely to have a chronic illness, prior medical hospitalizations, and more emergency room visits (15). Moreover, such findings indicate the problem of lack of access to services, since emergency room visits can be considered a proxy for limited access to treatment programs. The result is that medical comorbidities are worsened due to inadequate preventive and follow-up care.

Substance abuse also contributes to mortality. The Surgeon General's Report and other previous reports have noted the consistently lower life expectancy in African Americans in comparison to other racial and ethnic groups (1,2).

One of the most important comorbid conditions is AIDS. African Americans experience striking disparities in HIV infection rates compared with other populations, and they are at particularly high risk for developing AIDS (16). African Americans make up just 13% of the U.S. population, but more than half of the total AIDS cases diagnosed in 2004. Moreover, African American females accounted for 68% of the female HIV/AIDS diagnoses from 2001 through 2004, while white females accounted for 16% and Hispanic females 15%. Although African Americans in the 13 to 19 age group represent only 15% of U.S. teenagers, they account for 66% of new AIDS cases reported among teens. HIV infection has become the leading cause of death for African American women aged 25 to 34. Nora Volkow, director of the National

Institute on Drug Abuse (NIDA), has concluded that HIV/AIDS is now a pandemic that has literally put the world at risk. NIDA has established that drug abuse treatment is one of the most effective means of HIV prevention (17).

While intravenous drugs are well known as agents for the spread of AIDS, less recognized is the role that drug abuse plays more generally in the spread of HIV by increasing the likelihood of high-risk sex with infected partners. As a consequence, while the use of illicit substances by injection has featured prominently in the epidemic, the recent tendency to use agents intranasally such as opiates has not diminished the risk. Noninjecting drugs such as cocaine, marijuana, methamphetamine, and even alcohol are also significant cofactors that affect HIV transmission as well as the course and outcome of the disease.

Mental Illness Comorbidity

Substance abuse is often comorbid with mental disorders as well. Persons diagnosed with mood or anxiety disorders were about twice as likely to suffer also from a drug use disorder (abuse or dependence) as respondents in general. Similarly, persons diagnosed with drug disorders were roughly twice as likely to suffer also from mood and anxiety disorders (18). This observation has important implications for African Americans.

First, comorbidity may contribute to the misdiagnosis of mental disorders. It has been established in multiple studies that African Americans with mental disorders are often misdiagnosed or never diagnosed (4). As a consequence, they are often never treated or overmedicated, or not offered treatment by mental health professionals. Because drugs of abuse affect similar brain circuits or receptor mechanisms proposed for mental disorders, they can cause abusers to experience one or more symptoms of mental illness. The result is misdiagnosis and inappropriate treatment of those without a mental disorder. Second, mental illnesses can lead to drug abuse (18). In addition, individuals with overt, mild, or even subclinical mental disorders may abuse drugs as a form of self-medication. As a result, the mental disorder is ignored or considered yet another symptom of substance abuse. Treatment for mental disorder is delayed or never provided. This treatment deferral or delay is often seen in African Americans with mental disorders (2). Because drug use disorders and other mental illnesses are caused by overlapping factors such as underlying brain deficits, genetic vulnerabilities, and/or early exposure to stress or trauma, the very factors that we described earlier as risk factors for substance abuse also increase the risk of mental disorders. Finally, the combination of substance abuse and mental disorders adds greatly to the burden of illness (2). Treatment is more difficult. Services are less available, and the burden on the individual, family, and community is far greater.

Often African Americans face a triple burden as both disorders are important risk factors for general medical conditions such as HIV. In a recent study, individuals were assessed for psychiatric diagnoses, substance abuse, and HIV risk behavior using structured clinical interviews and self-report

questionnaires. The majority (75%) were sexually active in the past 6 months and reported high rates of sexual risk behaviors, including unprotected intercourse (69%), multiple partners (39%), sex with prostitutes (24%, men only), and sex trading (10%). Recent manic episode and greater drug severity were independent predictors of total HIV risk. Cocaine dependence was associated with increased risk of sex trading (19). Mental disorders and substance abuse, therefore, can interact to increase the risk for HIV.

Prevention

The paradigms of primary and secondary prevention are applicable, but they must be tailored to specific minority groups. Further exploration in this area is critical. The problem of awaiting the availability of treatment programs continues the devastating rates of HIV, violence, and incarceration for the African American population. However, a focus on a correctional approach, paucity of culturally competent providers, as well as an assumption of homogeneity in this population are barriers to the development of prevention programs.

As noted above, protective and risk factors can be identified that may impact on drug use. Such a strategy can be used to develop prevention interventions for high-risk youth. Prevention strategies indeed work. These can include parental monitoring and supervision. They may also include drug education and information for parents or caregivers. In addition, brief, family-focused interventions for the general population can positively change specific parenting behavior that can reduce later risks of drug abuse. These programs are particularly effective when culture is taken into account (19). In fact, studies have found that African American adolescents who endorse positive attitudes about being African American report more antidrug attitudes and less substance abuse (20). Therefore, enhancing racial identity may be one area that may prove beneficial for those at risk.

As noted previously, spirituality can have a protective effect (12). Spirituality has been found to be especially influential in substance abuse prevention and treatment for African Americans. Spirituality is often found to be incorporated into activities with the African American community, and most of these events are centered around the Black Church. In fact, spirituality and perceived social support were found to serve as protective factors for smoking and alcohol use among African American college students (21). Given these findings, involvement in the church may be especially salient for African Americans at risk for abuse.

Treatment

There is now little doubt that treatment can work, and it works for a variety of substances, across ethnicity, and in a variety of settings (5). Treatment programs, especially if they address cultural needs, are effective and have strong participation by ethnic minorities. Moreover, effective treatment also can mean reductions in behaviors that increase the risk of HIV (22).

Racial disparities in treatment participation and access are well documented. African Americans have more unmet

needs than other ethnic groups (23). They have less access to specialty substance abuse treatment services (24). Income and poverty are certainly important factors. As a result, African Americans have to depend on the availability of public facilities, which are sensitive to the political climate, and willingness to provide funding for treatment versus the correctional system. Also there is a perception among many African Americans that treatment programs are not culturally congruent or insensitive. However, differences persist even when income is controlled and culture is taken into account (24). Part of the disparity may be related to the unwillingness of African Americans to accept treatment. In fact, African Americans may discontinue treatment sooner, leading to a poorer outcome (25). Family privacy, lack of knowledge regarding treatment, and concerns about stigma and about medication have been reported as substantial barriers to accessing treatment. This finding is complicated by the fact that African Americans are less likely to receive outpatient care. When access to outpatient care was controlled for statistically, racial differences in residential care and overall treatment retention disappeared (26). Americans tend to have less access to professional services and more likely to include 12-step meetings, rehabilitation programs, and church-related support in their treatment (27). As a consequence, African Americans may have less access to newer treatment approaches.

The problem of access to service is further complicated by the type of services available in a given locale. In one study a city's racial composition is found to influence treatment center characteristics and services available, but the pattern is complex in that there are inequalities in treatment for certain types of services but not in others. For instance, cities with high percentages of Latinos and African Americans provide more treatment options, such as employment and domestic violence counseling or programs for gay/lesbian clients. However, minority cities have fewer integrated treatment centers that provide comprehensive assessment for substance abuse and mental health problems (28). Thus, the problem is not simply the quantity of services but the quality of services, which may greatly impact the poor and the underserved.

African Americans with substance abuse problems are more likely to be incarcerated. However, correctional settings for African Americans are more likely to be punitive rather than rehabilitative. Moreover, the limitations in personal freedom after incarceration further limit access to treatment (3,29).

African Americans have been found to have less access to newer, more effective treatment approaches in mental health services (4). The same appears to be true for substance abuse (27). For example, buprenorphine is a long-acting partial agonist that acts on the same receptors as heroin and morphine, relieving drug cravings without producing the same intense "high" or dangerous side effects. The Congress passed the Drug Addiction Treatment Act (permitting qualified physicians to prescribe narcotic medications [Schedules III to V]) for the treatment of opioid addiction. This legislation created a major paradigm shift by allowing access to opiate treatment

in a medical setting or private office rather than limiting it to federally approved Opioid Treatment Programs. Buprenorphine was found to be effective in reducing opiate abuse and is an effective tool in AIDS prevention (30). African Americans were as accepting of this treatment as other ethnic groups, yet the vast majority of those who have access to buprenorphine are white males (31).

Clearly, barriers exist that limit access to treatment. However, recent approaches to treatment have greatly improved access to care for African Americans. Untreated substance-abusing offenders are more likely to relapse to drug abuse and return to criminal behavior. This can bring about rearrest and reincarceration, jeopardizing public health and public safety and taxing the criminal justice system resources. Successful drug abuse treatment in the criminal justice system can help reduce crime as well as the spread of HIV/AIDS, hepatitis, and other infectious diseases. Introducing treatment to the correctional system improves treatment availability for African Americans because they are substantially overrepresented in this setting. Drug treatment is extremely effective in this setting in the correctional system (32). Treatment cuts drug abuse rates by half and reduces criminal activity and arrests. African Americans previously without access to treatment can have more treatment availability and avoid reincarceration. Moreover, such treatment also reduces the spread of HIV, which has been related to individuals in corrections returning to the community. Additional efforts such as drug courts to avoid incarceration and legislative changes that would make it easier for inmates to expunge a criminal record if substance use or possession is the only crime would go a long way to reduce the factors that contribute to involvement in the correctional system (3).

The notion of culturally relevant and culturally competent prevention and treatment programs has been supported by several studies. In an analysis of African American Youth in the National Cross-Site Evaluation, it was found that higher levels of satisfaction and improved outcomes were seen with culturally specific versus nonculturally specific programs (26). These studies underscore the importance of cultural aspects in the treatment of African Americans because they show a greater willingness to accept treatment and to be retained in the treatment program. There is widespread agreement that implementing an Afrocentric approach in prevention and treatment programs could prove beneficial for some communities (32).

CONCLUSION

Alcohol and substance abuse disorders greatly impact the African American community. While the prevalence of substance use is not substantially different from other ethnic groups, the burden to individuals and the community is greater. Drug abuse is clearly a problem that exacerbates the consequences of discrimination and poverty. Most importantly, substance abuse contributes to the disparities in morbidity and mortality seen in the general health in African

Americans and accounts for some of the excessive disease burden seen with mental disorders. On the other hand, there are clearly protective factors in African American culture. Moreover, advances have been made in understanding the behavior and neurobiology of addiction that has led to effective ways of detection, prevention, and treatment. These interventions work for African Americans when they have access to them and when they are culturally appropriate. The challenge is to create the public and political will to shift the addiction focus to prevention and treatment, to reduce disparities, and to improve treatment accessibility in African American communities.

INTRODUCTION

Despite the recent advances in the biopsychosocial treatment of addictive disorders, addiction to drugs and alcohol continues to be a major challenge among the different Hispanic American groups who reside in the United States. Additionally, disparities within the field of addiction are a major factor insofar as the lack of substantial progress among Hispanic American addicts who reside in this country is concerned. Racial and ethnic discrimination, excessive poverty, lack of parity between medical and addiction care, excessive emphasis on criminalization-oriented policies, lack of universal access to health care, insufficient preventive efforts, and the like all contribute to the current crisis faced in the United States insofar as access to care, full rehabilitation, and the biopsychosocial aspects of prevention of the Hispanic American addicts is concerned. As a result of this failure within the addiction system of care that currently prevails in the United States, a very large number of Hispanic American addicts do not receive appropriate treatment, and a very large number of Hispanic American addicts drop out from treatment prematurely (1). Among these previously eluded barriers to appropriate care for the Hispanic American addicts, the lack of medical insurance stands as a formidable one. Recent data originated from the National Household Survey on Drug Abuse depicts that 38% of Americans lack behavioral health coverage or do not know about their coverage (2). Among them, Hispanics, Asians, young adults between 18 and 25 years of age, adults in the lowest income levels, and less educated adults were the most likely groups to be uninsured. Obviously, untreated addictive disorders and conditions, as well as psychiatric disorders, are a major challenge to society in the United States in the 21st century. Policy makers across this country, whether it is at the local, state, or federal government, must reverse the current negative trend vis-à-vis mental health services that have prevailed in this country for several decades if not centuries. Our socially disadvantaged subgroups, especially the ethnic and minority populations, deserve to be given parity and much more attention from every sector of society (3).

Lack of culturally oriented manpower, insufficient cross-cultural expertise, lack of sensitivity toward ethnic, racial, and other minority groups, lack of appropriate educational levels, and excessive poverty levels are all contributing to the lack of preventive programs, quality of care, lack of access, insufficient psychosocial treatments, and inadequate research efforts vis-à-vis the Hispanic American addicts who reside in this

country, and we can also add to all ethnic, racial, and minority groups who reside in this country (4–6).

It is within this biopsychosocial context that in this chapter we plan to address all relevant factors pertaining to the Hispanic American substance abuser. In this respect, we plan to (a) define the population; (b) describe the relevant epidemiologic trends of the Hispanic American substance abuse groups; (c) focus on the role of migration and acculturative stress and sociocultural factors vis-à-vis substance abuse trends and rates; (d) discuss the most salient characteristics of the different Hispanic American groups who reside in this country within the realm of addictive behaviors; (e) depict the most relevant factors with respect to the minority connotations of the Hispanic American addicts; and finally (f) advance appropriate recommendations directed to effectively solve the most challenging issues within the Hispanic American addiction dilemma.

DEFINITION OF THE POPULATION

The number of Hispanics continues to grow in the United States, whether it is internal growth within the U.S. territory or via migration from Central America and the Caribbean, South America, or the Iberian Peninsula (7–9). As depicted in Table 60.1, the Hispanic population in the United States grew from 29.3 million (9%) in 1990 to 35.3 million (12.5%) in year 2000. This number does not include the Hispanic illegal aliens who are currently estimated to be about 11 million (7–9).

As seen in Table 60.2, the growth of the Hispanic population during the decade of 1990 to 2000 surpassed any other ethnic group living in the United States. Hispanics grew during this decade at a rate of 58%. In contrast, Asians grew 50%, Native Americans grew 17%, Blacks grew 16%, and the Whites grew only 3% (7,8).

The U.S. Census Bureau report, 2000 showed some very relevant data pertaining to the status of the structure of the families in the United States (8). As described in Table 60.3, 24.4% of the Hispanic families and 46.7% of the Black families living in the United States in the year 1997 were headed by women. Moreover, 39.4% of the Puerto Rican families were headed by women.

Another factor that needs to be taken into consideration with respect to the multiple ethnic and minority groups that reside in the United States is the U.S. median family income levels.

TABLE 60.1 U.S. population		
	2000	1990
	<i>N</i> (% of total)	<i>N</i> (% of total)
Total	281.4 (100)	248.8 (100)
Whites	194.6 (69.2)	188.3 (75.7)
Hispanics	35.3 (12.5)	22.4 (9.0)
Blacks	33.9 (12.1)	29.3 (11.8)
Asians	10.5 (3.7)	7.0 (2.8)
Native Americans	2.1 (0.7)	1.8 (0.7)
Other	0.5 (0.2)	N/A (N/A)
Two or more races	4.6 (1.6)	N/A (N/A)
Data from Refs. 7 to 9.		

TABLE 60.2 Population growth from 1900 to 2000	
Ethnic group	Population growth (%)
Hispanics	58
Asians	50
Native Americans	17
Blacks	16
Whites	3
Data from Refs. 7 to 8.	

TABLE 60.3 U.S. household status in 1997		
Women	Married (%)	Headed (%)
Whites	80.9	14.2
Asians	78.5	13.2
Blacks	45.5	46.7
Hispanics	68.2	24.4
Mexican Americans	72.2	20.2
Puerto Ricans	54.3	39.4
Cuban Americans	76.9	16.9
Central and South Americans	65.2	26.8
Data from the 2000 U.S. Census (www.census.gov/main/www/cen2000.html).		

As noted in Table 60.4, the median family income level for Hispanics who reside in the United States, in accordance with the U.S. Census Bureau report, 2000, was \$30,735, in comparison to \$51,205 for Asian families, \$44,366 for White families, \$30,784 for Native American families, and \$27,910 for Black families.

Given this level of median family income in accordance with the U.S. Census Bureau report, 2000, the percentage of the U.S. population below the poverty level as delineated in Table 60.5 was 10.2% for the total U.S. population, 22.7% for the Black population, 21.7% for the Hispanic population, 9.6% for the Asian population, and 5.7% for the Native American population (8).

From a different although important perspective, when defining the Hispanic population who reside in the United States, we should also address the uninsured population. In accordance with the U.S. Census Bureau report, 2000, as underlined in Table 60.6, 43.6% of illegal aliens in the United States were uninsured from a medical point of view; also, 34.2% of the foreign-born aliens were also medically uninsured; additionally, 18.2% of the naturalized U.S. population was medically uninsured, and, finally, 14.2% of the U.S. native-born population was medically uninsured (8).

TABLE 60.4 U.S. median family income in 1999

Ethnic group	Income (US\$)
Asians	51,205
Whites	44,366
Native Americans	30,784
Hispanics	30,735
Blacks	27,910

Data from the 2000 U.S. Census
(www.census.gov/main/www/cen2000.html).

TABLE 60.5 U.S. population below poverty level (\$17,029 for a family of four) in 1999

	Population (%)
Total population ^a	10.2
Blacks	22.7
Hispanics	21.7
Asians	9.6
Whites	5.7
Native Americans	N/A

^a32.3 million of 273.5 million.
Data from the 2000 U.S. Census
(www.census.gov/main/www/cen2000.html).

TABLE 60.6 U.S. uninsured population in 1997

Origin	Population (%)
Native born	14.2
Naturalized	18.2
Foreign-born alien	34.2
Illegal alien	43.6

Data from the 2000 U.S. Census
(www.census.gov/main/www/cen2000.html).

TABLE 60.7 U.S. uninsured population in 1997

Working full time	16.8%
Working part time	24.1%
Unemployed	26.2%

Data from Refs. 8 and 9.

TABLE 60.8 U.S. uninsured population in 1999

Ethnic group	Population (%)
Hispanics	33.4
Blacks	21.2
Asians	20.8
Whites	11.0
Others	13.6

Data from Refs. 8 and 9.

Likewise, as portrayed in Table 60.7, 26.2% of the unemployed population in the United States is medically uninsured, as against 24.1% of the part-time U.S. working population and 16.8% of the full-time U.S. working population (8,9).

According to the U.S. Census Bureau report, 2000, deeper analysis of the U.S. medically uninsured population, as depicted in Table 60.8, demonstrates that 33.4% of the total U.S. Hispanic population is medically uninsured, as against 21.2% of the U.S. Black population, 20.8% of the Asian population, and 11% of the White population (9).

Finally, Table 60.9 describes, in accordance with the U.S. Census Bureau report, 2000, the level of the medically uninsured among the poor population of the United States (8). In this context, 43.7% of the poor Hispanics, 41.7% of the poor Asians, 28.1% of the poor Blacks, and 28% of the poor Whites who resided in the United States were medically uninsured.

TABLE 60.9 U.S. health uninsured population in 1999^a

<i>Origin</i>	%	% Poor
Native born	13.5	28.4
Foreign born	33.4	56.1

^a Total population: 274.1 million; total poor population: 32.3 million.

Data from the 2000 U.S. Census (www.census.gov/main/www/cen2000.html).

CURRENT SUBSTANCE ABUSE TRENDS AMONG HISPANICS

Hispanics are currently the highest growing segment of the U.S. population. Similarly, 13% of the admissions in the Treatment Episode Data Set (TEDS) in 1999 were Hispanics (9). Likewise, in 1999, among Hispanic admissions to TEDS, 42% were Mexicans, 35% Puerto Ricans, 2% Cubans, and 21% other Hispanics (10). TEDS in this context represents those admitted for substance abuse treatment. TEDS also represents admissions for substance abuse treatment in facilities that receive some public funding. In 1999, in accordance with TEDS, the Hispanic gender distribution of substance abuse admissions was 69.6% Hispanic men and 31% Hispanic women. Also in 1999, the most common substances of abuse among Hispanics were alcohol (36%), opiates (32%), and marijuana (14%); other substances used by Hispanics were cocaine (11%) and stimulants (4%). The states with the largest percentages of substance abuse admission among Hispanics in 1999 according to TEDS are outlined in Table 60.10 (10).

By 2003, the gender difference with respect to Hispanic admissions for substance abuse treatment was 78% for men and 22% for women (11). Also in 2003, the Hispanic admission levels for substance abuse treatment in accordance with TEDS was 36% for alcohol, 28% for opiates, 15% for marijuana, 10% for cocaine, 9% for stimulants, and 2% for other substances. In 2003, the percentage of substance abuse treatment admissions among Hispanics between the ages of 25 and 34 was 27% for Mexicans, 31% for Cubans, and 35% for Puerto Ricans.

From a worldwide perspective, it is important to note that globally 4.4% of the burden of diseases is attributable to alcohol consumption; likewise, neuropsychiatric disorders due to alcohol use and abuse, including alcohol dependence,

account for 34% of the burden of disease and disability that is attributable to alcohol (12). Additionally, in some countries of the Americas and Eastern Europe, the estimated prevalence of disorders due to alcohol use is around 10% (12). Alcohol consumption is causally related to more than 60 international classifications of disease codes; among them liver damage, pancreatic damage, suicides, unintentional injuries, and hormonal disturbances are the prominent ones (12). In addition, disorders due to the use and abuse of alcohol also affect social services, fiscal sector, services related to law enforcement and criminal justice, fire services, transport, traffic regulations, the alcohol industry, the agricultural sector, tourism, hospitality, and the entertainment industry (12). Despite that the worldwide use of alcohol predominates among men, women are seriously affected by “alcohol use” and “alcoholism,” for instance, as a causative factor in domestic violence (12).

Within the same context, 200 million people worldwide were estimated to have used illicit drugs in the period 2005 to 2006. Among developed countries, the economic cost of illicit drug use has been estimated to be 0.2% to 2% of the gross domestic product (12). Illicit use of opioids was estimated to account for 0.7% of global DALYs in 2000 (12). The estimated number of injecting drug users worldwide is about 13 million. Cannabis is the most widely used illicit drug; that is, it is being used by 3.8% of the global population older than 15 years. Cannabis use accounts for about 80% of the illicit drug used worldwide (12). Along these lines, dependent heroin users have an increased risk of premature death from drug overdoses, violence, suicide, and causes related to alcohol. Additionally, 5% to 10% of new HIV infections worldwide are attributable to use of drugs intravenously or as a result of sharing contaminated equipment. Moreover, disorders due to use of illicit drugs are associated with an increased risk of other infectious diseases such as hepatitis B and C (12).

Finally, disorders due to the use of illicit drugs affect social services, the criminal justice system, educational sectors, and road traffic safety (12).

Undoubtedly, these worldwide examples and implications related to alcohol use and abuse, as well as substance use and abuse, have major negative impacts in a large number of Hispanics, not only in those Hispanics who live in the United States, but worldwide as well. Therefore, it is important that they are noted here and addressed fully in this chapter.

SOCIOCULTURAL CONSIDERATIONS

In recent years, a major emphasis and priority have been accorded to investigational and clinical efforts focusing on the basic social and cultural structures and processes that

influence directly or indirectly health in general, and mental health in particular, including addictive behavior. In general, social and cultural factors influence health and mental health outcomes, affecting exposure and vulnerability to illnesses, risk-taking behaviors, the efficacy of health promotion efforts, as well as access to, and availability of, health and mental health care, including addiction services, and the quality of such services. The factors that link the socio-cultural environment to health or mental health outcomes is of utmost importance. In this context, socioeconomic status, social class, gender-related issues, and ethnic and racial factors all relate to potential disparities in the health and mental health care systems. Undoubtedly, social policies and cultural norms have unique linkages to human behavior and personal health.

The influence of social and cultural factors with respect to coping strategies are intrinsically related to illness and disability, as well as the well-being of individuals, families, and community at large. Improving sociocultural conditions also have a direct impact on prevention and health promotion. In this context, many community-based practices might produce protective mechanisms against substance abuse in some populations via its influence on the structure and process of people's interpersonal relationships, as well as its impact on individuals' psychology and behavior (13). Likewise, it has been emphasized that stressors associated to cultural transmutation may exert particular pressures on Latino men, in particular to third-generation Latinos vis-à-vis substance use and abuse (14). In this study, lifetime psychiatric disorder prevalence estimates were 28.1% for men and 30.2% for women. Puerto Ricans, however, had the highest overall prevalence rate among the Latino ethnic groups assessed. Increased rates of psychiatric disorders were observed among U.S.-born, English language-proficient, and third-generation Latinos (14). This type of studies and their outcomes can certainly have an impact on clinical practice and also appropriately guide the program development.

In a recent survey conducted by the U.S. National Alcohol Survey in 2005, an attempt was made to assess the adverse impact of social disadvantages on the health status of minority populations and also, along these lines, on the relationship of social disadvantages and alcohol problems (15). The outcome of this very important survey demonstrated that Hispanic Americans and Blacks reported greater exposure to social disadvantage than Whites. Greater disadvantage in this context meant greater poverty, unfair treatment, racial/ethnic stigma, and cumulative degree of disadvantage. Additionally, the survey also showed that in all the racial and ethnic groups (Hispanic Americans, Blacks, and Whites) exposure to social disadvantage was fully correlated to problem drinking; moreover, frequent unfair treatment, high levels of racial stigma vis-à-vis Hispanic Americans and Blacks, and multiple sources of extreme social disadvantage were directly related to an increased, in the range of twofold to sixfold greater, risk of alcohol problems. This seriously detrimental outcome could be partially explained by psychological distress.

This finding is of great importance with respect to the role of sociocultural factors vis-à-vis substance use and/or abuse. Obviously, the result of this relevant survey strongly suggests that future research efforts should be dedicated to better assess causal directions in the relationships among social and economic hardships, level of stress, and alcohol problems.

On a different study, an attempt was made to assess whether ethnic and racial disparities in public-funded alcohol treatment completion are due to racial differences in attending outpatient or residential treatment (16). The outcome of this study showed that Hispanic patients were significantly less likely to complete treatment as compared with White patients. It is, therefore, expected that a reduction in racial disparities will certainly lead to an increase in enrollment of Hispanic patients who suffer from alcoholism into a residential alcohol treatment programs. A similar expectation will also hold true for Black patients. Obviously, more research is warranted insofar as the impact of disparities in alcohol treatment among ethnic and racial minorities.

From a similar viewpoint, another study focusing on Hispanic and African American adolescents who suffered from alcoholism problems demonstrated that culturally sensitive substance abuse intervention could have a positive impact in this patient population, particularly with those who demonstrate a tendency to delinquent behavior (17). In this context, cultural factors, such as ethnic orientation and ethnic mistrust, constitute influential factors among U.S.-born Hispanic youth with lower level of acculturation. This type of youth respond better to culturally sensitive methods of intervention to treat juvenile delinquency from multiethnic populations who suffer from alcoholism.

In another interesting study, it was depicted that outcome expectancy is associated with more alcohol problems based on the particular meaning of the outcome; this meaning, in turn, depends upon an individual's particular sociocultural perspective (18). These perspectives are, indeed, associated with gender and ethnicity; for instance, anticipated loss of control due to drinking excessively was more negatively related to Puerto Ricans and female alcohol problems than it was to Irish and male alcohol problems.

Ethnic identity and spirituality have both been evaluated with respect to their potential influences vis-à-vis treatment outcomes among Hispanic American addicts in treatment with methadone (19). This study showed that while spirituality has no influence vis-à-vis the increase of drug use and abuse at follow-up with methadone maintenance, ethnic identity definitely demonstrated to be related to a greater number of drugs used at follow-up with methadone maintenance treatment programs. No significant effects were found for spirituality.

In a statewide household survey of substance abuse conducted in New York State by the Division of Substance Abuse Services, Alcoholism, and Alcohol Abuse, it was demonstrated that certain correlates between culture and illicit substance use among Hispanics existed (20). For example, findings for Hispanics show that the stronger the ties to the Hispanic culture, the less likely the use of drugs is to occur; conversely, the

stronger the ties to the American culture, the more likely is the drug use. Fifty-three percent of Hispanics born in the United States reported using more illicit drugs during their lifetime, as compared to only 25% of those born in Puerto Rico and 11% of Hispanics born in other Hispanic countries. Along the same lines, 45% of Hispanics who spoke only English or mostly English had used some illicit drugs during their lifetime, whereas only 8% of those Hispanics who spoke Spanish or mostly Spanish did so. Puerto Ricans, as well as Mexican Americans, Cuban Americans, and other Hispanics who recently migrated to the United States, also must confront the additional disadvantage of a language barrier. This language barrier further complicates the acculturation process, thus increasing vulnerability to substance abuse.

To counteract these negative influences, Puerto Rican migrants who are older or have better economic resources frequently visit Puerto Rico and, thus, attempt to maintain their traditional values and customs. In contrast, younger Puerto Ricans identify more often with the "Anglo" mainland society and therefore are under greater pressure to reject their Hispanic cultures in favor of the "Anglo" majority culture. Many of them are caught between cultures, having given up or forgotten most of the cultural traditions of Puerto Rico, while not yet having developed a strong identification with the American way of life. This group is certainly very vulnerable to drug abuse. Indeed, the incidence of substance abuse among Hispanics, particularly Puerto Ricans, is higher among the youth.

In the case of Cuban Americans, there have been, so far, very limited opportunities to visit Cuba, a situation that has contributed to a stronger sense of survival within the United States. Fortunately for Cuban Americans, however, the process of acculturation has resulted in integration rather than assimilation, separation, or marginalization. The integration process has had a very positive impact insofar as substance abuse is concerned. Cuban Americans have fostered strong relations with the members of the majority "Anglo" culture, while preserving their Cuban cultural traditions and heritage. This has resulted in much less alienation and identity confusion among Cuban Americans than among other Hispanic subgroups that have migrated to the United States. Furthermore, it has assisted Cuban Americans to achieve economic success and independence in the United States.

The previously discussed sociocultural issues lead to a series of key questions concerning substance abuse among Hispanic populations. For instance, how do specific sociocultural factors common to all Hispanics affect types of drug use, patterns of abuse, and treatment needs? Despite all Hispanic subgroups having some common characteristics, such as the Spanish language, a Catholic background, Indian and/or African traits, or an Iberian heritage, they differ in the incidence and type of substance abuse. How can we account for the differences? Do Hispanics born and raised in the United States have different treatment outcomes than Hispanics born and raised outside of the United States and who later migrate to this country? If so, why? For instance, it has already been reported in the medical literature that different ethnic groups,

including Hispanics, vary in terms of response to drug dosages, side effects, and metabolism of certain psychotherapeutic medications (21). To what extent could this be physiologically caused and to what extent could this be culturally determined? These types of questions need to be investigated further so that the answers can be incorporated into the health care and substance abuse treatment armamentarium.

Also of great importance, particularly from a prevention point of view, are gender differences in current substance abuse trends. For instance, substance abuse among young Hispanic women in Puerto Rico and in the United States is on the rise, particularly for certain substances. The fact of female emancipation must be considered in the analysis of these trends, as well as the unnecessary prejudice and discrimination this emancipating process creates. Culturally determined family dynamics could also play a major role in the increased incidence of substance abuse among Hispanic women (22). Furthermore, a large number of Hispanic women in the United States are head of households and therefore are forced to function in a variety of different social roles. Undoubtedly, these situations lead to additional stress and thus to increased vulnerability to substance abuse.

Along these same lines, we must also address the special treatment needs of Hispanic female addicts. First of all, they must be treated with equality and respect. Personal and sexual issues must be addressed sensitively and with understanding, particularly when the counselors and therapists are men. The employment of Hispanic female staff is certainly indicated in programs with a large Hispanic female clientele.

In addition, the involvement of the family in the treatment process is critically important. Hispanic families have excellent networking systems, and these systems can play a positive role in both the treatment process and primary prevention. For instance, Hispanic families with no father figure are said to be more vulnerable to addiction. In these cases, the individual roles of all family members must be understood, respected, and utilized appropriately in treatment setting (1). Each member of the family plays a unique role in the dynamics of the family. For example, grandparents are respected for their wisdom, fathers for their authority, mothers for their devotion, children for their future role, and godparents (“padrinos”) for their potential available support in times of need.

At times, however, cultural values and norms may impact adversely upon the fight against substance abuse. For instance, it is well known that fatalism is an important trait among Hispanics. “Que sea lo que Dios quiera” (God willing) is an attitude frequently expressed by Hispanics (4). This posture can play a negative influence by leading an individual to avoid seeking assistance or drop out of a treatment program. We must combat, educate, persuade, and break those negative attitudes that are caused by poverty, feelings of hopelessness, and powerlessness. Conversely, key Hispanic cultural values such as dignity, respect, and love (*dignidad, respeto, y cariño*), which represent the core triangle of the Hispanic culture, can all be positively used in both treatment and prevention (1). At times, migration can also play a negative role in the fight against substance abuse because it could lead to a breakdown

of the family network system, thus making the members who migrate, as well as those who remain behind, very vulnerable to sociocultural stressors and therefore to addiction (20). Frequent visits to the native country, telephone calls, and correspondence between family members can all minimize these negative influences. In this regard, reinforcement of new networking systems, which could include treatment staff, should be maximized. This should be accomplished without fears of transference and other related psychodynamic issues.

These problems can also be addressed through the use of group therapy approaches. Group discussions with a focus on historical and/or patriotic themes, when skillfully used, could lead to improvement of individual self-esteem. In this regard, the role of church affiliation, such as Catholic, Pentecostal, and Jehovah’s Witness, or other nonorthodox religious beliefs, such as Spiritism, Santeria, Brujeria, and Curanderismo, could play a major positive role in the development of networking systems, treatment compliance, and primary prevention (16). On certain occasions, it is quite appropriate to develop linkage and liaisons between substance abuse treatment programs and religious institutions for the specific purpose of implementing preventive strategies, whether primary, secondary, or tertiary (1). These approaches have proved to be beneficial in other areas of health care, as well as in mental health, and thus could also be applied to the field of substance abuse treatment and prevention (1). Along these lines, it is important to recognize that Mexican Americans have a strong Indian heritage derived from the Aztec and Mayan cultures; thus, they share a widespread belief in Curanderismo. Similarly, Cuban Americans and Puerto Ricans have been highly influenced by the European Spiritist philosophy of Alan Kardec. Similarly, Cuban Americans, in common with many other Hispanic Caribbean populations, also believe in Santeria and Brujeria. Santeria and Brujeria are syncretistic religious beliefs that were brought to the Caribbean from Africa during the period of slavery (1).

As previously discussed and documented, sociocultural factors could play a major role in the prevention and treatment of substance abuse among Hispanics and are critically important to the development of comprehensive programs for the treatment of the substance abusers in the United States.

ETHNIC AND RACIAL CONSIDERATIONS

The term “Hispanic” describes a population that includes several ethnic subgroups representing different countries of origin. In accordance with the Drug and Alcohol Services Information System, in 2003 about 238,000 TEDS admissions were Hispanics; of this number, 41% were Mexican, 34% Puerto Rican, 3% Cuban, and 22% other Hispanic subgroups (11). It has also been advanced that Hispanics have similarities and also differences with respect to biologic factors related to drug abuse and addiction (23). Women from Hispanic origin also need to be taken into consideration with respect to addictive behavior; an estimated 1% of Hispanic women aged 12 years and older have injected drugs for addictive purposes

on at least one occasion; additionally, intravenous drug use is 4.6 to 6.5 times more often among 18- to 44-year-old Hispanic women in comparison to 12- to 17-year-old Hispanic women (24). With respect to drinking patterns among men, Mexicans report the most frequent and also the most heavy drinking, as well as the greatest prevalence of drunkenness and alcohol-related problems. Cubans report the lowest and Puerto Ricans and other Hispanic subgroups are in between Mexicans and Cubans (25).

Mexicans who migrate to the United States are considered to have a better mental health profile than do U.S.-born Mexican Americans; perhaps, this difference is due to a protective effect of traditional family networks and a lower level of expectations about what really constitutes “success” in Americans among Mexicans who migrate to the United States; however, the high rates of psychopathology among U.S.-born Mexican Americans may also be related to their easier access to abused substances and their elevated frequency of substance abuse (26,27).

In another study, it was demonstrated that smoking interventions for people of Mexican descent should be tailored in accordance with gender, nativity, and level of acculturation, as well as targeted to all ages, not just persons (28). In this study, smoking rates among Mexican-born women were lower than reported rates for Hispanics, non-Hispanic Whites, and African Americans. Among U.S.-born people, older age, male gender, a higher level acculturation, more than a high school education, and residing in a census tract with a higher median age predicted a history of smoking.

In a similar study focusing on Mexicans and Mexican Americans, men had higher rates of drug use than women for every drug; urban rates were higher than rural rates for both men and women; however, the combined effect of U.S. nativity and acculturation vis-à-vis drug use was greater among women than among men. Obviously, in this study, acculturation and U.S. nativity were risk factors for illicit drug use among Mexican origin men and women; however, women had increased vulnerability compared with men (29–31).

With respect to Puerto Ricans, a recent study has shown that Hispanic drug-using women in Puerto Rico and in New York City are exposed to severe drug treatment disparities (6). Additionally, in terms of HIV risk behavior among Puerto Rican injection drug users (IDUs), despite the decrease in the AIDS incidence in Puerto Rico, the prevalence of HIV risk behaviors in Puerto Ricans is very high (32). Another interesting study focusing on Puerto Rican addicts demonstrated that similar patterns of substance use were found for Hispanic youth living in Puerto Rico in comparison with Hispanic youth residing in the United States (33). Similarly, another study examined whether the place of residency is a factor associated with the reporting of positive HIV/AIDS, Hepatitis C (HCV), or sexually transmitted disease (STD) status in a sample of 400 IDUs residing in Puerto Rico and in the United States (Western Massachusetts). Additionally, this study showed that the Capacity Enhancement Model was successful in reducing drug use, HIV/AIDS, HCV, and STDs among

Puerto Ricans living in both Puerto Rico and Western Massachusetts (34). Along these lines, another study focusing on the role of acculturation vis-à-vis needle-sharing behavior among Puerto Rican IDUs demonstrated that incarceration could be a significant risk factor in the spread of HIV among intravenous drug users; for instance, Puerto Rican IDUs born in the mainland United States are 2.1 times more likely to share needles than their counterparts born in Puerto Rico, after controlling for gender, age, education, drug overdose, incarceration history, and psychiatric status (35–37).

PUBLIC POLICY CONSIDERATIONS

In discussing the subject of substance abuse among the different Hispanic populations residing in the United States, one must also address issues related to public policy development and implementation. To begin with, we recommend and expect that Hispanics be directly involved and fully participate in the design and implementation of such policies. This type of involvement will ensure identification with these policies and, more importantly, compliance with them. Hispanic consumers must also be involved at all levels of this process because they will be the recipients of the impact of these policies. Hispanics based on their clinical skills and cultural knowledge can better plan and design culturally sensitive program models geared to the treatment of Hispanic patients. In doing so, they can also serve as ideal role models for future generations of Hispanic mental health professionals.

An important public policy issue has to do with the development of an appropriate national database for Hispanics. So far, efforts in this regard have been limited. The collection of reliable data at a national level will be a positive step toward its application to public policy development. It was only recently that Hispanics began to be classified according to their country of origin, and that attention was given to this very important issue. Reliable national data is very powerful in calling attention to public health problems and thus leading to their solution.

Another issue that requires attention is the development of preventive and educational programs. While patient care is important, efforts directed at prevention are also essential. The spiraling costs of health care in this nation have negatively affected prevention efforts. However, the most effective method of reducing health care cost is to prevent illnesses.

We should also focus on the legal system in relation to public policy formulations. In this regard, drug legalization and decriminalization deserve consideration and attention. In analyzing legalization of drugs, we must focus on the pros and cons of drug prohibition policies. The total U.S. antidrug expenditure in 1990 was \$9.5 billion (38). Because legalization or decriminalization could lead to a reduction in the cost of the government’s antidrug expenditures, it could also lead to a redistribution of expenditures in the direction of treatment and prevention. Additionally, because legalization or decriminalization would result in lowering the cost of illicit drugs, it would also result in a decrease in drug-related criminal activ-

ities. This reduction in drug-related criminal activities would also further reduce the cost of the criminal justice system. In this regard, methadone maintenance programs represent a limited form of drug legalization and decriminalization. While the connection between drugs and crime could be seen as coincidental, it is nevertheless important. For instance, a survey conducted in 1986 among inmates of state prisons revealed that 43% were using illegal drugs on a daily basis (39). Furthermore, it is a well-accepted fact that some illicit drugs influence people to commit crimes by reducing inhibitions and increasing aggressiveness. Cocaine, for instance, is a drug that has gained this reputation in recent years. However, opponents of legalization or decriminalization claim that such measures would certainly increase drug availability, decrease their price, and remove the deterrent power of the criminal sanctions, thus leading to an increase in drug use and abuse. However, the use of tobacco has decreased in recent years as a result of educational and prevention efforts.

Undoubtedly, legalization or decriminalization of illicit drugs contains some risks. However, our current laws and policies have not yet yielded much permanent benefit. We must objectively evaluate all of our options, including legalization or decriminalization alternatives. Not doing so will help maintain the status quo and will further contribute to the deterioration on the living conditions of our ethnic minority ghetto populations, particularly Hispanics.

CONCLUSION

For decades, the substance abuse problem has been devastating for the Hispanic population residing in the United States. However, not enough attention has been given to this problem, particularly with respect to preventive approaches, epidemiologic research, culturally sensitive clinical interventions, treatment outcome studies, and public policy formulations. Additionally, program development and fiscal allocations have not been commensurate with the size of these problems. Recently, however, the substance abuse and HIV epidemics have extended into the White population of this country. As a result of this shift, the government, particularly at the federal level, has been forced to pay more attention to the substance abuse problem. Generally, traditional agencies and government bureaucracy have overlooked the need for basic awareness of the characteristics, conditions, and circumstances surrounding the Hispanic substance abuser.

Unfortunately, most of the non-Hispanic staff currently employed in substance abuse treatment programs servicing Hispanics are unprepared in terms of (a) Spanish language ability, (b) an understanding of the Hispanic substance abusers' socioeconomic background, and (c) awareness of the Hispanic culture and heritage. Undoubtedly, these critical gaps have had a negative impact on service effectiveness, positive treatment outcomes, and, even more importantly, prevention strategies. If Hispanic substance abusers are to be rehabilitated effectively, program designers and treatment staff must understand not only the values and norms inherent

in the Hispanic cultures, but also those circumstances which threaten that culture.

This chapter is aimed to shed light upon these problems and to present data to support our observations. Hopefully, through increased research efforts and appropriate financial support, we will eventually conquer this major tragedy that is currently faced by the Hispanic families.

Asian Americans and Pacific Islanders

John W. Tsuang ■ Edmond H. Pi

INTRODUCTION

Recent research findings have shown that biologic, psychological, and social/cultural factors affect the onset and course of substance abuse. Coinciding with the increasing numbers of Asian Americans and Pacific Islanders (AA/PIs) in the United States, there are increasing efforts to evaluate substance use issues among them. However, factors that influence substance abuse among AA/PIs remain multifaceted. This chapter reviews the available data related to the use of substances among AA/PIs, focusing on demographics, epidemiology, biopsychosocial factors, treatment, and prevention.

EPIDEMIOLOGY

AA/PIs are diverse in ethnicity, as well as their historical experiences in the United States. They represent heterogeneous groups differing in language, religion, culture, immigration pattern, generation, socioeconomic status, and the degree of acculturation into the mainstream American culture. However, despite all these differences, most epidemiologic studies have clustered all Asians and PIs into one grouping. Recent studies have shown a tremendous growth in the number of AA/PIs, with data suggesting that the percentage growth of the Asian population within a certain period was the highest in any ethnic group (1). This rapid growth has made existing data extremely complex, while also confusing. Thus, to simplify the issue, for the epidemiologic portion, we will summarize results for Asians and PIs as a group first and then discuss the subgroups subsequently.

The estimated number of U.S. residents in July 2007 who said they were Asian alone or Asian in combination with one or more other ethnic group was 15.2 million (1). This group comprised about 5% of the total U.S. population. Between 2006 and 2007, the percentage growth of the Asian population was 2.9%, the highest of any ethnic group during that time period (1). The increase in the Asian population during the period totaled 434,000. In 2007, there were 5 million self-identified Asians in California, the state with the largest Asian population. California also had the largest numerical increase from 2006 to 2007 at 106,000 (1). New York (1.4 million) and Texas (915,000) followed in population. Texas (44,000) and New York (33,000) followed in numerical increase. In Hawaii, Asians made up the highest proportion of the total population (55%), with California (14%) and New Jersey and Washington (8% each) next. Asians were the largest minority

group in Hawaii and Vermont. The estimated number of U.S. residents in July 2007 who said they were Native Hawaiian and Other Pacific Islander, either alone or in combination with one or more other ethnic groups, was 1 million (1). This group comprised 0.3% of the total population. In 2007, Hawaii had the largest population (269,000) of Native Hawaiians and Other Pacific Islanders (either alone or in combination with one or more other races), followed by California (262,000) and Washington (50,000). California had the largest numerical increase (2900) of people of this group, with Texas (2500) and Florida (1100) next (1). In Hawaii, Native Hawaiians and Other Pacific Islanders comprised the largest proportion (21%) of the total population, followed by Utah (1%) and Alaska (0.9%). Between 2006 and 2007, the percentage growth of the Native Hawaiian and Other Pacific Islander population was 1.6%. The increase in the Native Hawaiian and Other Pacific Islander population during the period totaled 16,000 (1).

In 2007, the major Asian groups in the United States were Chinese (3.54 million), followed by Filipinos (3.05 million), Asian Indians (2.77 million), Vietnamese (1.64 million), Koreans (1.56 million), and Japanese (1.22 million). Other Asian groups (13%) include Burmese, Cambodian, Hmong, Laotian, Thai, and Tongan. These estimates represented the number of people who were either of a particular Asian group only or of that group in combination with one or more other Asian groups or races. The major PI groups were Native Hawaiian—the largest Asian group—followed by Samoan, Guamanian or Chamorro, and other Pacific Island groups (1).

During the 1990s, the Substance Abuse and Mental Health Services Administration (SAMHSA) sponsored a series of national household surveys to measure the prevalence of illicit drug and alcohol use among Americans. AA/PIs were classified in the “other” category until 1999, when Asian and Native Hawaiian or Other Pacific Islander was separated (2). In the 2000 SAMHSA survey, 2654 AA/PIs were interviewed. It was estimated that 0.4 million (5.2%) of AA/PIs “used illicit drugs in the past year” and 0.2 million (2.7%) “used an illicit drug in the past month” (3). AA/PIs had the lowest rate of illicit drug use in comparison to the general population and to other ethnic subgroups (3). However, contrary to the popular myth of being the “model minority,” data showed that AA/PIs do use illicit drugs.

The SAMHSA survey showed that AA/PIs are more likely to drink alcohol and smoke cigarettes than to use illicit drugs (3). It was estimated that 2.3 million AA/PIs (28%) had

“used alcohol in their lifetime,” and in the 18- to 25-year-old age group, 3.2 million (39.4%) had consumed alcohol. Three million AA/PIs (38.8%) had “used cigarettes in their lifetime,” and 3.4 million (41.9%) in the 18- to 25-year-old age group had smoked in their lifetime (3). AA/PIs ranked the lowest among all racial subgroups in terms of proportions that drank alcohol or smoked cigarettes. However, the gap between AA/PIs and the next racial group (African Americans), in terms of smoking (41.9% vs. 50.2%) or drinking (39.4% vs. 43.9%), was much smaller than the differences in illicit drug use (3).

The survey showed a drop in illicit drug and alcohol use by AA/PIs when comparing data from 1999 to 2000. “Illicit drug use in the last year” went from 20.2% to 18.8%, and “any alcohol use” went from 30.7% to 28% (3). However, there were some disturbing trends in this study, as well as in others. The rates of heavy alcohol use by Asian youth (five binges in the last month) doubled from 1999 to 2000 (0.5% to 0.9%). Others researchers found that AA/PI high school students who met criteria for heavy drinking consumed more alcohol per day when they did drink (1.46 ounces/day) than did whites (0.86 ounces/day) (4). The SAMHSA survey showed that in the age group 26 years and older, Vietnamese Americans had the highest percentage of current marijuana use (2.8%). The “past-month hallucinogen use” for Asian youth was 1.4%, which is equal to the highest rates of hallucinogen use. Finally, AA/PI youths’ abuse of prescription drugs had more than tripled from 1999 to 2000 (5). One particularly concerning trend, though, is the evidence showing elevated rates of methamphetamine abuse and dependence among AA/PIs. These rates have been shown to be as high as 9% in some studies (6).

National treatment surveys showed that AA/PIs represent 4% of population, but less than 1% of them were admitted to Treatment Episode Data Set (TEDS, which is a compilation of data on those admitted to substance abuse treatment [DASIS]) (7). But the trend is changing; between 1994 and 1999, the number of AA/PI admissions increased by 37% (9800 to 13,400), while total admissions decreased by 3%. For AA/PIs, alcohol abuse counted for 34% of all admissions followed by marijuana (19%), stimulants (19%), opiates (15%), and cocaine (11%). At the time of admission, Asians were younger (average age 30 years) than the general population (average age 33 years), and a greater proportion of them were in treatment for the first time (51% vs. 36%, respectively). This increase in the number entering into substance abuse treatment might reflect more substance abuse by AA/PIs or the greater acceptance of need for treatment among Asians (7,8).

Critics have argued about the inaccuracy of national survey studies. In the SAMHSA study, results from the Native Hawaiian or Other Pacific Islanders were not reported because only 545 people were surveyed. This was unfortunate as PIs have high rates of substance abuse and alcohol use (9). By excluding them, the numbers of substance abusers among AA/PIs were artificially lowered. In addition, underreporting of substance abuse problems is prominent among AA/PIs (8).

Some Asian cultures incorporate substances use into their religious practices or daily accepted activities; thus, their uses are often not mentioned. Other issues, such as types of people surveyed, cultural and language barriers, and culturally insensitive questions, all can contribute to the lower rates of substance abuse (10). In summary, AA/PIs do have the lowest rates of illicit drug, alcohol, and cigarette use among all different ethnic subgroups. However, there is concern about increasing substance abuse among AA/PI adolescents and other high-risk groups. More current nationwide survey studies on substance abuse by different ethnic minorities need to be done.

Another behavioral addiction gaining more attention among AA/PIs is pathologic gambling. Recent community surveys have shown that approximately 30% of the AA/PI casino patrons surveyed met criteria for pathologic gambling that is strikingly high (11). Gambling problem is a century-old issue among certain Asian subgroups. However, little is known about the etiology and treatment of gambling addiction among AA/PIs. There are investigators attempting to study this area, but more attention is required.

PREVENTION

Various people have written about prevention strategies against substance abuse for AA/PIs, but the effectiveness of these measures has not been studied. Most authors agree with the thought that culturally responsive prevention strategies should be linked into the natural support systems of that particular Asian Pacific community, for example, in the Filipino community, using the church as a forum for prevention work. Prevention should provide Asian parents with the skills they need to help their children assimilate into American culture, such as helping them with their roles in the educational and recreational processes. Programs should develop strategies to minimize shame and loss of face in AA/PIs. One example of how this can be done is by using a community intermediary to manage interpersonal conflicts between parents and youth. Finally, community education programs might use more personalized contacts for prevention, such as a door-to-door education campaign in the high-risk community (8).

A family-oriented approach in which an extended family is included in issues of prevention, intervention, and treatment will have the best chance of success in the Asian community. One needs to address issues of denial, underreporting, and the need for getting outside help. It is very important to preserve the family unit as a hedge against substance use (12). Other strategies can include the use of media campaigns in their native languages and the use of high-profile community role models to advertise against substance abuse. One should also promote self-esteem and culturally appropriate life-skills building for Asian youth, and engage culturally specific human service networks for prevention process. It is imperative to understand that inclusion of family members in prevention of addiction among AA/PIs is extremely important. However, one needs to not forget the

issues of acculturation among the younger generation of the population, where society and peer values may triumph over family values. In such case, not only will the family need to be involved, but peer education in school as well as in the community will also be necessary. Needless to say, all of these recommendations on prevention approaches should be studied for their effectiveness (10).

TREATMENT

Despite the growing body of evidence that shows that addictive disorders in AA/PIs are significant, there remain many barriers to treatment. These barriers include cultural, individual, and practical issues (13). Studies have shown that AA/PIs have poor access to medical and psychiatric health care as well as to addiction treatment (14,15). This occurs despite the fact that AA/PI and non-AA/PI substance abusers do not differ in terms of treatment retention and outcome once they have received treatment (16). As seen from the TEDS data, an increasing number of AA/PIs are entering substance abuse treatment; however, they are still greatly underrepresented in various addiction treatment settings (7,17). This underrepresentation of AA/PIs in treatment may result from many factors (13,18). As for the cultural factors, the traditional way to “handle” an Asian addict is to either deny the problem or attempt to handle the issue within the family structure. Family members often rescue and enable the patient and try to solve the problem internally to maintain the appearance of normality. The strategy is to “save face,” which often causes the family to delay confrontation of the patient. By the time the addiction process becomes unmanageable, both a strong sense of failure and family shame have occurred. Thus, when an AA/PI patient is referred to a drug/alcohol treatment program, typically all other alternatives have been exhausted and they are further along in their addiction process. The family wants a “quick fix” from the treatment program, but the client is still reluctant to receive treatment. Often, abandonment of the patient can occur at this time when family support is most essential. Consequently, AA/PIs see entrance into drug and alcohol treatment programs as the last resort, while the addicts are often angry and feel abandoned, which makes their treatment even more difficult (19,20).

There are other cultural barriers facing AA/PIs for entering into a substance abuse treatment program. They include the stigma of suffering from addiction to drugs and/or alcohol, the lack of recognition of addiction as a medical disorder, the language and cultural barriers, and a sense of mistrust for the U.S. health care system. AA/PI clients also face the problem of openly acknowledging personal problems, the double standard for women, and the religious belief of fate and need for suffering. AA/PIs are also racially and culturally heterogeneous; they don't all fit well in just one type of treatment program. They probably will benefit much more from culturally sensitive and specific programs (8,19).

There are practical barriers to the delivery of care to the AA/PI population. Issues such as cost, lack of awareness that

such treatment exists, or lack of addiction treatment services are all potential limiting factors. Those who do not have access to care include those who do not speak English, recent immigrants, and the uninsured (14). Also, a critical system issue is the lack of culturally competent services tailored to specific AA/PI language, cultural beliefs, and values. Finally, the lack of evidence-based treatment program and the misinterpretation of “a cure” in substance abuse treatment, all make these important contributing factors deterring AA/PIs from entering into treatment.

Many authors have recommended strategies to overcome barriers, and understanding the cultural and practical barriers that exist is the first step to reducing them. Some have suggested that treatment programs for AA/PIs should be multicultural and multilingual (8,10,19). These services should be delivered from community-based sites with community inputs. The inpatient treatment should include a therapeutic community in residential treatment and the use of cognitive-behavioral treatment. The program should follow the traditional Alcoholics Anonymous (AA)/Narcotics Anonymous (NA) treatment strategies of combining 12-step approaches with meeting locations that are close to the local community. However, there should be some alterations to the “one-treatment-fits-all” approach. These modifications, specifically for AA/PIs, should include the strategy of reducing confrontation initially, so individuals can decrease the embarrassment, shame, and loss of face upon entering a treatment program. Additionally, having a trusted member of the Asian community present at these support groups might be helpful. Counseling approaches and peer groups should be supportive and educational, less confrontational. Family engagement, counseling, and support from the community will be crucial to the individual's recovery (8). Working with family members, even before the clients enter into treatment, might be beneficial in reducing enabling behaviors and negative emotions. Having bilingual meetings, help of local community cultural expert, and use of a medical approach that simultaneously treats medical and addiction issues might also improve acceptability of the treatment. Finally, any outside factors to increase motivation, such as court involvement (i.e., drug court), or to get the encouragement of the patriarchal member of the family will be helpful (19). Future tools to reduce barriers should be studied, and this should include collaborative efforts between the local Asian communities with the federal, state, and county agencies.

In addition to reducing barriers to substance abuse treatment for AA/PIs, one also needs to be aware of the high prevalence of mental illness among those suffering from addictive disorders. The presence of mental disorders can be a major obstacle to obtaining appropriate treatment. Studies have shown that more than half of people who meet a lifetime history of a *Diagnostic and Statistical Manual of Mental Disorders, Third Edition, Revised (DSM-III-R)* mental disorder diagnosis also have a concurrent substance abuse diagnosis, so-called co-occurring disorder patients (21,22). Given the growing evidence that mental disorders and substance abuse problems frequently co-occur, mental health assessment

among AA/PIs seeking substance abuse treatment should be conducted. Though there are no studies addressing the specific issues of treating AA/PIs with co-occurring disorders, most patients suffering from dual-diagnosis issues should be treated in an integrated treatment program for maximum benefit (23,24).

The state-of-the-art treatment for addictive disorders should include using psychosocial treatment combined with psychopharmacology. Several new pharmacotherapy agents have been developed to provide relief from acute withdrawal symptoms as well as relapse prevention and maintenance treatments. Agents for treatment of acute withdrawal are most relevant to dependence on alcohol and opioids. These include benzodiazepines, beta-blockers, barbiturates, valproate/carbamazepine for alcohol withdrawal, and buprenorphine, clonidine, and methadone for opiates (25,26). Prevention and maintenance treatments can be either blocking agents or substitution agents. In the United States, the Federal Drug Agency (FDA) has approved four agents for the treatment of alcoholism—disulfiram, naltrexone, acamprosate, and vivitrol (IM naltrexone) (25). As for opiates, FDA has approved methadone and buprenorphine for maintenance treatment (26). Unfortunately, no studies have been done for using these agents in the AA/PI populations. Thus, despite the approval of these addictive medications for treatment in the general population, their effectiveness in the ethnic Asian minority groups has not been established. One interesting side note is the fact that using pharmacotherapy for treatment of addictive disorders is not well accepted in the general substance abuse treatment community because of the belief of the need to be totally abstinent, the fear of medications, and the general distrust for the medical community. For AA/PIs, the use of medications might actually be more likely to be accepted by them, as some of the AA/PIs are more likely to associate the use of medication with treatment of medical disorders. Often they may look down upon psychosocial treatment only, and if it can combine with a legitimate medication, it might make the treatment more palatable. Thus, an unintended effect could be the better acceptance of medications and improved compliance of using them for treatment of addictive disorders.

FACTORS INFLUENCING SUBSTANCE USE IN THIS POPULATION

Genetic/Biologic Factors

Although multiple factors, including genetics, have been proposed to affect the addiction process, there is a striking lack of information between genetics and drugs of abuse in the AA/PI population. Yet the best genetic data came from the twin studies of alcohol abuse, so we use this as a model for much of the discussion that follows. Most recently, new findings have come out of China linking genetics to opioid addiction among Han Chinese. This exciting new discovery will be discussed at the end of this section.

The best-studied area is still the genetic contribution to the development of alcoholism. Family and adoption studies have found a significant hereditary contribution in alcoholism, although these data were not derived from the AA/PI population (27,28). For Asians, the transmission of alcohol genes and the mechanism for impaired alcohol metabolism are areas of special interests.

Approximately 50% of northeast Asians (Chinese, Japanese, and Koreans) have a genetically defined deficiency in the liver enzyme, aldehyde dehydrogenase (ALDH2) (29,30). This deficiency is inherited through one mutant ALDH2² allele, a dominant mutation that disrupts the function of the subunit polypeptide and reduces enzyme activity (31). The ALDH2² allele is prevalent among northeast Asians but is rare in non-Asians (32). Asians with ALDH2² alleles have slower oxidation of acetaldehyde during alcohol metabolism, resulting in the accumulation of acetaldehyde, and subsequently the exhibition of a “flushing reaction” after ingestion of alcohol (33,34). This response is accompanied by increased heart rate, visible redness, and feelings of warmth (35) that are presumably mediated through histamines and other vasoactive compounds (36). This genetically determined flushing reaction is thought to be one factor related to the reduction in alcohol consumption among Asians (37,38). Individuals with ALDH2² alleles (ALDH2^{1/2} heterozygotes or ALDH2^{2/2} homozygotes) drink less alcohol (37,39,40) and have lower rates of alcohol dependence (41,42) when compared with those with the ALDH2^{1/1} homozygous genotype. Conversely, most patients with alcoholic liver diseases have the ALDH2^{1/1} homozygous genotype (40,42).

Also 85% to 90% of northeast Asians possess an “atypical” alcohol dehydrogenase enzyme (ADH2) that can increase the capacity to convert alcohol into acetaldehyde, further contributing to the flushing reaction after alcohol ingestion (43). The ADH2 is a functional polymorphism of the alcohol dehydrogenase gene that protects against heavy drinking and alcoholism (36). To date, ALDH2 is the enzyme that is most likely to influence drinking behaviors, and it might be a protective factor for AA/PIs from alcohol dependence (30,36,40–42).

Illicit drug use and its genetic transmission is not well understood. Some researchers suggest that AA/PIs with certain genetic variations and metabolic differences might be at decreased risk for illicit drug use. For example, a recent study found that ALDH2 might be associated with the reduction in substance abuse behavior among Asians (30). Other factors such as the cytochrome P450 (CYP) system is involved in the metabolism of commonly used substances (36,44,45). Nicotine is metabolized to cotinine principally by the CYP2A6 enzyme. Individuals carrying the null (inactive) CYP2A6² or CYP2A6³ alleles have impaired nicotine metabolism compared to the active CYP2A6¹ and show reduced smoking and nicotine dependence (46). Genetic deficiency in CYP2D6 metabolism, which converts codeine to morphine derivatives, provides protection against oral opiate dependence (47). AA/PIs may show some polymorphisms in the cytochrome

enzymes that are responsible for this conversion. Thus, among AA/PIs, there are people who are extensive metabolizers (EMs) and others who are poor metabolizers (PMs) or slow metabolizers (SM), which can account for the fact that substances can be broken down in different rates. The relationship between genetic variations and the different rates of breaking down substances may all contribute to the lower rates of substance abuse by AA/PIs, and one needs to study this interaction further.

Other researchers have found evidence to suggest that genetic influences contribute to a common vulnerability for abusing marijuana, sedatives, stimulants, heroin or opiates, and psychedelics (48). In addition to this shared vulnerability, each drug has its own genetic vulnerability. For some abused drugs, there might be a stronger genetic impact on vulnerability than for other drugs (48). Results from the Wave Two study of genome-wide linkage of heroin-dependent Han Chinese found evidence for linkage at marker D17S1880, which maps to 53.4cM on chromosome 17q11.2. This has become the most strongly implicated locus for opiate addiction in this population (49). Other loci on chromosomes 1, 2, 4, 12, 16, and X also displayed significant evidence for linkage. As opioid dependence is considered a complex disorder, it is possible that other genes will make contributions to the overall risk for the development of opioid dependence. This is the strongest data thus far in the Han Chinese population that implicates a strong genetic contribution to the development of an addictive disorder. Other linkage studies are needed to find other loci as risk factors for the development of opioid and other substance abuse disorders not only in the general population but particularly among the AA/PIs.

Nonbiologic Factors

The genetic studies have made a major impact on our understanding of the inheritance of alcoholism. Even with this biologic predisposition, however, the expression of alcoholism can be affected by environmental, social, and psychological factors (40). It is difficult to disentangle the specific environmental factors that affect drinking, but for the purpose of discussion, we separate them into family/cultural, acculturation, and psychological factors.

Family/Cultural Factors

Family unity and other cultural factors play a significant role in the development of substance abuse issues. It was suggested that the relatively late age of onset of alcohol use for Asian American youth than for non-Asian American youth might be a result of parental modeling or cultural influences (30). Asian American students, who had a more abstinence-promoting environment than their European-American counterparts, were less likely to drink alcohol. Asian students were less likely to have “adult and peer influences to use alcohol or cigarettes,” “less offers of alcohol,” and “increased likelihood of having an intact family.” It was concluded that a strong family connection and the lower prevalence of parents and peer use might reduce Asian’s alcohol use (35).

The importance of norms and values in Asian cultures may moderate drinking by AA/PIs. One study proposed that attitudes about drinking, such as lack of negative feelings about alcohol by Chinese and Jewish communities, might be related to reduced alcohol consumption (50,51). Other cultural factors, such as responsibility to others, prescribed behaviors, interdependence, restraint, and group achievement, all may reduce drinking (52). Additional factors such as cultural traditions; Asian religions; respect for authority; Asians’ belief in order, propriety, and harmony; as well as concerns with shame and losing face can affect alcohol consumption (53). Some Asian cultural beliefs validate habitual alcohol and substance use. Many traditional medicines are alcohol based and are taken for energy boost (gelatin from tiger bones dissolved in alcohol) or for pain relief (opium in alcohol). Others, such as chewing of the betel quid or stimulant leaf, are done to produce euphoria (20,12,54). Use of sleeping pills to alleviate stress is also considered a culturally acceptable practice among some AA/PIs as a means of re-establishing equilibrium (12,54).

Other researchers have shown that peer pressure, acculturation, and family discord are the major factors associated with marijuana and cocaine use among AA/PIs (55). Factors related to a higher lifetime use of cigarettes, alcohol, and marijuana by high school students of Vietnamese and Chinese descent included poor school performance, low subjective well-being, lack of parents’ or peers’ disapproval of substance use, perceived tensions at school, and being male (55). At this time, although significant, not much is known about the environmental influences on illicit drug use by AA/PIs.

Acculturation Factors

The degree of acculturation into mainstream America has correlated significantly with the development of addictive disorders. This is the case not only for AA/PIs but also for Hispanics and some African Americans. The definition of the acculturation process varies, but some have based it on a number of generations residing in the United States and the ability to speak English and/or their ethnic languages. One study found that Asians who did not speak English well reported drinking less than those who did speak it well (56). It was also reported that alcohol consumption was related to generation status and birthplace. Third- and fourth-generation Asians in the United States reported more drinking than did first- and second-generation Asians. There appeared to be significant group differences in alcohol consumption between foreign-born Asians and Asians born in America (56). This was the case for Hawaiian residents of Chinese and Japanese ancestry who had lower mean levels of alcohol use if they were born in Asia than if they were born in Hawaii (57). Hawaiian residents of white ancestry had lower mean levels of alcohol use if they were born in Hawaii than if they were born on the mainland. For Hawaiians, whom many considered to be more acculturated than other AA/PI groups, alcohol use is intermediate between the lower levels found in Asia and the higher levels found in the United States. Some studies found that assimilation of recently arrived immigrant groups is associated

with increases in alcohol use. These results were found in Hispanic Americans (58), Mexican Americans (59), as well as in AAs (56,60). However, not all studies concurred with the idea that increased acculturation into Western culture will increase the amount of alcohol consumed (61,62). Nevertheless, it does appear that the acculturation process plays a role in the consumption of alcohol by AA/PIs. Some studies were done in the past to address the relationship between acculturation and addictive process, but more studies are required to better define acculturation and systematically determine the relationship between the degree of acculturation and alcohol and illicit substance use.

Psychological Factors

Psychological factors tend to be ignored by AA/PIs in the past, especially relating to addiction. Stress has been imputed to be a precursor to alcohol abuse in non-Asians as well as in Asians now (52,61,63). In general, psychological factors such as self-esteem, self-confidence, and assertiveness are related to alcohol use among adolescents (64). Psychological maladjustment was a significant factor associated with alcohol use among a sample of Chinese and Filipino youth (65). Other factors associated with risk for alcohol use among AA/PIs included pressure to succeed and a feeling of shame (10). For some Asians, the impact of immigration and accompanied psychological symptoms increased the risk for alcohol abuse (19). These immigrants suffered from feelings of personal failure and loss of control, which can lead to alcohol abuse (66). For example, Vietnamese and Highland Laotian (Hmong) immigrants reported using more alcohol as a means of coping with pain, insomnia, and alleviation of distress (20,63,67). The impact of stress and other psychological factors among people in general is obvious, and its effect on addictive process is particularly pertinent. For AA/PIs, many psychological reasons have been linked to increased alcohol abuse. However, this area continues to be poorly studied, and the degree of psychological impact on the precipitation and maintenance of alcoholism and illicit drug use among AA/PIs needs to be more intensely examined.

In summary, among AA/PIs, family and peer attitude, degree of assimilation, and psychological stresses, as well as cultural factors, appear to play a significant role in alcohol consumption. Although biologic/genetic factors are important, one must not forget the contributions of nonbiologic factors to explain racial/ethnic differences in alcohol consumption. Unfortunately, some of these studies had methodologic weaknesses, making it difficult to determine the extent of psychological/social/cultural influences on the onset and course of alcohol consumption; consequently, more studies are needed. In addition, more studies focusing on the relationships between environmental factors and illicit drug uses are needed.

CONCLUSIONS

With the rapid growth of the AA/PI populations in the United States, there is an increased need to address substance abuse issues among these populations. The limited epidemiologic data suggests that, in general, AA/PIs are at a relatively lower

risk for substance use than other ethnic groups. However, it also suggests that rates of alcohol use, smoking, and use of some illicit drugs may not be as low as generally assumed. Recent finding of a strong genetic contribution to the development of opioid addiction among Han Chinese supports the biologically mediated process in addiction but also the severity of the problem in China. We also know that environmental influences can also play a role in contributing to substance use patterns. Past findings of AA/PIs infrequently use substance treatment services, which have led to a misperception as a lack of need for services by them. In fact, AA/PIs who entered treatment are younger and appeared in treatment for the first time, suggesting an increased need and acceptance for treatment. At present, there is a paucity of empirical information on the effectiveness of treatment and prevention programs targeting AA/PIs. Professionals who treat ethnically and culturally diverse AA/PI populations with substance abuse should be aware of the issues described in this chapter, so that they can tailor therapeutic regimens to be “culturally responsive,” to assure high quality of care, and to meet the needs of population served. Because biologic, environmental, and cultural differences exist among different Asian ethnic groups, understanding similarities and differences between them can play an important role in ensuring that AA/PIs receive optimum substance abuse treatment.

American Indians and Alaska Natives

Daniel Dickerson, D.O., M.P.H.

INTRODUCTION

Living in balance and harmony has been highly valued traditional belief constructs among American Indians/Alaska Natives (AI/ANs) for many centuries. However, the introduction of the recreational use of alcohol to American Indians by English colonists hallmarked a deleterious change in the harmony and overall well-being of Indigenous groups residing in North America. Although some AI tribes fermented berries and grains to create alcohol prior to European contact, alcohol was used mostly for ceremonial activities. The first reports of overuse of alcohol among American Indians were associated with fur trading between American Indians and English colonists. The use of alcohol as a bargaining tool in fur trading by English colonists was substantial. For example, Charles Stewart, an agent to a tribe located within the colonies, believed that alcohol consisted of approximately 80% of the trade goods purchased by this tribe in 1770 (1). Consequently, many AI/ANs overindulged in drinking, which resulted in an immediate effect on tribal communities including widespread reports of violent behavior, fighting, and homicides (2). Furthermore, the effects of alcoholism in Indian communities were reported to endanger “the general Peace and Tranquility” of southern Indians (3). As a result, various ordinances and limits to alcohol trading were enacted in attempts to decrease drinking among American Indians. For example, in 1633, provincial officials in the Massachusetts Bay ordered that “noe man shall sell or give any stronge water to any Indian. [sic]” Although attempts were made to decrease drinking among American Indians during the U.S. colonial period, many have suggested that the introduction of alcohol and dysregulation of excessive trading of alcohol to American Indians for furs may have hallmarked the initial degradation and exploitation of North America’s Indigenous population and subsequent injustices experienced by this population.

Alaska Natives were introduced to alcohol in 1741 by Russian fur traders (4), in a similar fashion to American Indians. Fur traders relied upon rum and whiskey in their negotiations with Alaska Natives. Insofar as that, even the shrewdest traders or those who sought maximum profit refused to trade with a sober native (4). The demand for alcohol by Alaska Natives became significant and most likely contributed to the development of a concoction called *hoochinoo*, a fermented alcoholic beverage made from dried fruit, berries, flour, and yeast (4). This drink was made by Alaska Natives when alcohol usually supplied by Russians was not available. Alcohol use during the

1700s and 1800s throughout AN villages was significant, resulting in the prohibition of alcohol in the Territory of Alaska, which was under the jurisdiction of the U.S. War Department during this period.

The majority of AI/ANs do not experience significant substance abuse problems. However, continuing challenges exist today with regard to substance abuse in AI/AN communities. For example, compared to other racial/ethnic groups in the United States, the Indigenous populations have the highest rates of all drugs of abuse (5,6). Various reasons for significant substance abuse problems among AI/ANs include low socioeconomic status, traumatic exposure, family history of substance abuse, urbanicity, and co-occurring mental health problems (7). In addition, historical factors affecting AI/AN communities including forced relocations from native homelands and issues associated with loss of cultural identity have had profound effects among AI/ANs and may contribute to higher levels of stress and substance abuse.

Although AI/ANs have experienced significant substance abuse problems throughout the U.S. history, promising strategies for addressing the substance abuse prevention, treatment, and research needs of this population are evident and may assist in providing a comprehensive approach toward addressing this challenging public health issue. A resurgence of cultural pride and tribal recognition may also assist in addressing the many challenges associated with substance abuse in the AI/AN population.

EPIDEMIOLOGY

The study of epidemiology among AI/ANs with substance abuse is inherently challenging. Since the AI/AN population comprises 562 federally recognized tribes, characterizing substance abuse in this population as one distinct category is not possible because each tribe has its own unique history, culture, language, and traditions. In addition, there may be differences biologically as different tribal groups may have historical origins from various regions of the continent. In fact, from an anthropologic sense, AI/ANs are a part of a worldwide population of *Indigenous peoples*.

Limited information exists with regard to the epidemiology of substance abuse in AI/AN communities. The majority of studies and surveys performed have been conducted among specific tribal groups and specific regions in the United States. However, studies have demonstrated that AI/ANs have the highest rates of marijuana, cocaine, and

hallucinogen use disorders (5) and the second highest rates of methamphetamine rates, only behind another Indigenous group, Native Hawaiians (6). According to a Substance Abuse and Mental Health Services Administration (SAMHSA) survey, from 2002 to 2005, with regard to alcohol use and alcohol use disorders, a lower likelihood of using alcohol at least once in the past year was observed among AI/ANs aged 12 or older than among members of other racial groups (60.8% vs. 65.8%), but a higher likelihood of having a past-year alcohol use disorder was observed (10.7% vs. 7.6%) (5). Also according to this SAMHSA survey, from 2002 to 2005, a higher likelihood of having used an illicit drug at least once in the past year (18.4% vs. 14.6%) and having a past-year illicit drug use disorder (5.0% vs. 2.9%) was observed among AI/ANs aged 12 or older than among members of other racial groups. Also, according to the SAMHSA report, with regard to specific illicit drug use, past-year heroin use and nonmedical use of sedatives, pain relievers, and tranquilizers were similar between AI/ANs aged 12 or older and other racial groups. However, AI/ANs had a higher likelihood of using all other drugs analyzed. With regard to illicit drug use disorders, rates of past-year tranquilizer, stimulant, inhalant, pain reliever, and sedative use disorders were similar between AI/ANs and members of other racial groups, but rates were higher among AI/ANs for cocaine, hallucinogen, and marijuana use disorders. Past-year heroin use disorders were less common among AI/ANs than among members of other racial groups. Of note, anecdotal evidence suggests a rise in prescription pain medication and over-the-counter (OTC) medication abuse among AI/ANs. To date, studies analyzing prescription pain medication and OTC medication abuse among AI/ANs are very limited.

Death rates attributable to alcoholism are significant. For example, deaths attributable to alcoholism among individuals aged 15 to 24 are more than 15 times higher compared to a combined all-races group of the same age group in the United States (8). Also, death certificate data retrieved from 2001 to 2005 found that 11.7% of all AI/AN deaths were accounted for by alcohol-attributable deaths (AADs) (9). Motor vehicle accidents were identified as the leading acute cause of AADs (9). The largest number of AADs occurred in the Northern Plains (494), followed by the South West region (315), Pacific Coast region (23), and Alaska (86). Data from this analysis also found that alcoholic liver disease was the leading chronic cause of alcohol-related deaths (21.2%).

Psychiatric disorders may be significant factors among some AI/ANs with substance abuse problems. For example, high rates of comorbid psychiatric and substance use problems have been reported among American Indians (10). In a study conducted by Walker et al., among AI women with a history of alcohol dependence, higher rates of depression, anxiety, hostility, phobic anxiety, paranoid ideations, psychoses, and obsessive-compulsive behaviors have been found than among AI women without a history of alcohol dependence (10,11). Also, in a study conducted by Novins et al., among AI/AN adolescents in residential treatment, psychiatric comorbidities were reported including depression,

antisocial behavior, previous suicide attempts, and number of psychiatric symptoms (12). In addition, in a study conducted by Dickerson et al., significant psychiatric and substance use disorder comorbidities were found among a sample of AI veterans with nicotine dependence (13).

Various reports of traumatic exposure have been documented among AI/ANs with substance abuse problems. For example, American Indians with a history of childhood trauma have been shown to be more likely to use alcohol and drugs as adults. Also, an increased risk of alcohol and other drug dependence has been demonstrated among a sample of Northern Plains Indians with a history of childhood physical abuse (14). Also, among a sample of AI adolescents and young adults living on or near two closely related AI reservations, severe traumatic exposure was associated with increased odds of having an alcohol use disorder (15).

SAMHSA utilized data combined from 2002 and 2003 in its SAMHSA's National Survey on Drug Use and Health to evaluate risk factors for substance use among three categories (individual/peers, family, and school) (16). Risk factors were compared between AI/AN youth and other racial/ethnic groups among 46,310 individuals between 12 and 17 years of age. Findings revealed that AI/ANs were more likely than youths from other racial/ethnic groups to perceive moderate to no risk associated with substance use, to believe that all or most of the students in their school get drunk at least once a week, and to perceive their parents as not strongly disapproving of their substance use. In addition, AI/AN youths were less likely than youths from other racial/ethnic groups to participate in youth activities and to attend religious services regularly. However, parents of AI/AN youth were as likely to discuss with their children about the dangers associated with substance use, to praise the youth when they had done a good job and to let them know that they were proud of something they had done, to set limits with regard to the amount of watching TV, and to expect their youth to do chores around the house.

Studies analyzing predictors of relapse for AI/ANs have been limited. However, one study conducted among AI women enrolled in residential substance abuse treatment found that intrapersonal factors were the strongest predictors of relapse, followed by proximal and distal factors (17). Proximal factors are defined as factors that occur close in time to the relapse event and precipitate substance use. Distal factors are factors that occur farther back in the patient's history. Significant factors associated with alcohol relapse in the short term (6 months following entry into residential treatment) included being around individuals who use alcohol and drugs (proximal factors) and craving alcohol or drugs (intrapersonal factors). Significant factors associated with drug use relapse in the short term included having conflicts with other people at intake and within the proximal timeframe, the number of years that the client had used more than one drug regularly (not including alcohol), and being around others using alcohol or drugs. Significant factors associated with alcohol use relapse in the long term (12 months following entry into residential treatment)

included reported family conflicts at intake (distal), being around individuals who use alcohol or drugs (proximal), and craving alcohol (interpersonal). Predictors of drug use in the long term included having conflicts with family at intake, using polydrugs, being around others who use alcohol or drugs, and craving drugs. In addition, these authors found various factors associated with a reduced probability of alcohol use at 6 months, including having drug treatment experience, using drugs with family members, having a father who had warned about alcohol and drugs, having a positive rating in perceived physical health, and having a high self-efficacy score.

SOCIOCULTURAL CONSIDERATIONS

Studies analyzing how childhood characteristics are associated with the stage of substance use in adulthood have also been limited. However, in a study conducted by O'Connell et al. in 2007, utilizing data obtained from the American Indian Service Utilization, Psychiatric Epidemiology, Risk and Protective Factors Project (AI-SUPERPPF), investigators sought to analyze childhood characteristics associated with adulthood stage of substance use (18). In a sample consisting of two closely related Northern Plains tribes (NP) and a Southwestern tribe (SW), four correlates of substance abuse based on hierarchical stages were used including lifetime abstinence (Stage 0), use of alcohol only (Stage 1A), use of marijuana/inhalants with or without alcohol (stage 1B), and use of other illicit drugs with or without the previously listed substances (Stage 2). Findings revealed that SW females were more likely to report Stage 1 rather than Stage 0 substance use than SW males. Also, in this study, a history of sexual abuse significantly increased the odds of Stage 1B versus Stage 1A substance use. Witnessing family violence increased the odds of Stage 1A versus Stage 0 use among NP individuals, and significantly increased the odds of Stage 1B versus Stage 1A substance use in both tribes combined. Also, adolescent conduct problems resulted in a significant increase in the likelihood of higher stage substance use.

A study conducted by Stiffman et al. in 2007 sought to analyze the trajectory or path of substance use among AI/AN adolescents (7). In this study among 401 urban and reservation youth, data was analyzed from 2001 to 2004 to model behavior change trajectories, with psychological and environmental variables. Five trajectory groups were identified: (a) very high chronic, (b) high chronic, (c) high improving trajectory, (d) low stable, and (e) low improving. High improving group had sixfold higher proportion of reservation youths, less school problems, only about one-tenth depression symptoms, much less thoughts about attempting suicide, only half as many parents with mental health problems, and lower family conflict compared to the very high chronic group. Various reasons for improved treatment outcomes were considered. First, many changes to the reservation including a new casino, more community programs, and more jobs were observed. The community also added more service providers in schools, courts, and jails;

more family-oriented social treatment and prevention programs; as well as family programs for youths in treatment. In addition, the community also focused on programs for youth including recreational, physical, social, and employment programs. Urban areas did not have any service changes or new interventions between 2001 and 2004 in this study. Results from this study may suggest a need for a greater role of community/environment in AI/AN substance abuse treatment.

Findings in Stiffman's study mirror trends observed in other studies where lower substance use rates have been observed among SW tribes in comparison to NP tribal groups (18,19). For example, in the previously described study by O'Connell, the identified SW tribe was postulated to have larger and stronger social networks and low cultural stress due to fewer changes in culture, economy, and diet over the past 200 years (18). In addition, the SW tribal group was identified as a matrilineal society, with females having an expectation to conform to cultural norms more, thus possibly attributing to lower substance abuse among SW women. Thus, some cultural characteristics reported in these studies may have contributed to lower alcohol/drug problems among SW tribal groups.

Participation in cultural and traditional activities and traditional ceremonies has been an important area of research as it relates to AI/ANs with substance abuse problems. Culturally based treatments are utilized in numerous substance abuse programs serving AI/ANs. However, formalized studies analyzing the potential effects of traditional activity participations on substance abuse behavior are relatively limited. To date, studies conducted have found both positive and negative associations with cultural identity and traditional activity participation among AI/ANs with substance abuse problems. With regard to benefits, one study analyzing inhalant abuse among AI/ANs found a significant positive effect with participation in tribal activities among nonusers compared to users (20). Also, another study found that American Indians with a low orientation toward traditional culture were more than 4.4 times as likely to be heavy drinkers as more culturally oriented adults (21). Also, in a study among a sample of four AI reservations in the upper Midwest and five Canadian First Nation reserves, participation in traditional activities and traditional spirituality were positively associated with alcohol cessation, while cultural identity was not significantly associated with alcohol cessation in a multivariate analysis (22). However, the authors in this study caution that the data is cross-sectional and does not indicate directions of effects, warranting further longitudinal studies.

Cultural indicators have also been reported to be negatively associated with substance abuse treatment outcomes. For example, in a study analyzing tobacco use among AI adolescents, being more connected to AI culture increased the odds of cigarette use (23). Also, in a study conducted among AI/AN adolescents in Wisconsin and Minnesota, attendance at cultural events was positively correlated with marijuana and cigarette use. Participation in tribal ceremonies was weakly correlated with cigarette use and more strongly

correlated with marijuana use among males. Another study analyzing data among AI/AN youth participating in a substance abuse prevention program found males who rated the importance of Indian identity highly were more likely to use marijuana, and females who rated the importance of Indian identity highly were less likely to use alcohol (24).

PREVENTION

Preventing the initiation of alcohol, drugs, and tobacco has been known to assist in decreasing overall substance abuse rates in various populations. Implementing effective prevention protocols for AI/ANs is critical since AI/ANs are known to have earlier onset of illicit drug and alcohol use and more negative consequences compared to other racial/ethnic groups.

Identification of potential protective factors is important in implementing effective prevention programs. For example, potential protective factors that may be associated with tobacco nonuse may be related to family structure. In a study conducted by Beebe et al., higher rates of tobacco nonuse were found among AI/AN youth who lived in a two-parent households compared to AI/AN youth from one-parent households (25). Also in this study, having a nonparental adult role model was associated with not using alcohol. In addition, AI/AN youth with a family communication asset was associated with not using drugs. Families that demonstrated effective communication may suggest more family cohesiveness and family bonding. Bebe and colleagues emphasized the potential value of extended families and sense of collectivism that exists in many AI communities. Also, religion asset was found to be associated with drug nonuse and was observed to be potentially valuable in building traditional resilience.

A theme commonly observed among drug and alcohol prevention programs for AI/ANs throughout the United States is the integration of cultural strengths identified in the culture. For example, enhancing cultural identity through integration of various cultural activities and events in AI/ANs has been implicated as a vital approach toward decreasing the likelihood of alcohol and drug use. Adequate teaching and mentoring programs providing lessons in traditionally held beliefs and principles may provide foundations that may be conclusive to drug and alcohol abstinence.

Since approximately two thirds of AI/ANs reside in urban areas, creating and analyzing substance abuse prevention programs in the urban setting is important. The *Seventh Generation Program* is an urban after-school alcohol prevention program designed for youth in Colorado. The program blends general prevention approaches with culturally appropriate interventions including an emphasis on core AI/AN values and concepts associated with the *Medicine Wheel* of the Northern Plains (26). In a study conducted by Moran and Bussey in 2007, this approach was compared between a group of AI/ANs receiving this intervention and a no-intervention comparison group (26). Results revealed significant effects in areas of alcohol beliefs, social support, locus of control, and depression, and demonstrated increased benefits over time among participants enrolled in the *Seventh Generation Program* in comparison to

the nonintervention condition. An additional finding in this study demonstrated the benefits of booster sessions. Six booster sessions reviewed the basic content of this 13-week after-school-hour program.

A focus on bicultural competence among AI adolescents has been another substance abuse prevention strategy developed. Schinke and colleagues utilized concepts related to a bicultural approach, indicating that AI youth need to acquire skills to be able to function in both AI/AN and non-AI/AN settings (27). This application involves 10 group intervention sessions to learn bicultural competence skills and social learning principles. Communication skills; coping skills; discriminations skills; and school, family, and reservation resources are utilized. In a study conducted by Schinke et al. in 1988, AI youth who received the bicultural competence skills approach improved more than an AI adolescent no-intervention control sample (27).

Public health strategies and legislations have also played a role in addressing substance abuse in AI/AN communities. In addition, utilization of these strategies appears to be increasing. For example, tribes with statutes that permit alcohol increased from 29.2% to 63.5% from 1975 to 2006 (28). Some potentially useful alcohol control policies include changes in liquor sales regulations, a local alcohol excise tax, and alcohol server training (28). Tobacco public health policies also have significant potential to decrease smoking rates in AI/AN communities. Strict clean air laws, cigarette taxes, and community-tailored prevention programs may assist in decreasing smoking rates among AI/ANs. However, further knowledge about community support with regard to these tobacco control policies is needed.

Another proposed substance abuse prevention strategy is utilizing effective treatment strategies currently used in the general U.S. population with appropriate cultural modifications (29). This suggestion was proposed due to similar drug, alcohol, and tobacco use trends observed between AI/ANs and the general population. It is postulated that utilizing current proven effective substance abuse prevention strategies that have been shown to work in the general U.S. population may also be effective among AI/ANs with appropriate cultural modifications capitalizing on the inherent strengths of the culture in addition to increasing the acceptability of the approaches in the community.

TREATMENT

Need for Culturally Relevant Treatment Approaches for American Indians/Alaska Natives

Incorporating traditional aspects of healing has been recognized as being important in the development of effective treatment strategies for AI/ANs. For example, the Tribal Participatory Research (TPR) model, created by Philip Fisher and Thomas Ball, highlights the need for culturally specific interventions that allow for the incorporation of traditional practices and concepts and create the potential for testing indigenous models of health and well-being (30). Furthermore, identifying substance abuse treatments that will be both

beneficial and acceptable among AI/ANs may assist in higher treatment retention and completions rates and ultimately decrease substance abuse rates.

Developing culturally relevant substance abuse treatment approaches for AI/ANs has the potential to enhance treatment protocols in addition to a renewed sense of personal and cultural identity. For example, previous studies have observed themes of feeling renewed pride in their cultural heritage, feeling motivated to learn more about it, and coming to feel “worthy” of participating in it (31). It also appears to be true that many American Indians strongly believe that their problems with alcohol stem from their sudden disconnection with traditional AI culture (32). Furthermore, various researchers have reported that denying American Indians the opportunity to rely on those mechanisms may have increased the likelihood that American Indians would rely on less adaptive coping mechanisms such as excessive alcohol consumption (32).

Although the incorporation of cultural elements into substance abuse treatment and prevention is recognized as being particularly important among AI/ANs, some studies have found that currently provided substance abuse treatments without cultural adaptations may be effective. For example, results of a study conducted by Evans et al. in 2005 comparing alcohol and drug treatment outcomes between a sample of California American Indians and a non-AI comparison group utilizing the California Treatment Outcome Project (CalTOP) revealed that American Indians and non-American Indians demonstrated a similar level of severity before treatment in all seven domains measured by the Addiction Severity Index (ASI)—alcohol, drug, medical, psychiatric, family, legal, and employment—and demonstrated similar levels of improvement in all seven ASI domains (33). Also, another study observed no treatment outcomes differences between a sample of 279 AI/ANs and a non-AI/AN comparison group at 12 months posttreatment based on legal, employment, medical, and psychiatric measures (34). Results of these studies highlight the need for improving access to community-based AI/ANs since currently available substance abuse treatment may be beneficial for AI/ANs with substance abuse problems. However, various barriers exist with regard to AI/ANs receiving substance abuse treatment, which may limit their likelihood of receiving treatment, including low socioeconomic status, transportation barriers, a shortage of integrated substance abuse treatment models, and stigma associated with substance abuse in AI/AN communities. Thus, further attention is needed to ensure that AI/ANs with substance abuse problems have adequate access to substance abuse services since they may benefit from currently provided substance abuse treatment services.

Numerous studies have suggested a comprehensive treatment approach for AI/ANs. For example, in a study analyzing treatment outcomes among AI/ANs and a matched comparison group conducted by Evans et al. (2006), a more intense level of services addressing various problems among American Indians receiving substance abuse services in addition to American Indians receiving more group sessions addressing psychiatric problems was identified (33). In this study, additional family-

related and abuse-related services were received by AI/ANs compared to a matched comparison group, and may have assisted in addressing specific treatment needs of AI/ANs with substance abuse resulting in similar improvements when compared to non-AI/ANs. These results mirror many other reports of a significant association between substance abuse and traumatic experiences, abuse, and psychiatric comorbidities among AI/ANs with substance abuse problems (11–14). Thus, individual and group trauma-related treatments and community-based healing may especially be needed among AI/AN individuals in substance abuse treatment.

Cultural Considerations in Evidence-Based Substance Abuse Treatments for AI/ANs

Currently available psychotherapeutic interventions include motivational interviewing, cognitive-behavioral therapy, 12-step facilitation, psychodynamics, contingency management, network therapy, group therapy, and family therapy, which have been shown to be effective in various studies. However, their effectiveness and cultural relevancy among AI/ANs are relatively unknown. Currently available evidence-based treatments have not been thoroughly tested among various ethnic/minority groups; thus the assumption that these substance abuse treatments are effective among all patients is not valid. Although consisting of various distinct tribes, AI/ANs share many cultural characteristics including similarities in behavior patterns, lifestyle, values, beliefs, views, and attitudes. Thus, adequate attention to these factors is critical when providing evidence-based treatments to AI/ANs.

Motivational Interviewing for Native Americans

In 2006, Venner, Feldstein, and Tafoya developed a motivational interviewing (MI) manual culturally tailored for Native Americans—*Native American Motivational Interviewing: Weaving Native American and Western Practices* (35). This manual provides counselors a thorough overview of MI with particular attention toward relevant Native American cultural ideals and traditions including spirituality, community, and cultural identity. In addition to providing a fundamental overview of the MI treatment approach, relevant considerations with regard to how to incorporate these cultural elements into the delivery of this treatment strategy to AI/ANs are provided. Information utilized in this culturally tailored treatment approach was retrieved from focus groups among community members possessing knowledge regarding Native American communication styles and behavior health providers, which are meant to guide the practice of MI in Native American communities.

Another treatment approach that has been culturally adapted for AI/ANs with substance abuse problems is the Matrix Model. It is a multielement package of evidence-based practices delivered in a 16-week intensive outpatient program (36). The Native American adapted version was created by UCLA Integrated Substance Abuse Programs (ISAP) in collaboration with Friendship House, a residential treatment facility for AI/ANs in San Francisco through feedback obtained from elders and

Native American cultural experts to provide a treatment approach utilizing relevant cultural elements and culturally designed worksheets and diagrams and culturally appropriate quotes and references to AI/AN culture (37). Currently, this treatment approach has been widely accepted and utilized in many tribal communities across the United States.

Knowledge with regard to the utilization and acceptance of evidenced-based substance abuse treatments for AI/AN is limited. However, studies are being performed analyzing the use, acceptance, and implementation of evidence-based treatment strategies in AI/AN communities. For example, Douglas Novins, MD, University of Colorado at Denver and Health Sciences Center, is currently analyzing the use of specific evidence-based treatments in substance abuse programs serving AI/AN communities and is seeking to understand the factors associated with the implementation of evidence-based treatments in these programs and to identify methods for more effective dissemination of Evidence Based Practices (EBPs) to substance abuse programs serving AI/AN communities. In addition, Traci Rieckmann, PhD, Oregon Health Sciences University, is seeking to increase our understanding with regard to the use of evidence-based treatments in clinics providing substance abuse services to AI/ANs through an analysis of the utilization and adoption of EBPs in community-based treatment programs across the United States.

Medicine Wheel and 12 Steps

One of the most widely revered and utilized substance abuse treatment strategies utilized in many AI/AN substance abuse treatment programs is the *Medicine Wheel and 12 Steps*, by Don Coyhis of White Bison, Inc. (38). This program utilizes the fundamental philosophies and practices of Alcoholics and Narcotics Anonymous with a particular focus on the fundamental concepts of the Native American Medicine Wheel. The Medicine Wheel is a representation of Native American philosophy originated among the Northern Plains Indians. Particular attention is directed toward a focus on the culture as being an integral part of overcoming addictions among AI/ANs with substance abuse problems. The *Medicine Wheel and 12 Steps* approach states that the principles of Alcoholics Anonymous parallels many Native American cultural beliefs. The 12 steps are recognized as being interconnected and a process of natural order that assists AI/ANs with substance abuse problems and a process to establish or re-establish order within their own lives. This approach also teaches that “injured seeds” need a “Healing Forest,” illustrating that sobriety and the healing of an individual are not separate from the healing of the family and the tribal community.

Utilization of Traditional Healing Methods for AI/ANs with Substance Abuse Disorders

Traditional healing continues to be a highly valued form of treatment for urban and reservation-based AI/ANs with a variety of health problems, including addiction. Although a

variety of definitions and opinions exist with regard to what constitutes Native American traditional healing, traditional healing can be thought of as a spectrum of activities from participation in traditional activities including drumming, bead making, and attendance of powwows to participation in specific traditional ceremonies. Commonly used traditional treatments used in substance abuse facilities servicing AI/ANs include smudging ceremonies, sweat lodge participation, and talking circles, a traditionally founded form of group therapy. Participation in these ceremonies may contribute to a renewed elevated sense of self- and cultural pride, thus serving as a potential protective factor for substance abuse problems.

Providing traditional healing services necessitates that providers, community members, and cultural elders assist in ensuring that they are delivered in an appropriate culturally relevant manner. Exploitation of various forms of Native American traditional healing services may be considered offensive and disrespectful since these activities are considered sacred and private by tribal communities. Although traditional healing services may be especially useful for AI/ANs with substance abuse problems, particular attention must be paid toward protecting and respecting the use of traditional forms in order to protect the history and dignity of native cultures.

The integration of traditional healing with Westernized care as it relates to substance abuse treatment among AI/ANs has gained further recognition among treatment service delivery programs across the United States. Although traditional healing continues to be utilized among many AI/AN tribes within the clinical setting, established systems of an integrated system have been less common. Nonetheless, there are specific health care systems in AI/AN communities providing an integrated treatment model. For example, the Navajo Nation has developed an integrated model whereby AI/ANs have access to traditional healing and traditional healers. In addition, an integrated model has been recognized at the Southcentral Foundation in Anchorage, Alaska. Momentum for an integrated treatment approach for both substance abuse and mental health problems among AI/ANs in Los Angeles County through a project coordinated with the Los Angeles County Department of Mental Health has also been recognized. Some of the challenges with regard to successful implementation of an integrated treatment model may include reimbursement issues, “evidence” of effectiveness, and a process to validate the legitimacy of traditional healers within a community.

Medications to Treat Addiction for AI/ANs

Advancements with regard to the utilization of evidence-based pharmacologic treatments for addiction also hold tremendous promise toward addressing the treatment needs of AI/ANs with addictive diseases (i.e., naltrexone for alcohol dependence, buprenorphine for opioid dependence, and nicotine replacement therapy). However, information with

regard to the utilization and effectiveness of these medications among AI/ANs is significantly limited. However, one study conducted by O'Malley et al. in 2008 analyzed the effectiveness of naloxone, a Federal Drug Administration (FDA)–approved medication for alcoholism, among a sample of Alaska Natives ($n = 68$) (39). This study found naloxone to be effective in this population in addition to demonstrating its potential usefulness in Alaska Natives residing in both rural and urban areas. This trial also highlighted the potential benefits of pharmacologic treatment for AI/ANs with alcoholism. Further attention addressing significant logistical and financial barriers to receiving pharmacologic treatments for substance use disorders for AI/ANs is needed.

FACTORS INFLUENCING SUBSTANCE USE AMONG AI/ANs

Historical Trauma

Various historical and cultural factors may explain why substance abuse rates are high among AI/ANs. A growing body of literature, however, has cited various perpetuating psychosocial stressors experienced by AI/ANs as being ongoing risk factors. Specifically, the theory of “historical trauma,” developed by Maria Yellowhorse Brave Heart, postulates that various injustices impounded on AI/ANs have had a perpetuating, intergenerational traumatic effect throughout the U.S. history and have been responsible for setting the foundation for community stress, impoverishment, loss of cultural identity, and a sense of traumatic loss in the AI/AN population (40,41). Some traumatic events include the forced removal of AI/ANs from homelands, removal of religious freedom, and forced placement of children into boarding schools away from original homelands, in addition to numerous broken treaties between the U.S. government and tribal groups. These events have “laid the groundwork” for a host of potential risk factors for substance abuse problems and consequences associated with substance use. Furthermore, these effects associated with historically based trauma have been implicated as a causative factor for substance abuse among AI/ANs (42). The results of these traumatic events may be contributing to high rates of poverty, unemployment, high school dropout rates, and very limited access to comprehensive culturally appropriate substance abuse treatment services in both rural and urban settings. Thus, a significant risk for significant substance abuse problems among AI/ANs may be due to these intergenerational effects resulting in ongoing substance abuse problems among AI/ANs.

Genetics

It has been a widely held popular belief that “the reason” for high rates of alcoholism and substance abuse among AI/ANs is a genetic predisposition. However, to date, limited data exists that posits that genetic characteristics are significant risk factors for a wide variety of substance use disorders among AI/ANs. For example, in a study conducted among Southwest

California Indians, results revealed that heritability of the initiation of substance use may be similar to other population samples (43). Furthermore, another study analyzing genetic variations among Finns and American Indians concluded that there are likely to be independent, complex contributions among chromosomal regions (44). Nonetheless, studies analyzing the role of genes and gene–environment interactions may assist in furthering our understanding of substance abuse problems among AI/ANs.

SPECIAL CONSIDERATIONS

Human Immunodeficiency Virus/Acquired Immunodeficiency Syndrome (HIV/AIDS)

HIV/AIDS has become an emergent health problem among AI/ANs. Native Americans have the third highest rates compared to other racial/ethnic groups in the United States, behind African Americans and Hispanics (45). Furthermore, urban American Indians may be at greater risk for HIV infection than American Indians residing on reservations due to significant risk factors known to exist in urban areas. These risk factors include the tendency to trade sex for money or drugs, and unsafe sexual practices (46). In addition, various health-related disparities known to exist among AI/ANs may contribute to an increased risk of HIV/AIDS including limited access to culturally appropriate HIV/AIDS prevention and treatment programs, limited access to adequate health care, and decreased access to proper medical management.

An additional challenge with regard to providing effective HIV/AIDS prevention and treatment programs in AI/AN populations is the stigma associated with HIV/AIDS and homosexuality in many native communities. HIV/AIDS is often not seen as an “Indian problem” in many urban and rural AI/AN communities. Thus, further attention to the HIV/AIDS prevention and treatments needs of the AI/AN lesbian, gay, bisexual, and transgender (LGBT) community is needed. One innovative prevention approach is the *Red Circle Project*, developed by Elton Naswood, to target Native American Two Spirit/Gay Men in the Los Angeles area. The project provides resources, referrals, and information about HIV to the urban Native American community. In addition, this strategy provides a support group curriculum comprised of six workshops to address issues such as decision making, skills building, healthy image/body fitness, HIV/AIDS and STD information, risk reduction information, and storytelling.

Intravenous drug abuse (IVDA) is a significant risk factor for HIV/AIDS. Although studies with regard to IVDA among AI/ANs have been limited, recent reports have demonstrated noticeable trends of IVDA among some AI/AN groups. For example, AI/ANs aged 12 or older had the higher rates of injection drug use (0.24%) compared to any other single racial/ethnic group in the United States, with the highest rates being among “two or more races” (0.35%) (47). This is especially noteworthy due to the known significant rise in methamphetamine drug abuse among AI/ANs over the last

decade. Thus, further HIV/AIDS prevention efforts targeting at-risk groups including AI/AN who abuse intravenous drugs may assist in decreasing this trend.

Methamphetamine

The effects associated with methamphetamine abuse have exacerbated many significant psychosocial problems known to exist among AI/ANs. For example, methamphetamine has been associated with increased domestic violence crimes, burglary, assault and battery, and child neglect/abuse among AI/ANs. In a 2006 Bureau of Indian Affairs survey of 96 tribal law enforcement agencies, 74% ranked methamphetamine as the drug that poses the greatest threat to their community, 64% indicated increases in domestic violence and assault/battery, and 48% reported an increase in child neglect/abuse cases due to recent increases in methamphetamine use (48). Methamphetamine abuse has also been reported as a significant substance abuse problem among AI/AN groups residing in urban areas. For example, in a study conducted by Spear et al., in Los Angeles County, methamphetamine was shown to be the drug most abused by AI women and the second most abused drug among AI men (49).

Due to the significant effects of methamphetamine in tribal communities, the National Congress of American Indians (NCAI), in a coordinated effort with SAMHSA, and the leadership provided by Dale Walker, MD and the Association of American Indian Physicians (AAIP), a set of comprehensive strategies to combat methamphetamine abuse in tribal communities was created. Assembled in a creatively decorated box, the toolkit includes a variety of materials and educational information for tribal providers and health care leaders to use in their communities. The contents include an educational overview of methamphetamine basics in Indian country, tribal code-policy examples, public service announcements, preventative posters and flyers tailored to specific audiences, educational presentations, and “fun youth items” created to provide youth with an antimethamphetamine message.

Nicotine

While alcohol was introduced to AI/ANs by Europeans, tobacco was introduced to colonists by American Indians. Tobacco has been used by AI and other Indigenous groups throughout North and South America for religious and ceremonial purposes for at least 2000 years and possibly up to 7000 years. However, AI/ANs have the highest smoking rates compared to any other racial or ethnic group in the United States (50) and are at higher risk for many tobacco-related health problems. Various risk factors for smoking among AI/ANs include lower socioeconomic status and high rates of unemployment and poverty. These factors may also influence access to smoking cessation prevention interventions and prevention programs. Finally, high levels of stress exist in many AI/AN communities as evidenced by high rates of suicide, homicide, violence, accidents, and unresolved historically based traumas that may impede smoking cessation.

Urban AI/ANs

A significant number of AI/ANs currently reside in urban areas (two thirds). However, unique challenges exist with regard to providing the much needed culturally relevant treatment services. A significant shortage of comprehensive substance abuse services exists in the urban setting. In addition, many individuals who reside in urban areas may be unaware that clinics providing substance abuse services specifically for AI/ANs exist. In addition, challenging dilemmas exist with regard to understanding the “community of urban AI/ANs.” More aggressive outreach efforts are needed in order to increase AI/ANs who may require substance abuse treatments. Coordinating comprehensive substance abuse treatment and prevention programs for AI/ANs may be especially challenging since the most promising treatment and prevention strategies entail that a coordinated effort among various entities including mental health professionals, medical facilities, recreation and social networks, education systems, and the legal system is implemented. Within large metropolitan areas, such as Los Angeles and New York City, where the largest populations of AI/ANs reside, this effort may be especially challenging.

CONCLUSION

Substance abuse has significantly impacted the AI/AN population. Due to a variety of complicating factors including historically based traumas and various health-related disparities, a comprehensive approach to prevention and treatment programs should be considered. In addition, recognizing the need for blending currently available evidence-based treatment approaches with the incorporation of culturally relevant approaches is essential for optimizing potentially useful prevention and treatment programs. Also, due to the growing population of AI/ANs residing in urban areas, further understanding is needed with regard to providing effective prevention and treatment programs to this population. Furthermore, recognition of comorbid psychiatric issues may assist in optimizing treatment outcomes among AI/ANs with substance use disorders.

EPIDEMIOLOGY

Substance use disorders are highly prevalent in our society. Data from the National Epidemiologic Survey on Alcohol and Related (NESARC; $N = 43,093$), the largest and most recent study of substance use and other psychiatric disorders, estimates the 12-month prevalence rate of alcohol use disorders to be 8.5% and drug use disorders to be 2.0% (1,2). Similarly, data from the 2006 National Survey on Drug Use Disorders (NSDUH) found that approximately 22.6 million people (9.2% of the population aged 12 and older) met criteria for past year substance abuse or dependence (3).

Significant gender differences in rates of substance use disorders have been consistently observed in both the general population and treatment-seeking samples. In comparison to women, men have been shown to demonstrate significantly higher rates of substance use, abuse and dependence (2,4–6). However, recent epidemiologic surveys demonstrate that the gender difference in prevalence of alcohol use disorders has narrowed in recent decades. Surveys in the early 1980s estimated a male-to-female ratio of alcohol use disorders as five-to-one (7), whereas recent NESARC data found that men were 3.1 times more likely than women to meet criteria for an alcohol use disorder (2.3 times more likely to have alcohol abuse and 2.6 times more likely to have alcohol dependence) (8). Findings from two cross-sectional analyses of drinking across birth cohorts demonstrated little variation in lifetime drinking histories among men from different birth cohorts compared at similar ages. By contrast, women born between 1954 and 1963 had significantly more lifetime drinking than those born in the previous cohort of women between 1944 and 1953 (9). Increases were particularly significant among white and Hispanic women—beginning with those born in the United States after World War II (9).

Compared with alcohol use disorders, the gender difference in drug use disorders is somewhat less pronounced. NESARC data showed that men were 2.3 times more likely than women to meet criteria for a drug use disorder, 2.2 times more likely to have drug abuse and 1.9 times more likely to have drug dependence (4). Data regarding the use of prescription drugs is less consistent. Some data suggest that rates of nonmedical prescription drug use are higher among women than men, particularly for narcotic analgesics and tranquilizers (10). Other, more recent studies of nonmedical prescription opioid use report gender equivalent rates (3,11–13) or higher rates among men as compared to women (14–17).

Gender differences in nicotine use and dependence are also substantially less than for other substances of abuse (18).

TELESCOPING

The phenomenon of “telescoping” has been consistently observed in investigations of gender and substance use disorders. Telescoping is a term used to describe an accelerated progression found in women from the initiation of substance use to the onset of dependence and first admission to treatment (19,20). In particular, women are more likely than men to show an accelerated progression between regular use and treatment seeking for opioids, cannabis and alcohol (19). Thus, when women enter treatment for substance use disorders, they typically present with more severe clinical profiles (e.g., more medical, behavioral, psychological, and social problems characteristic of substance use disorders), despite having used the substance for a shorter period of time.

BIOLOGICAL ISSUES

Sex differences in the neurobiological correlates of substance use disorders have been elucidated in a growing number of studies over the past decade. In particular, sex differences related to responsivity to drugs of abuse and to relapse have been demonstrated in animal models and human studies in three areas: (a) neuroactive gonadal steroid hormones, as well as fluctuations of these hormone levels across the menstrual cycle; (b) sex differences in stress reactivity and relapse to substance abuse; and (c) sex differences in neurobiologic correlates evident from neuroimaging studies.

Neuroactive Gonadal Steroid Hormones

Animal models have demonstrated that neuroactive gonadal steroid (e.g., estradiol, testosterone, and progesterone) affect the reinforcing properties of drugs under numerous conditions (21). Neuroactive steroid hormones can have excitatory and inhibitory effects on the brain (22) and may influence the saliency of drug effects. These gonadal steroid hormones are linked in mediating neurobehavioral processes related to the reward system (21) and can mediate reinforcing effects of abused drugs. Ovarian steroid hormones (e.g., estrogen and progesterone), metabolites of progesterone, and negative allosteric modulators of the GABA-A receptor such as dehydroepiandrosterone (DHEA) are neuroactive and can

influence the behavioral effects of drugs (21). In animal models, for example, DHEA reduces self-administration and cocaine seeking in rats (23). Changes are also evident in brain function and neurochemistry across the phases of the menstrual cycle that are likely correlated with fluctuating levels of estrogen and progesterone (21), and these fluctuations have been correlated with the reinforcing properties of drugs of abuse in women.

In human studies, the follicular phase of the menstrual cycle is associated with greatest responsivity to stimulants such as cocaine (24,25). A number of studies indicate that during the follicular phase, when estradiol levels are high and progesterone low, the effects of stimulants are increased compared to the luteal phase when both estradiol and progesterone levels are elevated (24,26,27). It is unclear whether these effects are attributable to estradiol or progesterone (28). For example, in one study investigating response to cocaine administration, sex and menstrual cycle effects, women in the luteal phase reported lower ratings of feeling “high” than did women in the follicular phase of their cycle or men (24). It is not clear whether sex differences in response to stimulants is accounted for by enhancing effects of estradiol or attenuating effects of progesterone. However, a study of oral progesterone administration to males as well as to females in both phases of the menstrual cycle indicated that progesterone attenuates the subjective response to smoked cocaine in women but not men (28). Heart rate and subjective effects in response to smoked cocaine were greater in the follicular than luteal phase among female cocaine smokers (27).

In addition to menstrual phase cycle differences and the effects of gonadal hormones on response to cocaine administration, studies of alcohol and nicotine also demonstrate potential greater saliency for these substances in the luteal phase of the cycle (21,29–31). An early study of smoking cessation demonstrated that women in the luteal phase reported more fatigue, irritability, anxiety and depression symptoms in response to nicotine withdrawal than did women in the follicular phase (30). Other studies have replicated the finding that women have greater nicotine withdrawal symptoms and craving if they quit smoking in the luteal versus follicular phase (21,29).

The effect of gonadal steroids on behavioral and subjective responses to alcohol is less clear than for other substances of abuse. Animal studies have found no difference in the effect of alcohol across menstrual phases (32). One study examined the subjective and behavioral effects of alcohol in healthy women across the early follicular, late follicular, midluteal, and late-luteal phases of the menstrual cycle and found that the effects of alcohol did not vary across the cycle (33). Other research in women with and without premenstrual syndrome showed that alcohol infusion suppressed allopregnanolone serum concentrations in the late-luteal phase but had no effect during the follicular phase (34).

While opioids directly affect the hypothalamic–pituitary–gonadal system by inhibiting the release of luteinizing hormone releasing hormone, few human studies have examined the role

of gonadal steroid hormones in sex differences in response to opioids. Human studies have examined sex differences in response to pain, including pain thresholds across the menstrual cycle (35) and found that pain thresholds are the highest during the follicular phase and lower during luteal and premenstrual phases. Animal studies have yielded inconsistent results examining the effects of opioids on behavioral outcomes (21).

Overall, accumulating evidence from animal and human studies demonstrate sex differences in the role of neuroactive steroid hormones on drug abuse, but the findings vary depending on the drug studied, the species, and the specific outcome measured.

Sex Differences in Stress Reactivity and Relapse to Substance Abuse

In a related area of investigation regarding sex differences in the neurobiologic correlates of substance use disorders, the hypothalamic–pituitary–adrenal (HPA) axis controls gonadotropin and gonadal steroid hormone release through a complex feedback mechanism. The HPA axis is also the neuroendocrine pathway for the stress response. Sex differences in neuroendocrine adaptations to stress and reward systems can function as a mediator for susceptibility to drug abuse and relapse in women (36). Stressors and drug-related cues are important in facilitating drug seeking and drug reinforcement behaviors in humans and animals (36). Sex differences in neuroendocrine adaptations to stress and reward have been elucidated, including sex differences in stress-symptom neuroadaptations in substance-dependent men and women (36), the impact of sex hormones on stress response (27), attenuating effects of progesterone on stress response and drug craving (37,38) among other studies (39).

Human laboratory studies have examined sex differences in stress response and relapse to substance abuse (40–42), including sex differences in emotional and autonomic differences in response to stress and cues (36). Human studies, among cocaine-dependent subjects demonstrate greater stress response in men than women, with higher ACTH and cortisol levels following exposure to stress and drug cues (43). This HPA dysregulation in women may be associated with greater emotional intensity at lower levels of HPA arousal than men (38) and may be one key to enhanced vulnerability to use substances in response to negative affect among women. Similar results have been found in alcohol (44,45) and nicotine dependence (46).

Neuroimaging and Neurobiologic Correlates

Neurobiological correlates of substance use disorders can be assessed with neuroimaging techniques, such as functional magnetic resonance imaging (fMRI), which can measure information processing in discrete brain circuits that may not be behaviorally observed but may be connected with manifestations of alcohol or drug use disorders (47). Sex differences in neural activity have been demonstrated using fMRI techniques including the response of medial prefrontal

cortex for drug reward anticipation and receipt, and stress- and cue-induced craving (48,49). Another line of work indicates the possibility of neural correlates of sex differences in treatment outcome. For example, sex hormones may regulate the ventromedial prefrontal cortex, which is involved in extinction memory (50). In one study, men had greater recall of extinction memory than women in the late, but not early, follicular phase of the menstrual cycle (51). While observed correlations between BOLD fMRI findings in limbic areas and gene-gene interactions suggest endophenotypes that may be useful in exploring disease processes (47), the degree to which such processes may be associated with prognosis or treatment outcomes remains unclear (47). Translational research in this area might be targeted at understanding the way in which sex differences in the neurobiological correlates of substance use disorders are associated with prognosis and substance abuse treatment outcomes.

ROLE OF CO-OCCURRING DISORDERS

Mood and Anxiety Disorders

Mood and anxiety disorders are some of the most common co-occurring psychiatric conditions among women with substance use disorders (52). Epidemiologic studies utilizing the NCS and the NESARC data (53,54) show that lifetime rates of mood and anxiety disorders among individuals with substance use disorders are significantly higher among women than men. For example, among individuals with substance use disorders, rates of major depression range from 30.1% to 48.5% among women versus 9.0% to 30.1% among men. Rates of simple or specific phobia range from 28.2% to 30.7% among women versus 5.9% to 13.9% among men. Similar gender differences have been observed in the general population, as well (1).

A recent study by Goldstein (55) investigated 12-month prevalence, comorbidity, and treatment utilization rates for substance use, mood, and anxiety disorders among women in the Wave 1 NESARC ($n = 24,575$) (1,56), which was conducted in 2001 to 2002 by the National Institute on Alcohol Abuse and Alcoholism (NIAAA). Goldstein found that the 12-month prevalence rates of mood and anxiety disorders among women with substance use disorders were 29.7% and 26.2%, respectively. The most common mood disorder among women with alcohol or drug use disorders was major depressive disorder (15.4%) and the most common anxiety disorder was specific phobia (15.6%).

The order in which co-occurring psychiatric conditions develop may help elucidate the etiology as well as help determine the best treatment approach. Some individuals manifest depression prior to the development of a substance use disorder (i.e., primary depression), while others manifest depression following the development of a substance use disorder (i.e., secondary depression). A third group of individuals develop depression and the substance use disorder simultaneously. Of these three potential orders of onset pathways, the most common is secondary depression (57). Furthermore,

women are more likely than men to present with secondary depression, and therefore may be more likely to respond to depressive symptoms by “self-medicating” with alcohol and drugs (58,59). In fact, one study found that the risk of developing heavy drinking was 2.6 times greater for women with, as compared to without, a history of depression (60).

Given the high prevalence of co-occurring mood and anxiety disorders among women with substance use disorders, a comprehensive psychiatric assessment at treatment entry is critical. Because substances of abuse have profound effects on neurotransmitter systems involved in the pathophysiology of mood and anxiety disorders, chronic alcohol or drug use may unmask a vulnerability or lead to organic changes that manifest as a mood or anxiety disorder. One of the best ways to differentiate substance-induced, transient symptoms from a disorder that warrants treatment is through observation of symptoms during a period of abstinence from alcohol or drugs. Transient substance-induced symptoms will improve with time. The duration of abstinence necessary for accurate diagnosis should be based on the diagnosis being assessed and the substance used. For example, drugs with a longer half-life (e.g., some benzodiazepines, methadone) may require several weeks of abstinence for withdrawal symptoms to subside, but drugs with a shorter half-life (e.g., alcohol, cocaine, short half-life benzodiazepines) require less abstinence to make a valid diagnosis. A family history of mood or anxiety disorders, the onset of symptoms before the development of the substance use disorder, and sustained symptoms during lengthy periods of abstinence all suggest an independent mood or anxiety disorder (61).

Following a comprehensive assessment, women should receive or be referred to evidence-based treatments that will adequately address both conditions, especially given the fact that many women use substances in response to co-occurring psychiatric symptoms. Unfortunately, the large majority (91%) of women with substance use disorders and a co-occurring mood or anxiety disorder do not seek treatment (55). In particular, women with alcohol use, as compared to drug use, disorders demonstrate very low rates of treatment seeking. The highest treatment-seeking rates are seen among women with substance use disorders and co-occurring major depression, dysthymia, or panic disorder (55).

To date, few investigations have examined gender differences in response to psychotherapeutic or pharmacotherapeutic treatments for mood and anxiety disorders among individuals with co-occurring substance use disorders. The use of agents targeting substance use, such as naltrexone or disulfiram, as add-on treatment for individuals with co-occurring mood or anxiety disorders is under-explored. In one study of 254 alcohol-dependent outpatients with a variety of co-occurring psychiatric disorders, Petrakis and colleagues (62) investigated the efficacy of disulfiram and naltrexone, or their combination and found that active treatment with either medication was associated with improved frequency and severity of alcohol consumption. Among 100 (52 men, 48 women) alcohol-dependent outpatients, Pettinati and colleagues (63) examined gender differences in the

effectiveness of sertraline among Type A and B alcoholics, many of whom had current (up to 57.9%) or lifetime (up to 78.9%) major depression. Findings showed that Type A alcoholic men, but not women, responded more favorably to sertraline than placebo (i.e., longer time to relapse, fewer days drinking, fewer drinks per drinking day). No differences were seen with Type B alcoholics. More recently, Pettinati et al. (64) examined gender differences in response to a higher-than-typical dose of naltrexone (150 mg/day) among 164 individuals (116 and 48 women) with dependence on cocaine and alcohol. This dose was found to be effective in men, but not in women. In fact, among women the higher dose was associated with increased cocaine use. In this study, psychosis and mania were the only Axis I conditions excluded. None of the above studies, however, examined the effects of specific co-occurring psychiatric disorders.

Eating Disorders

Eating disorders (EDs) occur more frequently among women than men (65) with a lifetime prevalence in women estimated to be 2 to 3 times higher than in men (66). The large majority (90%) of the cases of Anorexia Nervosa (AN) and Bulimia Nervosa (BN) are found in women (67). In contemporary Western cultures, thinness in women has come to signify attractiveness, competence, success, and self-control and may negatively affect the development and perception of women's body image (65).

The *DSM-IV* (67) classifies EDs into three main categories: (a) AN, (b) BN, and (c) EDs not otherwise specified (ED NOS). A new ED subtype, Binge Eating Disorder (BED), is also included in the *DSM-IV* as a research category and is classified under the ED NOS category. Of the three categories, AN is the least common and BED is the most common (68). Lifetime prevalence rates of AN and BN are estimated to be 0.5% and 2%, respectively (67).

Women with substance use disorders demonstrate higher rates of EDs, in particular the purging subtypes of bulimia, than women in the general population (69–71). In their review, Holderness and colleagues (70) found that lifetime ED behaviors co-occurred with substance use disorders in up to 40% of women in clinical populations. More recently, the NCS-R estimated that rates of lifetime alcohol use disorders occurred in up to 34% of individuals with EDs, which is significantly higher than rates of alcohol use disorders in the general population. Rates of co-occurring lifetime drug use disorders up to 26% among individuals with EDs have been reported (66). Among women with BN, in particular, and co-occurring substance use disorders, there is also a high reported rate of severe childhood sexual abuse (72). Similarly, among women with BN or BED, rates of substance abuse are greater among those with, compared to those without, a history of sexual or physical abuse (73).

Evidence-based behavioral treatments for EDs include cognitive-behavioral therapy and interpersonal therapy. Psychopharmacotherapy for EDs has focused on antidepressant

medications. Given the biological, psychological, and social factors involved in the development of EDs, treatment is complex and requires a multidisciplinary approach. For example, in addition to behavioral and pharmacological treatment, nutritional counseling and medical supervision are indicated (74). Individual, group, and family modalities of treatments are also often utilized to treat EDs, with or without co-occurring substance use disorders. Even though research suggests that treatment for EDs is most effective when addressed in the context of programs specializing in the treatment of EDs (75), most ED patients tend to receive treatment in a general medical setting (66). At present, no integrated, evidence-based treatments for EDs and substance use disorders are available and few treatment programs provide integrated treatment for co-occurring eating and substance use disorders (69). Like many co-occurring psychiatric conditions, individuals with substance use disorders and EDs are usually treated in programs specializing in either substance use disorders or EDs, but do not receive services for both disorders. A recent review of screening and treatment practices at 351 addiction treatment programs revealed that only half (51%) screen for EDs at intake or assessment (69). Furthermore, only 29% of addiction programs admit patients who screen positive for EDs. Overall, fewer than 1 in 6 addiction programs (17%) attempt to treat co-occurring EDs and only 3% have a formal referral arrangement for patient to receive ED-focused treatment.

Posttraumatic Stress Disorder

Posttraumatic stress disorder (PTSD) is a syndrome marked by symptoms of intense horror, helplessness, or fear following exposure to a distressing event that involves real or perceived threat to physical integrity (67). PTSD typically results from an extreme, catastrophic, or overwhelming experience (e.g., sexual assault, natural disaster, combat exposure) and is characterized by the following three symptom clusters: (a) re-experiencing the event through flashbacks, nightmares, and intrusive memories, (b) avoidance of stimuli (e.g., people, places, thoughts, feelings) associated with the event, and (c) increased arousal, such as, hypervigilance, trouble sleeping and concentrating, and increased irritability (67). Among victims of sexual assault, prevalence estimates of PTSD range from 14% to 80% and, among victims of physical assault, from 13% to 23% (76–78). Notably, interpersonal victimization is more likely than non-interpersonal traumas, such as serious accidents and natural disasters, to lead to the development of PTSD (79,80).

Among individuals with substance use disorders, the prevalence of PTSD is 1.4 to 5 times higher compared to those without substance use disorders (81). Rates of physical or sexual abuse among treatment-seeking women as high as 99% have been reported (82–84). Repeated forms of trauma, such as, domestic violence and revictimization are also common (85). Among men with substance use disorders and PTSD, exposures to crime victimization (e.g., being physically assaulted or mugged) or combat-related traumas are common.

Consensus is lacking regarding the best approach to treat co-occurring PTSD and substance use disorders; however, an emerging body of clinical treatment research demonstrates the efficacy of integrated interventions (83,85,86). This is in contrast to earlier concerns that PTSD treatment may be too stressful for substance use disordered patients and may induce relapse (87,88). The studies that have been conducted to date on integrated treatments for co-occurring PTSD and substance use disorders show good tolerability and efficacy, including significant reductions in both PTSD symptoms and alcohol and drug use severity (83,89–91). Unfortunately, most individuals with PTSD and substance use disorders receive addiction treatment only (92). For those patients who do receive treatment for both the PTSD and substance use disorders, most receive a sequential form of therapy. That is, they first receive addiction treatment, while the trauma/PTSD related issues are deferred. It is unclear how many patients who are later referred for PTSD treatment actually seek and obtain it following the completion of addiction treatment. Insofar as abuse of alcohol and drugs occurs in response to PTSD symptoms, addressing trauma-related symptoms first, or early in treatment, may provide opportunity for improved likelihood of recovery from substance use disorders (86,89,93).

Although selective serotonin reuptake inhibitors (SSRI's) are the pharmacological treatments of choice for PTSD, only three published studies have examined their use among patients with co-occurring alcohol or drug use disorders, and all of those studies tested sertraline (94–96). There was a trend for the sertraline group to show less severe PTSD symptoms, particularly in intrusion and hyperarousal symptoms. Follow-up cluster analyses identified that the medication-responsive group tended to have earlier PTSD (i.e., primary PTSD). A secondary analysis of the Brady et al. (95) data found that the presence of a second anxiety disorder or depression did not detract from treatment response to sertraline (96).

Personality Disorders

Personality disorders (PDs) are serious mental disorders characterized by inflexible patterns of thoughts and actions that are pervasive across situations and that begin during adolescence or early adulthood (67). Individuals with PDs demonstrate impaired functioning in at least two major areas, such as interpersonal functioning and affectivity. Prevalence rate across genders for any PD is approximately 14.8% (1). According to the *DSM-IV* (67), there are 10 categories of PDs, divided into three clusters:

Cluster A (odd or eccentric): paranoid personality disorder, schizoid personality disorder, schizotypal personality disorder

Cluster B (dramatic, erratic, emotional): borderline personality disorder, antisocial personality disorder, narcissistic personality disorder, histrionic personality disorder

Cluster C (anxious and fearful): avoidant personality disorder, obsessive compulsive personality disorder, dependent personality disorder

Some studies have found that among individuals with substance use disorders, especially drug use disorders, the prevalence of co-occurring Axis II disorders is higher than that of Axis I disorders (97–100). For example, among individuals with an alcohol use disorder, one study in the general population found that 28.6% had at least one PD, and among those with a drug use disorder, 47.7% had at least one PD (1). Clinical samples reveal an even stronger association between PDs and substance use disorders (99,101).

Among both men and women, Cluster B and C PDs are the most prevalent co-occurring PDs among individuals with substance use disorders (100,102). The co-occurrence of specific PDs, however, differs by gender. For example, women with substance use disorders demonstrate a greater prevalence of co-occurring borderline personality disorder (BPD) than men (99,103), while the prevalence of antisocial personality disorder (ASPD) is greater among men than women with substance use disorders (99,104).

Individuals with co-occurring personality and substance use disorders are more likely to have greater severity and, earlier age of onset of their substance use disorders, as well as higher rates of polydrug use, and more use of illicit drugs (105–107). High rates of self-harm and suicidal behaviors are common in women with co-occurring personality and alcohol and drug use disorders, requiring careful assessment and close monitoring (105,108). Finally, women with co-occurring personality and substance use disorders present with many complex problems and urgent needs. A specialized cognitive-behavioral therapy intervention, Dialectical Behavior Therapy (DBT) created by Dr. Marsha Linehan, includes a variety of treatment modalities (e.g., individual therapy, skills group, telephone coaching, therapist consultation team) and was originally designed for suicidal patients with BPD. Over the past decade, DBT has been adapted to address problems associated with co-occurring substance use and BPD (109). The four core DBT skills include: (a) mindfulness, (b) distress tolerance, (c) emotion regulation, and (d) interpersonal effectiveness. These core skills are relevant to both substance abuse and other problem behaviors. Several randomized controlled trials indicate that DBT is associated with superior substance use outcomes, maintenance of treatment gains, and good retention among women with BPD and substance use disorders (110,111).

Another treatment for co-occurring personality and substance use disorders is Dual Focused Schema Therapy (DFST) developed by Samuel Ball (112). It represents an adaptation of Young's Schema Focused Therapy (113). In addition to targeting the maladaptive schemas related to self, others, and events that are assumed to be learned in childhood and that organize a person's beliefs and behaviors, DFST includes specific interventions to target maladaptive schemas and specific relapse prevention techniques to address substance abuse (e.g., coping with cravings and urges to use). A recent, 24-week randomized controlled trial compared DFST to standard 12-Step

Drug Counseling in a sample of 52 opioid-dependent, homeless individuals with co-occurring PDs and substance use disorders (114). Individuals in the DFST group attended more individual sessions, but low retention rates across both groups (40%) limited the researcher's ability to compare other treatment outcomes by group.

SPECIFIC SUBSTANCES

Alcohol

Gender and Epidemiology

In general, men consume and misuse alcohol at significantly higher rates than women (115). However, this gender gap has decreased over time due to women's increased use of alcohol (116). This phenomenon, known as the "convergence hypothesis," is well documented in several large epidemiological studies. For example, data collected from over 42,000 participants in the 2001 to 2002 National Epidemiological Survey on Alcohol and Related Conditions (NESARC) indicated that sex differences in rates of alcohol use and abuse or dependence were smallest for younger cohorts (with cohorts ranging from 1913 to 1932 to 1968 to 1984) (117). Similarly, examination of changes in the age of initiation of alcohol use over the past 50 years shows significant narrowing of the gender gap (9). Whereas the male to female ratio of initiation in the 10 to 14 year old age group was 4:1 in the 1950s, it was one-to-one by the early 1990s. Finally, epidemiologic data show that while males aged 12 and older demonstrate significantly higher rates of alcohol dependence, examination of 12- to 17-year-olds show no significant difference. Some researchers propose that women's increase in alcohol consumption can be explained by sociocultural factors, such as society's increased acceptance of women's use of alcohol (9).

Telescoping Effect

Compared to men, women experience shorter time intervals between the initiation of alcohol use and the onset of significant alcohol-related problems (e.g., medical, social) and entrance into addiction treatment (19,118,119). This accelerated course of alcohol dependence, or "telescoping" may be attributed to a variety of biological, socioeconomic, psychologic, and cultural factors. Women may be more adversely affected than men by alcohol due to the lower percentage of total body water, decreased first pass metabolism because of lower levels of alcohol dehydrogenase in the gastric mucosa, and slower rates of alcohol metabolism (20). Sociocultural factors, such as the negative stigma associated with women and heavy drinking, economic barriers such as lack of insurance and lack of childcare, may cause women to wait until symptoms are more severe before entering treatment (120).

Triggers for Alcohol Use

Gender differences in triggers for alcohol use have been observed. In general, women are more likely than men to consume alcohol in response to stress and negative emotions,

whereas men are more likely than women to consume alcohol to enhance positive emotions or to conform to a group (121,122). These differences in drinking motives should be considered when designing prevention and treatment plans for men and women with alcohol use disorders (123). As compared to men, women with alcohol use disorders are significantly more likely to have co-occurring psychiatric disorders, including EDs (specifically BN) (124,125) BPD (103), depression (1), and anxiety disorders, such as, PTSD (54). It is important to address co-occurring psychiatric conditions among women with alcohol use disorders, as these conditions may serve to impede substance use treatment efforts.

Treatment

Women are less likely than men to seek treatment, and some data indicate that once in treatment women are more likely to drop out or attend fewer sessions (126,127). These differences may be affected by gender differences in factors such as childcare responsibilities, transportation, financial status, and social stigma. Offering childcare, prenatal care, women-only admission, and services specific for women's issues may be particularly effective in getting women to initiate and continue treatment (128). To enhance women's treatment retention rates, researchers have developed and implemented interventions specifically designed for women-only groups. Early results are promising, indicating that women not only experience fewer relapses in women-only treatment groups, but also gave higher satisfaction ratings for the treatment (129,130).

Stimulants

Gender and Epidemiology

In contrast to alcohol, rates of stimulant use are similar among men and women (131). However, both preclinical (132–135) and clinical studies (136,137) suggest that women may be particularly vulnerable to the reinforcing effects of stimulant drugs. In the past, women may have evidenced lower prevalence rates of stimulant drug use (138), however, societal changes are altering the "protective factors" (e.g., social stigma) that once lowered the rates of drug use. Because women may be more susceptible to the reinforcing effects of stimulants and "protective factors" are diminishing, women may be particularly at risk for using stimulants (139).

More recently, public health monitoring has indicated that methamphetamine use in the United States and worldwide has been on the rise with an estimated 5.8% of individuals age 12 and older in the United States having endorsed use at least once in their lifetime (3). The Treatment Episode Data Set (TEDS) documents that treatment admissions for methamphetamine as the primary substance use problem have more than doubled from 3.7% to 9.2% between 1995 and 2005 (140). A recent population-based study of noninstitutionalized adults ($N = 4297$) aged 18 to 49 in the United States in 2005 found that the overall

prevalence of current nonmedical methamphetamine use was estimated to be 0.27% with lifetime use estimated to be 8.6% (141). There were no significant gender differences in current use rates (0.32% for men and 0.23% for women) although the 3-year prevalence rate for men (3.1%) was higher than in women (1.1%). In 1994, among pregnant women admitted to federally funded substance abuse treatment centers, 8% were admitted for treatment of methamphetamine dependence, whereas in 2006, that proportion had risen to 24% leading the study's authors to conclude that methamphetamine is the primary substance of abuse for which women seek care during pregnancy (142). A 2005 study conducted in four states in the western United States, found that 5.2% of pregnant women living in these areas were affected by methamphetamine use (140). Other research has indicated that the relative rise of women in the criminal justice system is in part accounted for by the rise of methamphetamine use (143).

Hormones

Hormones may play an important role in the reinforcing effects of stimulant drugs for women. Both basic and clinical studies indicate that estrogen increases the reinforcing effects of stimulants for women (26,132–135), whereas progesterone decreases the reinforcing effects (144,145). In response to cocaine administration, women have been found to report increased subjective feelings of “high” and increased heart rate during the follicular phase, when levels of estrogen are elevated and progesterone levels are low, as compared to the luteal phase, when levels of progesterone and estrogen are low (24,28). Furthermore, exogenous administration of progesterone has also been shown to result in attenuated subjective responses to cocaine administration among women (28).

Treatment

Preclinical studies suggest that women may have a harder time quitting stimulants than men (146,147). Elman, Karlsgodt, and Gastfriend (148) hypothesize that gender differences in response to drug cues may help explain this difference. Research suggests that cognitive-behavioral therapy is as effective in treating stimulant use disorders among women as men (149,150). One study focusing on 359 women methamphetamine-using offenders who were treated in a modified therapeutic community program ($n = 234$) or standard outpatient treatment ($n = 125$) found that both treatment groups improved on psychosocial measures with a greater effect size seen in the modified therapeutic community (143).

Currently, there are no approved pharmacotherapy treatments for cocaine dependence. However, preclinical studies suggest that baclofen, a GABA-ergic drug, may be more effective in reducing cocaine use for women than men. In one study, female rats injected with baclofen self-administered cocaine significantly fewer times than male rats injected with baclofen (151). Clinical studies using naltrexone to reduce cocaine use (64) and bupropion to decrease methamphetamine

use (152) indicate that these pharmacotherapies may be more effective in treating men than women.

OPIOIDS

Prescription Opioids

Gender and Epidemiology

In 2006, 5.2 million Americans reported using prescription opioids for nonmedical purposes (3). A 141% increase in prescription opioid abuse was reported from 1992 to 2003 (153). There are a number of potential explanations for this increase: prescription opioids are relatively easy to obtain from a variety of sources (e.g., primary care physicians, the Internet), less social stigma is attached to prescription drug use as opposed to the use of “harder” drugs like cocaine or heroin, and prescription opioids are less closely monitored by law enforcement than other illicit drugs (153,154).

Research on gender differences in rates of nonmedical prescription opioid use is inconclusive. Although two large epidemiological surveys found that women use prescription opioids nonmedically more often than men (10), other studies suggest that rates of use are similar between men and women (3,12), or that men use prescription opioids nonmedically more than women (17). Furthermore, some studies indicate that gender differences in prescription opioid use may occur within specific age groups. For example, data from the 2002 to 2004 National Surveys on Drug Use and Health (NSDUH) show that compared to men women aged 12 to 17 report higher rates of prescription opioid abuse and dependence, whereas women aged 18 to 25 report lower rates of abuse and dependence (155).

Triggers for Nonmedical Prescription Opioid Use

Carise and colleagues (14) found that 86% of individuals in treatment programs used prescription opiates to “get high” or “get a buzz.” Among college students, McCabe et al. (13) found that women were significantly less likely than men to report using prescription opioids for “experimentation” (18.4% vs. 35.3%) or to “get high” (24.4% vs. 39.4%). Among chronic pain patients, women have also been found to be more likely to engage in particular “aberrant” drug taking behaviors, such as, hoarding unused medications, and using additional drugs (e.g., sedatives) to enhance the effectiveness of prescription opioids (156).

Comorbidity

Compared to nonopioid users, individuals who have used prescription opioids nonmedically and/or are dependent on opioids are more likely to suffer from anxiety disorders, affective disorders, or other substance use disorders (157,158). Men are more likely to be diagnosed with co-occurring substance use disorders (157) and ASPD (158), whereas women are more likely to be diagnosed with an affective disorder (e.g., major depressive disorder) (158,159) and suffer from more severe occupational, economic, or medical problems (19,157,158).

Heroin and Intravenous Drug Abuse (IVDA)

Gender and Epidemiology

Data from the 2008 NSDUH indicates that 0.2% of the U.S. population aged 12 and older has used heroin (131). Using data collected from a community sample, one study ($N = 408$) found that in comparison to men, women use smaller amounts of the heroin, use heroin for a shorter period of time, and are less likely to inject heroin (59% of women heroin users endorsed a history of injecting vs. 76% of the men) (160). Among injection drug users only, no sex differences in the duration or amount of use were revealed. In general, IV users report more instability in employment, more problematic use, and more health problems (e.g., hepatitis C, HIV, cirrhosis) than non-IV users (161). A recent analysis of NESARC data explored gender differences among 578 individuals with opioid disorders (159) and found that women were twice as likely to have a mood or anxiety disorder. Women were also more likely to have a paranoid personality disorder and men were more likely to have ASPD. Women had a significantly higher risk of having several co-occurring psychiatric disorders compared with men who had greater odds of having other substance use disorders.

Triggers for Heroin and IVDA

As compared to men, women's injection of drugs may be more influenced by their sexual partner's injection risk behavior (162). For example, Powis and colleagues (160) found that women who injected heroin were significantly more likely than men to have a sexual partner who also injected heroin (96% vs. 82%). Female users are also more likely than male users to be introduced to injection by their sexual partners (160,163). For example, in Powis and colleagues' (160) research, 51% of the female heroin users were first injected by their male sexual partner, whereas 90% of men were injected the first time by a friend. Compared to men who inject, women who inject also report being more influenced by social pressure and by sexual partner encouragement (163). In another study of older individuals with heroin dependence, women were more likely to describe the adverse consequences of their addiction on their families but both men and women expressed concerns about hepatitis C and mental health issues (164).

Adverse Consequences of Needle Sharing

Individuals with IVDA who share needles or preparation equipment are at increased risk for numerous physical diseases, including hepatitis B and C (HBV, HCV), as well as HIV (163). Research to date is inconsistent as to whether sex differences in injection risk behaviors occur. Frajzngier and colleagues (163) found no sex differences in sharing needles during the first injection, but women were significantly more likely to share preparation equipment than men. Other results suggest that although women are more likely to share needles (165–167), they are also more likely to engage in protective behaviors such as carrying clean syringes (166).

Treatment

Less than one fourth of individuals with opioid use disorders receive treatment (56). Potential reasons for low rates of treatment include the belief that using opioids is not as serious as using other illicit drugs since they are prescribed by physicians (11). For individuals with co-occurring chronic pain, they may fear that the pain will return or be exacerbated if opioid use ceases. To date, little research has investigated gender differences in the treatment of opioid use disorders. Preliminary findings for a manual-based, 12-session group treatment specifically designed for women using methadone suggests this may be an effective way to treat opioid dependence in women (168).

With regard to opioid agonist therapies, methadone maintenance therapy has been associated with reduced heroin use and improvements in psychiatric, medical, and legal problems (169–171). Jones, Fitzgerald, and Johnson (172) found that both men and women remained in treatment for a significantly longer period of time when given methadone as opposed to LAAM and that women given methadone remained in treatment longer than women given buprenorphine (115 vs. 105 days), although this finding did not reach statistical significance. Although buprenorphine, LAAM, and methadone reduced drug use for all participants, results suggest that sex differences may occur in the effectiveness of these pharmacologic agents. For women, buprenorphine was associated with significantly fewer positive urine samples and less self-reported opioid use than methadone. For men, LAAM was associated with less drug use than buprenorphine.

Cannabis

Gender and Epidemiology

According to the 2004 National Survey on Drug Use and Health (NSDUH), approximately 96.6 million Americans (40.2%) have tried marijuana, with 25.4 million (10.6%) having used within the last year, making it the most commonly used illegal drug in the United States (173). Among individuals who used marijuana within the past year, approximately 35.6% abused or were dependent on marijuana (174).

In comparison to women, men are more likely to use marijuana daily (2.0% vs. 0.7%) (175), have more initial opportunities to use marijuana (176), and initiate marijuana use at a younger age (16.4 years vs. 17.6 years) (177). Men and women may also differ in their risk of becoming dependent on marijuana (174). For women, there is approximately a 1% chance of becoming dependent during the first 5 years after initial use. For men, during the first year there is a 1% chance of becoming dependent, but for the following 2 years, there is a 4% chance per year that men will become dependent on marijuana (6). Research suggests that women enter treatment for marijuana use disorder after significantly fewer years of use than men do (i.e., telescoping effects) (19).

Hormones

Unlike other substances (e.g., stimulants), no relationship between the menstrual phase and women's use of (178), or response to, marijuana (e.g., mood and pulse rate) (179) has been observed. However, marijuana use may be related to the menstrual cycle for women who have severe premenstrual syndrome (PMS) or premenstrual dysphoric disorder (PMDD) (179).

Negative Effects of Marijuana Use

Marijuana use may affect attention processes and memory up to 7 days after use (180) and the effects of marijuana use on neuropsychological processes may differ for men and women. When comparing heavy marijuana users to light users, Pope and colleagues (181) found that visual-spatial memory was impaired for women who smoked heavily as compared to women who were light smokers. For men, however, no such difference was observed.

Comorbidity

When compared to individuals without marijuana dependence, those with dependence are significantly more likely to have co-occurring psychiatric disorders (90% vs. 55%) (182). In particular, marijuana dependence has been found to be associated with conduct disorder, ASPD, alcohol dependence (183), mood disorders, anxiety disorders (182), depression (184,185), posttraumatic stress disorder (186), and social phobia (182,53). Although gender differences in rates of comorbidity have not been thoroughly explored, there is some evidence that differences may exist. For example, one study found that social anxiety disorder was correlated with marijuana use for women but not men (187).

Treatment

Due to low numbers of women in treatment, no studies have been published regarding gender differences in the effectiveness of treatment for marijuana use disorders. However, research (with predominately male participants) suggests that cognitive-behavioral therapy, contingency management treatments, motivational enhancement therapies, and administering oral THC and nefazodone are effective treatments for marijuana dependence (188–191).

Nicotine

Gender and Epidemiology

In 2008, approximately 70.9 million Americans (28.4%) reported currently using nicotine. This includes people who smoke cigarettes and cigars, use smokeless tobacco, and use pipes to smoke tobacco. Males use nicotine at higher rates than females (34.5% vs. 22.5%) (131).

While most people understand the serious consequences of nicotine use, few are aware that women may be at an increased risk for health problems caused by smoking. Compared to men, women who smoke are twice as likely to have a heart attack (192), experience faster lung deterioration, and

are at increased risk for chronic obstructive pulmonary disease (193) and lung cancer (194). Furthermore, smoking may cause women to commence menopause earlier, experience increased menstrual bleeding, have difficulty becoming pregnant, or experience spontaneous abortion (195). The children born to women who smoke while pregnant are at increased risk for sudden infant death syndrome (SIDs), death or severe complications caused by lung impairment, or low birth weight (196).

Triggers for Nicotine Use

Both pharmacological and nonpharmacological factors influence nicotine use and dependence. Nicotine is the main pharmacological factor in tobacco that plays a key role in the acquisition and maintenance of use. Nonpharmacological factors are stimuli that are often paired with nicotine, which can be both proximal (e.g., the smell of a cigarette) and distal (e.g., people associated with smoking) (197). Compared to men, women may be influenced less by nicotine factors (198,199) and more influenced by proximal cues (200). These gender differences in underlying motivations or triggers for use may help inform gender-sensitive treatment approaches.

Treatment

Women may have more difficulty quitting smoking than do men. Data from the Centers for Disease Control and Prevention (2006), which surveys over one hundred thousand U.S. citizens, indicates that over a million fewer women than men over the age of 35 are able to quit smoking (201). Menstrual cycle phase may be associated with women's success at smoking cessation (21,30). Women who attempt to quit during the first 14 days of their menstrual cycle (e.g., the follicular phase) may be more likely to be successful in their attempt than women who attempt to quit in the second half of the cycle (e.g., the luteal phase) and that women have greater nicotine withdrawal symptoms and craving if they quit smoking in the luteal versus follicular phase (21).

Nicotine Replacement and Nonnicotine Medication Research is inconclusive as to whether there are sex differences in the efficacy of nicotine replacement therapy (NRT). In 2004, a meta-analysis of 11 placebo-controlled NRT patch trials indicated that NRT is equally effective for men and women (202). More recently, however, Perkins and Scott (203) added three additional placebo-controlled trials to this meta-analysis and the results indicated that NRT is significantly more effective for men than women. Nonnicotine medication (bupropion and varenicline) are equally effective in men and women up to 12 weeks after treatment (204,205). However, no research has examined the abstinence rates following longer periods of time after treatment (206).

Behavioral Treatments Although medications are the standard approach to help individuals quit smoking, therapy and counseling generally enhance the efficacy of medication treatment and appear to be more effective in women than men (206). There are a number of approaches to counseling that

may specifically help women address obstacles to quitting. For example, interventions that teach women how to cope with cues (e.g., distracting oneself from cues), since research suggests women respond more to nonnicotine factors (200) may be particularly helpful. In addition, interventions that address co-occurring mood and anxiety disorders may help decrease women's susceptibility to smoking cigarettes in order to cope with negative affect. Bupropion, which has been found to be equally effective for both men and women, may be a particularly effective method for women because it has been found to also help relieve depression (205).

Another obstacle to cessation is women's concern about weight gain. Women worry twice as much about weight gain caused by smoking cessation than men (207), and relapse three times more often than men because of weight gain (208). Cognitive-behavioral therapy designed to address women's concern about weight gain has been found to be more effective than standard cessation counseling alone (200).

Smoking during pregnancy is another issue of concern for women. This is a complicated issue because of the social stigma attached to smoking during pregnancy. Often women report abstinence when they are still smoking (209). Behavioral treatment approaches are particularly important for smoking cessation during pregnancy, because many medications are contraindicated in pregnancy. Therapy should be modified specifically for pregnant women (e.g., incentives for cessation, such as vouchers that can be exchanged for baby supplies) both while women are pregnant and after delivery, since approximately 65% of women who quit while pregnant relapse within 6 months of delivery (210).

Treatment Outcome for Women with Substance Use Disorders

Treatment Seeking and Utilization

The Treatment Episodes Data System (TEDS) captures data on national treatment admission rates and provides information on the extent to which women participate in substance abuse treatment. Based on the TEDS data, the overall proportion of men to women within the treatment system has remained fairly constant (e.g., from 1995 to 2005) at 2:1 (211).

A recent review of the literature between 1975 and 2005 examining characteristics associated with treatment outcome in women with substance use disorders concluded that over their lifetime, women are less likely to enter treatment compared with men (212). However, once women enter treatment, gender itself is not a predictor of treatment retention, completion, or outcome (212). While gender itself does not necessarily predict outcome, there are a number of gender-specific predictors of outcome and patient characteristics and treatment approaches can affect outcomes differentially by gender (212).

A number of barriers to treatment entry affect women more significantly than men. The role of children in women's lives can be central to seeking treatment as well as recovery. The majority of women who enter substance abuse treatment

are mothers, and at least half have had contact with child welfare (213). Thus, the relationship with and responsibility for their children is likely a central influence on women's decision whether or not to enter treatment. One study of women entering methadone maintenance treatment found that women who were residing with their children were significantly more likely than women not residing with their children to enter treatment (214). For some women, however, residing with their children may serve as an impediment to entering treatment if they fear it may lead to the loss of custody of their children (215). Studies show that, once in treatment, women who were able to keep their children with them while in residential drug treatment or who retain custody of their infants while in intensive day treatment are more likely to stay in treatment (216).

Gender differences in sources of referral to treatment have been shown, highlighting the varying pathways by which women and men enter substance abuse treatment facilities. Overall, more men than women are referred to treatment through the criminal justice system (40% men vs. 28% women), whereas about twice as many women as men (15% women vs. 6% men) are referred from other community agencies, such as, welfare, mental health and other health care providers (209,217). One potential site for screening and referral of women is reproductive health services, such as obstetrics and gynecology (218). A study of eight obstetrics clinics demonstrated the feasibility of screening for alcohol use problems by using a brief screener in waiting rooms (219). The study found that 13% of pregnant women scored above the cutoff, indicating at-risk alcohol use, defined as binge drinking or more than one standard drink per week. At-risk use was predicted by earlier stage of pregnancy, indicating the feasibility of intervening early in pregnancies to reduce subsequent harm to the developing fetus. The criminal justice system is increasingly becoming more relevant to the lives of women with substance use disorders as the number of female prisoners in the United States is growing substantially (e.g., 53% since 1995), due largely to changes in sentencing for drug-related charges which have disproportionately affected women, particularly women of color (220).

Finally, differences in the sources of payment for substance abuse treatment have also been found, with a significantly greater proportion of men reporting self-pay (26% men vs. 18% women) and more women than men being dependent upon public insurance (26% women vs. 12% men) (211). This finding highlights how gender differences in economic and employment status are associated with gender differences in pathways to treatment, and suggest that women may be more vulnerable to changes in insurance-related benefits and coverage because of their greater reliance upon public insurance to pay for treatment.

In addition to financial and childcare issues, other factors may present as impediments to treatment seeking and utilization for women. For example, social stigma and labeling, lack of awareness of the range of treatment options, concerns about confrontational approaches that were pervasive in traditional substance abuse treatment, co-occurring mental disorders

and/or a history of trauma and victimization, as well as homelessness all present possible barriers for women (221).

Once in treatment, some studies indicate that women may be more vulnerable than men to drop out of substance abuse treatment (222–224). However, other studies suggest that men are more likely to drop out of treatment (225) or that rates of treatment completion are equivalent among men and women (226,227). Finally, larger, population-based investigations provide a convergence of results showing few or no gender differences in treatment retention (130,228,229). Even though no consistent gender differences in treatment retention has been observed, some characteristics have been shown to be associated with more favorable outcomes for both men and women, such as greater financial resources, fewer mental health problems, and less severe drug problems (212,226,227). Studies in women-only samples have found associations between certain characteristics and retention, including better psychological functioning, higher levels of personal stability and social support, lower levels of anger, treatment beliefs, and referral source (230–234).

Gender-Specific Treatment for Women with Substance Use Disorders

Historically, the majority of substance abuse treatment models have been designed for men and based predominantly on male norms (116,130,235,236). More recently, however, gender-specific interventions are beginning to emerge. Gender-specific interventions and services for women are designed specifically to provide information and services that are tailored for women. Gender-specific and gender-sensitive treatments have emerged in response to mixed-gender programs, which often fail to address women's specific needs, such as childcare assistance, pregnancy, parenting, domestic violence, sexual trauma and victimization, housing, income support, and social services (227–242). Furthermore, only a minority of women (7%) believe there is no difference between mixed-gender and women-only programs (241). Despite this, data from the most recent National Survey of Substance Abuse Treatment Services (N-SSATS), which collects data on both public and private treatment centers, indicates that only a third (33%) of treatment facilities offer special programs for women and only 14% offer programs for pregnant or postpartum women (173).

Arguments in support of gender-specific treatment include differences in interaction styles and men's traditional societal dominance, which might negatively affect women in mixed-gender programs (136,243–246). In addition, women may not respond well to confrontational therapy styles (247), but rather they may benefit more from less structured and rigid styles (236). Moreover, women and men with substance use disorders differ significantly in terms of risk factors, co-occurring psychiatric conditions, motivations for treatment, and risks for relapse (236,248). Gender-sensitive treatments can address these issues directly for women in treatment for substance use disorders and may help to improve treatment-seeking and retention rates, as well as treatment satisfaction.

With regard to outcome of gender-specific treatments, the findings remain unclear (128,243,244,249,250). However, only a few randomized clinical trials have examined the relative effectiveness of comparable women-only versus mixed-gender interventions (130,212). In a meta-analysis examining single-gender substance abuse treatment for women, Orwin et al. (239) concluded that single-gender treatment was effective, however its strongest impact was on pregnancy outcomes, psychological well-being, attitudes/beliefs, and HIV risk reduction. Only modest improvements in alcohol and drug use, or criminal activity were revealed (239). It is important to note that only a few of the studies compared gender-sensitive or gender-specific treatment to mixed-gender programs, which limits the interpretation of the findings (239).

Mixed results have been reported among studies comparing women-only versus mixed-gender programs. One study that randomized women ($N = 1573$) to women-only versus mixed-gender treatment failed to show treatment group differences in attrition (251). In contrast, another study that randomized crack cocaine-dependent women with infants to either a specialized women-only day treatment program or a traditional mixed-gender outpatient program found that participants in the women-only program had significantly higher retention rates at 4 months (60.2% vs. 46.1%) (252). In a more recent study, treatment outcomes and costs of women-only and mixed-gender day treatment programs were compared among 122 women randomized to a women-only program with gender-specific programming, or one of three standard mixed-gender programs (253). Participants in the women-only program demonstrated significantly lower total abstinence during the follow-up period as compared to the hospital-based program ($OR = 0.17$), but the hospital-based program cost twice as much. Limitations included a small sample size and the focus on only day treatment programs (253).

In a recent Stage I Behavioral Development Trial, Greenfield et al. (130) developed a manual-based, 12-session Women's Recovery Group (WRG) and compared WRG to mixed-gender Group Drug Counseling (GDC), an effective manual-based treatment for Substance use disorders. Women were randomized to WRG ($n = 16$) or GDC ($n = 7$). The WRG was equally effective as the mixed-gender GDC in reducing substance use during the 12-week in-treatment phase, but demonstrated significantly greater improvement in reductions in drug and alcohol use over the 6-month posttreatment follow-up phase. In addition, while satisfaction with both groups was high, women were significantly more satisfied with WRG than GDC (130). Secondary analyses of these data found a significant three-way interaction effect of treatment condition, time and baseline Brief Symptom Inventory scores, and found that women with greater baseline psychiatric severity made greater reductions in substance use during 12 weeks of group therapy and in the 6-month follow-up if they were assigned to the WRG rather than the mixed-gender GDC condition (254). Furthermore, women with low self-efficacy were more likely to have better treatment outcomes if assigned to WRG than mixed-gender group treatment (255).

Results from nonrandomized studies have shown mixed results (256–258). Comparisons of data from publicly funded residential women-only and mixed-gender drug treatment programs show that women-only programs have significantly longer lengths of stay (87.4 vs. 74.0 days) and higher rates of completion (16.9% vs. 7.6%) than women in mixed-gender programs.

A number of studies have shown greater success with treatments addressing problems more common to women with substance use disorders. Those include, for example, services for pregnant women leading to reduction of alcohol use (259), contingency management to increase abstinence from cocaine in pregnant women (260), a comprehensive services model for pregnant women (261), parenting skills for methadone-maintained mothers (262), relapse prevention for women with co-occurring PTSD (263,264), relapse prevention for women with marital distress and alcohol dependence (265), DBT for women with co-occurring BPD and drug dependence (266), and prison-based single-gender drug treatment for women offenders (248). Even though more data, in particular from randomized controlled trials, are needed, the results indicate that gender-specific interventions may lead to improved outcomes for specific subgroups of women.

Behavioral Couples Treatment

Dyadic conflict and relationship stress appears to affect the substance use of men and women differently. For example, studies show that women are more vulnerable than men to consuming alcohol subsequent to marital discord, divorce, negative emotional states, and interpersonal conflict (267,268). Furthermore, having a partner that abuses alcohol or drugs is more strongly related to relapse for women than for men (213).

Because relationships and family discord play a critical role in women's substance use problems, treatment interventions designed specifically to address these issues may be particularly beneficial. One such treatment approach is Behavioral Couples Therapy (BCT), which has been shown in numerous studies to lead to reduced drinking and positive dyadic adjustment among men with substance abuse problems, decreased IPV (269). BCT is founded upon two fundamental assumptions: (1) family members, specifically spouses or other intimate partners, can reward abstinence and (2) a reduction of relationship distress and conflict leads to improved substance use outcomes by reducing possible antecedents to relapse and heavy use. Compared to traditional individual-based treatments (IBTs), participation in BCT results in significantly less partner violence, lower substance use severity, higher rates of marital satisfaction, greater improvements in psychosocial functioning of children living with parents, and better cost-benefit and cost-effectiveness (269,270). In one trial (271), participants ($N = 138$) who were married or cohabiting women were randomly assigned to one of three interventions: (a) BCT, (b) IBT, or (c) a psychoeducational attention control treatment (PACT) condition. In comparison to women who received IBT or PACT, women who received

BCT reported significantly fewer days drinking and higher levels of dyadic adjustment during a 12-month posttreatment follow-up period.

ADDITIONAL ISSUES

Pregnancy and Substance Abuse

Alcohol Use in Pregnancy

Data from the 2008 National Survey on Drug Use and Health indicates that approximately 10.6% of pregnant women use alcohol, while 4.5% report binge drinking (131). Alcohol use during pregnancy may cause pregnancy-related complications (e.g., preterm labor, spontaneous abortions) and negatively affect the fetus. Approximately 1 in 300 to 1 in 1000 children born per year in the United States are diagnosed with a fetal alcohol spectrum disorder (FASD) (272). Children with FASD experience physical abnormalities (e.g., malformed ears, flattened midface) (273), cognitive and behavioral changes (e.g., impulse control problems, ADHD) (274), and psychiatric disorders (e.g., mood disorders, conduct and behavior disorders) (275).

Four main treatment interventions are used to treat/prevent alcohol use in pregnant women: (a) primary care treatment of women of childbearing age who meet criteria for alcohol use disorders, (b) detoxification, (c) follow-up programs for women who used alcohol while pregnant, and (d) brief interventions. Research suggests that brief motivational interventions may be particularly effective in reducing the use of alcohol during pregnancy (276). A recently conducted randomized trial of a single session brief intervention for 304 pregnant women and their partners demonstrated that drinking reductions were greatest among pregnant women with the highest levels of alcohol use (277). Research studies conclude that there should be consistent screening for prenatal alcohol use, followed by diagnostic assessment when screening results are positive, and if diagnosis of alcohol use is confirmed, interventions such as a patient-partner brief intervention for the heaviest drinkers is indicated (277).

Nicotine Use in Pregnancy

Past month prevalence rates indicate that 16.4% of pregnant women report using nicotine (131). Research indicates that using nicotine during pregnancy may cause maternal complications (e.g., vitamin and mineral deficiencies, pregnancy-induced hypertension) (278,279), neonatal complications (e.g., low birth weight, congenital malformations, and intrauterine growth restriction) (280,281), and long-term consequences for the children (e.g., cognitive deficits) (282). Although research suggests that bupropion (283) and behavioral interventions (284) are effective treatments for smoking cessation in women, nicotine replacement therapy (NRT) may increase negative birth outcomes (285) but studies indicate that it is unclear whether associated low birth weight is a direct effect of the NRT or rather the associated heavy smoking among women referred for NRT (286). More research in this area is strongly needed to help enhance effective

behavioral treatments for smoking cessation during pregnancy as well as to advance safe pharmacotherapy options for pregnant women wanting to quit smoking during pregnancy.

Marijuana Use in Pregnancy

Data from the 2001 Maternal Lifestyle Study indicates that 11.1% of pregnant women use marijuana (3,287). The use of marijuana during pregnancy can lead to maternal complications (e.g., negative effects on duration of pregnancy, implantation) (288), complications for the neonate (e.g., intrauterine growth retardation, acute myeloblastic leukemia) (289), and long-term effects on the children (e.g., slower motor development, increased depressive symptoms) (290,291). To date, no research has investigated specific treatment interventions for pregnant women using marijuana.

Opioid Use in Pregnancy

Approximately 7000 children born each year in the United States are exposed to opioids prenatally (292). Both the mother and fetus are at risk for overdosing, which can lead to complications such as, coma, hypothermia, and circulatory collapse (293). The use of opioids during pregnancy can also cause the fetus to develop neonatal abstinence syndrome, which includes symptoms such as irritability, temperature dysregulation, and seizures (294). Treatment options for pregnant women using opioids include methadone maintenance and detoxification (292,295). Studies suggest that treatment of pregnant opioid-dependent women and their children in specialized treatment programs can help enhance maternal and child outcomes (239).

Cocaine Use in Pregnancy

A multisite study of university hospitals found a 10% rate of cocaine use among pregnant women using illicit drugs (296). Cocaine use during pregnancy can cause significant maternal complications (e.g., pneumonitis and placental abruption) (297,298) and put the fetus at risk for adverse outcomes (e.g., HIV and harm fetal-placental circulation) (299). Since withdrawal is not life threatening for the mother or fetus, treatment to support cessation of use and ongoing relapse prevention and abstinence are indicated for cocaine use in pregnant women (300). Anticraving medications, for which effectiveness studies are inconclusive, are typically avoided, since the FDA has not approved the medications for pregnant women (301).

Cultural Issues

Epidemiology

Approximately 98 million minorities live in the United States (33% of the U.S. population) (302). Rates of illicit drug use vary by race/ethnicity, with rates being estimated as follows (from smallest to largest): Asian Americans (3.6%), Hispanics (6.2%), Native Hawaiians or other Pacific Islanders (7.3%), European Americans (8.2%), Native Americans or Alaska Natives (9.5%), African Americans

(10.1%), and individuals reporting more than one race (14.7%). Rates of substance abuse or dependence also vary by race/ethnicity, with rates being estimated as follows (from smallest to largest): Asian Americans (4.2%), African Americans (8.8%), European Americans (9.0%), Hispanics (9.5%), individuals reporting more than one race (9.8%), and Native Americans or Alaska Natives (11.1%) (122).

Risk Factors for Diverse Women

In order to effectively counsel diverse women with substance use disorders, it is imperative that clinicians are knowledgeable about cultural histories, norms, practices, and environments. Common correlates of substance use disorders are found among women from diverse ethnic/racial groups. Many women with substance use disorders may also experience other at-risk behaviors and conditions such as high-risk sexual behaviors (303), co-occurring psychiatric disorders (304), physical and medical problems (e.g., HIV/AIDS) (303), traumatic histories and victimization (e.g., rape, loss of children) (303,305), functional problems (e.g., unemployment) (306), incarceration histories (307), and experiences of racism (308).

Treatment

There is limited research available that addresses the treatment of substance use disorders among specific ethnic groups, due mainly in part to the strict criteria and guidelines in clinical research (309). Therefore, it is best practice at this time to use evidence-based treatment modalities and programs (e.g., cognitive-behavioral therapy) (303) modified to address common correlates found among diverse women with substance use disorders. For example, treatment programs should address co-occurring disorders (e.g., PTSD caused by trauma histories) or other functional problems in diverse women's lives.

Sexual-Minority Issues

Epidemiology

Limited research has been conducted to date on sexual-minority women and substance use disorders. Within these studies, definitions of sexual-minority women have varied, making the interpretation and generalizability of the results difficult. For example, while some studies define women as either "heterosexual" or "homosexual," other studies develop additional categories to adequately assess sexual behaviors and identity (e.g., "women who reported having sex with other women" (WSW) (310). Research suggests that using only two categories may cause researchers to overlook differences within the sexual-minority female population (311).

Compared to heterosexual women who report only having sex with men, sexual-minority women (including lesbians, bisexual women, and WSW) use alcohol at higher rates and have more alcohol-related problems (310,312,313). Lesbians and bisexual women were also found to be more likely to meet criteria for alcohol dependence and/or participate in

treatment than heterosexual women (311). Sexual-minority women are also more likely than heterosexual women who reported having sex only with men to use marijuana, analgesics, nicotine, and to meet criteria for substance dependence (314–318).

Risk Factors

Compared to heterosexual women, sexual-minority women report significantly higher rates of traumatic events, such as, discrimination, and verbal and physical attacks from peers, parents, and partners (319–321). Sexual-minority women also report higher rates of mood and anxiety disorders (322,323), suicidality (310,322,324), and psychological distress (325). Discrimination, traumatic events, and psychological problems may put sexual-minority women at increased risk for substance use disorders. Furthermore, social structures within the United States may also place sexual-minority women at risk for developing substance use disorders. Bars are one of the few social outlets that exist in the United States where sexual minorities feel free from ostracism or scrutiny, which may lead to higher rates of alcohol use among lesbian and bisexual women (326).

Treatment

Although homosexuality has not been considered a clinical disorder in the *Diagnostic and Statistical Manual of Mental Disorders* (327) for more than 25 years, some clinicians still support conversion therapy, designed to convert homosexuals to heterosexuals (328). Early research on substance use disorder treatment of sexual-minorities indicates that many programs either refused treatment to sexual-minorities, focused on “converting” the patients to heterosexuals, or had limited experience and training in treating substance use disorders among sexual minorities (329,330). A more current study conducted by Eliason (331) also found that many counselors are not trained to work with sexual minorities and are unaware of legal and family issues for sexual minorities.

Although little research has investigated the effectiveness of addiction programs for sexual minorities, treatment recommendations have been proposed. For example, it may be beneficial for clinicians to be trained and supervised in “culturally sensitive treatment for LGBT clients and patients” (p. 484), nondiscrimination literature should be placed in waiting rooms, and group therapies should be supervised in a way to create a supportive environment for everyone (332).

Legal Issues

Drug Use and Civil Law

Over the last 20 years, states have criminally prosecuted pregnant women using illicit drugs in an attempt to protect fetuses (333), which has led to women’s incarceration and the loss of custody of children (334). Limitations to the punitive approach include the fact that it may cause pregnant women using illicit drugs to choose an abortion or avoid medical care altogether (335).

Research shows that mothers who abuse substances are more likely to have their children placed in out-of-home care (336). Mothers using substances who lost the custody of their children experienced more psychological and functional impairments, homelessness, victimization experiences, higher frequencies of drug use, and engaged in more risky sex practices, as compared to mothers using substances who did not lose custody of their children (337,338). However, custodial mothers are less likely to start treatment for substance use disorders (337), and if started they are more likely to drop out of treatment, possibly due to childcare responsibilities (339). One line of research offering promise for effective treatment for pregnant and parenting women with substance use disorders reported that 61% percent of women who attended a residential substance abuse program for pregnant and parenting women were completely drug- and alcohol-free throughout the 6-month follow-up period (340).

Drug Use and the Criminal Justice System

Nearly 1.9 million individuals are arrested each year for drug abuse violations (341,342). Approximately 17% of crimes are committed for drug money and between 25% and 33% of crimes are committed under the influence of drugs (343). Within state prison facilities, 60% of the women (vs. 40% of men) were committed for property or drug crimes (344). It is estimated that 80% of incarcerated women used substances in the past and that approximately 60% of women met criteria for drug dependence (345).

Research indicates that correctional facilities are not adequately treating women and men with substance use disorders (346). Approximately 18% of local jail inmates with substance use disorders receive treatment while incarcerated (343). Research also indicates that addiction treatment programs within correctional facilities do not adequately address the histories of women in correctional facilities, including high rates of trauma, abuse, and co-occurring psychiatric disorders (343,347), which may help explain why treatment within correctional facilities may be effective only for men (347). Future research examining the effectiveness of gender-specific treatment programs within correctional facilities is needed (248).

CONCLUSIONS AND FUTURE DIRECTIONS

Over the last decade there has been an increasing number of studies focusing on gender differences in substance use disorders, as well as gender-specific treatments and outcomes for women with substance use disorders. Current research supports that there are important gender differences in biologic, psychological, cultural, and socioeconomic factors that affect the initiation, use patterns, disease acceleration, and help-seeking patterns in women, as well as gender-specific predictors of substance abuse treatment entry, retention, and outcomes for women. Further research will enhance our understanding of basic biological mechanisms that underlie these gender differences in substance use vulnerability, responsiveness, and neurobiologic correlates of addiction. There is also a concomitant need to understand gender differences

in response to standard behavioral and pharmacologic treatments, to identify characteristics of women who can benefit from single-gender versus mixed-gender treatments, and to develop and test effective treatments for specific subgroups of women with substance use disorders. Further research will also improve our understanding effectiveness and cost-effectiveness of gender-specific versus standard treatments.

Robert Paul Cabaj

Gay men, lesbians, and bisexual men and women are a special population with specific needs and concerns—a population defined not by traditionally understood cultural and ethnic minority criteria, but, rather, by having a sexual orientation that is different from the majority. A culturally competent approach is essential for working with gay, lesbian, and bisexuals (GLB) who have substance use or abuse concerns. Such competencies come from knowledge about and experience in working with GLB persons. To help with the knowledge component, this chapter discusses the nature of homosexuality and bisexuality; gay men, lesbians, and bisexuals themselves; the substance use and abuse concerns in this population; and the specific treatment issues that need to be addressed when working with people who are gay, lesbian, or bisexual. (Transgender people require a special focus on their behavioral health concerns and will not be featured in this chapter.)

Nearly all studies and reviews (1–3), and the experiences of most clinicians working frequently and extensively with GLB persons (3), estimate an incidence of substance abuse of all types at approximately 30%—with ranges of 28% to 35%, in contrast to an incidence of 10% to 12% for the general population. One study noted bisexuals might have even higher rates than gay men and lesbians (4).

The GLB population is benefiting from newer studies and research, often with a focus on a subpopulation. For example, recent reviews of GLB youth indicate the same higher rates, noted above, that persist into adulthood (5,6). Studies that focus on minority GLB persons also indicate higher rates of alcohol and drug use and abuse (7,8).

Rather than just report on the higher incidence, studies now try to address the reasons behind the higher rates and look into the risk factors. Some risk factors have been noted that differ between non- or light users from frequent or binge drinker. These factors include: race/ethnicity; gay bar attendance; depression; sensation seeking; peer risk behaviors; and age of alcohol initiation (9). Co-occurring problems are also being studied, one of the most important being the combination of substance use/abuse and suicide attempts, mirroring the very high rates of suicidal thinking and behaviors among GLB youth (1,4,8,9).

Some studies have focused exclusively on lesbian substance abuse noting both higher rates of use overall as well as higher abuse patterns as compared to the general population (10,11). A commonly noted risk factor is early exposure to alcohol in school and persistence into adulthood, as also noted above for minorities (9,12).

Currently, no study specifically focuses exclusively on the drug or alcohol use of bisexual men or women, although many such people are included in some of the studies already described. Most of the concepts in this chapter can apply to bisexuals, however, because the key roles of external and internalized homophobia, as will be described below, apply to this population as well.

Alcohol abuse has been the primary focus of most studies. No specific studies of injecting drug use (IDU) and the gay population are currently available. The annual Centers for Disease Control and Prevention (CDC) report on acquired immunodeficiency syndrome (AIDS) and human immunodeficiency virus (HIV) infections clearly indicate a subgroup of IDU gay and bisexual men, and one of the routes of HIV infection for lesbians is via IDU (12). One survey (13) did review the use of all types of abusable substances among gay men and lesbians, noting a greater use of cigarettes, marijuana, and alcohol than in the general population.

In the last decade or more, the use and abuse of methamphetamine (also known as “speed,” “crystal,” “tina,” “crank,” and other names) has emerged as a particular problem for gay men especially in urban areas on the West Coast, the South, and the Northeast Coast. Though use is not exclusive to gay men (adolescents across the country and urban younger Asian and Latina women are also noted to be high users), the problem has multiple psychological and medical concerns for gay men in particular. The frequent route of use is intravenous (i.v.), but it can also be inhaled/snorted or swallowed. Combined with its disinhibiting effect and sexual stimulating effect, the i.v. gay male users of methamphetamine are at extremely high risk for HIV infection via sharing needles and engaging in sexual activity that may last for hours and may not always follow safer sex guidelines. The use of the drug is highly associated with sexual activity and is popular at “circuit parties” where large numbers of gay men gather for partying, dancing, and sexual activity (often accompanied by drugs use) and with men seeking sexual partners over the internet (“party and play”) (14,15). Additional focus of crystal meth will be in the treatment section of this chapter.

SEXUAL ORIENTATION IN GENERAL

Homosexuality, as a term, is subject to some controversy. It was first used when homosexuality was considered a clinical, pathologic condition. Because the term “gay” is less prejudicial and has a long accepted history, this chapter refers to gay men,

lesbians, and bisexuals as people, and homosexuality and bisexuality in reference only to certain types of behavioral activities or orientations.

The understanding of certain terms is crucial to understanding homosexuality; failure to have clear definitions and understanding has led to much of the confusion in the literature about homosexuality and sexuality in general, and certainly has contributed to some of the prejudicial feeling about homosexuality. It is important to recognize the difference between sexual orientation and sexual behavior, as well as the differences between sexual orientation, gender identity, and gender role. Sexual orientation refers to the desire for sex, love, and affection, and/or sexual fantasies from or with another person, whereas sexual behavior is strictly sexual activities and may not coincide with primary sexual orientation. Gender identity is the sense of self as male or female, with no reference to sexual orientation or gender role. Gender role refers to behaviors and desires to behave that are viewed as masculine or feminine by a particular culture. Behavior that a particular culture may label as masculine or feminine is not necessarily a reflection of gender identity, but it is common to call behavior, styles, or interests shown by a male that are associated with women as “effeminate” (boys are often labeled “sissies”) and the equivalent by a woman as “being like a man” or “butch” (girls are often labeled “tomboys”).

Using both the pioneering scientific and psychological evidence collected by Dr. Evelyn Hooker that gay men were as psychologically healthy as matched heterosexuals (16) and subsequent research, the American Psychiatric Association (APA), in 1973, removed homosexuality per se as a mental illness from its list of disorders. Some psychiatrists who mistakenly thought the removal was a response to political pressure challenged this decision, but the APA supported its scientifically based decision via a vote by the membership and support by APA leadership. There was, however, a “political” compromise, with the creation of a nonscientific diagnosis called “ego-dystonic homosexuality.” In 1987, the APA recognized this error and removed that label from the *Diagnostic and Statistical Manual of Mental Disorders*, 3rd ed., revised (*DSM-III-R*) (17). The current *Diagnostic and Statistical Manual of Mental Disorders*, 4th ed., text revision (2000) (*DSM-IV-TR*) followed the same revisions.

This nonjudgmental, nonprejudicial framework on homosexuality has led to new thinking and revisions on homosexual behavior and on gay men, lesbians, and bisexuals, as well as an awareness of the heterosexist bias in earlier research (18,19). New literature founded on work with gays in psychotherapy and substance-abuse counseling continues to be generated (3,20–22). American psychoanalytic thinking has been extremely persistent in trying to view homosexuality as pathologic even at one point trying to assert “repressed” homosexuality was a cause of alcoholism, but most current psychoanalytical literature has been able to review and revise some traditional, conservative views on homosexuality (23).

HOMOSEXUAL BEHAVIOR AND BISEXUALITY

Homosexual Behavior

Besides the work of Dr. Hooker noted above, the famous Kinsey report helped put homosexual behavior *itself* in perspective (24). Although somewhat dated and challenged over representativeness, the extensive survey reported that 67% of American men have had at least one homosexual experience to orgasm after adolescence; 30% have had more than one experience; 5% to 7% have bisexual experiences but prefer homosexual ones; and 4% to 5% have homosexual experiences exclusively as adults. The often used estimate that 10% of the male population is primarily or exclusively homosexual in terms of sexual behavior is based on this data from 1948. These data point out the widespread occurrence of male homosexual behavior, not necessarily the numbers of self-identified gay men. People may engage in same-sex sexual behavior but not self-identify as gay or lesbian respectively. Many people who do self-identify as gay, lesbian, or bisexual may not be open to all about their orientation—especially in a medical or research setting—thus making the true measure of the numbers of GLB persons difficult.

Gay and bisexual people and homosexual and bisexual behavior are found in almost all societies and cultures around the world and throughout history (25). Tolerance and acceptance has varied throughout history, and varies from country to country, culture to culture, and community to community. Anyone may be gay, lesbian, or bisexual. Gay and bisexual men and women do not have uniform ways of behaving nor do they live uniform lifestyles.

Gay people are found in all segments of society and in all minority and ethnic groups, may be of any age, and may have any occupation or career. Most gay people are not readily identifiable, in spite of persistent stereotypes. Sexual behavior and sexual orientation itself are not necessarily fixed in an individual and may change over time. Intense homosexual longings in young adulthood or adolescence may change as one grows older, and, conversely, some heterosexuals may discover gay feelings later in life.

Bisexuality

Many people are clearly bisexual in behavior—being able to sexually function with either sex—but often prefer one sex to the other. The above noted Kinsey report (24) devised the Kinsey scale to describe this range of behavior: from 0 for exclusive heterosexual behavior to 6 for exclusive homosexual behavior. This classification puts the majority of men in a bisexual range, based on sexual experiences. As will be discussed, bisexuality and bisexual behavior are especially important in HIV infection prevention work, because many men have gay sexual experiences, without informing their spouses or other female partners. Many lesbians have had, and do have, sex with men. For many minority populations, bisexuality, but not homosexuality per se, is acceptable (or at least admitted to) in surveys and interviews. A recent survey

in New York City noted nearly 10% of men who reported sex exclusively with other men did not identify as gay—usually describing themselves as heterosexual or bisexual (26).

There are no specific studies of bisexuals and substance abuse, although with the focus on men who have sex with men as a risk factor for HIV infections, more information will no doubt be forthcoming. The issues that face men and women who are bisexual, especially if relating more strongly to the homosexual longings, will be the same issues that men who identify as gay and women who identify as lesbian will face.

GAY SEXUAL ORIENTATION

Gay men and lesbians are remarkably like everyone else. There are three major differences, however, which may be of help in understanding the high incidence of substance abuse: (a) having a sexual orientation expressed by the desire to have affectional, sexual, sexual fantasy, and/or social needs met mostly by a same-sex partner rather than an opposite-sex partner; (b) negotiating a process of self-identity and self-recognition as a gay person, different from the majority, known as “coming out”; and (c) confronting a widespread and insidious dislike, hatred, and/or fear of gay and lesbian people, homosexual activity, and homosexual feelings, known as “homophobia” or “anti-gat bias.” This last factor forms the largest barrier to gays and lesbians obtaining quality health care and substance-abuse treatment, and may be the primary factor in explaining the widespread incidence of substance abuse in gay populations. Homophobia is a result of societal heterosexism, that is, the perspective that the majority situation—heterosexuality—is the “norm” or superior in some way. Homophobia is parallel to such societal forces as racism and sexism (27).

In trying to understand the nature of homosexuality, there have been new insights into sexuality in general and in the nature of gender identity. In looking at the etiology of homosexuality, most new research indicates that a homosexual orientation is not learned and not a result of any family or social patterns. The “classic” psychoanalytical description of a close, seductive mother and absent, distant father does not occur more frequently in the backgrounds of gay men; in fact, it may occur more often in heterosexuals (28). New research continues to point out familial patterns that may indicate a genetic component (29) and/or biologic and biochemical factors (30). Such knowledge and awareness about the origins of sexual orientation may help to relieve both the patients who are having difficulty accepting their homosexuality and the families of patients who are gay or lesbian who may feel guilty, as if they had done something “wrong” to “cause” the sexual orientation.

Coming Out

Coming out is a complex process that may occur throughout the entire life cycle (31). The best way to conceptualize coming out is to view it as a series of steps that an individual negotiates at his or her own time and pace, with periodic steps

forward and backward. The individual must first become aware of his or her own sexual orientation as “different” from that of the majority. The next step is to accept the awareness and begin to integrate it into a self-concept and grapple with the negative feelings associated with homosexuality. Next, the individual may choose to act on the feelings (although some gay people with strong gay feelings do not engage in sex with others of the same sex, such as celibate priests or others). Finally, the person makes a series of lifelong decisions about whether to let others know and whom to let know, such as friends, family, work colleagues, peers, teachers, and medical providers. Some gay people only come out to selected people and not to everyone at once; some may come out, then deny it later or not continue to let new friends or people at new workplaces know. The bias and prejudice against people with AIDS and the often automatic, but mistaken, association of AIDS and gay men, rather than the association of HIV infection and behaviors that may lead to infection, may lead some men to “return to the closet” or hesitate in continuing the coming out process.

Homophobia and Heterosexism

Homophobia, both internalized and externalized, combined with heterosexism are the major forces that gays and bisexuals must deal with in our society (32). Almost all gay people develop some degree of internalized homophobia, having been brought up in a homophobic society that tends to promote prejudicial myths about gay people or, from the heterosexist concentric point of view, to just ignore gay and bisexual people in general. The coming out process may be delayed or undergo great difficulties depending on the intensity of internalized homophobia (if the person believes homosexuality is a sin, an illness, unnatural, evil, or will only lead to sadness, loneliness, and isolation) and may well require the help of psychotherapy.

Externalized homophobia is found at every level in our society: legal, medical, scientific, religious, political, social, educational, and judicial. Violent attacks on gay people, ranging from verbal threats to outright physical attacks and murder, are usually fueled by homophobia. Heterosexist thinking and homophobia and the fear of what others will do if they know an individual is gay or even think an individual is gay, are major factors in the difficulty of getting accurate data about gays and lesbians for scientific investigations (19). It follows that in undertaking research surveys, gay and bisexual people hesitate to disclose sexual orientation, even with great assurances of confidentiality. Gathering information on gay and bisexual people, therefore, is extremely difficult and contributes to the skewed samples, as already noted in the studies on substance abuse and the gay community.

Gay people also face many additional challenges that majority populations escape. There are many issues generated by two people of the same gender forming a relationship such as: finding comfortable and safe living quarters; financial concerns; legal battles over insurance and wills; acknowledgment of benefits; and, ability to marry which varies from state to state.

Because there is such a high incidence of substance abuse, there are many codependent relationships or relationships between two active substance abusers.

Gay and lesbian adolescents are a population of serious concern. Many studies indicate a much higher suicide attempt rate in these youth—30% versus 10% to 12% in the general population; a more volatile type of substance abuse than is seen in other adolescents, especially combinations of drugs and alcohol; and hesitancy to follow HIV infection risk-reduction guidelines (1,4,5,33). Older gays and lesbians face the same problems as other older adults, with added isolation, loneliness, and possible senses of hopelessness and resignation about substance abuse (34).

Lesbian Issues

Lesbians have some specific issues that need to be highlighted. As described previously, the incidence of substance abuse is equally high among gay men and lesbians. In general, lesbians may have additional social struggles and concerns. Compared to gay men, they are more likely to have lower incomes (as do women in general, when compared with men); lesbians are more likely to be parents (about one-third of lesbians are biologic parents); lesbians face the prejudices aimed at women, as well as those for being gay, including the stronger reaction against (and willingness to ignore) female substance abusers; lesbians are more likely to come out later in life (about 28 years of age vs. 18 years of age in men); and lesbians are more likely to have bisexual feelings or experiences, so that they are still at risk for HIV infection via a sexual route as well as possible i.v. drug use (11,13,28,35).

According to surveys noted above, lesbians are somewhat more likely to be in a long-term relationship than are the comparable gay men, so there needs to be a clear focus on relationships, parenting, and family concerns in working with lesbian substance abusers. Lesbians are also subject to the increase in violence, both verbal and physical, against gays; and, as is true with anyone, including gay men, they are subject to domestic violence. This latter fact is often ignored. Because there are correlations with domestic violence and substance abuse, clinicians need to be aware of this possibility in working with lesbians.

SUBSTANCE ABUSE AND GAY IDENTITY FORMATION

Many factors contribute to the prominent role of substance use and abuse in gay men, lesbians, and bisexuals. The two most important factors are genetic or biologic contributions, as well as the psychological effects of heterosexism and homophobia.

New research continues to support, in great part, genetic, biologic, and biochemical origins for the diseases of alcoholism and substance abuse. As already noted, there is continuing and growing evidence that homosexual orientation may have—at least in part—genetic, biologic, and biochemical components. Such parallel contributions to both sexual orientation and

substance abuse has led to some speculation of a possible chromosomal link between the genetic contributions to substance abuse and sexual orientation. Such a direct genetic link between sexual orientation and the propensity to substance abuse, however, is unlikely. The studies cited indicate that male homosexuality and female homosexuality may be different phenomena, with differing familial patterns. Substance abuse appears to have equal incidence among gay men and women.

Societal, cultural, and environmental factors, however, may lead to a greater expression of any genetic predisposition. By analogy, there has been an increase in the incidence of alcoholism in women since the beginning of the twentieth century. Although partially explained by better data collection, and awareness of the hidden homebound female alcoholic, the increase can also be explained by social factors. In the early 1900s, women were prohibited from drinking in public by societal pressures. As the social acceptability of drinking increased, more women drank, thus increasing the likelihood of exposure to alcohol, which, in turn, could trigger the genetic predisposition to alcoholism.

Gay men, lesbians, and bisexuals have faced great societal prohibitions, not only on the expression of their sexual feelings and behavior, but also around their very existence. Societal homophobia or heterosexism could well create enough stress that gay men, lesbians, and bisexual persons turn to alcohol and other substances for “relief.” This increased exposure could, in turn, lead to the higher degree of expressivity of the genetic potentials for substance abuse in gay men, lesbians, and bisexuals.

In addition, it is well known that societies or cultures in turmoil or undergoing social change have higher rates of alcoholism. Gay people can be seen as experiencing almost continuous stress and social change for most of the twentieth century. Societal pressures forced most gay people to remain “in the closet,” hiding their sexual orientation or not acting on their feelings. Responding to societal expectations rather than personal desire, some gay, lesbian, and bisexual people may marry someone of the opposite sex and raise a family, creating a potentially stressful situation. Legal prohibitions on homosexual behavior, overt discrimination, and the failure of society to accept or even acknowledge gay people have limited the types of social outlets available to gay men and lesbians to bars, private homes, or clubs where alcohol and other drugs often played a prominent role. The role models for many young gay men and lesbians just coming out may be gay people using alcohol and other drugs, who are met at bars or parties. Continuing societal homophobia, as well as the impact of HIV on gay men, lesbians, and bisexuals, further adds to the stress (36).

Some gay and bisexual men and women cannot imagine socializing without alcohol or other mood-altering substances. Gay men, lesbians, and bisexuals are brought up in a society that says they should not exist and certainly should not act on their feelings. Such homophobia is internalized. Many men and women have had their first homosexual sexual experiences while drinking or being drunk to overcome their internal fear, denial, anxiety, or even revulsion about

gay sex. For many men and women, this linking of substance use and sexual expression persists and may become part of coming out and the development of a personal and social identity. Many gay people continue to feel self-hatred. The use of mood-altering substances temporarily relieves, but then reinforces, this self-loathing in the drug-withdrawal period. Alcohol and many other drugs can cause depression, leading to a worsening of self-esteem and the “erosion of spirit” so well described by many of the 12-step recovery programs.

Given the state of acceptance of homosexuality and bisexuality in our society at this time, the stages of developing a gay, lesbian, or bisexual identity, influenced by such societal reactions, may be intimately involved with substance use. Although some substance abusers appear to have a genetic predisposition to substance abuse—supporting an illness model with psychosocial manifestations—not all people with such a genetic predisposition develop alcoholism or substance abuse in their lifetimes. Intrapsychic, psychological, and psychodynamic factors, influenced by psychosocial and parental upbringing, may lead certain people to turn to substance use and, therefore, potentiate a genetic predisposition for substance abuse.

The link between the psychodynamic forces in developing a gay, lesbian, or bisexual identity and the use or abuse of substances becomes clear in examining the early development and the progression through the life cycle for a gay person. Parents reward what is familiar and acceptable to them and discourage or de-emphasize behavior or needs they do not value or understand. Harm, of course, occurs when a parent is too depressed, preoccupied, or narcissistic to respond to the actual child and the actual needs and wants of the child. Children eventually learn to behave the way parents expect to get rewards, and to hide or deny the longings or needs that are not rewarded.

Many gay and bisexual men and women are aware of being different early in life—being aware, however subtly, of affectional and sexual needs and longings that are different from the majority of people around them. Some male children who will grow up to be gay may desire a closer, more intimate relationship with their father; this desire is not encouraged or even understood in our society. The prehomosexual child learns to hide such needs and longings, creating a false self. Real needs are often suppressed, or repressed, and rejected as wrong, bad, or sinful. Dissociation and denial, therefore, become major defenses to cope with internal feelings.

Some studies of familial patterns (29) point out that gay men have a greater-than-normal chance of having an alcoholic father and a greater chance of having a mother with a major affective disorder—either or both situations likely leading to growing up with emotionally unavailable parents. Therefore, the psychological, as well as genetic and emotional, backgrounds in the families of many gays and lesbians already predispose them to substance abuse.

The psychology of being different and learning to live in a society that does not accept difference readily shapes the

sexual identity development as the child emerges from childhood and the latency period. With the rewards for the “false self,” the child suppresses their more natural feelings. The child has no clear role models about how to be gay or lesbian; teachers usually cannot reveal their sexual orientation and there is still limited positive media attention for gays and lesbians. In latency, children who will become gay or bisexual—especially boys who may be effeminate—may fear other children, feel even more different, and become more isolated.

In adolescence, the gay sexual feelings emerge with great urgency, but with little or no context or permission. Conformity is certainly encouraged, further supporting denial and suppression of gay feelings. Adolescents often reject and isolate those who are “different.” The gay adolescent further develops dissociation and splitting off of affect and behavior. These various factors may help to explain the many problems facing gay youth (33). For example, gay youth may be subject to sexual abuse and violence, and sometimes are introduced to sex via hustling or prostitution, or get “used” sexually by others. The extreme difficulty many gay men and women have in coming out and integrating sexuality and personal identity makes sense from this perspective.

Substance use serves as an easy relief, can provide acceptance, and, more importantly, mirrors the comforting dissociation developed in childhood. Alcohol and other drugs cause a dissociation of feelings, anxiety, and behavior, and may mimic the emotional state many gay people had to develop in childhood to survive. The “symptom-relieving” aspects help fight the effects of homophobia; it can allow “forbidden” behavior, allow for social comfort in bars or other unfamiliar social settings, and, again, provide comfort through the familiar experiences of dissociation and isolation.

The easy availability of alcohol and drugs at gay bars or parties and the limited social options other than those bars and parties certainly encourages the use of substances early in the coming out and gay or lesbian socialization process. For gay men especially, sex and intimacy are often split off—dissociated. Again, substance use allows for acting on feelings long suppressed or denied, but also mirrors the dissociative experience and makes it harder to integrate intimacy and love. There is an easy relief of longings and needs, with sex and/or substance use, and the more challenging needs for love and intimacy may be ignored. Substances help many gay people brace themselves for rejection by others—either as a gay person coming out to friends or family, or from potential dates and sexual partners.

Substance use enhances denial and can even cause “blackouts” around sexual behavior. It can certainly make “living in the closet” with its built-in need for denial and dissociation easier or even possible (the “I-was-so-drunk-I-didn’t-know-what-I-did-last-night” scenario often used in high school and college). Because so many gay people are adult children of alcoholics, they are even more skilled at denying their own self and their own needs.

Finally, the internal state that accompanies internalized homophobia and that occurs with substance abuse are very similar—the “dual oppression” of homophobia and abuse (3).

The following traits are seen in both: denial; fear, anxiety, and paranoia; anger and rage; guilt; self-pity; depression, with helplessness, hopelessness, and powerlessness; self-deception and development of a false self; passivity and the feeling of being a victim; inferiority and low self-esteem; self-loathing; isolation, alienation, and feeling alone, misunderstood, or unique; and fragmentation and confusion. These close similarities make it very difficult for gay men or lesbians who cannot accept their sexual orientation to recognize or successfully treat their substance abuse. Self-acceptance of one's sexual orientation thus appears to be crucial to recovery from substance abuse.

The pervasive internal and social pressures to use mood-altering substances and the difficulty in creating or finding currently existing non-substance-using social situations certainly contributes to the greater expression of the alcohol and other drug-dependence potentials in gay men and women. One wonders if the rate of substance abuse in the general population would not be much greater if everyone in the United States was subject to such pressures. Possibly, there is no greater genetic predisposition to substance abuse in gays, but an increased potentiation of expression due to greater use and presence of such substances in gay society.

HOMOSEXUAL BEHAVIOR, SUBSTANCE ABUSE, HIV INFECTIONS, AND AIDS

Men-who-have-sex-with-men continues to be the largest “at-risk” group for current and new HIV-related infections and cases of AIDS in the United States. Although most clinicians and researchers attribute the spread of HIV in this population to certain highly risky unsafe sexual practices, the role of i.v. drug use is significant. The same CDC report noted that a good percentage of all adult cases were men who both had sex with men *and* i.v. drug users. Many men in the CDC statistics “i.v.-drug-users-only” category are also gay or bisexual, but fail to report this additional risk category for the reasons already discussed.

Besides the obvious potential spread of HIV through the i.v. drug-using segments of the gay population via needle sharing, substance abuse plays a not-so-obvious role in spreading the virus through sexual practices. In most reviews of gay men and safer sex practices, men who were knowledgeable about safer sex but failed to practice it uniformly report being under the influence of some substance, such as alcohol or other drugs, at the times they failed to follow the guidelines. In addition, some gay men seek to enhance and prolong sexual activity through the use of drugs such as amyl nitrite (known as “poppers”), alcohol, marijuana, ecstasy, and especially methamphetamines, or a combination of these substances (14,15,37–39).

The phenomena of “circuit parties” (this is a highly organized series of parties across the world that emphasize sex and drugs) and the club scene at local bars and dance clubs are not exclusive to gay men and lesbians, but both have taken hold of a significant number of gay people. Drugs are extremely frequently used in those settings—especially the

so-called club drugs such as ecstasy, special K, and methamphetamines (38). The drugs are used to enhance the dancing and party experience but are also frequently used to enhance sexual activity, with the same consequences as noted above.

Judgment is clearly suspended or altered during even the moderate, let alone heavy, use of alcohol and other substances. There is definitely a higher risk for exposure to HIV with larger numbers of sexual partners, but the risk is also higher in any one particular encounter when safer sex guidelines are not followed—whether because of suspended judgment with substance use, pressure by the partner to not bother, or having highly charged sexual feelings. Furthermore, there is clear evidence that many abused substances alter the immune system, which may well compromise the immune system's initial reaction to exposure to HIV in men engaged in risky sexual practices under the influence of substances. With the widespread use of such agents and such conditions in the gay community, it appears that substance use and abuse, especially of methamphetamines, is a definite cofactor in the spread of HIV through sexual practices.

ADDED FOCUS ON METHAMPHETAMINE USE AND ABUSE

Why gay men in particular are more likely to use and abuse methamphetamine may be tied to the sexual enhancement aspect of the drug in and of itself, but there appear several additional reasons, including the impact of internalized homophobia, for example, and lower self-esteem and social awkwardness many gay men experience. The situations described such as sex clubs and circuit parties for many gay men are tied to expectations of peak sexual performance, certainly enhanced by use of methamphetamines. Gay men of color are also at risk for use of methamphetamines, including a population that usually is not associated with great substance use—Asian and Pacific Islanders (40,41).

There are many routes of administration, including oral inhalation, nasal insufflation, absorption through the rectal mucosa, and i.v. use. Methamphetamine is experienced as heightening sexual feelings and duration of sexual activity—as well as sexual disinhibition, allowing some men to have sex for 12 hours or more. There are risks for increased exposure to HIV with multiple sexual partners and unprotected anal intercourse (sex without condoms) and IDU—all of which are associated with methamphetamine use (42,43). Some men who specifically wish to become infected with HIV (for a variety of psychological reasons) find using methamphetamine and unprotected sex a particularly successful route to accomplish their goal (44). Those gay men who prefer to have unprotected anal sex with all of its risks (known as “barebacking”) are also more likely to use methamphetamines (45).

The use of methamphetamines has clearly been linked to a higher risk for HIV infection due to the many factors already discussed. One study focused on gay male HIV-positive methamphetamine users who are sexually compulsive and the

high rates of unsafe sexual activity that puts so many others at risk (46). Other studies look at the use of sildenafil (Viagra®) and methamphetamine as contributing to the higher HIV-risk (since many users of methamphetamines have transient erectile dysfunction so use sildenafil in addition)(47).

Many urban areas have started to address the concerns specific to gay men and some treatment programs are emerging for gay methamphetamine abusers. Who is likely to seek treatment is not clear since many of the gay men who use with others and there are often social pressures to stay using even when problems develop. Many men enter treatment only after suffering great financial consequences or major health problems (48).

Several types of treatments have been studied, and more studies are looking specifically at gay men. Contingency-management types of behavioral modifications are showing promise as successful interventions (49). In San Francisco, a program called PROP (Positive Reinforcement Opportunity Project), a variation of contingency management with rewards for staying clean, is meeting the specific needs for some gay men and may well be used successfully elsewhere (50). The role of outpatient treatment alone or in combination with other interventions also needs additional study. Traditional 12-step programs are increasing with a focus specific to methamphetamine in many urban areas and Methamphetamine Anonymous (or Crystal Anonymous) groups are forming.

SPECIAL TREATMENT CONCERNS FOR GAY PEOPLE

Evaluation and Treatment Issues

Treatment must focus on both recovery from substance abuse and from the consequences of homophobia. To reverse and treat the denial and dissociation, the patient will need to address his or her own acceptance of self as a gay or bisexual person. Although no one should be forced to come out to any one, self-acceptance appears to be crucial to recovery. Treatment needs to be at least gay-sensitive if not gay-affirmative, as will be discussed. Many gay people, once in solid recovery, will need to deal with the grief and rage associated with mourning the loss of the “false self” and must learn how to get his or her own real needs met.

In the assessment of a gay man, lesbian, or bisexual person presenting for mental health services, clinicians need to be aware of the higher incidence of substance abuse in this population and, accordingly, routinely screen for symptoms of alcoholism or other substance abuse. In formulating a treatment plan for gay men, lesbians, or bisexuals determined to have a substance-abuse problem, the personalized treatment plan needs to include the influences and effects of the following for each individual: the stage in the life cycle; the degree and impact of internalized homophobia; the stage in the coming-out process and the experience of coming out; the support and social network available; current relationship,

if any, including married spouses and the history of past relationships; the relationship with the family of origin; comfort with sexuality and expression of sexual feelings; career and economic status; and health factors, including HIV status.

Homophobia is the major consideration in meeting the treatment needs of gay men and lesbians with substance-abuse problems, as well as the proper care and prevention of HIV-related infections. Few inpatient or outpatient detoxification and rehabilitation programs have knowledge about homosexuality and are often unaware that they have gay and lesbian patients, who may be too frightened to “come out” to the staff. Attitudes of the staff and treating clinicians about homosexuality are crucial in the success of treatment for gays and lesbians (51). Many gay and lesbian staff are afraid to come out because of administrative reaction and are not able to either serve as role models or to provide a more open and relaxed treatment.

Gay-sensitive programs—programs that are aware of, knowledgeable about, and accepting of gay people in a non-prejudicial fashion—are opening up around the country. Most current and well-established programs are training staff about gay concerns, although many centers still fail to even ask about sexual orientation or address it as a specific topic. The Center for Substance Abuse Treatment has put out a guideline on working with gay, lesbian, bisexual, and transgender substance abusers, an extremely helpful and resourceful guide.

Programs are also available across the country that are gay-affirmative, that is, actively promoting self-acceptance of a gay identity as a key part of recovery. Discussed above, substance abuse and sexual identity formation are often tightly woven together, and it is difficult to imagine much success in treating the gay or lesbian substance abuser without addressing sexual orientation and homophobia.

Aftercare may be a major problem. Twelve-step recovery programs and philosophies are the mainstays, of course, in recovery and in staying clean and sober. There may be no gay-sensitive therapists or counselors in the patients’ communities. AA, although open to all, is still a group of people at any individual meeting that may reflect the perceptions and prejudices of the local community and not be open to or accepting of openly gay members. Most communities now have gay and lesbian AA, Narcotic Anonymous (NA), and Al-Anon meetings, and AA as an organization clearly embraces gays and lesbians, as it embraces anyone concerned about a substance-abuse problem.

Some gay people in recovery, however, may not have come out or may not feel comfortable in such meetings, especially if a discussion of sexual orientation was not part of the early recovery. Some groups parallel and similar to AA have formed to meet the needs of these gays and lesbians, such as Alcoholics Together, and many large cities sponsor “roundups,” large 3-day-weekend gatherings focused on AA, NA, lectures, workshops, and drug- and alcohol-free socializing.

Although 12-step programs such as AA and NA recommend avoiding emotional stress and conflicts in the first 6 months of recovery, for the gay man, lesbian, or bisexual in

such programs, relapse is almost certain if the gay or bisexual person cannot acknowledge and accept his or her sexual orientation. Discussion about the conflicts around acknowledging sexual orientation and ways to learn to live comfortably as a gay or bisexual person are essential for recovery, even if these topics are emotionally laden and stressful.

Many localities now have gay, lesbian, and bisexual health or mental health centers, almost all with a focus on recovery and substance-abuse treatment. National organizations, such as the National Association of Lesbian and Gay Addictions Professionals, the Association of Gay and Lesbian Psychiatrists, the Gay and Lesbian Medical Association, the Association of Lesbian and Gay Psychologists, and the National Gay Social Workers, can help with appropriate referrals.

Some of the suggestions and guidelines of AA and NA and most treatment programs may be difficult for some gay men, lesbians, and bisexuals to follow. For example, giving up or avoiding old friends, especially fellow substance users, may be difficult when the gay or bisexual person has limited contacts that relate to him as a gay person. Staying away from bars or parties may be difficult if they are the only social outlets; special help on how to not drink or use drugs in such settings may be necessary. Many gay people mistakenly link AA and religion; because many religious institutions denounce or condemn homosexuality, gay men, lesbians, and bisexuals may be resistant to trying AA or NA. Harm reduction models and relapse prevention techniques are especially useful approaches.

Specific Additional Factors to Consider

Gay men, lesbians, and bisexually identified minorities who abuse substances must also deal with homophobia—often from within the same self-identified ethnic or cultural groups—in addition to possible racism and other prejudices in seeking recovery (6,8). Culturally competent services must address not just race, culture, and ethnicity, but also gender, gender identity, and sexual orientation.

HIV infections and AIDS are much better understood, especially routes of transmission and therapeutic interventions, and can be treated as chronic conditions without the old fear of imminent death at diagnosis. Substance-abuse treatment centers and programs, though, may still be frightened to work with HIV-positive individuals, despite the clear CDC guidelines, or may resist talking about safer sex because it is uncomfortable to talk about such matters or it is viewed as detracting from recovery issues. All one needs to do is remember that AIDS prevention education is just as lifesaving an intervention for a substance abuser.

There are many additional difficult clinical issues facing a substance-abusing gay man who is HIV-positive or who has AIDS, whether actively using substances or in recovery, such as suicidality, dementia, negotiating safer sex, and legal issues concerning wills and powers-of-attorney. Some communities now have AA groups with a special focus on HIV-positive individuals or people with AIDS, such as the Positively Sober groups.

Other factors affect the treatment of lesbians, gay men, and bisexuals. As noted above, many gay men, lesbians, and bisexuals are in long-term relationships, and treatment for these individuals must clearly focus on relationships, parenting, and family concerns. Again, gay men, lesbians, and bisexuals are also subject to an increase in violent attacks because of their sexual orientation, both verbal and physical. Reaction to such an attack may include a relapse to drug or alcohol use in a person in recovery or an increase in use by someone currently using or abusing substances. In addition, many gay men, lesbians, and bisexuals are victims of domestic violence. Because there are correlations with domestic violence and substance abuse, clinicians need to be aware of this possible combination.

Additional treatment issues facing all people in recovery, which have special impact on gays and lesbians and are beyond the scope of this brief review chapter, include learning how to have safer sex while clean and sober; learning how to adjust to clean and sober socializing without the use of alcohol or drugs to hide social anxiety; dealing with employment problems and adjusting to the impact of being out as a gay person at work; working with the family of origin regarding their acceptance of the sexual orientation of their gay, lesbian, or bisexual child; helping couples adjust to the damaging effects substance use may have had over the years and embrace a recovery that will avoid the negative impact of codependent relationships; maintaining confidentiality in record keeping, especially around discussion in the medical record of sexual orientation or HIV status; dealing with child custody issues when necessary; diagnosing and treating additional medical problems; and coping with the effects of legal problems.

Clinicians and counselors must be aware of their own personal attitudes regarding homosexuality. If a health care provider is homophobic and cannot get help in working out these attitudes with a supportive colleague or supervisor, the patient would be better off if he or she was referred to another staff member for help (5). Gay men and women facing recovery from substance abuse should not have to fight homophobia in a health care system to get quality care.

CONCLUSION

Taking a culturally competent approach to working with GLB persons provides the best way to help those dealing with issues of substance use or abuse. The knowledge that substances and alcohol can play a significant role in the lives of many GLB people and that there is indeed a higher incidence of use and abuse can alert the provider to add a more intensive review of substance use history and the possible consequences of such use on a person's life when starting to work with a new client. Knowing that some drugs are more likely to be used in some populations—such as methamphetamines with urban gay men—will also help the provider gather information needed to determine the most helpful interventions and treatment planning.

Understanding the unique social issues many GLB people face can also help shape a treatment plan tailored to the client

and improve outcomes. Recognizing the profound impact of homophobia and the developmental issues unique to most GLB people will also improve care and outcomes. The various types of treatments and interventions are not unique—12-step, motivational interviews, contingency management, pharmacology where appropriate, and so on—but the context in which such care is offered can be unique and very helpful. The gay-sensitive and gay-affirmative approaches are the most helpful and usually create a welcoming environment that helps the client address issues and work towards recovery. Openness and acceptance by the provider to all the issues facing GLB persons sets the frame for improved care.

Extended recovery is more likely to happen—indeed, may only be possible—if a gay man, lesbian, or bisexual person is able to accept his or her sexual orientation, address internalized homophobia, and discover how to live clean and sober without fearing or hating his or her real self. Providers less familiar with issues around differing sexual orientations will benefit from consultation with knowledgeable sources but may also wish to refer GLB clients to gay-specific service if available.

INTRODUCTION

Substance abuse is a significant problem among individuals incarcerated in jails and prisons throughout the world. Substantial research evidence from many countries has indicated that jail and prison inmates have a higher prevalence of preincarceration substance abuse compared to the general population. This is particularly evident with regard to illicit opioids (primarily heroin), cocaine, and the abuse of multiple substances—patterns of substance abuse that are most closely associated with adverse health and criminogenic consequences. Some inmates continue to use substances during incarceration, and most such individuals do not receive substance abuse treatment while incarcerated or upon release. As a consequence, substance abuse either continues or resumes quickly after release to the community, placing such individuals at increased risk for death from drug overdose, human immunodeficiency virus (HIV), and hepatitis B and C infections, increased criminal activity, and reincarceration. Correctional health officials, treatment providers, and policy makers need innovative, effective, and cost-beneficial approaches to help inmates with substance abuse histories successfully transition to the community following release from incarceration.

The impact of substance abuse among inmates, both during incarceration and upon release to the community, is exacerbated by the large numbers of individuals imprisoned throughout the world. According to the latest available estimate of the number of persons incarcerated and the rate of incarceration in 218 countries (1), there were 9.8 million individuals incarcerated in prisons throughout the world, with the United States having the highest number of prisoners and the highest rate of incarceration. Furthermore, in 71% of these countries, prison populations have been increasing (1), and this trend is expected to continue (2). Because of these circumstances, it is crucial that effective interventions designed to address substance abuse be developed, implemented, and evaluated.

To understand the context in which the above topics are discussed, it is important to understand the distinction between jails and prisons, which is most pronounced in the United States. Jails typically hold individuals who are awaiting trial or sentencing or are serving shorter sentences for less serious offenses (typically less than 1 year). Prisons typically confine individuals who have been convicted of more serious crimes and thus are serving longer sentences.

This chapter begins with a discussion of the epidemiology of substance abuse among incarcerated populations. Next, prevention strategies are examined. This is followed by a discussion of the availability and effectiveness of various substance abuse treatment interventions for incarcerated individuals. Afterward, the focus of the chapter turns to sociocultural considerations and factors influencing substance use in this population. A discussion of special considerations for jail and prison inmates and overall conclusions, respectively, comprise the final sections of this chapter.

EPIDEMIOLOGY

Epidemiologic studies have consistently found a higher prevalence of substance use, abuse and/or dependence among jail and prison inmates than the general population (2–5). This has been the case independent of nationality, gender, the measure(s) used to assess an individual's consumption of substances (e.g., use, abuse, and/or dependence), and the criteria used to assess substance abuse and/or dependence. A recent nationwide study in the United States (5) reported that only 2% of the general U.S. population met standardized diagnostic criteria (DSM-IV) of drug abuse or dependence in the last 12 months compared with 52% of state inmates and 44% of federal prisoners in the year prior to incarceration.

One of the most comprehensive reports of the prevalence of substance abuse and dependence among incarcerated individuals, a review of 13 epidemiologic studies (4), involved 7563 prisoners (4293 men and 3270 women). Nine of the studies were conducted in the United States; two took place in Ireland, and one each in England and New Zealand. Each of these studies, published between 1988 and 2001, used standardized diagnostic criteria (four studies used DSM-III criteria, four other studies used DSM-III-R criteria, and five others employed DSM-IV) and assessed substance abuse and dependence with regard to the year prior to incarceration. Results indicated that the prevalence of substance abuse and dependence varied considerably across the studies. The prevalence of alcohol abuse and dependence at prison entry ranged from 18% to 30% in men and from 10% to 24% in women. The corresponding findings for drug abuse and dependence ranged from 10% to 48% for men and from 30% to 60% in women. The authors noted that while both male and female prisoners displayed estimated prevalence rates of substance abuse and dependence that were higher than their counterparts in the general population, the discrepancy was even greater among women.

Furthermore, incarcerated individuals are also substantially more likely than the general population to have patterns of substance abuse that are most closely associated with adverse health and crime-related consequences, such as heroin and/or cocaine addiction and abuse of multiple substances (2,3). Long-term abuse of heroin, particularly by injection, along with abuse of multiple substances, strongly contributes to disproportionately high rates of HIV and hepatitis infection (2,3) as well as higher risk of death from overdose among newly released prisoners (3). Regarding the regular use of heroin, in the United States, recent studies have reported inmates' lifetime prevalences ranging from 12% to 15% (5,6). In each of these studies, regular use of heroin was defined as having used heroin once a week or more frequently for at least a month (5,6). An epidemiologic study of prisoners in England and Wales (7) found that 23% reported being dependent on heroin during the 4 weeks prior to prison entry. A similar study of new entrants to prisons in Italy (8) reported that 28% of prisoners indicated that they had used heroin on a daily basis at any time in their lives before the index incarceration. The comparable figure for use of heroin at least weekly was 33%.

Moreover, most epidemiologic studies of substance abuse among jail and prison inmates report on preincarceration behavior, either lifetime or the year prior to incarceration. Relatively few studies examine the prevalence of substance abuse during incarceration. A survey of male prisoners in England and Wales (9) found that 6% of these inmates reported acutely problematic use (defined as using cannabis more than once a day and/or any other drug four times per week or more) during incarceration compared with 65% in the year prior to prison entry. A review of studies of heroin-dependent prisoners in various European nations (10) reported that the percentage of such individuals who continue to inject during incarceration ranges from 16% to 60%, although a more recent report from Germany (11) indicated that 75% of injectors continued this behavior during incarceration. Estimates of the prevalence of in-prison drug use in the United States as detected by urine testing and hair testing were typically less than 10%, although one estimate reported 27% (12).

Finally, as emphasized below, most jail and prison inmates do not receive treatment for substance abuse, and without such treatment, jail and prison inmates are likely to return to drug abuse and crime shortly after return to the community (13,14), and rates of postrelease criminal activity among such individuals are very high (13). Among incarcerated individuals, those with preincarceration heroin addiction typically become re-addicted within a month of release from incarceration (14). Because of these circumstances, as well as the increased threat of HIV and hepatitis infection and overdose death, treatment interventions that begin during incarceration and continue in the community are urgently needed for such individuals (3,14,15).

PREVENTION

Prevention strategies can be classified in three different ways. Primary prevention involves prevention of new onset drug use, secondary prevention intends to prevent the progression from

drug use to symptomatic drug abuse or dependence, and tertiary prevention is concerned with reducing the adverse consequences for those with drug abuse or dependence (16). Ideally, given that substance abuse is a major contributor to suicide, criminal behavior, injuries, overdose death, and many types of infectious disease, perhaps the most promising approach would involve preventing the onset of use in childhood or early adolescence through a combination of interventions including those that enhance protective factors and reduce risk factors, as well as regulatory approaches (16). Examples of the former type of intervention would involve collaboration among parents, educators, physicians, and community leaders, whereas the latter strategy would include laws, policies, and enforcement to reduce supply and demand. These interventions have also been shown to prevent or at least delay the onset of delinquent and criminal activity as well, thus substantially reducing the risk for incarceration (16). However, many such interventions involving enhancement of protective factors and reduction of risk factors have not been evaluated in real-world settings (16). Moreover, a recent nationwide survey conducted in the United States indicated that teachers often do not have adequate time to provide such interventions, and parents' priorities have focused on economic concerns and survival, limiting their ability to devote sufficient time and energy to substance abuse prevention initiatives (17). Furthermore, given that over 80% of incarcerated individuals in both Great Britain (18) and the United States (5) and well over half of such individuals overall in the European Union (19) have been estimated to have a history of illicit drug use, in addition to the high prevalence of substance abuse reported above, perhaps the most feasible prevention strategy would involve harm reduction—decreasing the risk for life-threatening consequences (3)—more in line with tertiary prevention approaches defined above (16).

Among the most frequent and severe consequences resulting from drug abuse, specifically drug injection, in prison, are HIV and viral hepatitis infections (2,3). Increased risk of these diseases among prisoners has been documented in 16 countries, with injecting drugs and sharing injection equipment being major contributors to such circumstances (3). Unfortunately, most nations do not have adequate prevention services for incarcerated persons despite the fact that the Council of Europe and the World Health Organization have developed guidelines emphasizing that inmates have the right to the same prevention and treatment services to those available in the community (3). Furthermore, corrections officials at times have denied that substance use and drug injection occur in their facilities, and this circumstance, together with budgetary constraints and overcrowding, can contribute to the lack of services for infection prevention (3).

Harm reduction services include the provision of information and education with regard to drug-related disease, voluntary testing and counseling concerning HIV and hepatitis, and interventions designed to reduce risky sexual and injection-related behaviors (20). Such procedures have been implemented in several European nations, Canada, and

Australia (20). A major harm reduction intervention targeted toward reducing HIV and hepatitis infections in prison are needle exchange programs. Only a small number of countries have implemented these programs, starting with Switzerland in 1992 (3). A review of the literature on the effectiveness of prison-based needle exchange programs reported that they have substantially reduced the sharing of injection equipment, with no increases in injecting or drug use (21).

TREATMENT

Challenges to Implementation and Evaluation

Prisons and jails provide a significant opportunity to enlist individuals with histories of substance dependence into treatment (3,4,15). The provision of effective treatment in correctional settings has the opportunity to not only reduce the health- and crime-related impact of substance abuse postrelease, but also has the potential of decreasing the frequency and severity of facility management problems as more inmates become enrolled in treatment (3). However, in many countries, scarce resources are devoted to substance abuse treatment in correctional facilities, where security is the primary concern (3). Security concerns are increased when inmates need to be moved to different areas of the facility for treatment, and some corrections personnel may be opposed to certain types of treatment, particularly opioid agonist therapy, particularly in the United States (3,14,15). As a consequence, many incarcerated individuals with histories of substance abuse do not receive treatment, and the range of modalities offered is often quite limited. For example, in the United States, less than 20% of inmates with substance abuse histories receive treatment during incarceration (5,6), with drug education being the most common service provided (15). Furthermore, while the results of a recent survey of correctional programs and organizations in the United States indicated that most correctional agencies provide some type of substance abuse treatment, the median proportion of offenders with access to such treatment at any given time is under 10% (22).

Another challenge to the development, implementation, and evaluation of new correctional substance abuse treatment programs involves the different priorities, agendas, and beliefs about inmates on the part of treatment personnel and correctional employees (14,15). Treatment staff tend to view inmates with substance abuse histories as persons with some type of illness who are in need of help. In contrast, correctional personnel may view such inmates as individuals in need of punishment and control. Thus, establishing and maintaining new programs resulting from recent justice system/treatment collaborations has been challenging. Progress in this regard has been slow and gradual over the past several decades in creating novel initiatives that combine criminal sanctions with rehabilitation, such as residential drug-abuse treatment programs for incarcerated individuals and corrections-based therapy, including opioid agonist therapy, for inmates with

opioid addiction histories (14). Ongoing cooperation among diverse correctional, treatment, and research organizations is crucial for such new programs to operate continuously. Sufficient jurisdictional and/or correctional funding is also needed for the continuous operation of new substance abuse treatment programs (3).

It also needs to be emphasized that, given the diversity among incarcerated individuals with substance abuse histories with regard to severity of addiction, criminality, psychological functioning, and other relevant dimensions, a single approach is not likely to be effective for all individuals. Therefore, a persistent challenge to treatment providers, corrections officials, and researchers, has been to determine what types of treatment work best for what types of individuals. While this question has dominated the substance abuse treatment field for many years, achieving progress has been slow (4,14).

Furthermore, many correctional substance abuse treatment programs have never been rigorously evaluated, and most published reports on the effectiveness of substance abuse treatment for incarcerated populations are anecdotal and descriptive (14). Meta-analyses of correctional substance abuse treatment have consistently reported that most studies have major methodologic problems (23–25). Caution is advised in interpreting the results of a number of evaluations of substance abuse interventions because of limitations such as short postrelease follow-up periods, low postrelease assessment rates, infrequent use of comparison groups, multivariate methods, standardized assessment instruments, and appropriate control variables (14,26). Nevertheless, there have been some well-controlled studies of corrections-based substance abuse treatment which are discussed below.

Modalities

Therapeutic Community (TC)

The therapeutic community (TC) modality in a correctional setting operates on the premise that inmates with long histories of severe substance abuse must change their attitudes and thinking patterns to reduce the influences of lifestyles condoning violence, manipulation, and irresponsibility found in the prison environment (26). Because of these circumstances, inmates in TC treatment reside apart from other inmates in order to minimize such negative influences and to develop a sense of community in which the community members themselves serve as therapeutic agents. Inmates residing in the TC rely on their group leader, typically a recovering person, and peers to provide rewards and sanctions. TC members support and reward abstinence from substance abuse and crime and the adoption and maintenance of prosocial attitudes and values. Confrontation and sanctions are employed as a response to negative behaviors and positive feedback is employed as a response to positive behaviors.

There are challenges to the implementation and operation of TCs in the correctional setting (3,14). Similar to other substance abuse treatment programs conducted within prisons and jails, TCs require strong, consistent commitment to the

program on the part of correctional administrators and staff. Furthermore, a considerable amount of space within the facility needs to be devoted to provide TC members with housing, food service, and rooms to conduct group treatment sessions. As a result, TCs can be expensive to operate.

In their 1999 meta-analysis, Pearson and Lipton (23) concluded that there was evidence of effectiveness of in-prison treatment in terms of reducing readdiction and/or crime only for a TC approach, while rigorous research regarding other approaches was either insufficient and/or of poor methodologic quality to allow for firm conclusions regarding their effectiveness. More recently, Mitchell, Wilson, and MacKenzie (25), in a 2007 meta-analysis of 66 evaluations of incarceration-based treatment, 58 of which were conducted in the United States, found that the most consistent evidence with regard to reducing both postrelease criminal recidivism and relapse to drug use came from evaluations of TC programs, and that this result was robust to variations in method, sample, and program features. However, the positive effects of correctional TC treatment may be much smaller without the provision of postrelease aftercare (3,23,27).

There is evidence that offenders who receive a three-stage TC approach administered in a U.S. prison, in work release during the transition from the institution to the community, and in combination with aftercare involving outpatient individual counseling, group therapy, and reinforcement sessions had lower rates of postrelease relapse to drug use and criminal recidivism at 5 years postrelease than offenders who receive little or no treatment (26). Other long-term, methodologically rigorous follow-up studies conducted in the United States using comparison or control groups have reported similar results for incarceration-based TC treatment followed by community-based aftercare (27,28).

Among the most comprehensive evaluations of TC results was the one conducted by Inciardi and colleagues (26). In this study, 60-month postrelease outcomes were examined. Consistent with previous research involving 18- and 42-month postrelease follow-up periods, this long-term evaluation employed multivariate methods and multiple outcome measures. In addition, the two main outcome variables, drug-free and arrest-free status, were conservatively defined. In order to be determined drug-free, the respondent must have reported no drug use and have tested negative for drug use according to urine screening at each follow-up point. Similarly, the criteria for arrest-free status involved no self-report of arrest along with no official arrest records for new offenses since release from incarceration. Findings showed that treatment participation was a major predictor of both drug-free and arrest-free status. More specifically, examination of four comparison groups of research participants indicated that individuals who had completed prison treatment and had received aftercare were most likely to be both drug-free and arrest-free. Individuals who had completed prison treatment without aftercare had the second best outcomes, followed by those who were TC treatment dropouts. Individuals with no treatment were least likely to be both drug-free and arrest-free. While the authors noted

that their results were somewhat limited in that major control and confounding variables were not modeled and differences between voluntary versus mandatory supervision were not addressed, they concluded that the findings provide evidence for the value of providing a continuum of care from incarceration to aftercare in the community. Specifically, the transitional programming provided in this intervention served as a critical bridge spanning the prison and re-entry into society by offering assistance for reducing the many psychological, social, and legal barriers that lead to greater vulnerability for relapse to substance dependence and criminal recidivism among newly released inmates.

Similarly, another of the most rigorously conducted evaluations of TC treatment involved a 5-year postrelease follow-up of 715 male prison inmates who were randomly assigned to either TC treatment or a control (no treatment) condition (27). Results of this study, conducted by Prendergast and colleagues in the United States (27), found that while over 75% of the sample had been reincarcerated, inmates assigned to the TC group had significantly lower reincarceration rates than controls, with no group differences reported for relapse to heavy drug use. Prendergast et al. also found that completion of prison treatment followed by aftercare was significantly associated with reduced rates of reincarceration, but was not related to reductions in relapse to heavy drug use.

Cognitive–Behavioral Interventions

Because of the influence of substance-abusing peers and the multiple demands of housing, legitimate employment, and family are significantly diminished during incarceration, greater opportunity exists for focused, comprehensive treatment that intends to change patterns of behavior, thinking, and feeling that contribute to substance abuse and criminality. Some clinicians and researchers have contended that cognitive–behavioral treatment programs are among the most promising for reducing relapse to substance abuse and criminal recidivism because they focus on internal client factors and predispositions contributing to deviant behavior. Furthermore, cognitive–behavioral interventions are less expensive than therapeutic communities to operate as they place fewer demands on correctional staff and require less space.

Although cognitive–behavioral programs have been widely used throughout the world for over two decades, they have been subject to relatively few controlled evaluations (23–25).

Pearson and Lipton (23), in their 1999 meta-analysis of correctional substance abuse treatment, mentioned above, noted that although cognitive–behavioral approaches showed some favorable results with both offenders and substance abusers in general, very few rigorous evaluations had been conducted with incarcerated substance abusers. Subsequently, in a meta-analysis of 69 evaluations of corrections-based cognitive–behavioral treatment, Pearson et al. (24) reported that such treatment was generally superior to standard correctional programming in reducing re-arrest. However, these authors rated the methodologic rigor of 45 (65%) of these studies as either “poor” or “fair,” pointing

out the lack of specific details regarding the training and supervision of treatment staff, frequency of sessions, and treatment program duration. Furthermore, there were far more evaluations of the impact of corrections-based cognitive-behavioral treatment on postrelease arrest and reincarceration than on postrelease substance abuse (24,29).

Among the few more methodologically rigorous evaluations of prison-based cognitive-behavioral treatment was a multisite evaluation involving over 2000 inmates (30). Three-year postrelease outcomes, analyzed separately for men and women, indicated that while both male and female program participants had lower rates of re-arrest and drug use than their counterparts in the comparison group, the findings were only significant for males. Subsequently, a 1-year postrelease analysis of a cognitive-behavioral treatment program for women prisoners found that treated women had significantly less drug use and arrests than a comparison group (31).

Boot Camps

Boot camp programs, which primarily operate in the United States, are highly structured and are patterned after military basic training. They involve vigorous exercise (including obstacle courses), military drill, ceremony, and discipline. Inmates are required to wear uniforms and are subject to confrontation and sanctions on the part of drill instructors for rule violations. Proponents of boot camps claim that such interventions instill self-discipline needed to avoid relapse to substance abuse and criminal recidivism. Pearson and Lipton (23) and Mitchell et al. (25), in meta-analyses of correctional substance abuse treatment programs mentioned above, found no evidence for the effectiveness of boot camp programs with regard to reducing substance use and criminal recidivism.

Opioid Agonist Maintenance

The use of opioid agonists such as methadone and buprenorphine for the treatment of opioid dependence in the community is among the most rigorously and frequently studied of all the drug-abuse treatment modalities (32). These medications have been found effective in numerous randomized controlled trials (32) and are on the World Health Organization's list of essential medications because of their extensively documented ability to reduce heroin use and HIV-risk behaviors (33). These medications act by occupying the opioid receptor and blocking the euphoric effects of self-administered heroin or other opioids (32). Forty years of research evidence in community-based settings throughout the world has found that opioid agonist therapy, primarily involving the provision of methadone maintenance, is highly effective in reducing heroin addiction, criminal activity, and HIV-related risk behavior (3,14,32,34). In addition, methadone maintenance treatment has been found superior to other types of substance abuse treatment in retaining patients in treatment (14,32). Treatment retention is crucial to successful treatment outcome; research results have consistently reported that regardless of modality, greater treatment duration is related to reduced substance abuse and crime (14).

However, despite its effectiveness, opioid agonist maintenance treatment is underutilized in jail and prison settings, particularly in the United States (14,15). In contrast to the United States, a number of other countries have routinely offered it to incarcerated populations, including nearly all nations in the European Union, Canada, and Australia (34). In jails, opioid agonists can be used to detoxify newly incarcerated inmates from dependence on heroin or prescription opioids, to maintain methadone or buprenorphine patients whose treatment is interrupted by incarceration, or can be started and maintained for individuals in opioid withdrawal in order to link them to community-based treatment upon release. In prisons, it can be used to treat ongoing drug dependence (as it would be used in the community) or as a re-entry strategy. These aspects of corrections-based opioid agonist treatment are described below in more detail.

Jail-Based Agonist Treatment

- a. *Detoxification*: Jails bear the brunt of dealing with opioid withdrawal of newly incarcerated individuals. While there are many methods of providing opioid detoxification, methadone is a low-cost medication that is highly effective in resolving withdrawal symptoms. Detoxification with methadone while medically appropriate, humane, and preferred by some inmates (as compared to maintenance) is not highly effective in keeping individuals from relapsing upon release and does expose re-entering prisoners to the heightened risk of overdose death upon resumption of heroin use postrelease (34).
- b. *Initiating maintenance therapy upon incarceration*: An alternative to detoxification for newly incarcerated inmates who are opioid dependent is to initiate and continue maintenance therapy and then connect patients to community-based treatment upon release. This has been the practice at few facilities in the United States. The Rikers Island jail program in New York City has been in continuous operation since 1987, and treatment in this program has been found to facilitate community-based treatment entry as well as to reduce reincarceration (35,36). It has been estimated that the Rikers Island facility provides methadone maintenance and/or detoxification to over 4000 inmates annually (37). The rate of continuation in the community with this approach has been reported to be 75% (37). It is important to have arrangements with community-based providers to accept released individuals seamlessly (3). For those individuals who receive prison sentences and must be transferred to a facility which does not have the capability of providing opioid agonist therapy, a gradual dose taper is appropriate.

With the availability of buprenorphine, there is now a choice between methadone and buprenorphine for this purpose. There has been one study comparing the two medications initiated in a jail recently conducted by Magura and colleagues in the Rikers Island jail in New York City (38). Results showed that patients started on buprenorphine as

compared to methadone while in opioid withdrawal at the start of their incarceration were more likely to enter and remain in community-based treatment at 3 months postrelease although the rates of self-reported measures of relapse to drug use, re-arrest, reincarceration, and severity of crime committed did not differ between the two groups.

- c. *Maintaining existing patients:* It is crucial that jail inmates who were on methadone or buprenorphine treatment just prior to incarceration in the community be maintained on their medication, as they would be if they were on any other medication. Should they be released from jail, arrangements need to be made to return them to their treating clinician or clinic. Should they receive a long incarceration sentence and need to be transferred to a prison without opioid agonist treatment capability, they should be gradually tapered off medication over the course of a few weeks (depending on their dosage). This is the standard practice at Rikers Island.
- d. *Initiating maintenance therapy postdetoxification:* Some individuals who are detoxified at the start of their incarceration may wish to resume methadone or buprenorphine treatment prior to release to permit re-entry to community-based treatment and to prevent relapse to heroin use and overdose death. Dole et al. (39) studied just such an approach in New York City in a randomized trial in which 12 inmates were started on methadone approximately 10 days before release. At 7 to 10 months postrelease, these 12 inmates had lower rates of readdiction and reincarceration than 16 untreated controls. Because the patients had previously undergone detoxification while incarcerated and had lost tolerance to opioids, Dole started patients at a low dose (10 mg) and gradually increased the dose to a target of 35 mg over the course of 10 days. Patients who are initiated in this manner need to be carefully monitored by medical and nursing staff for oversedation and constipation and the dosage reduced and/or the dose increase schedule slowed as necessary. There have been no published studies to date of such an approach with buprenorphine, although the present authors are conducting a randomized clinical trial study in a prerelease prison with buprenorphine.

Prison-Based Agonist Treatment

In prisons in which there is a relatively high rate of illicit opioid use, prison-based agonist treatment can be used in a manner similar to opioid agonist treatment in the community. For example, in Puerto Rico, in a study using buprenorphine-naloxone, such an intervention was found to be feasible and facilitated community-based postrelease treatment entry (40). Similarly in France, there have been reports of prison-based buprenorphine maintenance treatment, found to be effective in reducing heroin use and reincarceration (41). Perhaps the most rigorously evaluated of these programs has been the one that began in a prerelease prison in Australia in 1986 by the New South Wales Department of Correction for inmates

with heroin dependence. Over 80% of participants either reported using heroin in prison a month before study entry and/or had morphine-positive hair test results upon admission to the study. Methadone maintenance began at 30 mg with 5 mg increases every five days until 60 mg was achieved. A randomized controlled trial of this methadone program compared to the wait-list for the prison program indicated that heroin use was lower among treated inmates during a 4-month, in-prison follow-up (42). At 4-year follow-up, greater treatment duration was associated with decreased mortality, reincarceration, and hepatitis C infection (43). Regarding mortality, no participants died while actively enrolled in methadone maintenance treatment, while 17 died while out of treatment. The risk of reincarceration was lowest during periods of methadone treatment lasting 8 months or longer, although methadone maintenance treatment of 2 months or less was associated with the highest risk of reincarceration (43).

However, there are circumstances in which inmates would have met the criteria of opioid agonist treatment prior to their index incarceration but who have been completely or largely abstinent from heroin use while in a controlled environment. These individuals may be at high risk of relapse upon release to the community and may wish to be on agonist treatment prior to re-entry. They may have had the experience of relapsing to heroin use every time they were released from prison or jail and not wish to repeat the same outcome. Since they are no longer tolerant to opioids, it is essential that such individuals be started at low doses of opioids (e.g., 5 mg of methadone or 1 mg of buprenorphine). Dose induction should proceed more slowly (especially at the lower doses) than for tolerant patients, in our experience at 5 mg of methadone or 1 mg of buprenorphine per week.

To our knowledge, there has been only one randomized controlled trial of this type of prerelease methadone treatment fashioned on the study by Dole et al. (39) in the prerelease jail.

The present authors conducted the first randomized clinical trial in the United States to examine the effectiveness of prison- (as opposed to jail-) initiated methadone treatment.

It was undertaken to examine the extent to which beginning methadone maintenance in prison prior to release with continued treatment in the community would be more effective than initiating methadone maintenance in the community or providing counseling only in prison with passive referral to community treatment upon release. Participants met criteria for methadone maintenance in the community for the year prior to their incarceration. They were started at 5 mg methadone daily for the first week and doses were increased in 5 mg increments weekly until a target of 60 mg was achieved.

Short-term results at 1 and 3 months postrelease (44,45) and longer-term findings at 6 months postrelease (46) found that prison-initiated and community-initiated methadone treatment were more effective than counseling only regarding heroin use and treatment entry. Subsequent results at 12 months postrelease (47) found that prison-initiated

Mean Days in Community-Based Substance Abuse Treatment 12 Months Post release

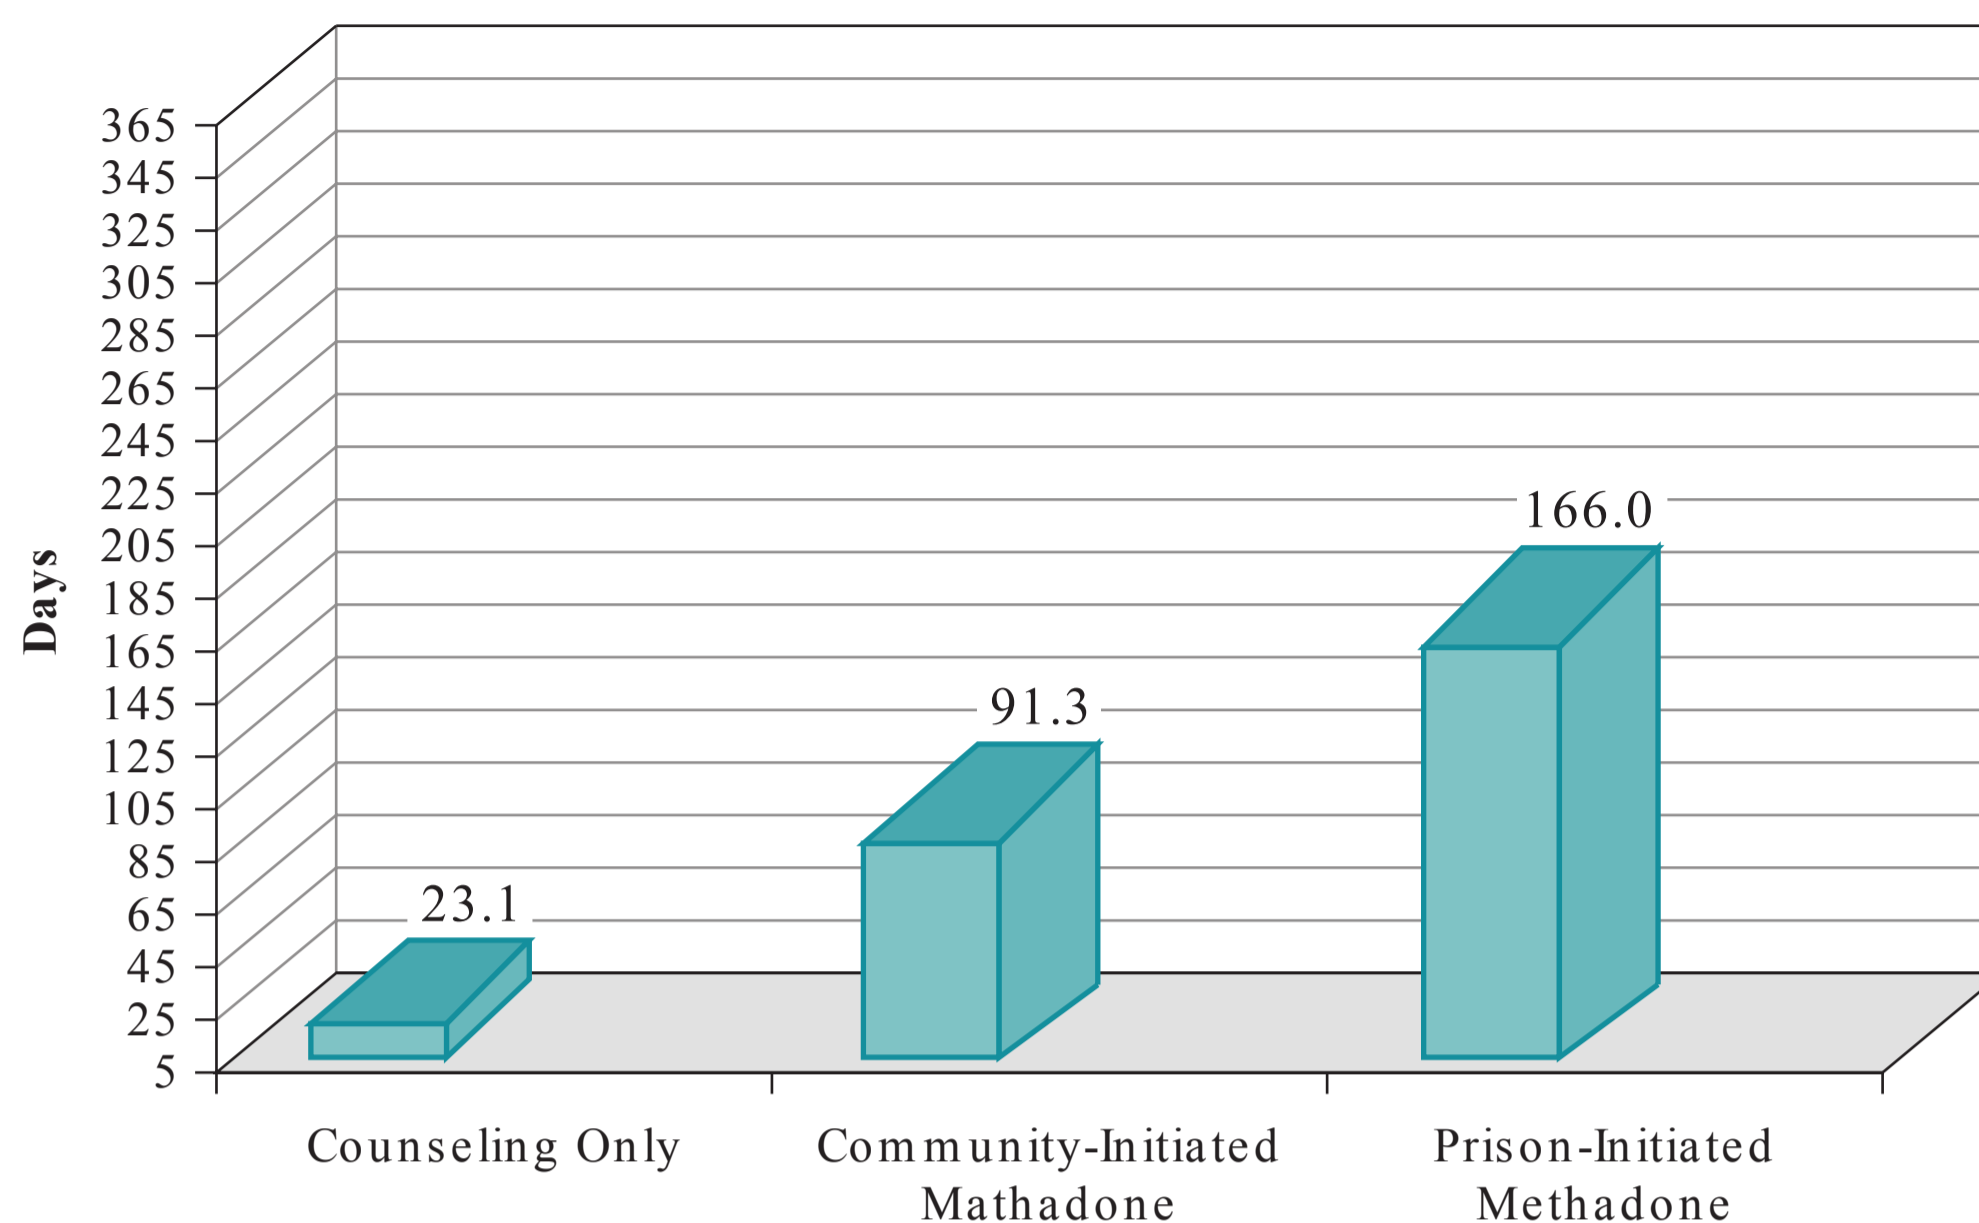

Figure 65.1. Mean days in community-based substance abuse treatment, 12 months postrelease. (Data from Kinlock TW, Gordon MS, Schwartz RP, et al. A randomized clinical trial of methadone maintenance for prisoners: results at 12-months postrelease. *J Subst Abuse Treat.* 2009;37:277–285.)

methadone had superior outcomes to the other two treatment conditions with regard to community-based treatment duration (see Fig. 65.1) and heroin use. Regarding self-reported crime and any reincarcerations, outcomes favored prison-initiated methadone compared to counseling only at 3 months postrelease. Results at 6 months postrelease regarding the number of days of self-reported crime also favored prison-initiated methadone over counseling only, although there were no group differences concerning the number of days reincarcerated. However, no differences among treatment conditions were found at 12 months postrelease on either the number of days of self-reported crime or the percentage of participants arrested.

SOCIOCULTURAL CONSIDERATIONS

It is strongly recommended that interventions for incarcerated individuals be tailored to the inmates' specific sociocultural needs. Individual characteristics of inmates may influence drug-use behavior and therefore the types of interventions that may be most promising for reducing drug use and its disastrous public health and public safety consequences (2–4,14). Ideally, all services to be provided to incarcerated populations need to be based on an assessment of individual inmate needs (3,4,15). The greater prevalence of substance abuse among women than men, both overall and compared to their counterparts in the general population, suggests that the gender of the inmate be one dimension that needs to be strongly considered in the development of appropriate interventions for inmates with histories of

drug abuse (4). In addition to gender, nationality, ethnicity, and rural/urban status are likely to be factors that have a bearing on one's pattern of drug use and thus the type(s) of treatment that may be most appropriate (2).

In addition, many individuals enter jails and prisons with poor health in addition to drug abuse, often brought on by socioeconomic conditions such as unsanitary living conditions and lack of access to affordable health care (20). These circumstances are typically exacerbated by the prison environment, where overcrowding, poor nutrition, and poor ventilation are commonplace along with violence, unprotected sex, and drug use and injection (2,20). These circumstances, in turn, can lead to the development of many infectious diseases, including HIV and hepatitis (20).

Furthermore, individual inmate differences in response to various types of drug-abuse treatment interventions have not been frequently reported (14). Because there are considerable individual differences among inmates with histories of drug abuse with respect to criminality, psychological functioning, and motivation for treatment (14), as well as types of drugs abused and route of injection (9), among other factors, a single treatment modality is not likely to be effective for all inmates with drug-abuse histories. Moreover, research on the processes of matching inmate needs with treatments needs to be significantly improved, and all too often funds are not available for services to be delivered (14). Because the failure to adequately match inmates to interventions could result in increased substance abuse and its attendant health- and crime-related consequences, funding appropriate services and assessment needs to be emphasized (14).

FACTORS INFLUENCING SUBSTANCE ABUSE

Since incarcerated individuals with histories of substance abuse typically begin using substances prior to incarceration, and many relapse or continue their involvement with substances following release, it is important to examine factors influencing such individuals' substance abuse during each of these periods.

Prior to Incarceration

A recent nationwide survey of prison inmates in the United States found that inmates with preincarceration histories of drug abuse and/or dependence were more likely than other inmates to report experiencing various adverse circumstances in their lives prior to incarceration, including physical and/or sexual abuse, homelessness, unemployment, parental substance abuse, and parental incarceration (5). Compared to other prisoners, inmates with prior drug abuse and/or dependence were more likely to report that several events had occurred during their formative years, including having at least one parent abuse substances, having their family receive public assistance, and/or having lived in a single-parent household. While the inmates were not asked whether any or all of the adverse circumstances they experienced prior to incarceration had caused the onset or continuation of substance abuse, previous research has established that these factors are among the antecedents of substance abuse and dependence (16).

Furthermore, Borrill et al. (48), in a survey of female prisoners in England and Wales, compared the backgrounds of inmates who had been drug dependent prior to incarceration with that of other inmates. Prisoners who had been drug dependent were significantly more likely than other prisoners to report dropping out of school during their formative years as well as being unemployed in the year prior to incarceration. Prisoners with drug-dependence histories were also significantly more likely than other prisoners to report experiencing or witnessing a physical assault at some point in their lives prior to incarceration. Similarly, inmates with prior drug dependence were significantly more likely than other prisoners to have experienced unwanted sexual contact, including sexual assault. While prisoners were not asked directly if these events had led to their substance abuse, such factors have been frequently identified by previous research as antecedents of substance abuse (16).

During Incarceration

Relatively few studies have examined the factors contributing to the use of substances during incarceration. A review of the literature by Dolan et al. (3) reported that the prison environment has a significant impact on inmate substance use and abuse in that corrections officials continually attempt to stop drugs from entering the prison, which often leads to inmates stopping or reducing use. However, these authors also reported that placing so many offenders with preincarceration substance abuse histories in close proximity with one another

with little constructive activity often leads to boredom, which, in turn, increases the likelihood of substance use, including injection (3).

Similarly, a survey of male prison inmates incarcerated in England and Wales found that boredom was a major reason why the inmates used various substances, including cannabis, heroin, and/or tranquilizers (9). The need for relaxation was another frequently cited reason as to why the inmates used one or more of the three substances mentioned above. Enjoyment and the calming effects of the drug were additional reasons inmates provided for using cannabis, whereas the need to block out their situation was also given as an important reason for using heroin.

While the prevalence of substance abuse during incarceration is, as indicated above, significantly less than that found in the community, the observation that the lack of productive activities can lead to boredom and subsequently to inmate substance use is another reason why effective treatment programs for inmates are needed. Although most studies of the impact of incarceration-based substance abuse treatment focus on postrelease outcomes, Dolan et al. found that illicit opioid use, as evidenced by both hair tests for morphine and self-reported heroin use, was lower at 4-month during-prison follow-up among methadone maintenance patients than untreated controls (42). Furthermore, treated participants reported significantly lower rates of drug injection and syringe sharing at follow-up. However, no group differences with regard to incidence of HIV or hepatitis C infections were found.

Following Release to the Community

It has been well documented that upon release from incarceration, individuals with histories of substance abuse typically experience multiple stressors that substantially increase their risk of relapse (14,15,26,28). Prominent among these factors are the need for stable housing and legitimate employment (14,15,26), the stigma of being labeled an ex-offender (15), poor or conflictual relationships with family members (14,26), and meeting multiple requirements regarding criminal justice supervision (14,15). In the United States, the escalation of parole and probation caseloads has made it increasingly difficult for parole and probation agents to effectively monitor and supervise their clients' behavior (14). Finally, as indicated previously, most newly released inmates do not receive drug-abuse treatment upon re-entry to the community.

Furthermore, many newly released inmates return to neighborhoods where drug abuse is rampant (15). Such individuals frequently encounter friends, neighbors, former drug business associates, and/or family members who are drug dependent and often pressure or otherwise encourage the former inmate to relapse (49). Such areas generally lack opportunities for legitimate employment as well (49).

In addition, there are neurobiologic factors associated with such environments that strongly influence the likelihood of relapse (15). Considerable research evidence indicates that addiction is a chronic brain disease greatly influenced by both

genetic and environmental factors (15). Repeated exposure to drugs in persons who are vulnerable as a result of genetic and/or individual factors leads to neuroadaptations in the brain that, in turn, lead to compulsive drug use and loss of control over behaviors related to drugs (15). Because environments in which many newly released prisoners with prior substance abuse return typically serve as triggers or cues for the individual to use drugs, the individual's reward/motivational processes are activated, leading to intense desires or cravings for drug use (15).

SPECIAL CONSIDERATIONS

Given the multiple stressors facing newly released inmates with substance abuse histories upon return to the community, as well as the high rates of relapse involved, it is crucial that jail- and prison-based treatment programs provide a continuum of care in the community (3,14,15,26,27,45,46). As emphasized above, the benefits of incarceration-based treatment are greatly enhanced by the provision of community-based aftercare. Perhaps the most promising programs for reducing relapse and recidivism may be corrections-treatment partnerships in which a single treatment team or primary counselor takes primary responsibility for provision of services, both during incarceration and in the community (26).

However, successfully developing and implementing such programs, independent of the modality involved, is a very challenging task because it involves frequent collaboration between various agencies (corrections and substance abuse treatment) with different, and often conflicting, priorities and agenda (3,14,15). It is helpful in this regard to first conduct a pilot, or exploratory study to alleviate interagency tensions and develop feasible procedures (14). It is strongly recommended that both treatment and corrections staff be equally involved in planning the intervention, with responsibilities of various agency personnel specified in advance. In addition, differences with respect to logistics and space need to be reconciled so that treatment procedures do not interfere with routine security and other procedures in the jail or prison.

CONCLUSIONS

From the above, there is considerable research evidence to indicate that jail and prison inmates have substantially higher rates of substance abuse than the general population. This is particularly evident with regard to patterns of use found to be most closely associated with adverse health- and crime-related consequences, such as addiction to opioids (primarily heroin), cocaine, and/or multiple substances, as well as drug injection. While substance abuse tends to be more frequent prior to incarceration than during incarceration, substance use, including injection, is not uncommon in jails and prisons. Unfortunately, most inmates with substance abuse histories do not receive treatment while incarcerated, and either relapse or continue substance abuse upon release, greatly increasing the likelihood of HIV and hepatitis infections, overdose death, criminal activity, and reincarceration.

As documented previously, there are a number of treatment interventions that can be effective in reducing substance use and its attendant health and criminogenic effects for incarcerated individuals. However, it is important to recognize that the benefits of incarceration-based substance abuse treatment may diminish following release to the community. Therefore, it is advised that a continuum of treatment spanning incarceration and the community be implemented to further help interrupt the pernicious cycle of relapse, recidivism, and reincarceration.

Furthermore, one of the effective treatment interventions reviewed herein, opioid agonist maintenance, is underutilized in jail and prison settings. Consistent with the recommendations of others (3,15,34,37), expanding the availability of such treatment in prisons and jails has several potential benefits, including reduction of heroin use and injection in facilities where such behaviors are common, alleviating withdrawal symptoms among newly arrived, opioid-dependent inmates, and reducing readdiction, transmission of blood-borne viruses, and overdose death following release. Therefore, in keeping with the longstanding positions of the World Health Organization (3) and the National Institutes of Health (37), we recommend that opioid agonist treatment be expanded in correctional settings.

It also needs to be emphasized that achieving long-term recovery from substance abuse for incarcerated persons is an exceptionally challenging endeavor. As Latessa (50) noted, "for those who have tried to lose weight, quit smoking, eat fewer sweets, or exercise more, it is not easy" (p. 548). Latessa went on to say that researchers often like to present their findings as logical reasons for behavioral change. However, he remarked that when one observes that 80% is the median rate for noncompliance with recommended health care practices by health care professionals, researchers' expectations that their results alone can convince inmates to change and correctional agencies to support their research agendas is too simplistic. Therefore, researchers need to make their findings understandable in a manner that assists potential clients and practitioners understand the value of the results and their potential benefits (50). Similarly, it is well documented that even in interventions where there is considerable research evidence for effectiveness in reducing relapse and recidivism, many clients continue to experience periods of relapse and recovery following the end of a treatment episode (14). The presence of such circumstances provides additional support for Latessa's contention that positive behavioral changes result from hard work and occur in small increments.

Another challenge to the successful development and implementation of effective and innovative incarceration-based substance abuse treatment programs is that agencies with different and sometimes conflicting priorities and agenda need to be in constant collaboration (14,15). It is crucial that both treatment and corrections staff establish and maintain an equal partnership with regard to planning the intervention, with responsibilities of various agency staff defined in advance. Furthermore, potential conflicts concerning logistics and the allocation of space for treatment-related activities need to be

reconciled so that intervention procedures do not interfere with routine security and other procedures in the jail or prison.

Moreover, both correctional and treatment personnel need to recognize individual diversity among jail and prison inmates with histories of substance abuse (3,14,15). It needs to be emphasized to practitioners, administrators, and policy makers, that no single intervention is effective for all clients. In view of the observation that failure to adequately match inmates to interventions may lead to increased substance abuse and its attendant health- and crime-related consequences, funding appropriate services and assessment needs to be emphasized (3,4,14,15).

Finally, the urgency of the need to provide effective substance abuse treatment to jail and prison inmates with histories of substance abuse needs to be emphasized. As documented earlier, without such treatment, the lives of not only the newly released inmates themselves, but also those of others are threatened given the increased likelihood of relapse, primarily to heroin and/or cocaine addiction and drug injection, patterns of use associated with overdose death and exposure to HIV and hepatitis infections. In addition to adverse health consequences, there are also public safety consequences in that relapse to the above-mentioned substance abuse patterns are related to an increase in the frequency of criminal behavior. These circumstances are exacerbated by the observation that increases in the worldwide prison population are expected to continue (1,2).

Substance Use Disorders among Health Care Professionals*

J. Wesley Boyd ■ John R. Knight

INTRODUCTION

The Greek philosopher Plato believed that if we had knowledge about any matter, then proper action would follow. If Plato were correct, then given their knowledge of medications and addiction, health care professionals would never abuse psychoactive substances. When it comes to this problem, Plato was wrong. Health care professionals know better than the general population just how dangerous psychoactive substances can be, but their overall rates of substance abuse are roughly equivalent to the general population (1). However, health care professionals' patterns of use differ from the general population.

Physicians who abuse substances often self-prescribe them and choose different substances than the general population. Nurses, who are often on the front lines of health care delivery, can easily divert medications from patients for their own use. Pharmacists, having perhaps the greatest direct access to psychoactive drugs of all health care professionals, are also prone to self-medication (2). Finally, dentists who are prone to addiction often turn to nitrous oxide, given its easy access for them (3,4).

EPIDEMIOLOGY

Lifetime rates of substance use disorders among health care providers are in the 11% to 14% range (5–9). The 1992 Physician Substance Use Survey (PSUS), which polled 9600 physicians about their own use of alcohol and other drugs, is the most extensive survey of physician substance use performed in the United States to date (1). The PSUS reported a lower rate of substance use disorders than other surveys: 8% lifetime rate for physicians. However, it relied on physician self-report and may have underestimated actual prevalence. Like physicians, the prevalence of substance abuse among nurses is comparable to that in the general public (10,11).

Health care professionals are more likely to abuse benzodiazepines and opiates other than heroin, more likely to abuse alcohol, and less likely to abuse recreational street drugs such as marijuana and cocaine than the general public (1,12). One older study found that pharmacy students were abusing drugs

at alarmingly high rates: up to 62% abused drugs at some point in the past and 19% were using a substance regularly (13). As recently as 2006, the American Nurses Association estimated that 6% to 8% of nurses practiced while impaired by alcohol or other drugs (14).

Among physicians, psychiatrists, emergency physicians, and anesthesiologists are at the highest risk of abusing substances (1,15,16). Conversely, pediatricians, pathologists, radiologists, and obstetrician-gynecologists have the lowest reported rates of substance abuse (16,17). Among physicians who misuse drugs, emergency medicine physicians tend to use more illicit drugs, anesthesiologists tend to misuse narcotic analgesics, and psychiatrists are more likely to misuse benzodiazepines. It is likely that availability and familiarity are contributing risk factors for medical specialists.

RISK FACTORS

A substantial number of health care professionals with substance use disorders report a family history of substance abuse, significant stress at both work and home, emotional problems, and sensation-seeking behaviors (12). When health care professionals do misuse substances—whether alcohol, tranquilizers, or other substances of abuse—they often do so for reasons of “self-treatment.” Physicians often work long hours, beyond any standard job description, and may find self-treatment an expedient alternative to taking the time to make and keep appointments with physician colleagues.

Being a female health care professional may also increase risk. Compared to their male counterparts, female physicians who have an identified substance abuse disorder are younger, more likely to have coexisting psychiatric or medical illness, and more likely to have suicidal ideation and/or to have attempted suicide while intoxicated (12,18). Furthermore, compared to men, once they had achieved initial sobriety, women physicians had significantly shorter time to first relapse (16,19).

Younger age may also increase risk. One study (20) found that older health care professionals are significantly less likely to suffer from a substance use disorder than their younger colleagues.

*We dedicate this chapter to the memory of Dr. Michael B., who shared his experience, strength, and hope with many physicians until his sudden, untimely death from a dissecting aneurysm. He died clean and sober, before the miracle of his recovery could be even half-completed. We will always miss him.

PREVENTION

Education on physician health and the risks of self-treatment should be a standard component of physician education at all levels, from medical school, to residency and fellowship, and throughout continuing medical education. Similar educational interventions are appropriate for nurses, pharmacists, dentists, and veterinarians. Every state in the United States except one has a physician health program, which may be an ideal agency to provide continuing education through presentations at hospital grand rounds.

Hospital chiefs, practice managers, administrators, and other health care leaders should consider substance abuse, among other health problems, when staff exhibit performance problems. Also, since health care workers may begin misusing substances in an attempt to treat their own physical or emotional discomfort, we recommend that all medical professionals have a primary care physician, resist the temptation to self-diagnose, and never self-prescribe. Seeking medications from colleagues—even a few painkillers here or there—is a bad practice that jeopardizes the career of the prescriber and the well-being of the person obtaining such medications. Physicians prescribing medications for another health care professional should do so only in the course of their usual medical practice, and always generate a note into an appropriate medical record indicating the reason for the medication and the dosing details.

With the possible exception of true emergencies, we recommend that health care professionals not prescribe for family or friends or bring drugs home from office supplies or samples. Many states limit or prohibit prescribing for self and family.

Health care professionals should attend to their own health and wellness. Studies have shown that physicians who exercise, do not smoke, eat well, drink in moderation, and are otherwise attuned to their own health are better caregivers across all measures (21,22). This may also be true for other health care professionals.

SIGNS AND SYMPTOMS

Initial signs of substance misuse among health care professionals almost always appear outside of the workplace. By the time problems arise at work, the substance use disorder may be quite advanced. One study concluded that physicians received treatment for substance abuse an average of 6 to 7 years after problem onset (23).

Initial warning signs of substance use disorders include difficulties at home, loss of interest in activities previously enjoyed, disrupted family relationships, vehicle crashes, accidents, and injuries. Behavioral symptoms are nonspecific, but include apathy, anxiety, lack of self-discipline, strained communications with others, personality changes, and abrupt mood swings (12).

Physical signs include change in eating habits and weight, poor self-care, a generalized deterioration in appear-

ance, dilated pupils, watery eyes, smelling of alcohol, slurred speech, conjunctival injection, dilated or constricted pupils, falling asleep at odd times, and, rarely, needle marks, bruises, or bandages. Health care providers who abuse IV drugs often inject themselves in areas of their body that are not exposed to view, such as lower extremity veins or those in the genital area.

Sometimes, health care professionals with substance use disorders will make direct statements of distress. These may include expressing constant sadness or tearfulness, excessive anxiety or irritability, unprovoked anger or hostility, expressions of hopelessness or worthlessness, and feeling or acting isolated.

When signs of substance misuse become manifest in the workplace, symptoms may include deterioration in the quality of work, repeatedly showing up late for meetings and appointments, recurring absences, continually seeking special accommodations, repeatedly having trouble in getting along with staff and patients, or not responding to pages when on call. While none of these warning signs alone confirm a diagnosis, taken together with other symptoms they may indicate the need for an evaluation.

The level of impairment by health care professionals varies according to pattern of use (e.g., morning vs. evening, weekday vs. weekend), onset and duration of action of the specific substance, the amount consumed, and the degree of tolerance. Some individuals with tolerance will tend to show symptoms when they are in withdrawal, whereas others will show more prominent signs when intoxicated (24).

INTERVENTION

The first step in helping a colleague who may have a problem is having him evaluated. One approach to a directive intervention is summarized by the acronym “FRAMER” (Fig. 66.1). The first step is to gather the **facts**. These facts should include written documentation of any oral complaints about the colleague. For example, if another staff member tells you he has seen signs and symptoms suggesting substance use, record them in a confidential e-mail or as private notes kept locked in your desk. These should state the facts and observations, and avoid drawing any conclusions.

The second step is ascertaining one’s own **responsibility** for reporting a colleague who is suspected of having a problem. Are there mandatory reporting requirements by the state licensing board? Health care providers in Massachusetts are required to report any physician to the licensing agency if they have a reasonable basis to believe that the individual may be impaired by alcohol or other substances. Massachusetts also allows for a waiver of the report if the physician has not broken any laws, placed any patients at risk of harm, and enters a treatment program within 30 days of the problem being discovered. Hospital rules and regulations, medical staff bylaws, and other regulations might also mandate a certain course of action. Regardless of law, health care providers may also have an ethical obligation

PRINCIPLES OF DIRECTIVE INTERVENTIONS

F	Gather all of the FACTS .
R	Determine your RESPONSIBILITY for reporting; consult confidentially with medical and legal experts.
A	Bring in ANOTHER PERSON .
M	Begin the meeting with a MONOLOGUE , in which you present the facts and summarize your responsibility.
E	Insist on a comprehensive EVALUATION . Refrain from giving a diagnosis.
R	Insist on a REPORT BACK , and signed releases allowing all parties to freely communicate.

Figure 66.1. Principles of directive interventions. (Reprinted with permission from Knight JR. A 35-year-old physician with opioid dependence. *J Am Med Assoc.* 2004;292:1351–1357.)

to intervene with a colleague before he or she can harm patients, a family member, or self.

The third principle is to have **another person** present at the initial meeting with the colleague. This person can serve as a witness to what you discuss and also might act as a buffer if things begin to heat up. Ideally, this other person should be a member of the hospital's wellness program, the department chief, or an addiction specialist. If you do not have administrative authority over the target physician, bring someone else who does.

The meeting should begin with a **monologue**, during which you list the observations that have led to your concern. The purpose of this monologue is to state facts, which are not open to debate. Avoid drawing conclusions, which may lead to arguing about details or having the individual spend all his time refuting each and every point of concern.

If the individual admits to having a substance abuse problem, then the colleague should be thanked for his or her honesty and referred to treatment immediately. If the individual denies any problems, insist on an independent **evaluation**. If the evaluation concludes that a substance use disorder is present, then the evaluation should be followed by appropriate treatment. The individual should be placed on immediate leave from all professional responsibilities and not allowed to return until the evaluation and any needed treatments are completed.

Finally, tell the individual that you will expect a **report back** from the evaluating or treating entity. This report should specify requirements for aftercare, a plan for re-integration into practice, any workplace restrictions, and any recommendations for continuous monitoring.

EVALUATION

The initial evaluation of any health care worker with a possible substance use disorder should begin with a discussion about any limits of confidentiality. In certain situations, licensing boards of other authorities may require evaluation records or treatment discharge summaries as a condition of return to practice. Ideally, a full history and physical examination should occur. When assessing the health care professional's substance use, evaluators should gather as much detail as possible about what drugs were abused and how the drugs were procured (were they self-prescribed, diverted from patients, samples stolen from an office), whether tolerance and withdrawal symptoms are present, whether they were used during working hours or in other dangerous situations (i.e., before driving, while tending to children, etc.), when use began, and what the peak amount ever used was. Evaluators must, however, exercise discretion in how much of this information to include in reports that may ultimately go to others.

Collateral history from family members can be helpful. However, family members may downplay problems in an effort to protect the professional. Also, asking family members for collateral information can potentially strain family relationships. It should be done only when essential and then as delicately as possible. Information should also be obtained from a small number of professional colleagues. Care should be taken to protect the health care professional's confidentiality to the greatest extent possible. An inadvertent misstep by the evaluator might result in significant harm to the individual once she or he is ready to return to work.

When the individual denies using substances, we recommend obtaining laboratory testing immediately. Some

substances of abuse (e.g., cannabis) may be detectable for weeks after cessation of chronic use. However, alcohol and many pharmaceuticals have a fairly narrow detection window in a blood or urine sample (12 to 72 hours). Hair samples can provide detection windows of up to 3 months and may be useful in certain circumstances. However, they are controversial for detecting smoked drugs, because passive exposure can contaminate the hair and cause a false positive result (25).

We recommend consultation with a toxicologist before collecting the specimen for testing. Every specimen should be collected under the federally mandated protocol (26). Given the significant legal and professional sanctions that health care professionals face, specimens must be handled properly and laboratories should use chain-of-custody procedures.

TREATMENT

If the evaluation of the health care professional confirms a substance use disorder, we recommend entry into a structured treatment program. This may be inpatient or outpatient; typical programs last between 2 weeks and 4 months. The American Society on Addiction Medicine has treatment placement guidelines, which may be helpful. Individuals who remain in treatment do better than those who drop out, but we could find no studies supporting a specific length of treatment for health care professionals. Residential facilities often provide medical stabilization of drug-dependent individuals, followed by an intensive psychosocial treatment program that includes group therapy, individual therapy, family meetings, psychopharmacologic evaluation, psychological evaluation, and 12-step fellowship meetings. Some programs offer aftercare plans which can include reunion gatherings for successful graduates.

Residential treatment can be quite costly (\$8000 to over \$50,000 per month) and insurance usually covers only a fraction, if any, of this cost. This expense may be prohibitive for younger professionals, especially those in training. Outpatient programs, or partial hospitalization, may be available closer to home, allow for greater family participation, may accept insurance benefits, and can be much more affordable.

MONITORING

Every hospital is mandated by the Joint Commission (formerly the Joint Commission on Accreditation of Health Care Organizations, or JCAHCO) to have a process apart from discipline by which physicians and other professionals can seek confidential help for health-related matters. However, not every hospital has such a committee, and those that exist have varying degrees of experience and expertise. Some situations regarding health care professional substance use may warrant immediate attention from a state's physician health program, nursing wellness committee, or some other nondisciplinary agency. The goals of these entities are to identify, assess, refer for treatment, and monitor health care providers with substance use disorders (and other impairing conditions). They can also provide guidance to individual health

care professionals, hospital administrators, and department chiefs, about treatment resources and licensing regulations. Given that these entities also monitor health care professionals, they can also provide advocacy for health care practitioners with documented recovery to licensing boards, insurance companies, and hospitals (27).

Comparing efficacy of various monitoring entities is often difficult because of differences in the criteria they assess and monitor. Variables include length of follow-up, total abstinence versus relative abstinence, ability to resume work, and others. Despite their differences, most professional monitoring programs report success rates in the 75% to 85% range, far better than those reported for the general population (16,28–30) (Table 66.1).

One large study of U.S. physicians who were monitored by 16 different state physician health programs found that 80.7% of physicians being monitored for alcohol and drug use successfully completed their respective state physician health programs (39). Of this group, 78.7% were working as physicians 5 years after successfully completing monitoring; 10.4% had either died, retired, or were lost to follow-up; and 10.8% had had their licenses revoked. These high success rates are likely related to the highly structured nature of the treatment and monitoring programs, along with accountability: the rewards of maintaining sobriety are great and the costs of relapse are quite high.

SOCIOCULTURAL CONSIDERATIONS

Because health care professionals are often among the socioeconomic elite, those outside of the profession may see them as immune from problems—including substance abuse. Within the professions, a culture of denial has sometimes turned a blind eye to substance use disorders. This blindness might stem from the fact that many health care providers do not see addiction as a treatable brain disease (41–43). Fortunately, this seems to be changing.

Some who fail to intervene with professional colleagues might do so for fear of triggering a disciplinary action, thereby preventing their colleague from being able to practice again. A few have advocated that, because patients' lives are at stake and the risk of relapse is too great, any health care professional who has had a substance abuse disorder should never be allowed to return to practice (44). However, the actual risk to patients by impaired physicians is quite low (45), and the likelihood of recovery is very high (16). We therefore recommend that health care professionals who are recovering from substance abuse disorders continue to practice, provided they accept close supervision, random drug screens, and are fully compliant with monitoring by the appropriate professional entity.

LEGAL CONSIDERATIONS

Many states mandate health care professionals to report professional colleagues who they suspect of being impaired because of substance abuse. (Some states, such as Massachusetts,

TABLE 66.1 Outcome of physician treatment and monitoring programs

Author	Intervention	Sample size	Outcome measure (definition of success)	Method	Follow-up interval (months)	Success rate
Gualtieri, 1983 (31)	Individualized treatment program and multiple-level monitoring system	117 participants in California diversion program	Able to continue practice	Not specified	Not specified	93%
Morse, 1984 (32)	3–6 weeks inpatient hospital program	53 physicians who completed treatment	Abstinence or 1 brief relapse	Self-report	1–5 years	83%
Crowley, 1986 (33)	Individualized treatment and laboratory testing	15	No drug use	Self-report, collateral report, laboratory testing	5–41 months	47%
Shore, 1987 (34)	Comprehensive initial evaluation and required adherence with individualized treatment plan	63 physicians on probation with Oregon Board	Engaged in medical practice, stable professional, and interpersonal relationships	Systematic record review	0–96 months	75%
Geyser, 1988 (35)	At least 4 weeks inpatient treatment followed by individual therapy, attendance at AA/NA meetings, and random testing	49 participants in Arizona state program	“Successfully rehabilitated”	Not specified	2–3 years	88%
Smith, 1991 (36)	Inpatient treatment for 2–3 months Inpatient treatment for 4–6 weeks Other	I. 47 II. 65 III. 21	Abstinence from alcohol/drug use	Record review	Not specified	I. 83% II. 31% III. 19%
Gallegos, 1992 (37)	Completion of initial treatment followed by individualized treatment plan, attendance at AA/NA meetings, and random testing	100 participants with Georgia Impaired Physicians Program	Complete abstinence from alcohol/drug use	“Reports from many sources,” random laboratory testing	20 months	77%

Reading, 1992 (38)	Individualized treatment plan	80	No use of alcohol/drugs by self-report, collateral report, laboratory testing	Survey	24 months	84%
Knight, 2007	Comprehensive initial evaluation and required adherence with individualized treatment plan including individual psychotherapy, attendance at AA/NA meetings, and random testing	120	No use of alcohol/drugs by self-report, collateral report, laboratory testing	Electronic database extracted	36–60 months	75%
McLellan, 2008 (39)	Monitoring of substance use by 16 different state programs	904	Licensed and working	Systematic review	5 years	78.7%
DuPont, 2009 (40)	Monitoring of substance use by 42 different state programs	All physicians in the state programs	Negative tests while being monitored; successful completion of monitoring program, as well as licensed and employed	Survey of individual state programs	5 years	78% with all negative tests while being monitored; 71% licensed and employed at 5 years
Adapted from Knight JR. A 35-year-old physician with opioid dependence. <i>J Am Med Assoc.</i> 2004;292:1351–1357.						

also mandate reporting colleagues suspected of impairment due to physical or mental instability as well.) Given the extensive professional scrutiny that can result, such a report should only occur after careful consideration of the facts, discussion with colleagues, and consultation with an attorney familiar with state licensing regulations. Individuals and health care entities that fail to report a colleague in these circumstances risk disciplinary action themselves.

These reporting regulations may include a waiver of the reporting requirement when referral is made to a professional health program for treatment and monitoring, provided the health care professional complies with all treatment and monitoring recommendations. This avenue is commonly referred to as a “diversion program,” because the report is diverted away from the licensing agency and made instead to a professional health program. Our experience is that physicians almost never refuse a referral to the state physician health program when they understand the alternative is a board report.

To support their addiction, some health care professionals may engage in illegal acts, such as self-prescribing, diverting medications, stealing medications, or prescribing for family members or fictional patients. These individuals should obtain legal counsel from an attorney who is experienced in dealing with health care professionals, hospitals, and licensing entities.

A final legal consideration is whether to self-report information to the licensing board about a possible infraction of their rules and, if so, how much information to disclose. Health care providers must honestly answer all questions on license renewal and other credentialing forms. Failure to answer questions honestly can result in sanctions that are more severe than those that might have occurred if the health care professional had disclosed the information initially. However, health care professionals should be cautious about providing unnecessary detail, which could lead to unwelcome scrutiny or disciplinary procedures. We recommend consultation with an attorney prior to disclosing any information about substance use treatment or monitoring.

ETHICAL CONSIDERATIONS

Ethical dilemmas arise when basic principles are in conflict with one another, which may occur when dealing with a colleague who has a substance use disorder. For example, we have a basic duty to respect the *autonomy* of others. However, when a health care professional is actively misusing psychoactive substances, this duty often directly competes with other guiding principles such as *justice*, *beneficence* (defined as “doing good”), and *nonmaleficence* (alternately defined as “preventing harm” and/or “not inflicting harm on others”).

These conflicts and tensions may be most pronounced when we are not certain about the cause of a colleague’s unusual behavior, when we might have suspicions about substance use but little confirmatory evidence. The peril here is failure to act, which may result in harm to the health care professional or others, versus false accusations that could result in the health care professional being forced out of work and numerous patients being left without their physician.

Ethical issues also arise because state physician health programs by their very structure are often coercive. Physicians are not free to refuse evaluation, treatment, or monitoring when the alternative is a report to the state licensing agency. Coerced treatment is effective, but should be applied cautiously and with ethical oversight (46–48). For example, physician health programs commonly require independent evaluations as a condition of initial evaluation, or when the meaning of a positive laboratory is in dispute. These evaluations can cost thousands of dollars. Programs have an ethical obligation to ensure that the physician they are referring for such an evaluation has the financial means to obtain it.

Furthermore, many centers that specialize in evaluating health care professionals also provide treatment at the same site. If a health care professional is sent to one of these sites for a 1- to 5-day evaluation and the recommendation is made for a 4- to 12-week stay (at even greater expense), can we be sure that financial incentives did not play a role in the recommendation? Once such a recommendation is made, it is often hard if not impossible for the state program to overrule it.

Further ethical questions arise because our testing for substances of abuse has become exceedingly sensitive, but serious questions remain regarding specificity of those same laboratory tests and the positive predictive value of their results. For example, many monitoring programs are now checking urine specimens not only for ethanol itself (which has a window of detection up to about 12 hours) but also for ethyl glucuronide (EtG), a metabolite of ethanol with a detection window of approximately 3 days, which can be positive at very low levels. We have seen low-level positive EtG results in individuals who have used alcohol hand wash or asthma inhalers (some of which contain alcohol as a propellant) but who have not purposely ingested alcohol or otherwise relapsed. The Substance Abuse and Mental Health Services Administration has issued an advisory cautioning that EtG testing be used for clinical purposes only, and not used solely as the basis of reports in forensic programs (49).

Given that reporting a positive EtG result can have significant deleterious ramifications for the health care provider, it may be that monitoring agencies should not use this test at all or, if ordered for clinical purposes, not report all positive results to licensing agencies and employers. Reporting all positive EtG results to the licensing board is ethically indefensible. Even if the board does not impose a sanction, the process of investigation has substantial economic and emotional costs for the monitored physician.

SPECIAL CONSIDERATIONS

How should a health care professional inform a potential employer about a history of substance use treatment? We generally counsel professionals to wait to make a disclosure until they know that they are interested in the position, and to make the disclosure in a face-to-face interview. We also advise them to have a short, factual statement prepared and practice it several times before friends or a sponsor. The statement should briefly state that they had a problem with a substance,

that they completed a treatment program and entered a continuing care program that includes laboratory monitoring, what they have learned from this experience, and how it has changed them for the better.

How should professional health programs respond when professionals who are being monitored suffer from conditions such as attention-deficit/hyperactivity disorder (ADHD), anxiety, or chronic pain that warrant treatment with psychostimulants, benzodiazepines, or narcotic analgesics? Most monitoring programs insist on abstinence from all intoxicating substances, including alcohol, illicit drugs, and psychoactive prescription drugs. However, many will allow health care professionals to receive appropriate treatment as long as it is provided by a usual treatment provider who is knowledgeable about the history of substance abuse. This course of action is appropriate. Those with co-occurring substance use disorders and ADHD can be treated safely with stimulant medications (50–53), and that those with co-occurring substance use disorders and chronic pain can safely be treated with narcotic analgesics (54–57).

And finally, medications such as naltrexone, methadone, and buprenorphine may have an important role in managing addictions in health care professionals. Some health care professionals who have had histories of opioid use have been allowed back to practice contingent upon taking daily naltrexone. We are also aware of health care professionals who lost their licenses because of opiate abuse and were eventually allowed to return to practice on buprenorphine maintenance therapy, with the full knowledge of the licensing board. In addition, we are aware of a small number of opioid-dependent physicians who are on methadone maintenance therapy, but as of this writing we are not aware of any who have returned to practice on this medication. We believe that there is merit in allowing health care professionals to return to work either while taking or contingent upon taking medications such as these. In some cases, including those in which healthcare professionals are taking methadone or buprenorphine, a careful neuropsychological assessment and addiction treatment consultation should guide any decisions about return to practice. Just as in general addiction practice, it is unclear when, if ever, these individuals should be weaned off maintenance therapy.

CONCLUSION

Health care professionals are neither immune from substance use disorders nor at higher risk for them. However, professionals' patterns of use often reflect both the availability and knowledge of psychoactive prescription medications. Everyone in the healing profession can facilitate early detection and treatment by helping to educate staff members about these matters, knowing how to refer a colleague for assistance without fear of hurting his or her career, and by ensuring that the colleague receives appropriate workplace support and accommodation.

Health care professionals whose lives have been affected by substance use can and do recover, and they usually can return to work safely and effectively. Early intervention is best, but intervention needs to occur whenever possible. Most states

offer treatment and monitoring programs for physicians, nurses, and other health care professionals. Health care professionals in recovery from substance abuse have high success rates. Great care must be taken to ensure that these professional health programs operate under the highest ethical standards.

INTRODUCTION

To understand the interaction between homelessness and substance abuse requires unraveling multiple strands of a very tangled condition. Statistically defining homelessness can offer some insight into the risk factors for problems with alcohol and drugs, but further elaboration of the myriad stressors of being homeless begin to shed light on the condition, on treatment, and barriers to abstinence. There is agreement that people who are homeless are at an increased risk for substance abuse and dependence. One condition does not automatically cause the other, but each can complicate problems associated with the other. Those who use or abuse substances are more likely to become chronically homeless, have difficulty accessing and receiving treatment for their multitude of problems, including addiction, and difficulty establishing and sustaining sobriety. Ethnicity, gender, and age influence drug of choice and treatment acceptance and success. Interestingly, homeless women substance abusers seem to respond in a more positive fashion to treatment; homeless youth are particularly difficult to treat. Philosophy regarding treatment has evolved from putting supports in place to minimizing the impact of a system that contributes to homelessness, to a focus on and assumption of individual pathology. The literature is replete with multiple treatment modalities that have been developed, although research reflects a gap between research and practice, and their limited success on the homeless substance-abusing population. Recognition and amelioration of the life-challenges, as well as collaboration among community providers to provide support, are imperative to prevent and minimize the disruption and devastation wrought by substance abuse and dependence in this vulnerable population. Ultimately the approach to successful treatment means embracing a more broad world view: Dr Larry Meredith, originator of Treatment on Demand in San Francisco, observed, “If we are going to make a difference with the substance abuse problem, then we have to realize that drug abuse is related to housing is related to health care is related to joblessness is related to poverty. You can’t deal with any one of those without dealing with all of them.” (1).

EPIDEMIOLOGY

Homelessness and substance abuse problems can be intertwined. Defining and discussing the prevalence of both situations will allow a better understanding of the interaction

between the two. There are approximately 2.5 to 3.5 million homeless people in the United States. Of these, 23% were reported to be chronically homeless. Temporary homelessness caused by disasters or evictions is different from episodic homelessness, and it is thought that *chronic* homelessness poses the most significant burden on those who experience it (2). Fifteen percent to 57% of those homeless in urban areas are considered chronically homeless. In a 2006 U.S. Conference of Major 23 City survey on hunger and homelessness, the population demographics of homeless were reported: Whites (39%); Hispanics (13%), Asians (2%); African Americans (42%); Native Americans (4%). Twenty-six percent of them were reported to have substance abuse problems, 16% mental health problems. Thirty percent were family with children, 51% single men, and 17% single women. Causes of homelessness reported from this survey included poverty, unemployment, lack of affordable housing, lack of needed services for substance abuse and mental illness, job loss, domestic violence, and prisoner re-entry (3).

Prevalence of substance abuse problems in those who are homeless has been notoriously difficult to establish because of different definitions, methodologies, and tools for assessment. However, it is generally agreed that about 20% to 35% of those who are chronically homeless have alcohol or drug problems (although some claim it is as high as 50%, with 23% reporting problems with alcohol and 27% with drugs). An additional 10% to 20% have dual-diagnoses (mental illness and substance use disorders) which may exacerbate their life difficulties. In a survey of adult homeless shelter users, Culhane et al. found that *two-thirds of those queried* admitted to mental health or substance abuse problems some time in their life (4). Problems with alcohol use are three times more common in homeless men than homeless women; crack-cocaine dependence is reportedly more common in urban homeless African American men and women. The prevalence of seeking and/or receiving treatment by those who are homeless with substance abuse problems has been poorly studied, although it is suggested they have significantly limited success in accessing services (5). Intriguingly one article reports that in their study 30% of their homeless population reported using more substances when homeless, 71% reported using less, with 50% of those using less because they were in recovery, while 22% reported using less because they simply could not afford the drugs (6).

Men are two times more likely than women to receive treatment. Those aged 18 to 25 are thought to have the highest

rate of treatment need, *but* the lowest rate of treatment receipt. About 18% of those homeless who have substance abuse problems receive substance abuse treatment from a specialty facility. Of those who are admitted for inpatient substance abuse treatment, those there for first admission report marijuana as their drug of choice; those with greater than four admissions report their drug of choice is opioids, and are more likely (24% vs. 8%) to be homeless (7). Thirteen percent of those in substance abuse treatment were homeless at the time of admission (this translates into >120,000 admissions for substance abuse treatment by persons who were homeless) (8). It is reported that one-fourth of the homeless admitted for substance abuse treatment had co-occurring disorders (mental health and substance abuse), and that one-third to one-half of homeless vets have co-occurring disorders. Among jail detainees with mental illness, 72% had co-occurring disorders (3). Homeless addicts also impact on other systems of care. A recent study reviewed over 5000 acute hospitalizations of those who were admitted because of suicide and substance abuse (substance-induced suicide syndrome). These folks were more likely to be homeless, unemployed, uncooperative, have shorter lengths of stay, and have more rapid improvement in their symptoms. This study concluded there is a need for intensive addition component to outpatient care and additional outpatient services to care for suicidal substance-abusing patients (9).

Those who are homeless are at risk for being substance abusers. Risk for substance abuse as predicted by gender, length of time afflicted with substance dependence, and ethnicity can be powerful reflections of the need for services. Co-occurring disorders are common (and discussed in another chapter). It is readily apparent from the extant literature that these people are living disrupted lives and are in desperate need of support and treatment.

SOCIOCULTURAL CONSIDERATIONS

There are numerous sociocultural risk factors to consider in understanding the development of substance use/abuse in the homeless population. Osher and Dixon (10) declared there were three factors contributing to the link between substance abuse and housing problems:

1. *Systems issues* (like the restricted eligibility for housing for those who used substances and the exclusion of those with dual diagnosis to access to public housing)
2. *Legal issues* (limitations of providing SSI for those with substance abuse, those with criminal records not eligible for public housing)
3. *Clinical factors*. For example, people with substance abuse often have histories of social awkwardness, psychotic behavior, poor hygiene, daytime sleep (with nighttime wandering), smoking in undesignated areas (or leaving doors unlocked for easy outside access to smoke), or violence. Landlords view these behaviors as unacceptable and are considerably less likely to rent to people with these kinds of behaviors.

Other comorbid conditions predict homelessness as well: poor treatment compliance, medical problems, poor money management skills, and greater use of crisis services (11).

SAMHSA (Substance Abuse Mental Health Service Administration, a federal oversight organization that coordinates setting of federal standards, monitoring, and research funding) notes other challenges for those with substance abuse and homelessness that can complicate their lives:

1. *Inadequate access* to appropriate screening
2. *Fragmented services*
3. *Lack of appropriate discharge planning*
4. *Poor integration of care*
5. *Insurance coverage limitations*
6. *Stigma and discrimination* (6)

Individual characteristics can also interfere in treatment considerations and delay engagement by the consumer into treatment: these include disaffiliation/social isolation, distrust of caregivers and authority, mobility, and multiplicity of needs (6). Although society and governmental and funding agencies may be distressed by homeless people with substance abuse problems, some of these homeless people do *not* view substance abuse treatment as a high priority, or even important. A recent survey asked homeless persons what they needed urgently. They responded: finding a job (42%), help finding permanent housing (30%), and assistance paying expenses. The 13th most frequent response was treatment for use of alcohol or drugs; only 5% mentioned detoxification (12).

Other social/cultural considerations are extant as well. Men are more likely to report alcohol- and drug-related problems, while homeless women are more likely to report higher rates of mental illness. Koegel and Sullivan found substance abuse service use was predicted not by need but by other factors (race/ethnicity, location, perceived social support, health insurance). Women need child care; once offered, this enhances positive outcomes for women in treatment. Research reflects that there are more positive results in treatment of homeless women with substance abuse, perhaps because programs take into account physical and sexual abuse and motherhood (13). In a group of adolescents studied for several years, it was noted that ultimately about 5% become homeless. Risk factors associated with this included poor family functioning, few financial supports, and separation from parents or caregiver. These observations might have an impact on decisions for early intervention (14).

And finally, conceptualization of substance use and abuse as an issue of individual responsibility has influenced the development of treatment protocols. In lieu of addressing individual needs for housing, stable funding, work, social skills development, substance abuse often is considered, by policy makers and funders, to be a disease of choice, and treatment philosophy embraces addressing individual pathology instead. System level features (how and which services are provided, how access to services is structured) affect how

homeless people with substance abuse problems access the care they need.

FACTORS INFLUENCING SUBSTANCE USE IN PEOPLE WHO ARE HOMELESS

Numerous factors contribute to the development and maintenance of substance abuse in the homeless population. *Access to care* remains a huge obstacle for those who are homeless and have substance abuse. But access must be more broadly drawn; a wide variety of services are necessary to keep people supported once they are housed, and access to these services is critical: “health care, mental health care, money management, benefits assistance, job training, transportation, parenting skills” (15).

Funding of mental health and substance abuse services is often along separate funding streams, with discrete lines for monitoring, reporting, standards, and accountability. As such, patients needing access to both kinds of treatment may find themselves treated by two sets of clinicians who often have opposed therapeutic skills sets and different established goals and expectations of outcomes.

Funding for housing must always be a salient consideration. While Section 8 housing is often refused for consumers with a known history of substance abuse, other federal resources have been made available: Community Development Block Grants (CDBG) and the McKinney-Vento Act in 2000 have authorized federal homeless assistance programs to provide transitional and permanent housing to the homeless; access to stable housing is paramount in the battle for sobriety (15).

The concept of *treatment matching* (matching patient needs and characteristics) with specific treatments has been studied, but not supported by research. Exploration of what types of clinician “treater styles” work most effectively with what kind of patients is an intriguing research paradigm, but one that is as yet unexplored.

TREATMENT

Before turning to an explicit discussion of models of care, it is important to consider defining successful outcomes: these can include complete sobriety, graduation from treatment programs, attainment of life skills objectives (employment, school, money management, housing), change in psychological realms, improvement in interpersonal relationships, ability to cope with problems and stress, and a global improvement in one’s life. Which goals are pursued and achieved will depend on a variety of factors, including the system of care and personal attributes of the individual. For now, present research seems to focus mainly on treatment program completion.

Different models of care have been proffered for the treatment of homeless persons with substance abuse problems. A survey has reported that the *most frequent* inpatient treatment for homeless persons with substance abuse is hospital detoxification, and the most likely outpatient treatment is a 12-step recovery program. Interestingly, however, most research has been done on day treatment and therapeutic communities.

Models of care include the medical model, the social model, 12-step recovery, harm reduction, intensive outpatient, day treatment, case management, and contingency management interventions.

The *medical model* (particularly medical detoxification) was an early focus in the treatment of addiction; however, only about 5% of people with alcohol dependence need acute medical intervention. A consistent finding in research effectiveness treatment is the connection between length of time spent in treatment and positive treatment outcomes; unfortunately dropout rates can be as high as two-thirds. Brief interventions have not been found to be useful in the homeless substance abuse population (5). As such, an acute care model like the medical model is typically insufficient for someone with chronic homelessness.

The rise of the *social model* reflected the different needs of a chronically ill population; its key characteristics include

1. *Use of nonprofessional staff* often in the midst of their own recovery, who do not make diagnoses, but instead act as role models;
2. *Open admissions* with less record keeping and no standardized assessment;
3. *A reliance on natural recovery* (vs. therapeutic treatment)
4. *A focus on experiential knowledge* and spiritual understanding (compared to formal diagnoses and professionally driven treatment plans) (16).

While both models are typically noninstitutional, and view alcoholism as a treatable disease that requires personal responsibility for recovery, the social model is considered more cost-effective, and as such, primarily serves indigent populations. Unfortunately, there are no reports of randomized clinical trials for efficacy of social model patients followed longitudinally.

12-step recovery programs, which include self-help and peer support, are the dominant approach to treatment of alcoholism in the United States. There is some support for the effectiveness of this treatment (17), but little research on the efficacy of this approach with homeless substance abusers per se, although there is speculation that it might be helpful in addressing the need to connect with a supportive community (5). The focus on sobriety may not meet the total needs of the homeless individual (which include affordable housing and stable employment), which would leave them at risk for relapse.

Another model of substance abuse treatment is known as *harm reduction*, which is designed to provide a variety of services to meet the individual needs of *each* drug abuser; instead of demanding users conform to rigid program requirements, treatment is designed to meet the individualized needs of persons with substance abuse problems (5).

Results of treatment may differ depending on client makeup (solely substance abuse vs. dual diagnoses), model of delivery, and availability to and intensity of additional services (5). Treatment for this challenging population must include addressing *both* the homelessness *and* the substance abuse. As noted above, multiple programs exist to address

housing. Once established in housing, many individuals, with supports, are able to remain housed, are less likely to use crisis services or hospitals, or end up detained by law enforcement (15). *Housing First models* (see discussion below) seem to enhance users' acceptance of treatment, as well as retention, particularly if wrap-around high-intensity services are proffered.

Given the statistics above, it is apparent that those who are homeless have an increased need for treatment but will probably face more difficulty in accessing it. Multiple models of care have been developed and efficacy research performed. Unfortunately, considerable flaws in design and execution, as well as small sample size and ethical concerns, have conspired to limit interpretation of results as well as replicability. Issues regarding dropout rates must be addressed; dropout rates as high as two-third are common, so the occurrence of relapse (and the offer of relapse prevention) must be expected, and hopefully used as opportunities for growth and change via *nonjudgmental* intervention (6). Predictors of poor housing stability include assaultiveness, self-destructiveness, and medication noncompliance.

A variety of housing modalities have been offered and studied (6):

1. *Supportive housing* (either scattered site or congregate)
2. *Housing ready* (compliant contingency, stay if sober, ready to occupy housing, psychiatric stability, sobriety, willingness to comply)
3. *Housing First* (placement in housing regardless of clinical status or receipt of mental health or substance abuse services). As per Dr Tsemberis, "Once housed, individuals' priorities shift from ensuring their survival to improving the quality of their lives, and that's when they become interested in other services." Studies show that those enrolled in Housing First had 80% housing retention compared to 23% in usual care group; a significant reduction in hospitalization was also reported (18).
4. *Wet housing*: where substance use is discouraged but allowed without consequence on site; abstinence may be an unrealistic standard for most dually diagnosed residents during the engagement and pretreatment stages.
5. *Damp housing*: where substance use is discouraged, not allowed on site, but tolerated off-site.
6. *Dry housing*: where substance abuse is not allowed; any use results in dismissal from the program.
7. *Transitional housing*: location in housing that is stable, but temporary; occupancy changes as one advances through program.
8. *Permanent housing*: stable housing considered an end point (no further moves necessary); typically associated with wrap-around services (learning social skills, activities of daily living, help with transportation to appointments, accessing medication) that help the patient remain in independent living. Of note, the strongest predictor of program completion is the existence of social supports.
9. *Therapeutic communities*: where substance abuse is conceptualized as a disorder of the whole person, with problems not just with drugs or alcohol but also in conduct, attitudes, moods, emotional management, and values. Therapeutic communities promote sobriety, and set goals of eliminating antisocial behavior and facilitate a change in lifestyle, including attitudes and values (19).

Stabilization of housing should always be part of the consideration in the overall treatment plan. As noted above, numerous housing models have been attempted with mixed results. A recent meta-analysis of 30 studies on housing models for persons with mental illness examined 44 different housing situations; the results reflect that more stable housing results if the patient participates in a program that assumes a model of care (vs. nonmodel housing). Permanent supported housing (where a consumer is established permanently and offered considerable support to remain in independent living) has the largest effect on stabilizing housing, but there was no statistical difference between the housing models (permanent supported housing, residential) (20).

Linkage to services necessary to survive being homeless also plays a huge role in the recovery of homeless people with substance abuse problems. The need for an integrated, comprehensive, community-based system of care has been shown numerous times. These services can lead to employment, permanent housing, decrease in legal problems, decreases in substance abuse, and improved mental health (6). To meet the challenges for this population, multiple supports should be offered: aggressive outreach, permanent housing, treatment environment, strategies to increase motivation, family-based therapy, and peer leadership.

This *Linkage Model* is somewhat diffuse and less demanding, and may be the only form tolerated by those who are actively using (5).

Others have come forward noting that linkage to services, while important, misses a major consideration: the individual. Mueser et al. have written extensively on the use of the *Integrated Model* to approach housing instability in those with dual diagnoses. The basic guidelines of treatment approach by Mueser et al. include (21):

1. *No wrong door* (the patient can enter services via housing, substance abuse, or mental health treatment door)
2. *Shared decision making*
3. *Treatment that is comprehensive and assertive*
4. *Less focus on negative consequences*
5. *Time unlimited*
6. *Multiple therapies offered*
7. *Culturally sensitive*

Mueser et al. encourage clinicians to remain "invested and optimistic" (p. 309), avoiding, if they can, blaming clients for their addiction.

In Mueser's paradigm of Integrated Treatment, it is understood that individuals possess variable levels of motivation to begin treatment and become sober. As such, a process of assessing, inviting, and strengthening motivation is key and includes multiple steps.

Engagement

This is the first step in treatment. A working relationship is established, typically via outreach to the patient in his or her own environment, or in a safe, nonthreatening environment. Practical assistance is offered, including crisis intervention, support, stabilizing medical and mental health problems, reducing legal issues, and encouraging family involvement. A study of homeless dually diagnosed men and women reflected that men say themselves as forced into treatment; as such, it has been suggested that motivational interviewing might enhance the men's need for control and as such might be particularly effective for this subset of the population (22).

Persuasion

The patient slowly becomes aware that substance abuse is creating problems in his life. The individual and family begin to meet, and group meetings discuss the pros and cons of substance abuse. Nonsubstance abuse social skills are encouraged (how to get together in nonsubstance abuse venues). Structured activities are offered, including social and recreational outlets. Damp housing is considered, and a focus on psychiatric stabilization ensues. The patient is approaching a time when they understand the consequences of their substance use, and are sufficiently engaged and supported to move into active treatment.

Active Treatment

Active treatment is comprehensive. It includes outreach and case management. It is interesting that Mueser et al. caution against reliance on self-report, because even at this stage, consumers notoriously underreport or do not report substance use. Hopefully, substance use begins to abate, and the consumer is offered strategies to reduce substance abuse, like social skills to resist peer pressure. Self-help groups like AA (Alcoholics Anonymous), NA (Narcotics Anonymous), and Recovery Anonymous are encouraged. Individual therapy is offered and patients learn to substitute healthy activities for substance using activities. Medications (disulfuram [an alcohol antagonist], naltrexone [an opioid antagonist]) are considered to help maintain sobriety. Dry housing can be offered, as well as techniques for coping with stress.

Maintenance/Relapse Prevention

Maintenance and extended recovery are the focus. Interpersonal social skills are honed, as are problem-solving skills. Lifestyle improvement can be tackled (smoking cessation, improved diet, and exercise). Independent housing can be attempted and the consumer can offer himself or herself as a role model for those in earlier stages of recovery.

Efficacy of Integrated Treatment has been a focus of research. The following results have been reported (integrated treatment vs. usual care): increased retention (55%), decreased

substance use (40%), employment (40%), stable housing (60% vs. 50%), money for basic needs (70% vs. 45%), \$6000 per individual in criminal justice savings from fewer arrests, and fewer hospitalizations.

Beyond Integrated Treatment, other forms of treatment reported in the literature include

1. *Intensive outpatient treatment* to homeless people (23) should include linkages to shelter and/or public housing; provision of food, medical care and social services, case management, long-term rehab, and strategies to engage chronically homeless.
2. *Day treatment* found to be useful in homeless cocaine abusers (17). This includes active programming each day (6 to 8 hours), including community meetings, psycho education (relapse prevention, assertiveness, medical awareness, relaxation, 12 steps, and job training), and individual and group counseling, with eventual transition to aftercare programs for relapse prevention (24).
3. *Assertive outreach*: case managers diligently and robustly reach out to potential consumers with the hope of engaging them in treatment.
4. *Modified therapeutic communities* seek to incorporate additional services to address the needs of those who are homeless (education, jobs, legal, housing); they are somewhat more flexible than traditional therapeutic communities and often last 18 to 24 months. Research reflects they are a viable treatment option for homeless mentally ill consumers.
5. *Contingency management interventions* where housing/work placement are contingent on provable sobriety. There is little research to support the concept's usefulness.
6. *Intensive case management*: includes "outreach, assessment, treatment planning, linkages, monitoring and evaluation, client advocacy, crisis advocacy, system advocacy, supporting counseling, practical support, and program linkage." (5) This form of support seems particularly challenging with a homeless population who suffers with issues of control and trust (as they may have a fear of being watched or monitored and dislike intrusiveness and drug testing). While its general efficacy has not been established by research, it definitely decreases hospitalization and emergency department visits.
7. *Residential programming* where the intent is to stabilize housing so that access is gained to the patient to begin engagement in treatment.
8. *Lottery*: for allotted time periods of sobriety or completing therapeutic tasks, patients earn "lottery" tickets that offer them a chance to win prizes.
9. *Payeeships* where a person besides the recipient of a disability check is named to supervise the use of the check. Research shows those involved have fewer days of homelessness, but there were no positive substance abuse outcomes.

A wide variety of treatment models have been tried, proved effective with some individuals, but overall, no statistical significance between treatment modalities has been

reported in the literature. One key issue does resonate: treatment must be long-term. Brief interventions have been reliably demonstrated to have no long-lasting effects when utilized with those who are homeless and have substance abuse problems.

Experience has demonstrated that interagency collaboration is imperative. People who are homeless and have substance abuse problems have complex multiple needs that require responses from a wide variety of agencies. Linkage to said agencies is imperative. Unfortunately, there are funding limits, limits in information technology, lack of available services, lack of political will, and legislative/political opposition (6).

Unfortunately, there have been sustained limits and/or decreases in funding. For example, CSAT funding dropped 10 million over 3 years (2005 to 2008) to 91 million. This occurred even in the face of positive results from CSAT treatment for homeless program that showed an increase from 50% to 72% of participants in terms of sobriety from drugs and alcohol. In addition, homeless families have benefited from CSAT treatment (1600 families studied and placed in treatment, illegal drug use dropped from 25% to 14% over 14 months of treatment). Regardless, funding has been capped for many substance abuse treatment programs.

In spite of gloomy economic times and possible further cutbacks, efficacy research still occurs and is being published. Use of case management has been researched with some positive effects (25) reflecting statistically significant decreases in psychosocial problems, homelessness, health insurance, and SSI, emergency room use and cost. Okin et al. (26) also reported efficacy in the use of case managers. Fifty three high-service utilizers were studied (pre and post case management). With intensive case management, median emergency room visits dropped from 15 to 9, and costs were significantly reduced because of fewer admission. Homelessness dropped by 257%. Alcohol use dropped by 22%, and drug use by 26%. Every dollar invested yielded \$1.44 reduction in hospital costs.

Retaining patients in treatment is a core issue (recall the correlation between the length of stay in treatment program and successful outcomes). Retention is more difficult in the homeless population than those in stable housing. Provision of housing increases retention but as research reports these gains are negated when housing is bundled with *high-intensity* services. People do leave programs for a variety of reasons; perhaps if programs discern the patient's concerns the program might be able to do a mid-process correction that will entice the consumer to stay. People quit because of "A lack of motivation, a desire to return to outside world, a delay in starting treatment, dissatisfaction with degree of program structure, dissatisfaction with program environment, difficulty with transportation, and failure to see value." (27).

In one study it was demonstrated that homelessness dropped 43% over 3 years; the most consistent predictor of failure (more risk of homelessness) was crack as drug of

choice. Less risk (or more likely success of sustaining housing) was associated with others depending for food/shelter on the identified homeless person with substance abuse problems. Unfortunately, specific treatment factors did *not* predict outcomes (28). It has been demonstrated that crack-abusing homeless persons who were enrolled in an abstinent-contingency work/therapy/housing program could successfully complete the program. Certainly postdetox stabilization is associated with improved outcomes for homeless addicted person, demonstrating the treatment modality might slow the "revolving door phenomenon of relapse" after detoxification among homeless people (29).

Limits of research into treatment efficacy include concerns about the validity of patient self-report and ethical constraints of placing homeless people in randomized experiments.

In spite of these barriers, ultimately it would appear that programs that are the most effective are ones that address homeless client's tangible needs (housing, employment) as well as their addiction, are initially flexible and non-demanding, are targeted to specific needs of sub-populations (gender, age, diagnoses), and provide long-term continuous interventions (5).

Meyer and Schwartz note (30): "In practice, despite the conceptual understanding of the role of structural causes of homelessness, homelessness has been studied as if it were a disease, an outcome defined as residing in the individual." As such, the federal response has been to support programs to halt alcohol and drug abuse rather than address issues regarding housing markets and urban economies. Studies and services focused on individual pathology models might have minimal impact on the structural issues that "exacerbate or even cause these individual pathologies; substance abuse problems among homeless individuals and their treatment needs should be viewed from a structural perspective as one piece of a much bigger societal problems." (5). A focus on tangible needs of the homeless (housing, money, employment) is certainly necessary, but to date, in the research literature specific *treatment* modality does not appear to differentially affect outcomes. Certainly, "global" treatment has positive effects, but even these diminish over time if treatment is not sustained.

Stuart Gitlow

INTRODUCTION

The status of disability, a legal finding, is based upon an individual's level of impairment as determined through medical examination. Clarity in the field of impairment and disability can be difficult to achieve. A patient with 20/20 vision is less able to see distant items than an individual with 20/10 vision, but is the patient impaired? Would the answer differ if the patient himself had previously enjoyed 20/10 vision? What if the patient's occupation is "sharpshooter," a position dependent upon his having 20/10 vision? Impairment and disability may be assessed in comparison to the average abilities inherent in the general population, the average abilities of a population of individuals of similar age and heritage, or to a baseline level of ability for a given individual. In another example, an individual has occasional but rare seizures; how common must the seizures be for this person to be impaired through a restriction from driving? And would the person be permanently restricted from driving, or would the restriction be time-limited based upon the date of the most recent seizure? Would we change our assessment if the vehicle being driven were a school bus or ambulance rather than a personal car? Would the restriction be determined based upon population epidemiologic studies, or would it be based instead on an educated opinion from the treating physician? How do we weigh risk to the individual and to society as a whole versus the potential individual productivity and societal benefit? Whole textbooks exist to focus upon these issues, yet such texts have given minimal attention to the topic of addiction.

Under the 1990 American Disabilities Act (ADA), drug addiction is included among the list of physical and mental impairments. An individual with addictive disease is noted to be disabled if the addiction "substantially limits one or more major life activities," if the past addiction was limiting, or if the individual is "regarded" as having addictive illness. The law then makes an exception, excluding those engaged in illegal use of drugs, such as underage use of alcohol, use of controlled substances without prescription, or use of illicit substances. This exception underscores the role of the legal system in the determination of disability: two individuals with equivalent addictive disease, where one uses alcohol and the other marijuana, may have equivalent medical findings and impairments but one is found disabled and the other not.

In 2001, the World Health Organization (WHO) endorsed the International Classification of Functioning, Disability, and Health (ICF) (1). The ICF recognizes that disability is a universal

experience in which every individual will at some point likely have a decline in health and thereby experience some degree of disability. Disability is therefore no longer perceived only as a medical or biologic dysfunction. That said, there are multiple working definitions of impairment and disability applied throughout industry for purposes of Social Security, worker's compensation, and insurance coverage. The earlier 1980 WHO construct is an approach still sometimes applied in industry:

"A disease, disorder, or injury produces an impairment causing a change to ordinary functioning. Impairment refers to ... loss or abnormality of psychological, physiological or anatomical structure or function. A disability refers to the resulting reduction or loss of ability to perform an activity in the manner considered normal for a human being. ..." (2)

More recent WHO statements indicate impairments as "problems in body function or structure such as a significant deviation or loss" (3). Other models include the United Kingdom's Disability Discrimination Act of 1995, which indicates that individuals are disabled if they have "a physical or mental impairment which has a substantial and long-term adverse effect on her or his ability to carry out normal day to day activities" (4). The Act contains guidance as to how to interpret terms such as "normal" contained within the text.

In essence then, impairment is often defined as an alteration in function from the population normal, not from the individual's premorbid state. However, there are times when impairment would be present without departure from the population normal. Imagine that dementia has caused degradation of IQ in a specific individual from 140 to 100. The individual now has normal IQ but can no longer perform the same tasks as he could formerly perform, at the same pace, or with the same degree of accuracy. This might result in decline in his ability to litigate as a lawyer, to play on stage in an improvisation, or to win at gambling. While this individual is not impaired when compared to the population norm, his own inherent abilities to do what he once did have deteriorated. Rather than looking at impairment as being the abnormality of structure or function, it could be defined as the deterioration of structure or function, with disability as one potential consequence of such impairment.

Just as an individual can be suffering from severe illness without resulting impairment, an individual can be impaired without being disabled. An example of impairment could be a decline in IQ from 140 to 125 after a head injury. But perhaps this same individual shows that he can still interact socially, play guitar, and carry out the usual activities

of his daily life and work as he did in the past. Impairment is present—a measurable and objective decline in function as a result of a medical event—but there is no resulting adverse effect of the impairment, and therefore no disability.

Returning to the 2001 ICF brings up two additional terms of interest: limitations and restrictions. Disability is referred to as limitations of activity, those actions that an individual is *unable* to carry out. Handicap now is covered as restrictions in participation, those actions an individual *should not* carry out. Differentiating limitations from restrictions is a frequently encountered section within disability forms filled out by clinicians. A mildly intoxicated person may be able to drive, but should not drive due to the loss of coordination and potential risk to self and others; that person would therefore be *restricted* from driving. At higher blood levels of substance, the level of intoxication would be so high that the person would be unable to walk to the car, open the door, get in, or start the car. At this point, the person would be *limited* with respect to ability to drive. Occupational limitations are often tied directly to the type of limitations that are present. It is therefore inappropriate for the clinician to indicate simply that a patient is unable to work unless the clinician is aware of the diagnosis, impairments secondary to that diagnosis, the resulting limitations, and the degree to which those limitations would directly impact the patient's ability to carry out the activities inherent in his or her occupation.

It is evident by now that determination of disability secondary to an impairment is more than a question of science. Moral and policy issues have therefore been explored in the literature in depth (5).

PRIMARY INFORMATION SOURCES

Several sources of disability information are available; each has a somewhat different perspective and different purpose but can be used together to gather information related to disability secondary to most given illnesses or conditions.

- Guides to the Evaluation of Permanent Impairment (6)
- Occupational Medicine Practice Guidelines (7)
- Official Disability Guidelines (8)

The current edition of the *Guides to the Evaluation of Permanent Impairment* has a chapter dedicated to mental and behavioral disorders, but no separate section related to addictive diseases. The mental disorders chapter provides a method of evaluating psychiatric impairment, perhaps the closest the text comes to evaluating addiction-related impairment. There is broad recognition within the text that the presence of a psychiatric illness does not necessarily reflect the presence of impairment or related limitations. For example, an individual might be so depressed as to commit suicide, yet a retrospective analysis of that individual's life might reveal him to have been carrying out all of his usual activities without any apparent difficulties. That individual would have potentially had severe psychiatric illness, yet no impairment. Conversely, a tractor-trailer driver following an accident might have only mild anxiety when seen in the

physician's office upon examination, yet could be markedly limited with respect to his ability to function occupationally due to findings which would only arise while at work.

The *Guides* indicates four domains within which psychiatric function can be assessed:

- Activities of Daily Living
- Social Functioning
- Concentration, Persistence, and Pace
- Deterioration or Decompensation in Complex or Worklike Settings

Depending upon findings within these areas, a degree of severity may then be applied to impairment within each domain, chosen from these categories: none, mild, moderate, marked, and extreme. Finally, dependent upon the number of domains in which one has significant severity, an assessment may be made regarding the degree of overall impairment and resulting limitation.

The *Official Disability Guidelines*, unlike the *Guides*, specifically addresses issues of addictive disease. This text focuses on the duration for which an individual with a given illness is likely to remain limited in terms of his ability to carry out his occupational function. For addiction, whether to alcohol or other drugs, these guidelines indicate that patients are no longer impaired after approximately 1 month—at worst. Patients who do not require inpatient care or rehabilitation are presumed to be unimpaired after only several days. Since addictive disease is a chronic lifelong illness, it seems reasonable that these guidelines are focused upon an individual who is actively using substances, then stops, with the number of days starting at the time of abstinence. This, however, is an assumption on our part and is not specifically stated within the guidelines.

The *Occupational Medicine Practice Guidelines*, while it currently has reference to stress-related disability, does not contain addiction-related information specifically.

DISABILITY AND ADDICTION

Within the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV), the diagnosis of substance dependence may include the criterion, “important social, occupational, or recreational activities are given up or reduced because of substance use” (9), suggesting impairment. But the diagnosis can be met without that specific criterion being met. This is not the case in some primary psychiatric diagnoses such as major depression, which require that “. . . symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.” As a result, the simple presence of a diagnosis of substance dependence differs from some psychiatric diagnoses in that it does not, by itself, indicate the presence of impairment. Axis V of the multiaxial diagnostic system refers to the Global Assessment of Functioning scale. The title of this scale implies that the score for any given individual is a direct reference to that individual's level of function, thereby suggesting that any provided score can be interpreted as the clinician's assessment regarding impairment. *DSM-IV-TR*, however, is quite specific that the scale be used to indicate “symptom severity OR level of

functioning.” As a result, individuals can be accurately given a score of 41 if they have serious symptoms of substance dependence, even if they have no significant impairment in any domain. The GAF therefore cannot be used alone as an indication of impairment level when substance use disorders are present.

For the purposes of disability, one can look at addictive disease as having several phases (Figure 68.1). In phase I, an individual has a sense of discomfort and lack of coping skills necessary to address the discomfort. We can ascribe the discomfort to the genetic aspect of addiction while the lack of coping skills results from the environmental underpinnings of the disease. In phase II, the individual has discovered that use of psychoactive substances leads to acute but impermanent relief of discomfort. The psychoactive substance use therefore represents a coping mechanism, albeit an imperfect one, with which the patient deals with the existing discomfort. In phase III, the individual is using the psychoactive substances to his or her own detriment. In phase IV, the individual has stopped using psychoactive substances and is essentially back at phase I but for the knowledge that discomfort can be relieved temporarily by psychoactive substances. A relapse would lead back to phase III or recovery leads to phase V, in which an individual leaves the circular cycle by discovering new coping strategies (perhaps as addressed within 12-step programs) or by relieving the original sense of discomfort, potentially with pharmacologic or other therapeutic input. Each phase carries with it the potential for differing restrictions and/or limitations with potentially resulting disability.

Phase I

Traditional diagnostic approaches unfortunately do not yet allow for the diagnosis of addiction prior to the onset of substance use itself. Given that addictive disease is not caused by

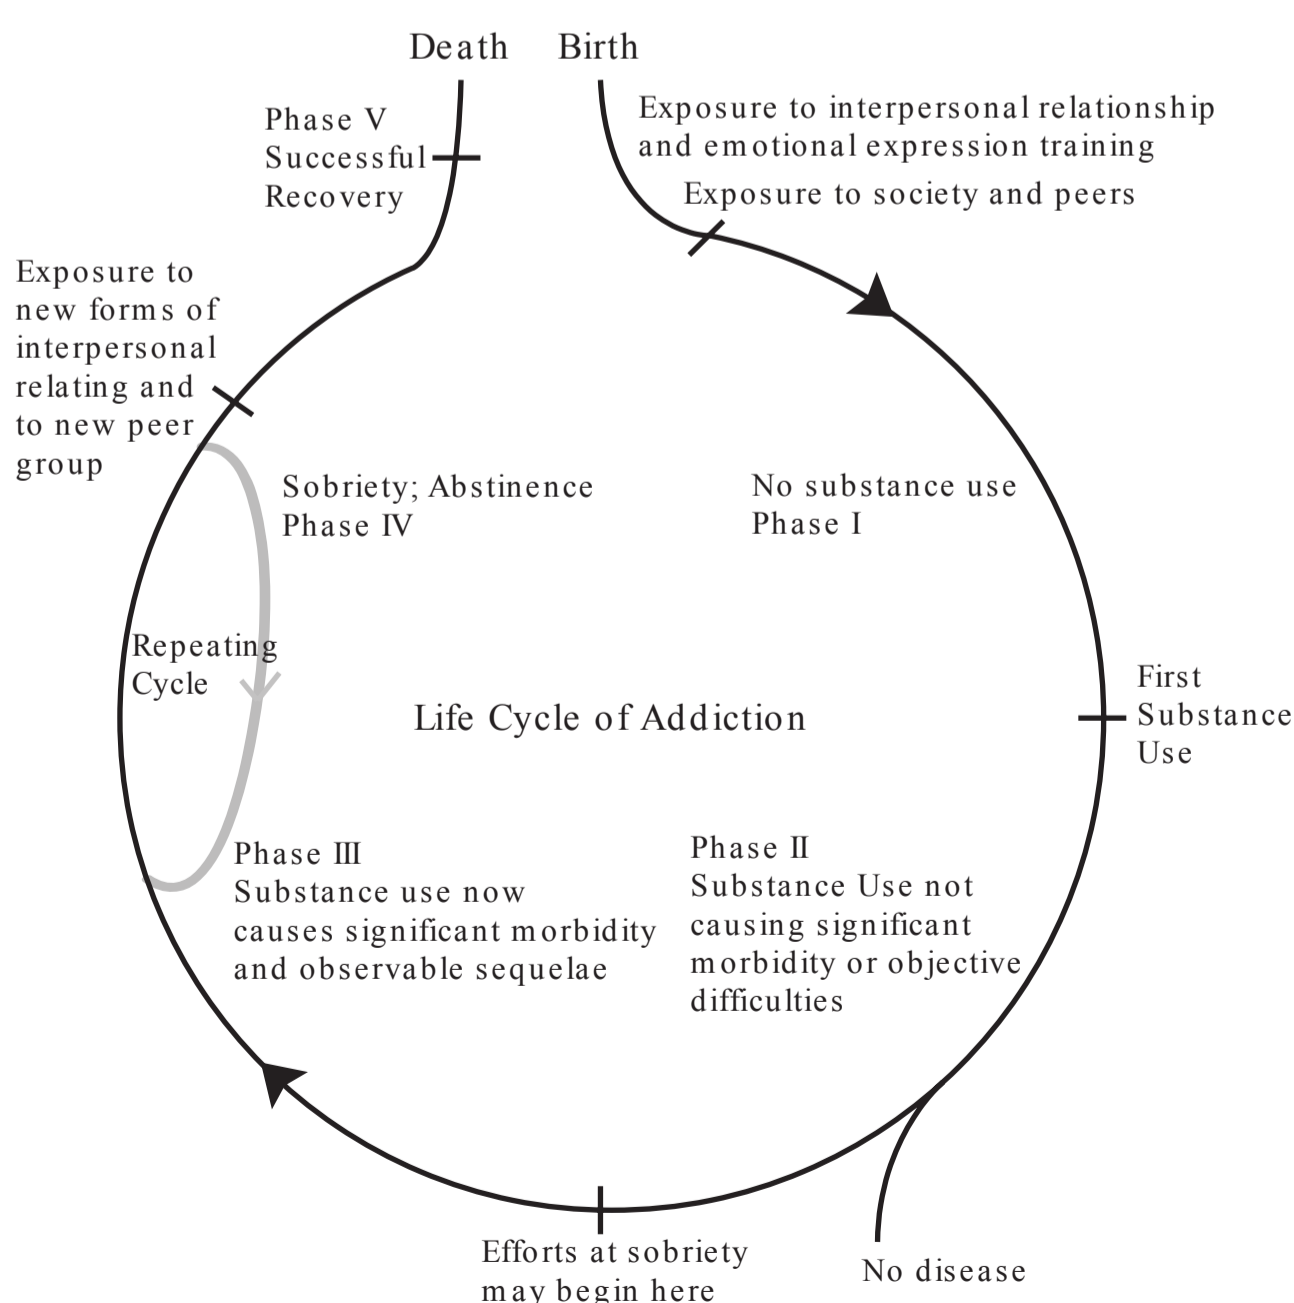

Figure 68.1. Life Cycle of Addiction.

the psychoactive substance involved, it is reasonable to suspect that it exists prior to the initiation of substance use. What is likely to be observed during this time are difficulties with respect to anxiety, or mood variation beyond normal parameters. Since the psychiatric diagnostic approach is largely based upon observed characteristics and subjective reports rather than upon neurochemical studies, patients in phase I of addictive disease, if diagnosed with any disease, are likely to be diagnosed with a primary psychiatric illness. It is unknown whether treatment of the psychiatric symptoms at this stage results in a reduced likelihood of eventual substance use or dependence or whether treatment in these cases has the same degree of efficacy as it does in actual primary psychiatric disease cases. Ultimately, some of these patients may have two disease states, but Occam's razor would suggest that what we are observing is a single disease state not yet fully expressed, comparable to prediabetes or prehypertension. This issue is important as patients will often state that their substance use represents "self-medication" of underlying distress. Their perspective may therefore be that they are treating a primary non-substance-related disease, but objectively this is what addictive disease represents. An individual without addiction, when experiencing a primary psychiatric illness, would not self-medicate with psychoactive substances over an extended period of time. Since, during this phase, addiction is not yet diagnosed, any measurable dysfunction and related disability would be caused by what is diagnosed as a primary psychiatric illness.

Phase II

Here, our theoretical patient has discovered psychoactive substances. Typically, this is a youthful individual who is using alcohol or marijuana, but a middle-aged individual prescribed opioids for the first time is another common scenario. Other substances are frequently involved, often depending upon the geographic region in which the patient resides. Some areas have a high incidence of heroin use, while in others methamphetamine is widespread. LSD and psychedelics are commonly used in some parts of the world as well. During this phase, substance dependence might not be diagnosed. Rather, the user might be placed in a category of substance "misuse" or "heavy use." If patients are first encountered when in this phase, psychiatric symptoms might be ascribed to the substance use itself, as in an alcohol-induced mood disorder.

VIGNETTE 1

Melissa is a 20-year-old college student. She began drinking with her friends on weekends while in high school, never with any resulting difficulties. She graduated in the top quarter of her class and went on to college. Melissa has never experienced any psychiatric issues though she was briefly in therapy after her parents divorced. She now presents to the psychiatric emergency room with a distant gaze and apparent responsiveness to internal stimuli. She is accompanied by a friend who refuses to give his name but who states, "Two days ago, on Saturday, Melissa took a hit of LSD. She said she hadn't tried it before. It looked

like she was feeling good when we all went to sleep early Sunday morning. No one saw her on Sunday, but on Monday when she didn't show up for any of her classes, we had the dorm manager open her room. We found her there—like this.” The patient is admitted to the hospital. Three weeks later, after treatment with antipsychotics, Melissa has shown some improvement but is still delusional, slow to respond to questioning, and showing significant signs of an ongoing thought disorder.

Vignette 1 is a slightly altered actual case from the late 1980s. In disability cases, there are two initial questions—is there impairment, and if there is impairment, is it the result of a medical process? In some legal contexts, those questions may be reversed: Is there a medical process, and if so, is it causing impairment? As we will see later, a third question is often posed: is the medical process involved an addictive illness? In Vignette 1, there is clearly impairment with resulting adverse effects: our patient is unable to think clearly, respond normally within social situations, focus or attend to conversation, or carry out simple instructions. The cause, however, is not clear. Prior to the single use of LSD, Melissa had no history of a substance use disorder or of psychiatric illness. Following one use of LSD, Melissa now has a psychotic disorder. Perhaps Melissa was predisposed to the development of psychotic illness, and in this case the illness was triggered by the effects of LSD. Or perhaps the LSD was contaminated by a substance that led to organic brain damage. In the first few days after LSD use, we might most appropriately determine that impairment is secondary to the acute effects of LSD. Now that several weeks have passed, we might instead find that impairment is due to a primary psychotic disorder. In both cases, LSD represents the likely cause, but the disability determination is different, and can therefore lead to a different final decision in related legal cases.

Another example for clarification would be that of a heavy smoker who develops chronic obstructive pulmonary disease with related impairments. Barring other causes of COPD, the smoking in such a case is a likely cause of the pulmonary disease. In such a case, the pulmonary disease would now be the proximate cause of impairment despite its having arisen as a result of an underlying addiction. Tobacco use or nicotine dependence, taken alone, is not described in any resource as a source of impairment or disability. So looking again at Melissa, the cause of her psychotic disorder is not germane to a finding of impairment as the impairment would be a direct result of the psychosis independent of the etiology of the psychotic state.

Use of substances that is independent of addictive disease may be confusing as such use can lead to impairment. For example, a patient might have three glasses of wine over the course of each evening for many years, then present with insomnia, anxiety in the morning, and low mood. The insomnia may cause difficulties with attention and focus to such an extent that impairment is present. Advising the patient to discontinue alcohol use, if it leads to successful cessation, is an indicator that alcohol dependence was not present; if symptoms remit, that would suggest that alcohol-induced impairment had been present. So one can have substance-induced difficulties without having a substance use disorder. Further, substance use alone,

where such use is independent from addictive illness, can lead to brief periods of impairment secondary to acute intoxication or to the acute withdrawal effects that follow. Acute impairment is not generally a consideration in disability determination. Longer periods of withdrawal with related impairment would generally be found only after extended periods of substance use, more likely found in phase III.

Phase III

Within this phase, individuals are actively using substances despite their best interest. Note that frequency and quantity of use are not related to whether a person falls into this category. Individuals might therefore vary widely from one another: the 75-year-old who has fallen while intoxicated twice, breaking a rib and hip as a result, yet still drinks from time to time; the 25-year-old drinking a pint a day despite losing several jobs as a result; the 18-year-old who does not go to class without first smoking marijuana, despite failing two classes the previous semester; the 30-year-old snorting cocaine on weekends, despite having used up her savings as a result. It is this phase of addictive disease to which the *Official Disability Guidelines* appears to refer.

VIGNETTE 2

Rebecca is a 30-year-old who has been using cocaine for about 5 years. At age 27, she sought medical care for worsening mood variability, with the presence of periods of irritability, depression, and anxiety. She was diagnosed with bipolar disorder and started on a mood stabilizer. A retrospective review of the early medical record reveals that Rebecca had failed to be forthcoming about her cocaine use. Her physician had not done a complete workup for nonpsychiatric causes of mood variability and no drug screen was ever performed. The mood stabilizer failed to have any efficacy and Rebecca's medications have been changed several times in the years since. She now presents to a new physician on an atypical antipsychotic, still having mood variability, but now also having increased weight and worsening results of fasting blood sugar tests. She claims that she cannot work as a result of her symptoms of bipolar disorder and wants disability paperwork filled out. A complete history, obtained from the patient and family members, suggests significant difficulties with social functioning. Further, family members indicate that Rebecca has become unreliable due to her disorganization and lack of focus. She sometimes stays in bed for days and fails to participate in many of her activities of daily living without assistance or encouragement. The new physician performs a urine drug screen and finds a positive cocaine result. Rebecca initially denies any use of cocaine but over the course of early treatment, and following another positive urine screen, acknowledges that she has been spending hundreds of dollars per week for cocaine for years.

In this case, Rebecca most likely was suffering from cocaine dependence and a cocaine-induced mood disorder. The mood variability was due to both the acute effects of cocaine and to its withdrawal effects. Unlike the case of Melissa in

Vignette 1, where the psychiatric symptoms persisted long after a single use of LSD, in this case the psychiatric symptoms have been present only during the ongoing use of cocaine. The proximate cause of any resulting impairment is therefore the cocaine dependence. Naturally, arguments can be made to the contrary. One could speculate that Rebecca has a pre-existing bipolar disorder being self-medicated with cocaine, although even so, there would be no evidence that the pre-existing bipolar disorder was impairing absent the addition of cocaine use. One might also argue that Rebecca was predisposed to development of bipolar disorder, which then arose coincidentally during the time in which Rebecca was using cocaine actively. Again, though, it would not be clear that the bipolar disorder is impairing in the absence of cocaine use, since no such time period has yet taken place.

If we view impairment as a medical question, and disability as a legal one, it is clear in this case that Rebecca is impaired, but the cause of disability must be demonstrated to a legal rather than a medical standard. Two potential sources of information would be necessary to demonstrate that the impairment in this case is not secondary to cocaine use. The first source would be the existence of a medical record prior to the initial substance use while the second would be an evaluation performed after the direct and withdrawal effects of cocaine have passed. Difficulties are present in both situations. Few patients with addictive disease are forthcoming about their substance use, especially during the early phases of their illness. It can be difficult, if not impossible, to accurately determine the initial date of substance use or to determine if early medical records reflect substance-induced disease rather than a primary psychiatric illness. Difficulties with the second possibility, the evaluation after cocaine use has been terminated, arise due to the long period of time that passes before brain function returns to its original or new baseline. It is also critical from both legal and medical perspectives that ongoing urine drug screens be regularly collected. These, if negative, will serve the legal requirement of representing an objective measure of the absence of cocaine-induced disorders, as well as the medical requirement of ensuring that the proper disease is receiving ongoing treatment. Long-term withdrawal effects are possible not only with cocaine but with other drugs such as alcohol, where sleep, for example, takes many months to return to baseline, potentially resulting in impairment for an extended duration.

Phase IV

Impairment resulting from the acute effects of substance use is no longer present by this phase, and patients here are abstinent from substance use. They are not participating in an active recovery program, but psychiatric symptoms are minimal and mental status exams will often reveal no significant findings. Treatment for the substance use disorder is often terminated after the completion of rehabilitation despite the lifelong nature of addiction. The patient in this phase is therefore still suffering from an ongoing illness, but denies any symptoms on history and indeed has no significant objective findings on exam.

VIGNETTE 3

Don is a 48-year-old bartender who was diagnosed 10 years ago with alcoholism. He went through rehabilitation at the time of diagnosis, then returned to his family and his occupation. Three years later, he relapsed, drinking steadily for 12 months though continuing in his position as bartender. He went through rehabilitation a second time, was discharged, and returned to his prior life. Again, he remained abstinent for several years. Finally, however, he relapsed again last year. He presented for treatment, this time with hepatic abnormalities on lab studies, went through medical and addiction treatment, and now presents for follow-up. His liver enzymes are back to baseline, within the normal range. There are no abnormalities on mental status examination. Don has remained sober for 2 months and feels ready to return to work. He is active at home, carrying out all his regular activities without difficulty. He is able to drive and often spends part of his day caring for his young children, again without difficulty. There are no signs of impairment present.

Don is not impaired and therefore is not limited. There remains a significant question as to whether Don should be restricted. That is, is it in Don's best interest to return to his job as bartender? Or should Don be restricted from working in occupations where there is frequent exposure to alcoholic beverages? There is no scientific literature upon which to draw a conclusion. The literature contains references to relationships between work-related stress in general and alcohol use behavior, but does not contain specific studies dedicated to determining the ability of alcoholics to return to a workplace where alcohol is used. One could make the argument that this would be akin to having the fox guarding the henhouse, that the exposure to alcohol on a daily basis would eventually lead to a lack of willpower on the part of the patient who would therefore inevitably succumb. However, one could also posit that alcohol is omnipresent in society, available in every corner liquor store, advertised and promoted in billboards and on television, and that the slight added convenience imposed through work in a bar would not necessarily prove devastating.

A middle ground could be developed that would look at available information:

- Number of years in which the patient was actively using the drug
- Number of years in which the patient has been sober
- Family history (degree of genetic loading)
- Recovery participation and ongoing treatment
- Medical and psychiatric comorbidities
- Number of prior relapses following treatment

This information could then be used to essentially calculate the odds ratio of relapse comparing a return to bartending versus an entrance into another occupation. If indeed it is found that the odds are against the patient should he return to bartending, that alone would not be sufficient for a restriction to be in place. Indeed one might find that the odds of having alcohol-related disease are higher for anyone bartending versus not bartending. For a restriction to be imposed, the

odds ratio would have to be significantly worse for the addictive disease population than it would be for the control population. Otherwise, the entire population would be restricted from this type of work. And again, there are no data available to demonstrate such a comparative odds ratio finding.

Phase V

In this phase, the patient's addictive illness is still present, but the patient no longer has evident symptoms of the disease. The patient is actively participating in a recovery program, regularly sees his physician, and has his health monitored with respect to his substance use disorder. Urine drug screens, liver function tests, and other quantitative studies are performed in addition to collection of subjective reports in order to ensure or support those reports. Direct effects of former drug use are now minimal, though there may be some continued nonimpairing difficulty with sleep, motivation, and mood stability depending on the original drug of choice and assuming no comorbidities.

VIGNETTE 4

Mary is a 41-year-old anesthesiologist who was caught using Fentanyl while in the OR. She was turned in to the state's physician health board and her license to practice medicine was suspended. Three years have passed. Her license to practice has been returned. She has been abstinent from all addictive substances for 3 years. She has been attending 12-step programming regularly. She currently has no psychiatric or medical symptoms. History reveals that Mary had been using Fentanyl on an intermittent basis while in the hospital for 2 years. Her use began after she had been prescribed opioid pain relievers for lower back pain. Prior to that time, there was no relevant addiction history. There have been no relapses of opioid use and Mary indicates that her back pain is now well controlled with OTC pain relievers.

VIGNETTE 5

Robert is a 37-year-old anesthesiologist who had been using opioids since high school. His use was minimal at first as his drug of choice was marijuana. However, after becoming an anesthesiologist, the ready access to narcotics led to increased use of those substances preferentially. Robert went into treatment at the encouragement of his family, returned to the OR where he relapsed. This cycle occurred twice. Robert was then referred to the State Board of Professional Medical Conduct and was placed into an Impaired Physician program. Five years have now passed. Robert works at home as a medical reviewer. He is considering a return to the practice of medicine, but in another specialty. He has anxiety and fears that if he returns to anesthesiology, he would relapse. Robert participates actively in a 12-step program, sees his addiction specialist physician every 2 weeks, and shows no evidence of ongoing impairment in any domain.

Both Mary and Robert are socially active, can carry out their daily activities without deficit, and are able to focus and

concentrate on any reasonable task. They therefore have no limitation. Are they restricted, however, from returning to their original occupation, as a result of their addiction? These two cases have similarities, but they differ significantly in terms of the severity of the addiction itself. One may speculate, using some of the specifiers described in the phase IV discussion, that Robert would be more likely than Mary to relapse upon returning to work as an anesthesiologist. A paucity of literature addressing this topic led me to bring this question to several experts in fields of pain medicine and addiction medicine. Some said that neither of these individuals should return to anesthesiology. Their relapse risk would be higher than it would be should they engage in some other occupation, they said. Other experts disagreed, pointing out that re-engagement in work when accompanied by active and ongoing treatment has not been demonstrated as having higher risk, though studies did not focus precisely upon anesthesiologists with a history of opioid use. One study that did focus on this group was Domino's 2005 work in which 11 years of outcome data from the Washington Physicians Health Program was reviewed; this study noted that anesthesiologists have a higher rate of abuse of opioids than do other physicians (10).

Domino indeed noted that the risk of relapse of substance use was increased in health care professionals if they had used a major opioid, if they had a coexisting psychiatric illness, or if there was a family history of substance use disorder. Research has demonstrated a high mortality rate among anesthesia residents relapsing upon opioid use (11). Berge, Seppala, and Lanier indicate in their 2008 discussion of the topic that there appears "to have been a national consensus that narcotic-dependent anesthesia personnel in recovery should be allowed to return to the practice" of anesthesiology "in a closely monitored setting" once they are in recovery (12). The authors of that essay suggest that such individuals be directed to lower risk occupations, either within medicine or outside the field, though they agree that data to support the potential of lower risk through such a maneuver do not exist. They conclude that "sometimes we do not need time-consuming prospective studies to do the right thing. . . ." But what is right may be dependent upon one's perspective, one's desires, one's history, and a restriction may be the correct answer in general, but might stop an individual who possibly has a low risk, such as Mary, from returning to her desired profession. Indeed, it might be that there is such a high risk of opioid dependence among anesthesiologists that the risk is actually lower in the population of closely monitored recovered physicians than it would be among the general group. In that case, which group should be restricted?

IMPAIRMENT SECONDARY TO ADDICTIVE SUBSTANCES

In phase II, above, we specifically noted the potential for impairment secondary to substance use that falls short of addictive illness. An individual can suddenly die in response to a single use of cocaine. If the use of cocaine was not part of a distinctive pattern of substance use, then the death would not be the result of addiction but rather of a single event in which the

individual was, perhaps, irresponsible. Thus far, there have been only the two potential origins of the substance use and resulting impairment: addiction and social use. The social use may be licit or illicit, but there are no significant medical differences between an individual using alcohol at age 20 and another individual using alcohol at age 21, or between a marijuana user in Pittsburgh and a marijuana user in Amsterdam. The question of legality is therefore eliminated from issues of medical impairment. But there is indeed a third potential origin of substance use and impairment, that of prescribed substances.

Opioid prescribing patterns have changed markedly over the past two decades (13). From 1993 to 2003, there has been a 32% increase in the visit rate for opioid prescriptions in medical offices. The American Medical Association's Council on Science and Public Health noted in a recent report that hydrocodone-combination products are the most commonly prescribed medication in the United States with more than 110 million prescriptions issued in 2007 alone (14). At the same time as this increased demand for opioids has arisen, physicians have been encouraged to adequately relieve pain. There have been many guidelines recommending use of opioids in appropriate patients who have chronic noncancer pain (15,16). The AMA report concurs that the current practice environment is "...more conducive to managing acute nociceptive pain in patients suffering from cancer, terminal illness, and [HIV]." Opioids are also recognized within these same guidelines and consensus statements as being related to potentially serious adverse effects including addiction.

The APS-AAPM Clinical Guidelines for the Use of Chronic Opioid Therapy in Chronic Noncancer Pain specifically note that there are short-term adverse events secondary to opioid prescription, but none fall within the mental health rubric except sedation and somnolence. There are no significant data to indicate the presence of any long-term mental health harm secondary to ongoing prescription of opioids. There are also no randomized or controlled trials that look directly at the use of prescribed long-term opioids in patients who have an addiction history.

As a result, an individual may have opioid addiction and related impairment as described earlier, but when excluding patients with addictive illness, there is little if any evidence to indicate that mental impairment arises from long-term opioid prescribing. This conclusion is markedly dissimilar from the situation with long-term use of sedative-hypnotics.

Benzodiazepines and nonbenzodiazepine sedative agents are also widely prescribed agents, generally used for brief, intermittent, relief of anxiety. Therapeutic doses lead to physiologic dependence, as with the opioids, but with the sedative class of medication, symptoms are often present between doses as a result of rebound effects. Cognitive impairment, psychomotor retardation, and impairment of memory have also been noted in patients taking sedative-hypnotics for an extended period of time (17,18). The American Psychiatric Association Task Force report noted that such risks are greater in patients receiving sedatives for longer than 4 months, in those of advanced age, and in those receiving higher potency and shorter half-life substances.

Ashton, in 1987, reported a case study of 50 consecutive patients who presented for discontinuation of prescribed benzodiazepines (19). On presentation, all the patients had symptoms that included incapacitating agoraphobia, irritable bowel syndrome, poor memory and concentration, and panic attacks. Many of the symptoms were such that clinicians might be tempted to increase the sedative dose in an effort to obtain what might be seen as an efficacious dose. Long-term benzodiazepine use was found to be associated with considerable morbidity. Ashton demonstrated that, apparently paradoxically, the majority of the patients had a positive response to sedative discontinuation.

The paradox is solved by recognizing that all sedatives, including alcohol, have two pharmacologic effects:

- Effect 1 is a brief period of sedation, the amplitude of which is controlled by the dose and the duration of which is controlled by the half-life of the drug.
- Effect 2 is a longer period of agitation, the amplitude of which is less than that of the amplitude of the previous sedation, but the duration of which is almost four times longer than the duration of the first effect.

The effects add upon one another with the ultimate result being that if sedatives are taken over a long enough period of time, the symptoms being treated are primarily those arising from Effect 2 rather than from the original morbidity. The patient is now not only uncomfortable from the original illness but from side effects of medication.

As a result, the potential for impairment from sedatives, including the benzodiazepines, the barbiturates, the so-called "Z-Drugs," meprobamate, and the prototypic sedative, alcohol, is always present even when no addictive disease is present.

VIGNETTE 6

Mark is seen regularly at the community mental health center. He acknowledges drinking a pint each day and receives ongoing treatment for depression. He occasionally is admitted for detoxification but relapses almost immediately after discharge. He lives with friends, who let him sleep in the basement, but is more often homeless and staying in shelters. He has tried to work on several occasions in the last 2 years, but inevitably is let go as he fails to show up to work in a timely manner. He reports that he lacks the energy and motivation to go to work. He tends instead to spend the day in bed. His physician opines that he suffers from major depression and prescribes an antidepressant in addition to recommending that he stop his alcohol intake. One of Mark's friends offers him a diazepam tablet, indicating that it will help him stop drinking. Within a short period of time, Mark indeed stops drinking alcohol but is now using a variety of solid sedative agents which he obtains on the street. His difficulties with depression persist and he applies for Social Security Disability Insurance (SSDI).

John has a nearly identical history to Mark's. John, however, is prescribed a combination of diazepam and zolpidem. John also stops drinking alcohol. His difficulties with depression persist and the dosages of sedatives are

gradually being increased by his physician. John therefore applies for SSDI.

Both John and Mark have a sedative-induced mood disorder. Mark has alcoholism as well. Mark's sedative-induced mood disorder is the result of illicit substance use, while John's is the result of poor medical care. The legal disability determination may be significantly different for these two individuals despite the similarities from a medical perspective. One could make the argument that Mark's illness is the result of his addictive disease while John's is the result of side effects of prescribed medical care, and it is not the disability determination system's role to play arbiter with respect to whether the provided medical care represents the standard of care or follows currently acceptable guidelines. Since John is not actively using psychoactive drugs as part of his addictive illness—and recognizing that this is arguable as well—it is possible that he will be found eligible for SSDI while Mark will not.

SOCIAL SECURITY DISABILITY INSURANCE

In 1996, over 200,000 individuals were receiving SSDI or Supplemental Security Income (SSI) benefits secondary to addictive illness (20). Such recipients were required to be in treatment with monitored compliance. They were also required to have a representative payee. Benefits were available under such a program for up to 3 years as a result of 1994 legislation limiting the duration of benefits for addictive disease. In 1996, Congress terminated the provision of SSDI to claimants disabled by drug addiction, including alcoholism, through Public Law 104-121, effective the following January. Prior to January 1, 1997, beneficiaries disabled by addiction were granted benefits under both SSDI and SSI programs. Claimants who had received such benefits were allowed to apply for recertification, but only two thirds of those eligible did so, and only half of those cases were resolved in favor of the claimant (21). One study revealed that “many of those who lost benefits had significant self-reported psychiatric problems in the absence of active substance abuse” (22). In 2004, Hanrahan reported that the 1996 law change had adverse effects on other vulnerable populations, notably those with psychiatric disorders (23). Staff interviews in that study suggested that those needing the benefits most were the ones least able to follow through with the reapplication process. In 2005, the Centre for Addiction and Mental Health in Canada explored the sensibility of a new policy in Ontario in which those with substance dependence would no longer be eligible for welfare (24). The review led to the conclusion that this was an “ill-advised policy for Ontario” and that its continuation was not recommended. This was based upon the scientific view of addiction as a chronic illness, the fostering of stigma by exclusionary social policies, and negative impact upon mental health and homeless status. A 2006 study at Yale explored whether receipt of SSI or SSDI was associated with increased drug and alcohol use (25). Although such use was measured by self-report and clinician ratings rather than by more reliable objective measures, the hypothesis that disability benefits facilitate drug use was not supported by longitudinal data.

Under Social Security law, evaluation of disability on the basis of mental disorders, including addiction, requires (26):

1. Documentation of a medically determinable impairment. This documentation must be from an accepted medical source. The documentation must include more than subjective description of symptoms. Rather, objective findings are necessary, whether resulting from psychological testing, urine drug test results, or mental status exams, again as conducted by an accepted medical source. Acceptable medical sources are licensed physicians and psychologists. Therapists and other allied medical professionals *may* be referenced, but only to demonstrate severity of impairment and impact upon work (27).
2. Consideration of the degree of limitation such impairment may impose on the individual's ability to work.
 - a. Activities of Daily Living—marked impairment is defined by the nature and overall degree of interference with function and indicates that the individual has serious difficulty performing ADLs without supervision, in a suitable manner, or on a consistent, useful, and routine basis without undue interruptions or distractions.
 - b. Social Functioning—marked impairment is defined by the nature and overall degree of interference with function.
 - c. Concentration, Persistence, or Pace—marked impairment is noted to some extent by clinical findings, but these data must wherever possible be supplemented by other available evidence. An emphasis is given upon how independently, appropriately, and effectively a claimant is able to complete tasks on a sustained basis. Deficiencies apparent only in performance of complex procedures or tasks do not fall into the marked impairment category.
 - d. Episodes of Decompensation—three episodes within 1 year, each lasting for at least 2 weeks, represents the equivalent of a marked level of severity for this category.
3. Consideration of whether these limitations have lasted or are expected to last for a continuous period of at least 12 months.

Disability is then defined as the inability to “engage in any substantial gainful activity by reason of any medically determinable physical or mental impairment which can be expected to result in death or which has lasted or can be expected to last for a continuous period of not less than 12 months” (28).

Substance addiction disorders are defined within Social Security as behavioral or physical changes associated with regular use of substances that affect the central nervous system. If the changes are primarily behavioral, they are then evaluated under listings for organic mental disorders, depressive syndrome, anxiety disorders, or personality disorders.

VIGNETTE 7

Lisa is seen for treatment of depression and anxiety by a therapist. She receives medication from a nurse clinician with whom the therapist regularly works. Lisa is noted on the initial

history to use marijuana on a daily basis. The diagnoses written in the record by the treating therapist are major depression and generalized anxiety. No further reference is made to the marijuana use. No toxicology report is present in the record. Two years later, Lisa applies for SSDI due to ongoing depressive and anxiety-related symptoms. The state Disability Determination Service (DDS) sends Lisa to a psychiatric consultant for an examination. Lisa tells the consultant that she uses marijuana on a daily basis and has done so for many years. She is noted by the consultant to have marked impairment in multiple areas of function. The consultant reflects upon the ongoing use of marijuana and diagnoses the claimant with marijuana dependence and marijuana-induced mood and anxiety disorders. He reflects that the claimant might have primary mood and anxiety disorders but that these have not been demonstrated due to the ongoing substance use. Lisa fails to qualify for SSDI.

This case highlights two features of Social Security related disability. The first is that the therapist and nurse clinician do not meet the criteria for being a medically acceptable source of diagnostic information. The second is that the burden of proof of disability is, as a matter of law, upon the claimant. The claimant's records must therefore substantiate the presence of not only impairment, but of the impairment being related to a mental disorder *other than* addiction. Once the chart indicated that there was use of a psychoactive substance, the potential that addiction was the cause of impairment had to be ruled out. From a medical perspective, we are uncertain; from a legal perspective, this uncertainty may amount to the claimant's not meeting her burden of proof.

SSDI DISCUSSION

The Social Security Administration has several potential sources of clinical information for each disability applicant:

- Clinical records are gathered and submitted for review.
- A treating physician report can be requested by the state DDS. Within these reports, the clinician is asked to opine specifically about impairment resulting from diagnosed illness.
- A consultative exam (CE) can be requested by the state DDS or by the administrative law judge (ALJ) reviewing a case for the Office of Disability Adjudication and Review.
- A medical expert (ME) can be requested by the ALJ. The ME reviews the entire file, including treating physician reports and CE's, if any, and presents the case either in live testimony, through written interrogatory, or through telephonic review.

Treating physicians and ME's composing reports should be aware of these issues:

- Initial diagnostic formulation should be the result of an evaluation by a physician or a psychologist. Although in many states, other clinicians are eligible to make diagnoses or to compose treatment plans, these sources remain outside the boundaries of "acceptable" under Social Security

law. Of note, the American Medical Association maintains policy stating that diagnosis of disease constitutes the practice of medicine (Resolution 904, I-06).

- Medical records thereafter should include ongoing evaluations by a physician. These evaluations must include documentation of objective measures demonstrating functional capacity or lack thereof.
- A patient statement in the initial evaluation that no drug- or alcohol-related difficulties are present does not represent an objective finding. Given the high percentage of psychiatric symptoms caused by addictive substances and the high prevalence of addictive substance use in the population overall, a urine drug screen is an appropriate part of a full psychiatric workup. Such a screen also prevents the entire diagnostic formulation from being disregarded from a legal standpoint should other records in the case demonstrate the presence of substance use.
- If the patient applying for disability is abstinent from substance use, document that abstinence through objective measures. Regular urine drug screens represent the best such measure for drugs other than alcohol. Documentation that the applicant has been attending AA/NA regularly, that he has a sponsor, that he is a sponsor, or that he is otherwise participating actively in recovery programming are helpful in demonstrating that addictive disease is no longer the impairing factor. Note, however, that such documentation also suggests that there is no or minimal impairment in social function.
- If the patient is not abstinent from substance use, document how the diagnosis of a primary psychiatric disorder was determined, perhaps during a period of extended and objectively demonstrated abstinence, and describe the impairments that were present during that specific period.
- A treating physician report stating simply that substance use is not material to either the diagnosis or the impairments, when the overall record indicates otherwise, is not likely to lead to a favorable outcome for the disability applicant (29).
- Ensure that the applicant is not being prescribed addictive substances. Besides simply being a wise approach to the treatment of addictive illness, an ongoing prescription of addictive substances blurs the picture as to whether the patient is able to prove impairment secondary to a psychiatric disorder rather than to a substance-induced disorder. If opioid prescriptions are medically necessary for treatment of pain, this should be well documented in the record.
- Be particularly savvy about use of an electronic medical record. Many such records carry over information from one entry to the next. If the majority of such entries are identical with unchanging treatment, the record will reflect overall stability and a low level of overall severity. Higher levels of severity usually result in treatment intensity increases, changes of medication, or other modality of treatments being initiated.
- Do not exaggerate the degree of impairment present. Indicating that the patient has marked impairment of

concentration, persistence, and pace is illogic if that patient is also described elsewhere in the record as driving long distances to visit family members. Note that driving is a complex task that requires sustained attention, something that would not be possible in an individual with marked impairment in this domain. Exaggeration of impairment levels can lead to an entire conclusion being disregarded. Ensure that the degree of impairment which you are indicating is supported by objective findings in your serial mental status examinations.

A final point must be considered not only for Social Security cases but for all cases:

- The role of treating physicians is not to obtain disability benefits for their patients, but to honestly and appropriately document the presence of a specific disease state first, and second, any restrictions or limitations arising as a direct result of that disease state. It is then the role of the insurance carrier, or state or federal agency to determine whether disability benefits are warranted.

HISTORICAL AND CULTURAL BACKGROUND

Immigrants

Since its inception as a nation more than 200 years ago, the U.S. population has often consisted of 10% to 20% foreign-born people. In the 2000 census, 31,107,889 people were foreign born, and an additional 3,527,551 people were born outside of the United States in various territories (e.g., Puerto Rico, Virgin Islands). Together these two groups comprise 12.3% of the total 281,421,906 people counted in the census. A conservative estimate of 3 million illegal residents in the United States (1) brings the total to around 38 million, or approximately 13.5% of the total population. In addition, the United States has several million visitors per year, including foreign students, visitors, temporary workers, tourists, entertainers, and representatives of foreign governments (military, embassy staff). Immigrants, refugees, and these special categories of visitors all include individuals who seek services for substance abuse in the United States.

From 1980 to 2000, the number of counted foreign-born people in the United States rose by 224%. Although Canada and Australia also have many foreign-born residents, the number of immigrants to the United States has exceeded the number of immigrants entering all other countries of the world in recent years (2). In sum, clinicians in the United States must be prepared to address substance abuse problems within immigrant and refugee groups.

In the 2000 census, the continent-wide origins of foreign-born people in the United States were as follows: the Americas, 16,916,416; Asia, 8,226,254; Europe, 4,915,557; Africa, 881,300; and Oceania, 168,046. National origins of the most numerous immigrants included the following: Mexico, 9,177,487; China, 1,518,652; Philippines, 1,369,070; India, 1,022,552; Korea, 864,125; Canada, 820,771; El Salvador, 817,336; and United Kingdom, 677,751. Immigrants bring new types of substance use and abuse to the United States, including opium smoking, betel nut chewing, and qat chewing. These traditional substances may involve drugs or modes of administration unfamiliar to American clinicians.

Refugees

Unlike other immigrants, most refugees would have preferred to remain in their country of origin. Refugees have fled their homeland to avoid prejudice, incarceration, or even death for

their political or religious beliefs, or their ethnic affiliation. Although people have fled war and social tumult throughout human history, the number of people involved in such flight has dramatically increased. A United Nations report estimated that 45 million people had left their homelands between 1945 and 1967 (3)—a trend that continues annually (4). This recent trend has greatly increased the number of people coming from underdeveloped countries, from which many arrive poorly prepared for life in the United States.

There are several definitions of refugees, ranging from strict United Nations definitions to lay terms such as “economic refugees.” For immigration and legal purposes in the United States, a refugee is defined as such by the federal government. The status extends special privileges to anyone so labeled. As clinicians, we may identify someone as seeking refuge, but the person may not have federal status as a refugee in the United States. Likewise, some legal refugees may resemble immigrants in that they have experienced no trauma and have left the home country willingly to come to the United States for personal reasons.

From a health perspective, refugees can pose a special challenge in view of their exposure to war or other trauma. This group is at special risk to numerous health problems. Drug trafficking and substance abuse sometimes accompany war and civil unrest—factors that can haunt a resettlement country (5).

CLINICAL ASSESSMENT

Working with Translators

In the 2000 census, 9.5 million inhabitants of the United States reported that they spoke English either “not well” (6.3 million) or “not at all” (3.2 million). The greatest proportion was Spanish speaking, accounting for 4.1 million. The second largest group was Asian–Pacific Islanders, with 1.6 million. Indo-Europeans comprised 1.3 million, with the remainder coming largely from Africa. Patients with inadequate skills in English will need a translator for an adequate assessment, unless the clinician speaks the patient’s language.

Prior to working with a translator, the clinician should have a model for understanding the process of interpreting the clinician’s queries and the patient’s and family’s responses. Three models common to the clinical context are as follows (6):

- The “black box” model. The clinician views the translator as a magical “black box” in which all queries and responses are accurately and completely translated. This model does not function well with psychiatric or substance use interviews.
- The “junior clinician” model. The clinician views the translator as a junior assistant clinician, whose task is to obtain the relevant clinical data being sought by the clinician. This model may work well if the translator is also a trained clinician whose work is being supervised by an experienced clinician-educator.
- The “three partners” model. The clinician, translator, and patient share the difficult task of informing one another regarding various queries and responses. This task is rendered complex through the absence of shared language and shared culture between clinician and patient. Typically, the translator has extensive experience in both languages and cultures but not in clinical assessment and care. The task is further complicated by a three-sided series of transference and counter-transference relationships. Despite its challenges for the clinician, this model lends itself best to psychiatric and substance use interviews.

Training the translator to this task requires more than a brief orientation. The translator’s own views and attitudes toward substance use disorder can obstruct the clinician–patient relationship in a myriad of ways. The translator’s own lay attitudes, use of substances, and choice of words can either enhance communication or seriously undermine it.

Case Example

An Asian foreign student, trained as a translator in a nonclinical setting, developed a personal relationship with a patient outside of the clinical setting. She did not initially reveal this to the clinic staff. As this friendship developed, the patient became less open and at ease in clinical setting. When asked about this change, the patient revealed his hesitance to express himself openly without first considering the effect it would have on his deepening friendship with the translator. Following this explanation, another translator was assigned to the case. The original translator received additional training regarding the special ethical, legal, and professional boundaries needed when working in a clinical setting.

Obtaining a Substance Use History

Substance use and abuse manifest many similarities across cultures. Through a supportive, informed, and empathetic approach, the clinician can usually obtain a complete picture of the patient’s substance-related problem. At times, the clinician may have to seek help from the literature if the substance, route of administration, or pattern of use is unfamiliar. PubMed and other Internet-based sources can assist in bringing a broad published literature to the service of the patient abusing unfamiliar drugs, and consuming them in an unfamiliar way.

The chronologic sequence of substance use vis-a-vis migration should be established. Did the patient begin use in the country of origin? Or in the United States? Or in another country? How was the patient introduced to the experience? What were the patient’s circumstances at the time? Was the initial use of the substance a culturally deviant or syntonically activity?

Case Example

A veteran-immigrant born and raised in Latin America returned from a combat rotation with the American Army in Iraq, where he served with a combat unit. His combat experience included killing the enemy (although distinguishing bystanders with combatants was at times unclear), injury and death of members of his combat unit, and an open arm wound with a brief period of unconsciousness from an explosion. While he was overseas, his mother died of a drug overdose, and his father died of AIDS. A member of his unit, who had been threatening suicide, shot himself in the head in the patient’s presence. Although he had not abused drugs previously, upon discharge from the military he began to abuse opioid and sedative medications prescribed for his arm injury. When Veterans Administration (VA) physicians would no longer prescribe opioids for him, he began to purchase opiates on the street. He entered treatment when he developed an abscess in his forearm from injecting drugs. With abstinence from opioids, posttraumatic stress disorder (PTSD) symptoms emerged.

Establishing the family or community attitude toward drug use is health care generally. For example, in this case most of the patient’s family members abused opioid drugs. Moreover, obtaining illicit opioids for one’s personal use was commonplace in his community of origin. Had his VA physicians been aware of these early experiences, they might have monitored his opioid treatment more judiciously.

Culturally Competent Evaluation

In most respects, the evaluation continues largely as it would for other patients from indigenous ethnic groups. Review of systems should emphasize specific queries regarding psychological symptoms (e.g., anorexia, weight or sleep changes, fatigue, crying spells, fears, chronic pain, headache, bowel changes, anhedonia, hearing or seeing things not perceived by others), since foreign-born patients might not spontaneously report such symptoms to a nonkin person. While taking a family history, the clinician should be alert to patriarchal or matriarchal kin systems, because patients may not consider nonkin to be relatives in the biogenetic sense. A social history should reflect the patient’s former life in the country of origin, as well as the past and present life in the country of immigration.

Mental status should be culturally informed because orientation in time and space can be affected by culture (e.g., Buddhist and Islamic calendars, differences in counting floors of a building). Education can affect the ability to do arithmetic or replicate figures with paper and pencil. English fluency and literacy can affect naming, reading, writing, and

enunciating. To interpret proverbs, the patient needs to consider a proverb familiar to the patient's culture. Ability to discern similarities in unlike objects depends upon education and familiarity with the objects.

The final step consists of putting the entire story together into a coherent, integrated whole. This process should provide information regarding the patient's cultural identity, his or her explanation or understanding of the disorder, and socio-cultural factors that favor recovery or chronicity. The clinician should consider the cultural aspects of the doctor–patient relationship. Finally, cultural factors that might support or impede the diagnosis and care plan should be considered.

Acquiring the Migration History

Immigrants and refugees come from every corner of the world, from the largest and most sophisticated cities to the most remote and undeveloped of rural villages. Inquiry into this premigration phase of the patient's life can enhance the clinician's understanding of the patient and the presenting clinical problem. This dialogue also enables the patient to inform the clinician regarding that unknown portions of the patient's past life.

During this exercise, the clinician can inquire into the patient's early exposure to substance use and abuse in the country of origin. In turn, this can lead to a family history of substance use and other psychiatric disorders. Models of treatment or recovery from substance abuse in the former country can lead to recommendations familiar to the patient and family.

Many immigrants and refugees do not come directly to the United States. The patient may not report these peregrinations if not asked about them. Inquiry may elicit important circumstances regarding the genesis of substance use.

A premigration history informs the clinician regarding the patient's competence, accomplishments, losses, and stressors before reaching the United States. This history provides a history of the individual within the culture of origin, or in countries of first refuge for refugees. Typically, early successes forecast subsequent successes. This is not always the case, however. An occasional person who did well in the homeland does miserably in the United States, and vice versa.

Special Comorbidity Risks

Refugees are at special risk to diverse posttraumatic psychiatric disorders, which can accompany substance use disorder (SUD). The latter include PTSD, major depressive disorder, phobic disorder, generalized anxiety disorder, and panic disorder (7). Somatization and somatic presentations are also highly prevalent among migrants (8). These disorders may predate SUD, occur around the same time, or appear after SUD has been successfully treated.

PTSD may affect not only refugees, but also some immigrant groups (9). Ruling PTSD out may not be easily accomplished, as the migrant may be alexithymic vis-a-vis perceived emotional distress, denying or suppressing past traumatic

events, somatizing the emotional distress, or embarrassed or ashamed to reveal the trauma and its consequences (10). Rapport sets the groundwork for gentle probing of traumatic experiences. Inquiry regarding nightmares, intrusive thoughts, or hypervigilance can also suggest past trauma. Pan-system somatic symptoms (e.g., frequent headache, dizziness or faintness, appetite change, sleeping problems) can reflect past trauma (11). Missed grieving or delayed grieving may also co-occur in situations where traumatic experiences involved the deaths of friends or family members (12). Addictive disorders can contribute to delayed or missing grieving.

Other externalizing disorders besides SUD may also accompany SUD. Externalizing disorders in adulthood include pathologic gambling, eating disorders, tobacco dependence, antisocial personality disorder, compulsive shopping, and kleptomania (13). Prolonged insecurity (14) or numerous negative life events (15) during childhood or adolescence may contribute to these disorders in refugees and some immigrants coming from insecure areas. Mechanisms include possible prolonged cortisol elevation due to stress (16) and/or prolonged nicotine exposure (17)—both common in certain premigration circumstances. Loss of traditional values can also favor externalizing disorders (18). International adoptees have shown an increased risk to the externalizing disorders (19).

Physical problems can serve as a clue to comorbid problems that may not improve with sobriety alone. For example, chronic pain may be a clue to PTSD (20). Mild to moderate brain damage is prevalent in some refugee groups (21).

INTERPRETATION OF FINDINGS

Acculturation

The “melting pot” in the United States has introduced new models and methods of substance use. European Americans not schooled in the ceremonial use of tobacco, developed tobacco dependence along with its myriad biomedical disorders. Some young Somali refugees, with no exposure to alcohol use in their Islamic families, have chosen weekend drunkenness as an “American” recreational form.

Cultural changes can include changes in traditional substance use. For example, the Hmong, a refugee group from Southeast Asia, formerly had a rigid protocol for alcohol drinking, with few problems (22). However, in the United States, many of the animistic Hmong converted to abstinence-oriented Christianity. This social change undermined the former stability in drinking practices, resulting in diversity from those who drank nothing to those who drank in a secular and sometimes dissocial fashion, that is, at times and in amounts that they choose (23). Another example is the traditional use of qat in Somalia, Ethiopia, and nearby countries (24), where groups largely used it under socially controlled circumstances. However, some refugees from these groups have become addicted to qat when using it to relieve physical or emotional symptoms following migration. In contexts of rapid socio-cultural change, old traditions of use can give way to new patterns of use adopted.

Other changes also modify the drinking or drug use context following relocation to a new society. For example, the nature of work, transportation, and other technology can increase the risk associated with even mild intoxication or morning-after hangovers. Increased access to high-speed vehicles, complex machinery, and the smooth interaction and coordination of many workers can render intoxication newly risky for the immigrant. In addition to the individual, society at large bears the cost of vehicular and industrial accidents (25).

As a consequence of these changes, alcohol and/or other drugs can become a virtual scourge for certain subgroups in the United States. For them, substance abuse is a major cause of child neglect, family disruption, divorce, vehicular accidents, injury, and death.

Case Example

A 36-year-old Asian refugee had fled his country of origin a decade earlier with his military unit, leaving family behind. In the United States, he drank heavily and episodically with ethnic peers, much as he had done as a young soldier in Asia. During one of these episodes, he was involved in a serious accident in which a friend was killed and he sustained a traumatic brain injury. Treatment was not provided for either the alcohol abuse or the brain injury. Subsequently, he married an American woman and had three children. His episodic heavy drinking persisted, primarily on weekends and holidays, but at times after work. Following a long weekend holiday of drinking with American friends, he killed his wife, three children, and mother-in-law while they were asleep. In the morning, discovering with horror the massacre, he called the police, who established beyond doubt that he had murdered his family, apparently during one of many alcoholic “black outs” that he had been having.

Cultural Diversity within Groups

Groups of immigrants to the United States differ greatly. The same is true of individuals within these groups, for whom the new country presents many choices and alternatives. Some immigrants remain staunchly traditional to their country of origin. Others assimilate to a considerable extent with the “mainstream” American culture. Years following relocation, immigrant groups often manifest greater differences among themselves than were previously manifest in the country of origin.

Failure to acculturate successfully to the new country can increase the risk of substance abuse. Successful acculturation can be identified by the immigrant’s ability to speak English, hold a job, use the social institutions of the receiving society (e.g., banks, libraries, health care), access the mass media, and establish relationships outside of the immigrant’s own group. Acculturation failure is manifest by dependence on others, declining mental health, social isolation, ignorance of social forces at play in the community, confusion regarding how to plan one’s future life, and increasing lack of control over one’s life.

Substance abuse may provide an alternative to young immigrants caught between the “old country” culture and the new culture. Some of the superficial accouterments of American culture, for example, fast cars and drug or alcohol use, may substitute for a more fundamental acculturation. Petty crime or drug trafficking may be pursued as a means of paying for this apparent “American” lifestyle (26).

Migratory History and Onset of Substance Abuse

Some cases of substance abuse begin after migration. However, most cases among adult migrants involve continuation of premigration substance abuse or dependence, rather than new cases. The following case exemplifies this pattern.

Case Example

A 26-year-old Palestinian graduate student had become a heroin addict in his native Palestine. Formerly a good student, he was unable to obtain a job consistent with his education. Berated by his father for his inability to support the extended family despite his education, he found solace in spending his time with a group of unemployed college graduates. Exposed to heroin in this group, he was soon addicted. His father arranged for him to attend graduate school in the United States, following detoxification in Israel. For 6 months he did well academically and socially. Exposed to the opportunity to use heroin, however, he soon became readdicted. Failing academically, he sought treatment for his addiction (as he had done previously in Israel). However, he was unable to maintain his grades at that point, was dropped from school, and returned to Palestine.

Krupinski studied the appearance of new cases of substance abuse among post–World War II immigrants from East Europe to Australia (27). Most immigrants abused alcohol. Typically, these immigrants were in Australia for several years before heavy drinking began, and then several years more before seeking treatment for alcoholism. This chronologic pattern was unlike postmigration mood, anxiety, or psychotic disorders, which tended to appear within months to several years following relocation. Factors that may delay onset of substance disorder following migration include the following:

- Immigration officials screen out obvious cases of alcoholism or addiction.
- Purchasing alcohol or drugs requires disposable income, so years may pass before the immigrant has sufficient funds to purchase alcohol or drugs.
- On average it requires about 3 years of heavy cocaine or heroin abuse before initial treatment seeking, and about a decade of alcohol or opium abuse before initial treatment seeking (25).

Analysis of an opium smoking epidemic among refugees in the United States revealed two groups of addicts, that is: (1) those who became readdicted in the United States and (2) those who became addicted for the first time in the United States (28). Of relevance to Krupinski’s observations, the first

use of opium in the United States did not appear in this refugee group until they had been in the United States for several years. At that time a large-scale smuggling operation developed to bring opium from Mexico and Asia to the United States, along with some local poppy production.

These studies from Australia and the United States indicate that older immigrants are most likely to abuse substances traditional in the country of origin. Young immigrants may also abuse the traditional substance if they remain ensconced within the immigrant community, as occurred among the young Hmong opium addicts. However, young immigrants may abuse substances that are not traditional within the immigrant community, but are substances abused within American society, in an abortive attempt to join, or at least emulate the majority society.

High-Risk Immigrant Groups

As a nation composed largely of immigrants and refugees, we tend to idealize these groups as harking back to our own origins. However, idealization should not render us blind to subgroups at high risk to substance abuse. The propensity of foreign countries to “dump” their problematic citizens in the United States (and other immigrant countries) was first recognized more than 150 years ago, when several European countries sent prisoners and debtors to the United States at public expense as a means of being rid of them (29).

Immigration laws have removed this historical trend to a considerable extent, because foreign countries are liable for the return of their mentally disabled citizens at their own expense. Nonetheless, refugee groups can include individuals at high risk to substance disorders. Perhaps the most flagrant modern example was President Carter’s acceptance of thousands of criminals in the “Mariel” flight from Cuba (Mariel referred to the prison from which the refugees originated). Although many of the 120,000 participants in this flight were not addicted or criminal, thousands of “Mariel refugees” appeared in jails and treatment facilities across the United States soon after their arrival.

Case Example

A 36-year-old Mariel refugee had been a petty criminal and alcohol abuser in Cuba. Upon arrival in the United States, he discovered that his contacts in the Hispanic community gave him access to cocaine trafficking. He became a street trader, buying from smugglers and selling on the streets. He soon became addicted to cocaine himself, resulting in his “cutting” his product with inert substances. This practice led to a conflict with a client, as a result of which he shot the client. He is now serving a sentence in the United States for murder.

Another general category at risk consists of young, single men who were members of defeated armies allied with the United States. Often illiterate or poorly educated, they may not have sufficient skills to sustain them in the United States. Unfortunately, the United States has not provided veterans’ benefits nor acculturation training and education for these high-risk young men.

Case Example

A refugee had been a soldier from the age of 17 years in his homeland, coming to the United States at age 26 years when his national army was defeated. He fled without his wife and daughter, whom he has never been able to locate. Although he was literate in his own language and had risen to the rank of noncommissioned officer, his former achievements did not predict success in the United States. A shrapnel wound to his forehead followed by several hours of unconsciousness suggested a possible head injury. Unable to learn English, he worked principally as a dishwasher and unskilled laborer. His recreational activities consisted entirely of gambling and drinking in the company of men similar to himself. At the age of 44 years he was incarcerated for killing an ethnic peer in a fight that occurred in a context of drinking and cannabis use.

TREATMENT AND RECOVERY

“Mainstream” Treatment Modalities

Addicted persons of virtually any ethnic background accept care in detoxification centers, emergency rooms, and inpatient hospital units. The challenge to continued treatment begins beyond this acute phase. Once beyond the pain of withdrawal or other health emergency, the addicted person may become more selective about continued care.

The “three A’s” integral to successful rehabilitation following early acute care are as follows:

- **Availability:** The treatment must be reasonably close at hand, so that the person can participate in the recovery-centered endeavors. Telemedicine services can greatly facilitate services to rural areas or ethnic neighborhoods.
- **Access:** The patient must have access to the program; lack of insurance or language barriers can prevent entry.
- **Acceptance:** The patient and the program must accept each other.

An analysis of barriers in one health care system revealed four categorical sources of cultural barriers to mental health care (30). Two of these general barriers lay on the health care side, that is, the clinicians and the health care system. The other two categories consisted of the patient barriers (e.g., antitherapeutic attitudes, ignorance, lack of resources) and the patient’s family and community (e.g., not supportive, do not understand).

Self-Help in Recovery

Some self-help activities can occur regardless of ethnic affiliation, such as avoiding people and places associated with use (31). However, other forms of self-help may differ across cultures. These differences can be due to cultural values, customs, or institutions.

Alcoholics Anonymous can change form and content considerably when translated across culture and language (32). Entire communities can engage in self-help, through eliminating substance abuse and associated problems (33).

For example, in cultures that view self-disclosure as self-centered, “confession” of addiction-related “sins” may prove unacceptable.

Religious Conversion and Recovery

Conversion to abstinence-oriented religion has alleviated addictive disorders for many around the world. For example, Hispanics throughout the Americas have joined abstinence-oriented fundamentalist Christian religions as a means of achieving sobriety and resisting invitations to drink (34). Buddhist monasteries have served as places of recovery, especially when a charismatic abbot leads the way (35). Galanter described the “large-group psychotherapy” that may attend membership in an abstinence-oriented or recovery-oriented religious group (36). Some programs, such as involvement in the Native American Church, may be restricted to members of the ethnic groups sponsoring them (37). Even without conversion efforts, spirituality and religiosity tend to increase during the early months of sobriety (38), providing a rationale for the efficacy of religious conversation in fostering recovery.

Previous Exposure to Treatment

We sometimes assume that treatment for addiction is available only in a few industrialized societies. However, treatment exists virtually wherever addiction occurs (39). Inquiry into previous treatments in the country of origin can provide important information.

Treatment can include community sings, herbal medications, and sweat lodges. Often these modalities possess a ritual or ceremonial dimension (39). Ceremonies can be useful in engendering social support for the recovering person, establishing a new social persona, and fostering new attitudes toward a sober lifestyle (40). Inquiry about traditional modalities can aid in appreciating the patient’s understanding of addiction treatment.

Psychotherapies

English literacy or advanced education is not necessary for successful psychotherapy. Supportive counseling can be applied in any setting; it can be especially efficacious if the immigrant patient is seeking an advisor for successful adjustment to the new society. Cognitive-behavioral therapy (CBT) and behavioral modification can apply to members of any group. Examples include desensitization for phobic disorder or PTSD.

Family therapy may involve special considerations, depending on the family structure and traditions in the patient’s culture and family. In family therapy, the explicit family hierarchy will often hold sway, so that family members do not typically confront a matriarch or patriarch in front a therapist. This special challenge is not a rationale for circumventing the family, however. Whenever possible, the family should be involved in the patient’s assessment and care (41), as well as

other members of the patient’s social network who are committed to the patient’s recovery (42). Elements of interpersonal psychotherapy and psychodynamically oriented psychotherapy can also have their place in cross-cultural care.

As indicated above, delayed or missed grieving may appear once the addicted person becomes sober. Bereavement may involve the deaths of friends and family members. Especially in the case of refugees, bereavement may involve other losses (9), such as:

- Separation from family and friends, still alive in the home country
- Loss of home, community, work, familiar recreation, and nation
- Rejection by the country of origin
- Failure of the family, religion, or homeland to provide safety and security
- Shame at behaviors needed to survive (e.g., theft, lying, duplicity, prostitution, abandoning relatives or friends, killing)
- Inability to discharge one’s responsibilities to family, friends, or society.

Pharmacotherapy and Culture

Medications are often thought of as mechanistic modalities that affect neurotransmitter systems, but have no cultural relevance. To some extent, this may be true. For example, one does not have to understand the pharmacotherapy of diazepam (Valium) to obtain relief in the midst of alcohol withdrawal.

Medications can also play important social and cultural roles. For example, disulfiram (Antabuse) and naltrexone (ReVia) have provided an excuse for recovering alcoholics to refuse friendly invitations by peers to go out drinking or drug using (43). The following case of a refugee demonstrates the principle.

Case Example

A 42-year-old immigrant from Puerto Rico had difficulty refusing his peers’ invitations to drink on weekends, despite his strong intent to remain sober. His relatives and neighbors accused him of trying to act better than them, or of abandoning their long relationship. A recovered neighbor told him to ask his doctor for disulfiram (Antabuse), as this could provide an acceptable excuse for not drinking. The patient did request and received disulfiram from his physician. As the neighbor indicated, his weekend drinking buddies took this as an acceptable excuse. They knew that the man could not drink on Antabuse, and they accepted the doctor’s authority and knowledge providing an acceptable rationale.

Acculturation Therapy

By the time an immigrant has been failing in acculturation and has become an SUD patient, it is unlikely that simple referral to job training, education, or other local forms of

rehabilitation will succeed. Special programs for those failing in the acculturation task are required.

An “acculturation failure” group should include individuals from a variety of cultures and languages. Combining a culturally diverse clientele into a single large group offers certain economies of scale. Because all clients are unlikely to require all elements of such a program, a “smorgasbord” approach should permit each client to engage in those aspects of the program that the client needs. Elements of such a program may include

- Taking English-as-a-second language (ESL) instruction
- Training in elemental aspects of community life (e.g., shopping, taking public transportation, food preparation, accessing health services, obtaining police protection, using financial services)
- Knowing the history, government, laws, and cultural values and norms of the United States
- Child raising and family laws in the United States
- Acquiring job skills and learning how to acquire job
- Learning how to keep a job and progress in employment
- Participating in recreational activities that do not require substance use
- Coping with bias, prejudice, and racism.

Return to the Culture of Origin

Forcible removal to the culture of origin, while not a therapy per se, sometimes becomes an undesired but inevitable disposition. Those working with immigrants must accept this as potential outcome in some cases. Clinical considerations rarely dissuade immigration officials from a deportation decision.

Return to the culture of origin may produce clinical improvement in the substance abuse. The largest naturalistic study involved American military in Vietnam. Among those who abused opiates in Vietnam, few ever returned to opiate abuse in the United States (44). Many expatriate opiate addicts in Laos did well upon return to their respective countries of origin in Europe, North America, and elsewhere (45).

PREVENTION

Religious affiliation with groups that forbid any use of alcohol or other recreational drugs has been effective as prevention, as well as a treatment. Abstinence-oriented religion also provides easier access to leadership as compared to religions that require clergy to study for many years before becoming leaders; immigrants themselves have become the leaders and clergy in fundamentalist sects. Community consensus against alcohol abuse or use of illicit drugs may evolve from these church enclaves. A danger is that the abstinence-oriented sect may ultimately turn against addicted people, lumping the persona with the drug.

Prevention among refugees and immigrants can be fostered by making culturally sensitive medical and psychiatric

care available to immigrants and refugees as a means of preventing self-treatment with alcohol and dependence-producing drugs. Immigrating individuals and families can be educated to the early signs and symptoms of substance abuse in family members, and to methods of supportive confrontation of drug and alcohol abuse. Awareness of enabling and rescuing behaviors by family members, and their detrimental effects on the course of substance abuse, should be promulgated.

To reduce the availability of illicit drugs in immigrant communities, expatriate police officers must be represented on the local police force. As with health care, the civil security network must be available to expatriate social networks.

Immigrant groups bring their unique histories and traditions to the societal mainstream in the United States. In addition to their rich customs, they also bring their vulnerabilities to psychoactive substances, whether traditional substances from the past or new substances. In a few instances, they bring new substances to the United States. American society and its institutions should recognize its contributions to immigrant use and abuse of substances, and its responsibility in supporting prevention. Likewise, immigrant groups should realize their role in contributing to the well being of the society at large. Prevention requires the efforts of both the mainstream society and the immigrant groups.

For immigrants themselves, brief-but-repeated introspection can prove valuable in maintaining function, helping planning, and avoiding malfunction such as alcohol and drug abuse. One method fostered by Australian aborigines struggling to adapt to the surrounding Australian society has been to consider and discuss with others the following three questions:

- Who am I?
- Where do I come from?
- How is my life meaningful?

Part of the task lies in figuring out the questions. Queries that are so broad and open-ended do not make for obvious answers. Discussing the query with others helps to clarify the nature of the question for one’s self. Each question can be freestanding, but they also have underlying unities. Thus, responding in considerable detail to the earlier query facilitates addressing the subsequent query. And finally, the responses are dynamic and changing for the immigrant, who is changing over time. Since recovery from SUD also entails numerous changes, these three queries contribute to the recovery process.

INTRODUCTION

Substance use and abuse, including heavy alcohol use, illicit drug use, and tobacco use, have long been associated with military life. The armed services have experienced problems with alcohol abuse from the earliest days of military service, in part because heavy drinking has been an accepted custom and tradition that continues today (1–4). In the past, alcohol was thought to be necessary for subsistence and morale and as such was provided as a daily ration to sailors and soldiers. There are numerous early documented accounts of alcohol abuse among military personnel, for example, in the British army in the 18th century (5) and during the U.S. Civil War in the 1860s (6). Within the predominantly male U.S. military population, heavy drinking and being able to “hold one’s liquor” have served as tests “of suitability for the demanding masculine military role” (7). A common stereotype has been to characterize hard-fighting soldiers as hard-drinking soldiers. Alcoholic beverages have been available to military personnel at reduced prices at military outlets and, until recently, during “happy hours” on base (7,8). In addition, alcohol has become part of the military work culture and has been used to reward hard work, to ease interpersonal tensions, and to promote unit cohesion and camaraderie (4,9).

Similar to alcohol, illicit drugs (including illegal drugs as well as prescription drugs used nonmedically) have been used by soldiers since they discovered that certain herbs reduced pain, lessened fatigue or increased alertness, or helped them cope with times of boredom or panic that accompany battle. During the U.S. Civil War, medical use of opium resulted in addiction among some soldiers. In the modern U.S. military, drug use was not a notable problem until the Vietnam War in the late 1960s and early 1970s. Heroin and opium were widely used among U.S. military personnel in Vietnam, in part as a way to tolerate the difficulties of war and cope with a threatening environment. Approximately 20% of Vietnam War veterans reported having used narcotics on a weekly basis, and 20% also were considered to be addicted based on reported symptoms of dependence (10). Although few personnel continued using heroin when they returned home, there were concerns about addiction. This finding, along with the subsequent discovery in the 1980s that drug use was more widespread among military personnel (11,12), led the Department of

Defense (DoD) to develop policies and approaches to reduce it (13).

Tobacco use has also been common among military personnel and its use was sanctioned in the U.S. military beginning in the early years of the 20th century. Although there was initial debate in the armed forces about whether cigarettes were in keeping with proper military discipline, the onset of World War I gave rise to widespread encouragement of tobacco use in the military (14). A turning point for easy access and encouragement of tobacco use came in response to the famous plea by General Pershing: “You ask me what we need to win this war. I answer tobacco as much as bullets” (15). The response was organized efforts by volunteer groups such as the YMCA and the Salvation Army to raise funds to buy and distribute cigarettes to the troops. Despite these well-meaning efforts, supporters found it difficult to ensure delivery to all servicemen. Amidst complaints of uneven distribution of tobacco by volunteers, in 1918 the War Department assumed responsibility for equitable distribution and did so by issuing tobacco rations. This action made tobacco readily accessible and implied strong organizational support for its use. Indeed, the sharing of a cigarette symbolized the camaraderie of war. This sentiment continued during World War II with widespread radio and print cigarette advertisements praising service members (16). Cigarettes continued to be included as part of the K-rations and C-rations and sometimes became more valuable for trading or selling than the food items in the rations (16).

Currently, alcohol abuse (i.e., binge or heavy drinking), illicit drug use, and tobacco use are strongly discouraged within U.S. armed forces because of their negative effects on the health and well-being of military personnel and because of their detrimental effects on military readiness and the maintenance of high standards of performance and military discipline (17). In the U.S. military, alcohol abuse is defined as alcohol use that has adverse effects on the user’s health or behavior, family, community, or the DoD, or that leads to unacceptable behavior. Drug abuse is defined as the wrongful use, possession, distribution, or introduction onto a military installation of a controlled substance (e.g., marijuana, heroin, cocaine), prescription medication, over-the-counter medication, or intoxicating substance (other than alcohol). Tobacco use is defined as use of cigarettes, cigars, pipes, snuff, or chewing tobacco and is discouraged because of its negative effects on performance and association with disease.

DEVELOPMENT OF MILITARY SUBSTANCE USE POLICY

The Vietnam War and the resulting reports of substance abuse from returning servicemen led to the development of DoD policy on substance use and abuse. In 1967, DoD convened a task force to investigate drug and alcohol abuse in the military and in 1970 formulated a drug and alcohol abuse policy based on task force recommendations. The policy emphasized the prevention of drug and alcohol abuse through education and law enforcement procedures focusing on detection and early intervention (18,19). However, treatment was provided for problem users with an emphasis on returning them to service.

In response to continuing public concern about reports of serious drug addiction among U.S. forces in Southeast Asia, President Nixon in 1971 directed DoD to take additional measures to address the drug problem. The result was the establishment of a urinalysis testing program that initially consisted of mandatory testing for service members leaving Southeast Asia and grew to include mandatory, random urinalysis for all U.S. forces worldwide. The program experienced problems in the mid-1970s due to a legal challenge that the Fifth Amendment protection against self-incrimination was being violated (20). Subsequently, Congress discouraged use of wide-scale drug testing as not cost-effective, which resulted in the program becoming dormant from 1976 to 1981. During this period, there were reports of increased drug use among U.S. military personnel, especially those stationed in the Federal Republic of Germany, which kept attention focused on the problem.

In 1981, the crash of a jet on the aircraft carrier *Nimitz* riveted public attention on the military's drug abuse problem, particularly marijuana use. Autopsies of the 14 Navy personnel killed in the crash showed evidence of marijuana use among 6 of the 13 sailors and nonprescription antihistamine use by the pilot. As a result of this incident and other concerns about drug use in the active-duty services, the military reinstated urine testing for drugs, and the Navy launched its War on Drugs in 1981. New breakthroughs in drug-testing confirmation procedures and more rigorous chain-of-custody procedures for tracking urine samples were adequate to overcome earlier legal objections. Urine tests, which are conducted either randomly or when an individual is suspected of using drugs, have become a major tool for the detection and deterrence of illicit drug use in the military (17).

Beginning in 1986 and continuing into the 1990s, policies on drug and alcohol abuse were placed in the broader perspective of a coordinated, comprehensive policy on health promotion that recognizes the value of good health and healthy lifestyles for military performance and readiness. A 1986 directive defined health promotion as those activities designed to support and influence individuals in managing their health through lifestyle decisions and self-care (21). Smoking prevention and cessation, as well as alcohol and drug abuse prevention, physical fitness, nutrition,

stress management, and prevention of hypertension, were included in the directive. Smoking prevention and cessation programs were to include information on the health consequences of smoking provided at initial entry and permanent change of station. The health promotion strategy was developed to encourage changes in lifestyle to make healthy behaviors the norm and thereby foster the belief that unhealthy behaviors, such as smoking and drug and alcohol abuse, were incompatible with military service.

During this period, DoD also examined the impacts of the sale of tobacco in the military, including the impact of increasing prices of tobacco products. The resulting report clearly recognized the negative health impacts of smoking and the importance of individual choice (22). In 1986, the Secretary of Defense issued a memorandum calling for an intensive antismoking campaign with an emphasis on the negative health impacts of smoking. Smoking rates and effects on health continued to be monitored, and positive steps were taken to reduce the impact of "passive smoking," including restrictions on smoking in certain common areas and prohibition of smoking by medical personnel in the presence of patients (23,24). All of the services now prohibit smoking on base except in designated smoking areas and offer smoking cessation programs to encourage smokers to quit (25,26).

U.S. military substance use policy continues to be updated periodically and has focused mainly on illicit drug use and alcohol abuse (13,27). Current DoD policy requires the following with regard to drug and alcohol abuse programs and resources:

- Education and training on DoD policies for drug and alcohol abuse and/or dependency, and on effective measures to alleviate problems associated with drug and alcohol abuse and/or dependency
- Prevention programs designed to deter substance abuse to include Drug Demand Reduction (DDR), a urinalysis testing program, mandated across the services supported by a program manager at the installation level to oversee urinalysis testing and outreach programs
- Treatment and/or rehabilitation for military personnel who abuse alcohol
- Periodic assessment of the nature and extent of drug and alcohol abuse in DoD

EPIDEMIOLOGY

Health Behavior Surveys

To help monitor the extent of substance use, DoD initiated a series of comprehensive health behavior surveys among active duty military personnel in the Army, Navy, Marine Corps, and Air Force. The first survey was conducted in 1980 (28) with subsequent surveys conducted in 1982, 1985, 1988, 1992, 1995, 1998, 2002, 2005, and 2008; the Coast Guard was added in 2008 (12,29). The goal of the surveys has been to

provide data to help assess the prevalence, correlates, and consequences of substance abuse and other health behaviors in the military.

The surveys have all been conducted using similar methods. Civilian researchers first randomly selected a sample of approximately 60 military installations to represent the armed forces throughout the world. At these designated installations, the civilian researchers randomly selected men and women of all ranks to represent all active duty personnel. Personnel were omitted from consideration if they were recruits, academy students, undergoing a permanent transfer to a new location, or absent without leave. Civilian research teams administered printed questionnaires anonymously to selected personnel in classroom settings on military bases or aboard ships. Personnel who were unable to attend the group sessions (e.g., those who were on leave, sick, or temporarily away from the base) were mailed questionnaires and asked to complete and return them. Participants answered questions about their use of alcohol, tobacco, illegal drugs (e.g., marijuana, cocaine, tranquilizers, heroin), their misuse of prescription drugs (e.g., stimulants, tranquilizers), and problems resulting from their drug or alcohol use. These data collection procedures yielded from 12,000 to 28,000 completed questionnaires for the various surveys. From 59% to 84% of those eligible to take part actually did so. After participants completed the surveys, the data were weighted to represent the eligible population of the active duty force.

Substance Use Definitions

Heavy alcohol use was defined as five or more drinks per typical drinking occasion at least once per week. Any illicit drug use was defined as the use of marijuana/hashish, cocaine, inhalants, hallucinogens, or heroin, or nonmedical use of prescription-type drugs, including stimulants, sedatives, tranquilizers, or analgesics one or more times during the past 30 days. Any cigarette use was defined as having smoked one or more cigarettes in the past 30 days and having smoked at least 100 cigarettes in the lifetime.

Sociodemographic Characteristics of Active Duty Personnel

Table 70.1 presents estimates of the distribution of sociodemographic characteristics among military personnel in selected survey years—1980, 1988, 1998, 2002, 2005, and 2008. Because of the omission of some personnel from the surveys (i.e., recruits, service academy students, people absent without official leave, and people who had been transferred to a new base at the time of data collection), these estimates may differ slightly from the characteristics of the total active force but are still very close approximations. As shown, the military population in all survey years was predominantly male, white, and concentrated in pay grades E4–E6. When looking at the profile pattern across the 28-year period, the proportion of women, Hispanic and other

racial/ethnic groups, college-educated personnel, and personnel aged 35 years or older increased significantly between 1980 and 2008, and for some characteristics nearly doubled. The demographic profile for 2008 is quite similar to the profile for 2005.

Trends in Substance Use

Figure 70.1 presents the trends from 1980 to 2008 of the percentage of active duty military personnel who engaged in heavy alcohol use, illicit drug use, and cigarette use during the 30 days prior to the survey. Coast Guard data were omitted from analyses of the 2008 survey estimates to provide comparable data across survey years. As shown, heavy alcohol use decreased between 1980 and 1988, showed some fluctuations between 1988 and 1998, increased significantly from 1998 to 2002, and remained at about that same level in 2005 (19%) and 2008 (20%). The heavy drinking rate for 2008 (20%) was not significantly different from when the survey series began in 1980 (21%), although use increased during the past decade (from 15% to 20%).

The prevalence of any reported illicit drug use (including prescription drug misuse) during the past 30 days declined sharply from 28% in 1980 to 3% in 2002. In 2005, the prevalence of illicit drug use for the past 30 days was 5% and in 2008 it was 12%. Improved question wording in 2005 and 2008 may partially account for the higher observed rates, which are largely attributable to reported increases in misuse of prescription pain medications. Because of wording changes, data from 2005 and 2008 are not comparable to data from prior surveys and are not included as part of the trend line. An additional line from 2002 to 2008 shows estimates of illicit drug use excluding prescription drug misuse. As shown, those rates were very low (2% in 2008) and did not change across these three iterations of the survey.

The percentage of military personnel who smoked cigarettes in the past 30 days decreased significantly from 51% in 1980 to 30% in 1998. It increased significantly from 1998 (30%) to 2002 (34%), and has been slowly trending downward since then, such that the rate in 2008 (30.5%) was similar to the rate in 1998.

Despite the significant downward trends in illicit drug use, cigarette use, and heavy drinking (in the earlier years), the question arises as to whether these changes are due to military programs and policies or to other factors. One possible explanation for the changes could be shifts in the demographic composition of the armed forces noted in Table 70.1. From 1980 to 1998, demographic changes were favorable to lower levels of use in that military members were more likely to be older, to be officers, to be married, and to have more education (all groups with lower rates of use). In contrast, the increases in cigarette use and heavy drinking between 1998 and 2002 could be associated with a shift toward younger personnel joining the military in response to the events of September 11, 2001. Bray and Hourani (11) examined this issue and found that the differences across the years were still evident even after adjusting for the demographic differences. This suggests that the sociode-

TABLE

mographic changes in the makeup of the military were not sufficient to explain the trends in Figure 70.1. Other factors such as changes in military culture, norms, and attitudes resulting from military programs and policies as well as possible differences in smoking patterns of civilians selecting to join the military were more likely to account for these changes.

Characteristics of Substance Users

Table 70.2 allows us to gain a better understanding of the sociodemographic characteristics of the heavy alcohol, illicit drug, and cigarette users from the 2008 survey. It presents the prevalence and the odds ratios (i.e., the odds that persons are

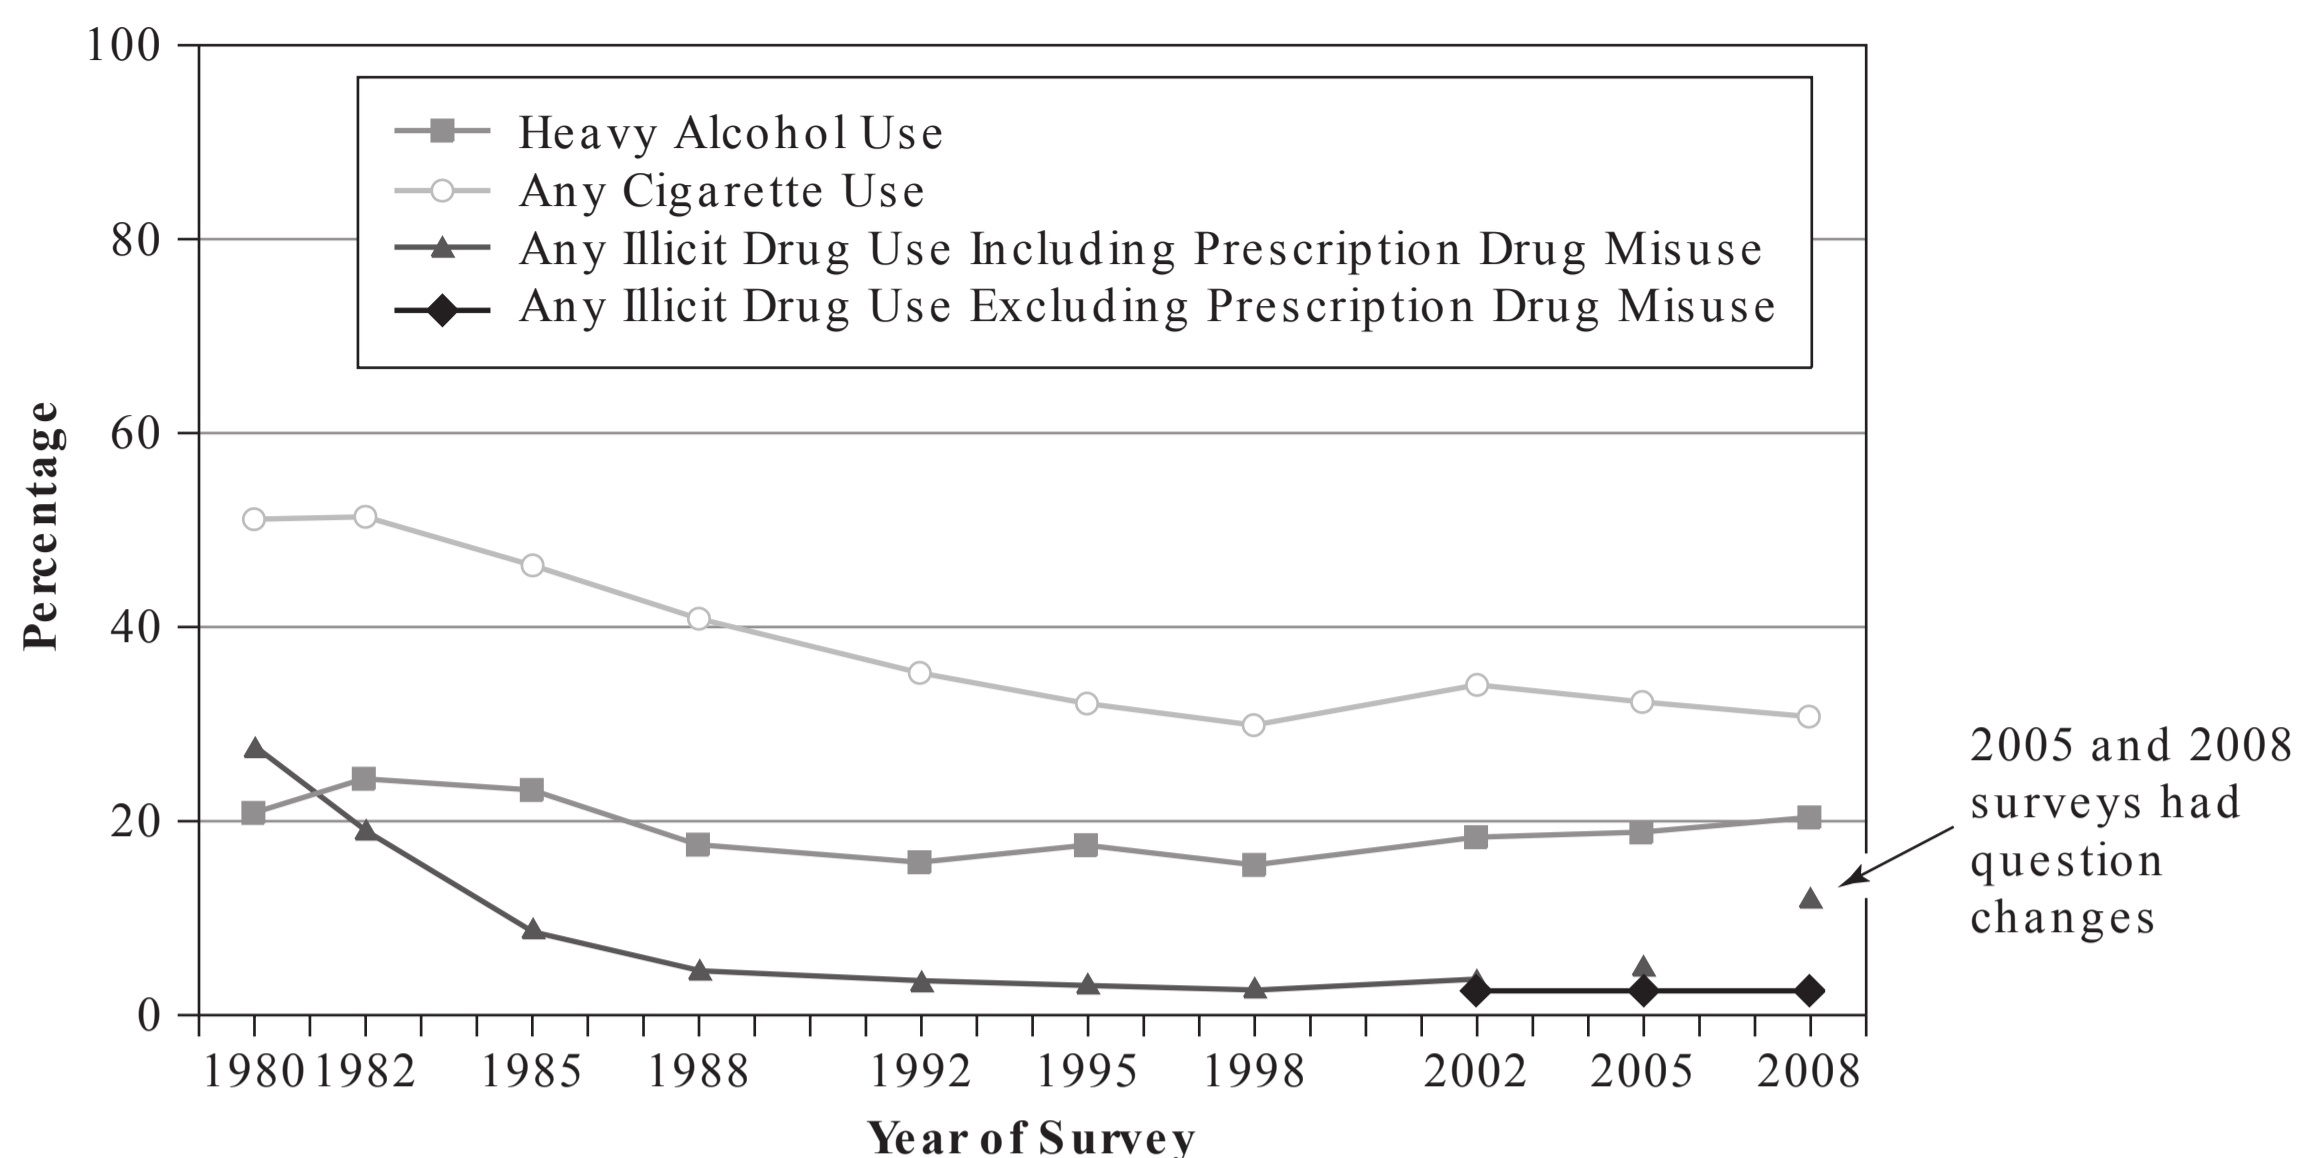

Figure 70.1. Trends in past 30-day substance use, total DoD, 1980–2008. Heavy alcohol use is defined as five or more drinks on the same occasion at least once a week in the past 30 days. Any illicit drug use including prescription drug misuse is defined as the use of marijuana, cocaine (including crack), hallucinogens (PCP/LSD/MDMA), heroin, methamphetamine, inhalants, GHB/GBL, or nonmedical use of prescription-type amphetamines/stimulants, tranquilizers/muscle relaxers, barbiturates/sedatives, or pain relievers. Any illicit drug use excluding prescription drug misuse is defined as the use of marijuana, cocaine (including crack), hallucinogens (PCP/LSD/MDMA), heroin, methamphetamine, inhalants, or GHB/GBL.

users compared with a reference group) adjusted for all of the other characteristics in the table. As shown, the overall adjusted prevalence of heavy drinkers was 20%. Although a number of subgroups were significantly higher than the specific reference group, the higher rates of heavy alcohol users occurred among persons who were serving in the Marine Corps or Army, were men, were white or Hispanic, had less than a college degree, were single or married but unaccompanied by their spouse, and were of any rank (pay grade) except senior officers (O4–O10). The overall prevalence of illicit drug use (excluding prescription drug misuse) was very low at 2.2%. Drug users were more likely to be serving in the Army, Navy, or Marine Corps relative to the Air Force, and were more likely to be men and to be single or married but unaccompanied by their spouse. Cigarette use prevalence was 30.7%. Smokers were more likely to be serving in the Army, Navy, or Marine Corps, and were more likely to be men, to be white non-Hispanic, to have less than a college degree, to be single, to be enlisted (especially pay grades E1–E6), and to be stationed outside the continental United States (OCONUS). The findings for demographic characteristics are highly similar for heavy alcohol users and cigarette users.

Military and Civilian Comparisons

To help gauge the progress of substance use policies and programs, military leaders often use the civilian population as a comparison benchmark. To make this comparison, military data were drawn from the 2008 health behavior survey and

civilian data from the 2007 National Survey on Drug Use and Health (NSDUH), a nationwide survey of substance use. Military and civilian data sets were equated for age and geographic location of respondents, and civilian substance use rates were standardized (adjusted) to resemble the demographic distribution of the military. Comparisons were made for four age groups: those aged 18 to 25, 26 to 35, 36 to 45, and 46 to 64.

Results shown in Figures 70.2 and 70.3 indicate that the patterns varied by substance and by age groups. As shown in Figure 70.2, military personnel aged 18 to 25 or aged 26 to 34 were significantly more likely than civilians in those age groups to have engaged in heavy drinking, whereas this pattern was reversed for those aged 46 to 64. Rates of past month cigarette use were lower for military personnel aged 36 to 45 or aged 46 to 64 than for civilians in those age groups, whereas there was no significant difference between military personnel and civilians in younger age groups. As shown in Figure 70.3, service members aged 18 to 25 were less likely than civilians in that age group to engage in illicit drug use, whereas this pattern was reversed for service members aged 36 to 45 or aged 46 to 64. Note that this higher prevalence of illicit drug use among these older age groups is due to the misuse of prescription drugs; when looking just at illicit drug use excluding prescription drugs, the rates were lower for service members than for civilians in each age group.

The findings indicate that substance use patterns in the military do not simply mirror similar use among civilians. The lower rates of drug use (excluding prescription misuse)

Note: Prevalence estimates are percentages among military personnel in each sociodemographic group that reported heavy alcohol use, any illicit drug use excluding prescription drug misuse, and any cigarette use in the past 30 days. Adjusted prevalence is a model-based, standardized estimate. The main effects of service, gender, race/ethnicity, education, family status, pay grade, and region were included in the standardization model. Heavy alcohol use is defined as consumption of five or more drinks on the same occasion at least once a week in the past 30 days. Any illicit drug use excluding prescription drug misuse is defined as the use of marijuana, cocaine (including crack), hallucinogens (phencyclidine [PCP], lysergic acid diethylamide [LSD], methylenedioxymethamphetamine (this is ecstasy)[MDMA], and other hallucinogens), heroin, inhalants, or gamma hydroxybutyrate /gamma butyrolactone [GHB/GBL]. Any cigarette use is defined as any use of cigarettes in the past 30 days.

^aOdds ratios were adjusted for service, gender, race/ethnicity, education, family status, pay grade, and region.

^bAn asterisk “*” beside an estimate indicates that the estimate is significantly different from the reference group.

^cRefers to personnel who were stationed within the 48 contiguous states in the continental United States.

^dRefers to personnel who were stationed outside the continental United States or aboard afloat ships.

among military personnel compared with civilians suggest either that military policies and practices deter drug use in the military or that military personnel hold attitudes and values that discourage substance use. Because of the military's stringent policy prohibiting drug use and the urinalysis testing program to enforce it, it seems likely that the difference in drug use prevalence between military personnel and civilians results from military policies and practices. In contrast, the higher rates of heavy drinking among

younger military personnel suggest that certain aspects of military life may foster heavy drinking or that those military policies and programs directed toward reducing these substances have not been as effective as similar efforts among civilians. The comparable or lower smoking rates in the military relative to civilians suggests that military and societal factors both are likely playing a role in smoking behavior. Unfortunately, nearly a third of these populations still smoke cigarettes at least monthly.

PREVENTION, INTERVENTION, AND TREATMENT

To help address the challenges of military life, especially during periods of conflict, the military has implemented prevention, intervention, and treatment programs that address substance use issues. These programs have changed over time to adapt to the changing social and military environment and vary by service, but they typically share common models and elements. Substance abuse programs take a community approach that encourages responsible choices based on leadership involvement, individual responsibility, base installation community participation, and local community partnerships. Other programs are tailored to fit the severity of the problem.

Prevention

All services include drug abuse prevention information as part of general military training, ranging from the earliest days of recruit training to other times during their career. Education includes information on the hazards of drug use, administrative and punitive consequences, responsible decision making, and healthy alternatives to drug use. Many commands use drug detection dogs to periodically search barracks and vehicles at installation gates. Selected high-risk target groups, such as units preparing to deploy to areas where drug use is prevalent, often receive tailored drug abuse prevention information and education.

The military also has a drug-testing program, commonly referred to as urinalysis, that plays a key role in drug use prevention. The purpose of drug testing is to deter service members from using drugs and to permit commanders to detect drug abuse and assess the security, readiness, and discipline of their commands. Drug testing is conducted under a number of different situations, including random testing at least once per year, probable cause searches, during inspections, and during any valid medical examination, including emergency room treatment.

Prevention of alcohol abuse has also been a key component of military substance abuse programs. Each service stresses the importance of alcohol abuse prevention through various training and education classes. These include providing members with basic information on alcohol and alcohol abuse, and emphasizing early detection and early intervention as critical in the prevention of alcohol abuse. A member's on-base driving privileges are revoked if the member is convicted of driving while intoxicated (DWI). Many commands offer safety stand-downs and red ribbon campaigns prior to holidays and the vacation season, reminding members of the dangers of drinking and driving. National Drunk and Drugged Driving Awareness week is another opportunity that commands use to make members aware that "drinking and driving don't mix." Commands encourage their personnel to use designated drivers for situations where alcohol will be available, and most bases provide server training for employees of on-base clubs and restaurants that serve alcohol. It is common for bases to set up driving mazes at gates and other

checkpoints to detect intoxicated drivers, especially on weekends. Alcohol deglamorization campaigns stress the importance of food and nonalcoholic beverages at command-sponsored social events. In addition, the armed forces emphasize personal responsibility and caring for your "buddy." Designated drivers often receive free nonalcoholic beverages from various clubs and restaurants. Supervisory personnel are expected to lead by example and be role models for junior personnel, both on and off duty.

A comprehensive effort to address tobacco prevention in the armed forces was launched in 1999 by DoD's Alcohol and Tobacco Advisory Committee (ATAC), which developed a tobacco use prevention strategic plan that is still in effect. The plan set forth a series of goals and tasks, metrics and objectives, requirements for policy, programs, practices, and resources, along with a timeline for achieving the goals. The goals of the plan were and are to (a) reduce the smoking rate and smokeless tobacco rates, (b) promote a tobacco-free lifestyle and culture through education and leadership, (c) educate commanders on how to promote healthy lifestyles, (d) promote the benefits of not smoking and provide tobacco counter-advertising, (e) decrease accessibility, (f) identify users and provide targeted interventions, (g) provide effective cessation programs, and (h) continue to assess best practices in tobacco use prevention.

Intervention and Treatment

Through the years, DoD and the services have developed and implemented intervention and treatment programs that address alcohol, tobacco, and illicit drug abuse issues. These programs have changed over time to adapt to the changing social and military environment. Early intervention services are provided for personnel at risk of developing substance-related problems; outpatient services treat service members' level of clinical severity to help achieve permanent changes; intensive outpatient treatment/partial hospitalization includes education and treatment while allowing patients to apply newly acquired skills; and inpatient services provide a planned regimen of care in a 24-hour live-in setting.

The following are examples of efforts that DoD has implemented. The Air Force Alcohol Drug Abuse Prevention and Treatment (ADAPT) program and DDR program provide services that support the wellness of airmen and their families. A key component is the Culture of Responsible Choices initiative that involves a community-based working group to provide leadership, encourage individual responsibility, and involve the base and local communities. The Air Force also utilizes additional prevention programs, such as the "That Guy" media campaign and the Enforcement of Underage Drinking Laws (EUDL) to combat underage drinking.

Navy programs address varying levels of substance abuse. The Level 0.5 is an early intervention service for specific individuals who, for a known reason, are at risk of developing substance-related problems or for those for whom there is not yet sufficient information to document a substance use disorder. Level I programs provide outpatient services to treat

an individual's level of clinical severity and to help the individual achieve permanent changes in his or her alcohol-using behavior and mental functioning. These services address major lifestyle, attitudinal, and behavioral issues that have the potential to undermine the goals of treatment. Level II programs provide intensive outpatient treatment/partial hospitalization. The program provides essential education and treatment components while allowing patients to apply their newly acquired skills within "real-world" environments. The program provides comprehensive biopsychosocial assessments and individualized treatment plans. Level III programs encompass organized services staffed by designated addiction treatment and mental health personnel who provide a planned regiment of care in a 24-hour live-in setting. This level of treatment provides for individuals who need safe and stable living environments in order to develop their recovery skills. Level IV provides medically managed intensive inpatient detoxification at a major medical treatment facility.

DoD requests that all commands provide their personnel with effective tobacco cessation programs. Lectures, films, pamphlets, and other forms of health promotion incorporate the latest available medical research information on tobacco, smoking, health, and treatment. Tobacco cessation programs take many different forms, and local installation commanders are authorized to implement activities that are appropriate to their sites and populations. Most bases offer some form of tobacco cessation classes, generally presented by personnel from the installation hospital or clinic, substance abuse counseling facility, health promotion office, or family service center. Physicians and other health care providers are expected to evaluate all their patients for use of tobacco products and, where indicated, to recommend appropriate cessation activities. When clinically determined as safe and appropriate, nicotine replacement therapy (NRT) is prescribed. This includes the use of nicotine gum or a nicotine patch. NRT is most effective when used in combination with other cessation activities, including counseling/social support and skills training that enable one to achieve and maintain abstinence.

Despite the regulations, directives, and programs the military has put into place, DoD and the military branches have provided only limited assessment and evaluation of the effectiveness of these prevention, intervention, and treatment programs (30). Some of the programs, such as urinalysis testing, are likely having their desired effect of reducing illicit drug use. Others, however, may not, and although they may appear to have face validity, they need to be evaluated to determine if they demonstrate evidence-based best practices for confronting and dealing with substance use issues.

FACTORS INFLUENCING SUBSTANCE USE IN THE MILITARY

There are a number of complex factors that contribute to substance use and misuse in the armed forces, including individual, social, cultural, and environmental influences. Individual factors include demographic, genetic, and psychological

components. Individual factors such as age and genetic makeup are also possible risk factors for substance use. For example, as shown in Table 70.2, young adults and males are more likely to engage in substance use than their older or female counterparts. Genetic makeup also plays a role in addiction. Drugs such as heroin and nicotine are well known for their addictive properties. Psychological components include individuals' beliefs, attitudes, intentions, and values, some of which lead to higher risk for substance use and some persons with substance use problems self-selecting into the military. Bray et al. (31) found evidence of selection as a partial explanation for heavy alcohol use in the military.

Social factors include family, friends, and norms or shared expectations about desired behavior. Peer pressure to fit in with friends (an example of normative influence) may lead service members to engage in the heavy drinking, drug use, or smoking habits of their buddies. Haddock et al. (32) found that social factors are strong predictors of tobacco use and that service members are at increased risk of becoming smokers if they have friends who smoke and view smoking positively. Social factors identified with initiation of smoking soon after joining the Navy were curiosity, friends smoking, and wanting to be "cool" (33). Similarly, Bray et al. (31) found that socialization about the regulations and normative expectations regarding substance use helped explain lower rates of heavy drinking among military personnel in regular units compared with rates of heavy drinking by recruits prior to joining the military.

Cultural factors include perceptions about traditions and acceptable practices, and acceptance, support, and tolerance for use. As suggested in the introduction to this chapter, over the years a culture and resulting stereotype has developed of the military being composed of heavy-smoking, hard-drinking, adventuresome service members (16). Indeed, there is evidence suggesting that military culture could be encouraging tobacco use (34). Clearly, many positive steps have been taken since then to modify this stereotype (e.g., the ban on tobacco use during basic training, smoke-free federal buildings, the introduction of alcohol treatment programs), but some of this perception remains. Incidents such as the Tailhook scandal in 1991, in which excessive drinking resulted in rapes and misconduct by many Navy and Marine officers, serve as a reminder of the magnitude of the negative impacts of alcohol abuse. The findings that heavy alcohol use and tobacco use rates are higher than those in the civilian population (at least among young adults—see Figure 70.2) indicate some level of acceptance, tolerance, and/or lack of enforcement of policies among some services, installations, or commanders.

Environmental factors include such things as high availability and easy access to substances, advertising that encourages use, and lack of enforcement of policies to control use. With the exception of basic training, where substance use is banned, alcohol and tobacco are readily available to service members and priced favorably (at least tobacco), and use is encouraged via advertising (e.g., tobacco and alcohol advertisements in military news publications such as *Army and Navy Times*) (35). Illicit drugs may be less available generally,

but pockets of use suggest that users have internal networks that allow them to gain access. These factors may contradict and interfere with some policies and programmatic efforts to reduce substance use in the military. However, drug use policy appears as a positive example of what can be achieved with a rigorous and clear protocol that is strongly encouraged and closely monitored at all DoD levels.

CONCLUSIONS

Heavy alcohol use, illicit drug use, and cigarette smoking constitute significant detriments to the health, productivity, and welfare of military personnel. Substance abuse is a major contributor to mortality and morbidity and also adversely affects work performance. To address these issues, DoD has set forth a series of policies designed to decrease the impact of substance abuse on military personnel. Alcohol abuse, drug abuse, and smoking policies are now included in a broader health promotion framework that encourages healthy lifestyles to promote high-level military performance and readiness. Current policies include prevention, intervention, and treatment components and have been the genesis for a wide range of programs to address substance abuse issues. Although the programs appear to have face validity, more research is needed to demonstrate their efficacy and effectiveness.

Assessment of substance use patterns indicates that the military has made steady and notable progress in combating illicit drug use and cigarette use, particularly during the 1980s and 1990s. Illicit drug use has shown dramatic declines since 1980, and in 2008, rates of use among military personnel (omitting prescription misuse) were lower than those among civilians. Although cigarette use has shown declines over the last 25 years, over 30% of military personnel are current smokers. In contrast, the military has made less progress in reducing heavy drinking. In 2008, heavy drinking affected one in five active duty personnel and was significantly higher than among civilians.

Despite impressive progress, more remains to be done. A variety of individual, social, cultural, and environmental factors within the armed services contribute to continued substance use and need to be addressed to further reduce substance use, especially heavy drinking and tobacco use.

Medical Education on Addiction

Karen Drexler

BACKGROUND

Although Benjamin Rush, MD, America's first Surgeon General, referred to drunkenness as a disease (1), alcoholism and other addictions have not been widely recognized as warranting medical attention. The American Medical Association (AMA) first formally recognized alcoholism in 1956 (2). That declaration heralded a movement to improve medical education in the treatment of alcoholism and other addictions that continues to the present time.

The need for physicians and other health professionals to have competence in detecting and treating alcohol dependence and other addictions is clear from the magnitude of their negative impact on human health and well-being. In the United States, tobacco, alcohol, and illicit drug use represent 3 of the top 10 actual causes of death, accounting for 537,000 deaths in 2000 (22.3% of all deaths) (3). In 1995, the total cost of alcohol and drug abuse to society in the United States was estimated to be \$276.4 billion (or 3.7% of total gross domestic product) (4).

Screening and brief intervention in health care settings reduce smoking, hazardous drinking, and medical consequences of alcohol and tobacco use (5). Reduction in drinking is associated with improved health and quality of life (6). Behavioral interventions and medications are effective for treating substance use disorders (7).

Despite the significant effect of alcohol and drug use on public health and the availability of effective prevention and treatment strategies for health care professionals, physicians have been slow in implementing evidence-based screening, brief intervention, and treatment. Numerous surveys of physicians and other health care professionals across the globe and across several decades indicate these professionals' lack of confidence in the ability to deal with patients with addiction (8–11). Physicians and other health professionals fail to detect alcohol use disorders in routine patient encounters (11). When intoxication or problems with alcohol use are detected, few physicians follow up with appropriate intervention and referral (12). House staff in internal medicine and family medicine score significantly better on management of hypertension than of alcoholism (13). Approximately one third of medical students endorse personally consuming more alcohol than guidelines recommend for safe alcohol consumption, exceeding rates for employed individuals (14).

Physician ownership of prevention and treatment has been slowly improving in the area of smoking cessation where the number of patients receiving advice to stop smoking has doubled since the mid-1990s. Consequently, success in quitting has improved such that the number of former smokers has surpassed the number of current smokers (15). Physicians' rates of smoking are far less than that of the general population in the United States, Japan, and the United Kingdom (16). There is recent evidence that physicians' skills in screening and brief intervention for at-risk alcohol use are also improving, but treatment of alcohol use disorders and detection and management of other substance use disorders still lag (17).

This chapter will review the history, current state of the art, and evidence-based best practices in medical education on alcohol and other drug (AOD) use and addiction.

HISTORY

Recognition of drunkenness as a disease by Dr. Rush (1) was not widely accepted by American physicians in the 18th century. Physicians had noted for centuries the utility of opium and alcohol for pain relief. Some noted the risk of repeated use leading to addiction, but the greater concern was that using opium to relieve pain would mask an underlying serious illness (18). In the early- to mid-19th century, prominent physicians extolled the benefits of opium, morphine, and cocaine for treating a variety of diseases, and their use became widespread (18). In the late 19th century, some prominent physicians began publishing papers on the devastating effects of addiction to these substances, but there was a widespread belief that the risk of addiction was limited to lower socioeconomic classes, those of weak moral fiber, and psychopaths (18). With increasing availability, Civil War veterans and upper class citizens increasingly became addicted and medical attention increased. The concept of a vice disease (i.e., one that was easily acquired, progressively damaging, and difficult to cure) became widely accepted for opium addiction, alcoholism, and syphilis. Some physicians practiced maintenance treatment for narcotic addiction, but many regarded this as immorally keeping patients addicted for the physician's monetary gain (18). In the late 1800s and early 20th century, governments began to restrict the availability of narcotics and alcohol in hopes to reduce the costs of addiction

to society. Overly optimistic claims of cure by nonphysicians together with significant legal penalties for physicians prescribing narcotics to patients for maintenance treatment essentially eliminated maintenance treatment by physicians. In 1929, the U.S. Congress established two “narcotic farms” or prison hospitals for the treatment of narcotic addiction (19). Disappointment in the high relapse rates after detoxification (reported to be about 75%) led physicians to ignore addiction treatment (18).

In the mid-20th century, increasing optimism in the effectiveness of Alcoholics Anonymous, of in-patient rehabilitation, and of medically managed alcohol withdrawal led to increasing interest by some physicians in medical treatment for alcoholism. In 1954, the New York City Medical Society on Alcoholism (NYCMSA) held its first scientific meeting with one of its goals to improve medical education on alcoholism (20). In 1956, the AMA recognized alcoholism as an illness warranting treatment and advocated that hospitals not deny admission to patients with alcoholism (2). By 1966, the AMA had established a Committee on Alcoholism (21), which drafted a report on alcoholism as a disease. In 1967, the NYCMSA became the American Medical Society on Alcoholism (AMSA), with one of its goals to improve physician education on alcoholism (20). In that same year, the Cooperative Commission on the Study of Alcoholism published *Alcohol Problems: A Report to the Nation* (22), which noted that

There has been a virtual disregard of problem drinking in the curricula of professional institutions. Medical schools along with schools of nursing and social work have virtually ignored it.

The 1970s witnessed a historic growth in physician education and interest in addiction treatment. In 1972, the AMA Council on Mental Health and the Committee on Alcoholism and Drug Dependence issued a position statement (23), stating that it was “not appropriate at this time to suggest a specific plan or a model for a program on psychoactive drug dependence,” but emphasizing a biopsychosocial concept of addiction, pharmacology of psychoactive drugs, iatrogenic drug abuse, and special risk of physicians to development of addiction.

Recognizing alcoholism as “the Number One Public Health Problem of the United States,” the National Council on Alcoholism (NCA) sponsored a conference in 1970 on “Professional Training on Alcoholism,” which brought together experts in the field to share “experience, strength, and hope” in improving education on the treatment of alcoholism. Surveys of health care personnel identified negative attitudes toward alcoholic patients as a major barrier to providing appropriate treatment. Many conference speakers noted that negative attitudes of role models presented a major barrier to effective education. In his opening remarks, Dr. Seixas noted,

... We not only have neglected alcoholism, but, by precept and example, by gesture and joke, have given the medical student an antieducation in the subject.

There was lively debate over the best strategy to improve physician attitudes—whether improved diagnostic and treatment techniques would lead to improvement in attitudes or whether current treatments were sufficient and efforts should focus primarily on changing attitudes (24). The conferees recommended specific strategies to improve professionals’ education on alcoholism:

1. Increased grant support and change in research to focus more on pathophysiology and treatment of the primary disorder (25)
2. Clinical resources and treatment facilities affiliated with medical schools so that trainees could participate in clinical rotations and observe positive responses to treatment
3. Coordination of the curriculum to develop a cohesive plan (25)
4. Research into effective teaching strategies for the addictions

In 1971, the National Institutes of Health (NIH) launched the Career Teacher Program in the Addictions, providing faculty development grants to 63 of the 124 medical schools (26). This program provided salary support for a career teacher at 59 medical schools (27), conferences where career teachers were able to collaborate and share best practices, and significant advances in the quantity and quality of medical education (20). Career teachers faced significant barriers in changing the traditional allocation of training hours, but succeeded in increasing academic attention to addiction education over the 10-year program. Among the career teachers’ accomplishments were

1. Quantitative surveys of medical education on the addictions (28).
2. Increases in the number of required hours in medical school curricula. Schools with career teachers realized larger gains, but the total number of required hours devoted to addiction remained less than 1% of the total curriculum time (28,29).
3. Founding of the Association for Medical Education and Research in Substance Abuse (AMERSA) in 1976 to expand and improve medical education on the addictions (20).
4. The NIDA task force working with the National Board of Medical Examiners (NBME) developed an examination on drug and alcohol use disorders for medical students. Six hundred twenty-nine medical students scored more poorly on this exam than on traditional content of the NBME exam. They scored better in areas of pharmacology, Alcoholics Anonymous, and treatment of delirium tremens (30).
5. Results of this examination informed development of curriculum guides for medical schools on addiction.

Private foundations and the NIH also supported development of model curricula as a means of enhancing medical education on addiction. In 1977, Dartmouth Medical School received a large grant from the Kroc Foundation (Project Cork) to develop a model medical school curriculum on alcohol and alcoholism. Its primary emphasis was to increase

attention on alcohol throughout the curriculum. For example, cardiology expanded from one mention of alcoholism in a lecture on cardiomyopathy to include alcohol's effects on hypertension and hyperlipidemia and appropriate use of alcohol by heart patients. Similarly, the psychiatry course expanded from a brief mention of alcohol's effects on psychotropic medications to include diagnosis and treatment of alcohol use disorders. Clerkships included medical management of alcoholism (8). In 1984, Johns Hopkins launched a comprehensive training program on alcoholism detection, management, and referral for all levels of practitioners—medical students, house staff, and attending physicians (31). Georgetown University School of Medicine introduced exposure of medical students to panels of recovering physicians (8).

Also starting in the early 1970s, several independent initiatives began to improve physician competency in addiction treatment through postgraduate certification. In 1972, in response to a new California law, the California Society for the Treatment of Alcoholism and Other Drug Dependencies (CSTAODD) was incorporated to focus on medical education and to certify physician competency in the addictions (20). In 1975, G. Douglas Talbott organized the American Academy of Addictionology in Atlanta, Georgia, to certify physicians in the practice of addiction medicine. In the 1970s, the first postgraduate fellowships in addiction medicine were established (27). In 1983, the Kroc Foundation sponsored a meeting to encourage collaboration between the various organizations devoted to improving physician education in addiction treatment. The American Medical Society on Alcoholism and Other Drug Dependencies (AMSAODD) became the umbrella organization and accepted the task of developing continuing medical education (CME) courses and administering a national examination for competency in addiction medicine (32). Conferees debated the merits of pursuing specialty or subspecialty recognition for addiction medicine, but decided that the addiction medicine certification should be separate and distinct from the American Board of Medical Specialties (ABMS) certification process.

The 1980s and 1990s witnessed unprecedented growth and maturity of specialist training in addiction treatment. In 1985, the American Academy of Psychiatrists in Alcoholism and Addiction (AAPAA) was formed with one of its missions to improve competency of psychiatrists and allied health care professionals in treating addictions and to pursue this in part through subspecialty ABMS board certification (33). In 1996, the organization renamed itself the American Academy of Addiction Psychiatry (AAP). Also in 1985, the Accreditation Council on Graduate Medical Education (ACGME) added a requirement for training in addictions to the general psychiatry residency training requirements (34). In 1986, AMSAODD accepted its first applications for the addiction medicine certificate. Family practice (32%) and psychiatry (28%) constituted the two largest areas of specialty among the applicants and were overrepresented compared to the distribution of these specialties among practicing physicians. Internal medicine constituted the third largest group at 24%,

similar to their proportion among practicing physicians. The majority of the applicants were board certified in their primary specialty (26). AMSAODD renamed itself the American Society of Addiction Medicine (ASAM), and from 1986 until 2008, the organization certified over 4200 physicians in addiction medicine.

In 1989, the New York University Center for Medical Fellowships in Alcoholism and Drug Abuse was established with the support from AMERSA and AAPAA. Its goal was to promote postgraduate training in the addictions by developing standards for medical training in the addictions, disseminating information on existing fellowships, and facilitating establishment of new programs (35,36). By 1989, there were 27 addiction fellowships training 44 fellows each year, with two thirds of fellowships accepting physicians from all disciplines (34). In 1991, the American Board of Psychiatry and Neurology (ABPN) received ABMS approval to offer certification in addiction psychiatry. In 1993, ABPN offered the first certification examination (37). In 1997, the ACGME accredited the first addiction psychiatry residency training programs (38). These 12-month, fifth postgraduate year (PGY-5) clinical training programs were designed to prepare board-eligible psychiatrists for ABMS subspecialty certification in addiction psychiatry. By 2000, there were 38 ACGME-accredited addiction psychiatry residency training programs offering 83 positions. In addition, there were four non-ACGME addiction fellowships. However, 23 positions were unfilled in 1999, prompting calls to expand postgraduate training in addiction to include other medical specialties (27).

Beginning in the 1980s and continuing through the 1990s, there was continued steady progress in formalizing addiction treatment training for all health care professionals. Noting that physicians' negative attitudes toward alcoholics represented a major barrier to effective assessment and treatment and the limited time in the medical school curriculum, Nocks recommended a 6-hour course aimed at changing medical students' negative attitudes toward patients with substance use disorders (39). In 1984, the Society of Teachers of Family Medicine published a residency training curriculum guide on addiction treatment, and in 1985, the American College of Physicians published a position paper on the subject (20). Also in 1985, AMERSA, NIAAA, NIDA, the Betty Ford Center, and the Annenberg Center cosponsored a consensus conference on the knowledge, skills, and abilities that physicians needed to diagnose and care for patients with substance use disorders (20). Out of this conference grew specialty societies in internal medicine, family practice, pediatrics, and psychiatry as well as NIAAA and NIDA contracts to develop and implement model curricula. One of these, Project ADEPT (Alcohol and Drug Education for Physician Training in primary care), began at Brown University to develop routine integration of drug and alcohol training throughout the primary care curriculum through trained faculty in six departments—internal medicine, family medicine, pediatrics, psychiatry, community health, and obstetrics and gynecology (20). NIAAA and the Center for Addiction Research and

Education (CARE) at the University of Wisconsin developed a model curriculum for training primary care providers in screening and brief intervention (40). Another model curriculum was developed at the University of Toronto, which included both didactic and clinical curriculum throughout the second and third years of medical school. Goals of the curriculum were that students would have the knowledge, skills, and abilities to identify and address alcoholism in patients treated in their chosen fields and that they would avoid personal difficulties with substances (41).

In 1990, the Institute of Medicine (IOM) issued a report, “Broadening the base of treatment for alcohol problems,” that called for increasing the types and availability of alcohol treatment and for research to determine appropriate treatment matching (42). In 1996, the College of Family Physicians of Canada Alcohol Risk Assessment and Intervention (ARAI) project began providing national and regional trainings and a resource material packet for CME (43). In 1997, the Residency Review Committee on Internal Medicine instituted a requirement for “instruction in the diagnosis and treatment of alcoholism and other substance abuse” (27).

In the early 21st century, previous trends continued. Further maturation of specialty practice in addiction treatment progressed at a rapid pace. Under the leadership of Elizabeth Howell, the ASAM formed the Medical Specialty Action Group (MSAG) in 2006 to investigate ABMS recognition for addiction medicine. The MSAG recommended formation of an independent American Board of Addiction Medicine (ABAM) separate from ASAM, and in 2007, ABAM was formed with the goal to pursue ABMS recognition for addiction medicine (44). More information is available through the ABAM website <http://www.abam.net/about/default.aspx> or the ASAM website <http://www.asam.org/abam.html>.

Gains in general medical education on addiction continued at a slower pace than that of specialty training due to a variety of factors. In the late 1990s, experts continued to note that practising physicians’ skills in detecting and managing substance use disorders lagged behind their skills in managing other chronic diseases (45) and that the historical gap in addiction education resulted in a lack of skills in medical school faculty that was likely to persist for some time (46). In 2000, a survey of select residency training directors in multiple specialties including internal medicine, pediatrics, family medicine, obstetrics and gynecology, psychiatry, and emergency medicine found that 56% of programs had required training on substance use disorders (ranging from 38.1% in pediatrics to 95% in psychiatry). The median number of curricula hours ranged from 3 (emergency medicine and pediatrics) to 12 (family medicine). Overall, 47% of the graduate medical education programs surveyed reported a required rotation in addiction treatment, ranging from 12% of programs in obstetrics and gynecology to 74% in psychiatry. The authors concluded that primary care medical training in the diagnosis and management of substance use disorders remained inadequate (47). McAvoy noted that there were multiple guidelines for evidence-based management of alcohol problems in primary care, but few evidence-based best practices for teach-

ing these skills and no systematic plan for implementation (48). Other factors contributing to a lack of enthusiasm for physician management of substance use problems included lack of reimbursement for these activities by third-party payers and a denial of coverage for another illness if it was deemed to be substance related.

Evidence demonstrating that screening and brief intervention in primary care is a cost-effective means of reducing high-risk substance use began mounting in the early 2000s (49). Recognizing the importance of the physician’s role in demand reduction for drugs, the Office of National Drug Control Policy (ONDCP) took a leadership role in bringing together federal stakeholders and medical educators through a series of National Leadership Conferences on Medical Education in Substance Abuse. The first of these conferences convened in 2004, the second in 2006, and the third in 2008. Among the recommendations were calls for champions in each medical school and a list-serve to improve communication and sharing of best practices; for the ACGME and ABMS to add requirements and exam questions regarding screening, assessment, and brief intervention to all graduate medical education programs and specialty exams; and for continuing education for all medical specialties to increase competency in these areas perhaps through Web-based trainings (50). Through the dialogue at these conferences, ONDCP recognized financial disincentives for physicians to embrace “screening, brief intervention, and referral to treatment” (SBIRT) and began advocating for Medicare procedure codes for screening and brief intervention for hazardous substance use. The National Institute on Alcohol Abuse and Alcoholism published a Web-based training on screening, brief intervention, referral, and treatment of at-risk alcohol use and alcohol use disorders—the *Clinician’s Guide for Helping Patients Who Drink Too Much* (51)—available at <http://www.niaaa.nih.gov/Publications/EducationTrainingMaterials/VideoCases.htm>.

With the passage of the Drug Addiction Treatment Act of 2000, the Substance Abuse and Mental Health Services Administration (SAMHSA) initiated training for physicians in the office-based practice of buprenorphine maintenance through its Center for Substance Abuse Treatment (CSAT). SAMHSA/CSAT (along with the manufacturer of buprenorphine) supported CME buprenorphine training courses through the American Psychiatric Association (APA), ASAM, the American Osteopathic Association (AOA), and the AAAP. CSAT also supported an innovative program called the Physician Clinical Support System (PCSS), which provided ongoing mentoring of new practitioners in addiction treatment (52). Although many physicians completed the training and obtained a waiver, significant barriers prevented more widespread availability of treatment including lack of institutional support, lack of reimbursement by third-party payers, and lack of demand among current caseloads of patients (53).

The IOM published two reports, which highlighted attention to alcohol and other substance use and addiction. The IOM report on improving neuroscience and behavioral health education in medical schools noted that using tobacco, being overweight, and having excessive alcohol use together

TABLE

71.1

AMERSA Project Mainstream: critical core competencies in substance abuse education for physicians

Level I: All physicians with clinical contact should:

- 1) Be able to perform age, gender, and culturally appropriate substance abuse screening.
- 2) Be able to provide brief interventions to patients with substance use disorder (SUD).
- 3) Be able to use effective methods of counseling patients to help prevent SUD.
- 4) Be able to refer patients with SUD to treatment settings that provide pharmacotherapy for relapse prevention.
- 5) Recognize and treat or refer comorbid medical and psychiatric conditions in patients with SUD.
- 6) Be able to refer patients with SUD to appropriate treatment and supportive services.
- 7) Be aware of the ethical and legal issues around physician impairment from SUD and of resources for referring potential impaired colleagues, including employee assistance programs, hospital-based committees, state physician health programs, and licensure boards.
- 8) Identify the legal and ethical issues involved in the care of patients with SUD.

Level II: All physicians co-ordinating care for patients with SUD in addition should:

- 1) Use effective methods to assess patients with SUD.
- 2) Provide pharmacologic withdrawal to patients with SUD.

Level III: All physicians providing specialty services to patients with SUD in addition should:

- 1) Provide pharmacotherapy for relapse prevention in patients with SUD.
- 2) Provide, or refer for, psychosocial counseling for relapse prevention in patients with SUD.

accounted for half of the deaths each year in the United States and recommended greater attention in medical school to “patient behaviors” leading to morbidity and mortality (54). In 2006, *Improving the Quality of Health Care for Mental and Substance-Use Conditions* recommended that

The health care workforce has the education, training, and capacity to deliver high-quality care for mental and substance-use conditions (55).

Meanwhile, AMERSA broadened its focus to include multidisciplinary health care professional education with the initiation of Project Mainstream and the publication of its *Strategic Plan* (56). The knowledge and skills recommended for all health care professionals mirrored those of other guidelines and included the following:

1. All health professionals should receive in their basic core curricula knowledge that substance use disorders are disorders for which appropriate treatment can lead to improved health and well-being.
2. All health professionals should have a basic understanding of substance use disorders and their effects on the patient, family, and community. Each professional should have an understanding of the evidence-based principles of universal, selected, and indicated prevention strategies as outlined by the IOM.
3. All health care professionals should be aware of the benefits of screening for potential and existing substance-related problems and of the benefits of intervention.

4. All health care professionals should possess basic knowledge of treatment and be able to initiate treatment or refer for appropriate assessment and treatment. At a minimum, all health professionals should be able to communicate an appropriate level of concern and the requisite skills to be able to offer information, support, follow-up, or referral to an appropriate level of services (57).

Core competencies for physicians were included in the strategic plan and are outlined in Table 71.1.

CURRENT MEDICAL EDUCATION REQUIREMENTS

There currently are requirements for education regarding substance use and addiction at each level of medical education in the United States. The Liaison Committee on Medical Education (LCME), a collaboration between the Association of American Medical Colleges (AAMC) and the AMA, accredits U.S. medical schools. The LCME refrains from proscribing a specific curriculum or minimum time spent on any given topic; however, its accreditation standards include requirements for training in six clinical disciplines including psychiatry and in “behavioral and socioeconomic subjects, in addition to basic science and clinical disciplines.” “Substance abuse” is included as one of 33 “behavioral and socioeconomic subjects” (58). In 2005, the AAMC reported that of the 131 accredited MD-granting U.S. medical schools, 122 included

TABLE 71.2 ACGME-required addiction psychiatry curriculum content

Residents must acquire knowledge and skills in the following areas:

- 1) Knowledge of the signs and symptoms of the use and abuse of all of the major categories of substances enumerated in V.B.3.b (i.e., alcohol; opioids; cocaine and other stimulants; cannabis and hallucinogens; benzodiazepines; other substances of abuse, including sedatives, hypnotics, or anxiolytics; and miscellaneous/unusual drugs, e.g., nutmeg, designer drugs, and organic solvents/inhalants) as well as knowledge of the types of treatment required for each.
- 2) Knowledge of the signs of withdrawal from these major categories of substances, knowledge and experience with a range of options for treatment of the withdrawal syndromes, and the complications commonly associated with such withdrawal.
- 3) Knowledge of the signs and symptoms of overdose, the medical and psychiatric sequelae of overdose, and experience in providing proper treatment of overdose.
- 4) Management of detoxification: in-patient management of substance-related disorders; experience in working collaboratively with specialists in the emergency department and intensive care units in the diagnosis and management of acute overdose symptoms.
- 5) Knowledge of the signs and symptoms of the social and psychological problems as well as the medical and psychiatric disorders that often accompany the chronic use and abuse of the major categories of substances.
- 6) Experience in the use of psychoactive medications in the treatment of psychiatric disorders often accompanying the major categories of substance-related disorders.
- 7) Experience in the use of techniques required for confrontation of and intervention with a chronic substance abuser, and in dealing with the defense mechanisms that cause the patient to resist entry into treatment.
- 8) Experience in the use of the various psychotherapeutic modalities involved in the ongoing management of the chronic substance abusing patient, including individual psychotherapies (e.g., cognitive-behavioral therapy), couples therapy, family therapy, group therapy, motivational enhancement therapy, and relapse prevention therapy.
- 9) Experience in working collaboratively with other mental health providers and allied health professionals, including nurses, social workers, psychologists, nurse practitioners, counselors, pharmacists, and others who participate in the care of patients with substance-related disorders.
- 10) Knowledge and understanding of the special problems of the pregnant woman with substance-related disorders and of the babies born to these women.
- 11) Knowledge of family systems and dynamics relevant to the etiology, diagnosis, and treatment of substance-related disorders.
- 12) Knowledge of the genetic vulnerabilities, risk and protective factors, epidemiology, and prevention of substance-related disorders.
- 13) Familiarity with the major medical journals and professional-scientific organizations dealing with research on the understanding and treatment of substance-related disorders.
- 14) Critical analysis of research reports, as resented in journal clubs and seminars.
- 15) Experience in teaching and supervising clinical trainees in the care of patients with substance-related disorders.
- 16) Understanding of the current economic aspects of providing psychiatric and other health care services to the addicted patient.
- 17) Knowledge of quality assurance measures and cost-effectiveness of various treatment modalities for substance-related disorders.

“substance abuse” in a required course and 62 offered elective training in this area (59).

In order to practice medicine in any U.S. state or territory, physicians must pass the United States Medical Licensing Examination (USMLE). This examination consists of three parts: Step 1 assesses knowledge of sciences basic to the practice of medicine, Step 2 assesses clinical knowledge essential to the supervised practice of medicine, and Step 3, taken after

1 year of postgraduate training, assesses clinical skills necessary for the independent practice of medicine. All three steps include content related to substance use and addiction including content on prevention, detection, and diagnosis (60). However, specific requirements regarding treatment including screening and brief intervention or medications (e.g., naltrexone, bupropion, nicotine, varenicline, buprenorphine) for treatment of substance use disorders are not mentioned.

The ACGME is responsible for accrediting postmedical school medical training programs in the United States (38). Residency training program requirements are developed by Residency Review Committees (RRC) for each medical specialty. Requirements for postgraduate training in emergency medicine, family medicine, pediatrics, psychiatry, and obstetrics and gynecology specifically include recognition of substance abuse or addiction. Requirements for anesthesiology, internal medicine, neurology, and pain medicine refer to recognition of co-occurring psychiatric conditions or behavioral aspects of care, but not specifically substance abuse or addiction. Preventive medicine, physical medicine, and rehabilitation and surgery have no references to required knowledge of substance use disorder detection, prevention, or treatment. Psychiatry is the only medical specialty with a minimum length of time devoted to a clinical rotation in addictions treatment—1 month (or 2% of clinical rotation time).

The ACGME RRC requirements for addiction psychiatry are specific. The RRC defines addiction psychiatry as

... the psychiatry subspecialty that focuses on the prevention, evaluation, and treatment of Substance-related Disorders as well as related education and research. In addition, the addiction psychiatrist will be fully trained in techniques required in the treatment of the larger group of patients with dual diagnoses of addictive disorders and other psychiatric disorders.

In order to be eligible for the program, candidates must have “satisfactorily completed an ACGME accredited general psychiatry residency prior to entering the program” (38). The duration of clinical addiction psychiatry training must be 12 months. The curriculum must contain 17 specific aspects of addiction psychiatry (see Table 71.2). Clinical experiences must include evaluation, consultation, and management of patients with substance-related disorders related to the following substances: alcohol; opioids; cocaine and other stimulants; cannabis and hallucinogens; benzodiazepines; other substances of abuse, including sedatives, hypnotics, or anxiolytics; and miscellaneous/unusual drugs (e.g., nutmeg, designer drugs, and organic solvents/inhalants). Specific program requirements can be found at the ACGME website www.acgme.org.

The ABPN is an ABMS member whose mission is “to serve the public interest and the professions of psychiatry and neurology by promoting excellence in practice through certification and maintenance of certification processes” (37). The ABPN provides certification and maintenance of certification examinations in addiction psychiatry. It publishes its exam content outlines on its website http://www.abpn.com/content_outlines.htm.

The Accreditation Council on Continuing Medical Education (ACCME) accredits CME for activities by U.S. physicians in independent practice. All states require continuing education for renewal of licensure to practice medicine. The ACCME does not prescribe specific content for CME; rather it emphasizes that CME content address important “practice

gaps”—differences between current medical practice and evidence-based best practices particularly those that have a major impact on public health. In 2008, the ONDCP partnered with ACCME to address important practice gaps in physician management of patients with high-risk substance use and addiction as a prototype for bridging gaps in health care quality that would apply to physicians in all medical specialties. A video primer on addressing a practice gap on screening and brief intervention is available online at <http://education.accme.org/video/accme-interviews/addressing-substance-abuse-cme-part-1-2>. More detailed information on the specifics of screening and brief intervention is available at <http://sbirt.samhsa.gov/about.htm>.

EVIDENCE-BASED BEST PRACTICES IN MEDICAL EDUCATION ON SUBSTANCE USE AND ADDICTION

The evidence base for medical education in substance use and addiction has been growing in volume and sophistication since the career teachers began the first quantitative analyses of medical education in the 1970s. Studies range from surveys of educational offerings and physician opinion and self-reported practices to knowledge tests before and after an intervention to randomized controlled trials of different educational interventions with and without cost-benefit analyses.

CAREER TEACHER OR CHAMPION MODEL

In 1978, Pokorny and colleagues published the results of a survey on the state of U.S. medical education on drug abuse 5 years after implementation of the Career Teacher Program (61). The survey was sent to all 117 medicine schools, and 90% of schools responded. Twelve of these received a site visit to verify their responses (10 of 12 site visits agreed with survey: 83% accuracy). Required hours devoted to addiction teaching ranged from 0 (9 schools) to 126 hours (mean = 25.7 hours). Most of the basic science hours (mean = 7.6 hours) were spent in teaching pharmacology (mean = 4.7 hours). Most of the clinical science hours (mean = 17.7 hours) were spent in teaching psychiatry (mean = 12.0 hours). The percentage of required hours devoted to addictions ranged from 0% to 3.1% (mean = 0.6%). Schools with career teacher had significantly more hours of instruction on addictions (mean = 36.3 hours) than those without a career teacher (mean = 19.8 hours). Eighty percent of schools had one or more addiction treatment programs in their affiliated hospitals. Forty-nine percent of the schools indicated that there was no instruction in addiction treatment in their residency programs; 31% indicated it was taught in one program; 19% reported 2 to 6 programs included addiction treatment teaching. Seventeen percent indicated that they offered CME related to addictions. The authors concluded that compared to previous reports, teaching on addictions was improving. The richness of experience could be gauged by three factors—the number of required hours, the number of elective courses, and the presence of an affiliated treatment program.

Compared to the prevalence of the disorder, teaching on the subject was far too little, leaving graduating physicians feeling unprepared to deal with their patients' substance use disorders. In 1983, the authors published results of a follow-up survey to measure the impact of the Career Teacher Program (28). The follow-up survey was abbreviated to include only the questions that gave the most useful data in the first survey, and the sample was also limited. Schools were divided into four groups—"rich" (those reporting the most hours of addiction instruction) and "limited" programs (those falling in the lowest third in addition instruction on the first survey), with and without a career teacher. On average, the number of hours in required addictions teaching increased by 5.8 hours with poor schools experiencing the greatest increase and rich schools remaining unchanged whether or not a career teacher was present. The largest increases in didactic and clinical rotation hours were in psychiatry and family practice departments. The presence of a career teacher had a significant positive impact on the number of elective opportunities. In 1992, Australian medical schools implemented a faculty-training program based on the career teacher model from the United States. Nine of ten schools implemented a drug and alcohol co-ordinator, and those schools realized a 158% increase in required teaching hours related to addictions and a 383% increase in electives opportunities (62).

UNDERGRADUATE MEDICAL EDUCATION

Some of the early quantitative research on medical school education in addiction involved examining participants' responses to novel educational activities. In 1983, Siegal and Rudisill reported on medical student reactions to their participation in educating DUI (driving under the influence) arrestees in a weekend intervention program, which provided "an intense exposure to alcohol and drug dependent individuals' intervention and treatment." Students rated the experience as "highly enjoyable and effective" (63). Viewing of a video montage of commercially available films and training videos on the signs and symptoms of substance intoxication and withdrawal was rated as helpful by over 90% of students (64). Teaching of specific interviewing skills and use of role-plays were rated as "highly acceptable" by both students and teachers (65) and were better predictors of clinical performance than attitudes toward alcoholic patients (66). Medical students assigned by convenience to complete a Web-based training module ($N = 82$) or a lecture ($n = 81$) on alcohol use disorders then evaluated a standard patient with an alcohol use disorder. Students completing the Web-based module scored significantly higher on specific elements of screening and brief intervention (67).

Randomized trials of teaching interventions have shown significant improvement in skills using standardized patients from before to after the intervention. In one study, 76 medical students were randomized to receive a 3-hour workshop on problem drinking (intervention) or depression (control). All students then participated in eight simulated office visits (Objective Structured Clinical Examination [OSCE] stations). Those who had the training scored significantly higher on checklist scores for assessment and management of high-risk

alcohol use than those in the control condition (68). In a second study, 55 medical student volunteers were randomized into one of two teaching conditions. Both participated in standardized patient interviews before and after training. Both received a detailed 35-page reading on the subject, a traditional lecture, and videotape demonstration interview. The experimental group also recorded a 20-minute simulated patient interview and received feedback on their performance in a small group setting. Both groups demonstrated significant improvement in their interview skills from before to after training with no significant difference between groups (69). Finally, in a third study, replacing 1 week of a 6-week psychiatry clerkship with an experience on an addiction treatment unit resulted in increased tolerance and positive regard for patients with alcoholism. Knowledge of psychiatry based on end-of-course exams was not changed from before to after the intervention (70).

GRADUATE MEDICAL EDUCATION

Educational interventions on the diagnosis and treatment of substance use disorders are associated with increased knowledge and skills among house staff and more positive attitudes toward patients with substance use disorders. Family medicine residents indicated a high level of satisfaction with a new 20-hour course on alcoholism that included didactics, supervised intake assessments, and participation in group sessions (71). Implementation of a longitudinal didactic series over a 3-year internal medicine residency mitigated the usual negative effect of graduate medical education on attitudes toward patients with high-risk alcohol use and alcoholism (72). Pediatric residents receiving an AOD curriculum that included interactive didactics, participation in a community-based adolescent AOD program, role-playing practice, and interview skill sessions performed significantly better than untrained controls on tests of knowledge, skills, and abilities in assessing and managing AOD disorders (73). Participants in a Chief Resident Immersion Training Program demonstrated significantly improved knowledge, skills, and confidence related to addiction treatment than nonparticipating peers at 6- and 11-month follow-up (74).

Measurement of physician behaviors from before to after a clinically supervised addiction education activity resulted in improved performance by resident physicians. Introduction of an in-patient rotation on an addiction treatment unit corresponded to a significant increase in the diagnosis of substance use disorders by family medicine residents as indicated by chart reviews (75). Education on alcohol use disorders increased the diagnosis of alcohol dependence from 2.5% to 4.1% by internal medicine residents and nurse practitioners in a primary care clinic (76). Increased clinical supervision training on the use of the CAGE questionnaire (have you felt you should Cut down on your drinking, Annoyed by people criticizing your drinking, felt bad or Guilty about your drinking, used an Eye-opener in the morning?) to screen for alcoholism and incorporation of the CAGE questions into clinic forms increased screening with the CAGE from 5.9% to 76.7%, and asking about the quantity/frequency of alcohol use

increased from 26.5% to 93% (77). Introduction of a drug and alcohol treatment unit rotation was associated with a 10-fold increase in the number of interns' emergency department notes that addressed alcohol use and a significant increase in appropriate prescribing of benzodiazepines (78).

Education on SBIRT (screening, brief intervention, and referral to treatment) results in improved skills from before to after the intervention. A 4-hour didactic, video-based, and skills-based training program significantly increased emergency medicine residents' knowledge scores and practice in screening and intervention for alcohol from 17% before to 58% after the intervention and compared to a control group (79). Internal medicine residents who received clinical supervision on NIAAA recommended guidelines for screening and brief intervention increased the frequency of asking about alcohol use twofold and of counseling threefold (80). Implementation of a staged screening and brief intervention protocol in a family medicine residency clinic using the AUDIT-C was associated with increased screening rates. Nurses followed up a positive AUDIT-C with a full AUDIT, and residents provided counseling and referral if needed. Screening rates increased significantly from before to after the intervention (81). Primary care residents randomized to receive an 8-hour interactive training on a brief alcohol intervention (BAI) were significantly more likely to explain safe drinking limits and to elicit the patients' opinions about their drinking than controls who received training on lipid management; however, BAI-trained residents implemented an average of only 2.4 of the 15 elements of BAI (82). Adherence to national guidelines on quantifying alcohol intake and screening for drug use increased modestly from a high baseline after a 2.5 day SBIRT training (83). Surgical interns demonstrated significant improvement from baseline and compared to a control group in SBIRT skills using standardized patients 5 weeks after an 8-hour interactive training course on SBIRT. Trained surgical interns showed significant improvement in asking permission to discuss drinking, informing the patient of blood alcohol level and recommended limits, using less closed-answer questions, offering hope, encouragement and a menu of options. They also were less likely to engage in arguments over referral to treatment (84).

CONTINUING MEDICAL EDUCATION

CME interventions for addictions have been associated with mixed results.

Brief experiential training aimed at improving optimism and attitudes toward patients with addiction has had mixed results. Brief training on alcoholism and the implementation of a brief questionnaire to assess drinking resulted in modest improvement in alcohol histories and no change in smoking histories based on in-patient chart review (85). A learner-centered, experiential training program increased the confidence of faculty (80% internal medicine) in diagnosing and managing patients with substance use disorders and increased their optimism about patient outcome (86). Primary care multidisciplinary teams demonstrated a significant change in

attitude after a 2-day experiential training on alcohol use disorders, whereas trained emergency medicine teams and control teams demonstrated no change in attitudes (87). General practitioners and nurses in a primary care clinic received training and supervision for a 3-month period in alcohol screening (CAGE and MAST) and referral. Both reported increased optimism about alcoholism treatment and improvement in the frequency of asking about alcohol problems (88). Interactive training sessions teaching general practitioners to use the drink-less brief intervention package significantly increased practitioners' confidence in implementing the elements of screening (49% to 90%) and brief intervention (40% to 92%) for high-risk alcohol use (89).

Brief training aimed at teaching new clinical skills is associated with improved implementation of these skills. Patients of general practitioners who volunteered for university-based training with ongoing supervision to implement a protocol for primary care-based management of patients with alcohol use disorders were more likely to attempt abstinence, to repeat attempts at abstinence, and to have more days of abstinence than patients of physicians who did not volunteer for the training (90). A 2-hour skills-based training on a brief negotiation interview (BNI) was effective in teaching emergency physicians. Ninety-one percent passed the proficiency examination and performed the BNI in an average of 7.75 minutes (91).

Web-based training programs on Alcoholics Anonymous (92) and on Network Therapy and naltrexone (46) have demonstrated feasibility with access by both specialists and generalists. The majority of website visitors who completed a questionnaire reported that the training was useful (70%) and that it would improve their management of patients on naltrexone (67%) (46,93).

Brief training and office support is associated with improved implementation of evidence-based SBIRT. Primary care providers with enhanced training in SBIRT and office support were significantly more likely to talk with their patients about alcohol use and were more likely to provide evidence-based counseling. This difference persisted throughout the 32-month follow-up phase (94). Physicians and mid-level practitioners were randomized to receive training in the management of a maintenance phase of care for alcohol dependence. Trained providers received an initial 2.25-hour training, a booster session, study materials, and chart-based prompts. Of 164 patients, 67% saw intervention providers. Intervention patients were significantly more likely than controls to report that their provider asked about alcohol use (95).

Studies that have examined comparative cost-effectiveness of training have found mixed results. Three different methods for disseminating training in screening and brief intervention for family practitioners were compared for effectiveness and cost-effectiveness. Telemarketing was significantly more effective than mailing print media and more cost-effective than academic detailing (96). Relative cost-effectiveness of four forms of training (academic detailing, interactive continuing education, computerized reminders, and targeted payments) was compared for their efficacy in decreasing risky drinking in the patients of Australian general practitioners. Academic

detailing and computerized reminders were the most effective. Targeted payments were least cost-effective, whereas cost-effectiveness of the other three was comparable (97).

In their review of teaching methods for SBIRT, Polydorou and colleagues concluded that interactive teaching methods that enable skill demonstration, practice, and assessment have been shown to be most effective (98).

CONCLUSION

Tobacco, alcohol, and other substance use continue to take a tremendous toll on health. Physicians have the potential for significant positive impact in preventing and treating high-risk substance use and substance use disorders. Medical education has not kept pace with advances in prevention and treatment of substance use disorders such that many physicians are unprepared to effectively manage patients with high-risk substance use and addiction. Ongoing efforts to address this significant practice gap include training of addiction specialist champions for medical school faculty, development of model curricula, and updating requirements at every stage of medical training to include appropriate training for physicians in every patient care specialty. Empirical data support novel educational approaches to improve physician competency in screening, brief intervention, and treatment of at-risk substance use and substance use disorders. Continued efforts to refine educational approaches and reduce institutional barriers such as lack of reimbursement or other institutional support are needed to further improve medical education in addiction prevention and treatment.

Psychologists are uniquely trained to assess and treat disorders that frequently co-occur with substance abuse and substance dependence, and the treatment of the co-occurring disorders enhances an individual's chances of recovery. Despite these unique skills, few psychologists themselves are adequately trained in the assessment and treatment of substance use disorders (SUDs), thus limiting their effectiveness within this population. Research conducted by Alcoholics Anonymous (AA) reveals that 60% of AA membership sought some form of psychological counseling prior to their joining a 12-step program and treatment was discontinued due to dissatisfaction with the care provided by the psychologist (1).

In the general U.S. population, approximately 1 in 10 individuals has an SUD (2). In psychiatric in-patient facilities, the prevalence rate climbs as high as 1 in 2 (3), and 90% of offenders entering prison meet diagnostic criteria for an SUD (4). With prevalence rates this high, adequate training and education of psychologists in the assessment and treatment of SUDs can no longer be elective or absent entirely from training curricula.

Each year, drug and alcohol abuse contributes to the deaths of more than 120,000 Americans. SUDs cost taxpayers in excess of \$360 billion annually in preventable health care costs, extra law enforcement, auto accidents, crime, and lost productivity (5). A sizable portion of the general population uses psychoactive substances in response to anxiety or depressive disorders (6), both areas in which evidence-based practices have excelled. Adding a core SUD education and training component to skills already inherent in quality psychology programs would place psychologists in a uniquely qualified position to effectively treat SUDs.

The President's New Freedom Commission on Mental Health (2003) highlighted the importance in cross-training practitioners in the treatment of psychiatric and SUDs. The expert panel noted, "A key challenge to developing integrated treatment programs is overcoming the traditional separation between mental health and substance abuse treatment . . . much remains to be accomplished" (p. 65). They went on to advocate that both mental health and SUDs should be considered primary disorders, and endorsed the 5-year blueprint for action contained within the Substance Abuse and Mental Health Services Administration's (2002) *Report to Congress on the Prevention and Treatment of Co-occurring Substance Abuse Disorders and Mental Disorders*, which recommended the co-ordinated treatment of mental and substance abuse

disorders in a manner "seamless to the client" (p. 113). While the latter report suggested that such co-ordinated treatment could be conducted among different collaborating providers, it would clearly be advantageous to have clinicians available who are trained in both disorders to minimize the possibility of patient attrition when treatment is received from two (or more) providers when each disorder is addressed separately.

The existing literature that examines the training in substance abuse for doctoral-level psychologists is scarce. A survey of rehabilitation psychologists (7) found that while most treated patients with alcohol and drug abuse issues, few felt adequately trained to intervene with such patients, with a majority rating their training as poor. Twenty percent reported receiving no formal training in substance abuse. Of those having received some training in this area, most had either completed a graduate course where substance abuse was discussed (42%) or participated in a continuing education or postgraduate workshop on substance abuse (40%). Only one in five reported having completed a graduate course fully devoted to substance abuse.

In another survey (8), this one of doctorate psychology programs accredited by the American Psychological Association (APA), only 38% of programs offered at least one course in alcohol or substance abuse, and 95% of these were elective, not required, courses. On the other hand, 62% of schools indicated that substance abuse was part of some course in their curriculum, with 78% of these courses being required ones. It was estimated that about 10% of the time in these latter courses was devoted to alcohol or drug abuse, suggesting that substance abuse was typically incorporated into a broad course on psychopathology. To our knowledge, there has not been a more recent survey of doctoral psychology programs than this one, which was conducted in 1991 to 1992.

Harwood and colleagues (2004) surveyed a large sample of behavioral health practitioners, including psychologists, about their education and training in substance abuse. Not surprisingly, substance abuse counselors reported receiving the most formal coursework in substance abuse, although even here, the 69% of substance abuse counselors endorsing such coursework seems low, given the concentrated focus of their role. About half of other practitioners, such as marital and family therapists and professional counselors, reported formal coursework in the addictions, while only 30% of psychologists reported such coursework. Thus, it was more common for practitioners at the predoctoral (i.e., master's) level to have taken coursework in substance abuse than psychologists, most

of whom are required to obtain a doctoral degree. The authors concluded, “Continuing education, including seminars and workshops, is the primary mechanism through which these behavioral health practitioners received training in substance abuse treatment” (p. 200). With respect to psychologists, however, it would be difficult to argue that their training in substance abuse treatment, mainly through continuing education, is truly “continuing,” given their lack of initial training in this area during graduate school and internship.

To get a sense of the current state of training in the addictions, we examined the online curricula and course offerings of 33 doctoral psychology programs sampled from the APA’s list of accredited programs with functioning websites in the summer of 2009. These programs included both Ph.D. and Psy.D. programs and schools from different regions across the United States and Canada. Of our sample, only three programs required a course in substance abuse or chemical dependency, while seven programs offered elective coursework in substance abuse. One university-based program offered a practicum in motivational interviewing for advanced students. Thus, fewer than half of the programs examined had coursework in the addictions available to their students. Of the three schools mandating a course in substance abuse, all were professional schools offering the Psy.D. degree.

What can account for this dearth of training in the addictions? As Harwood and colleagues (2004) noted, “The low rate of formal training in substance abuse among professionals such as psychologists is due, at least in part, to the curriculum design of graduate education programs” (p. 193). Indeed, the available survey and anecdotal evidence suggests that any substance abuse education at the graduate school level is likely to occur in the context of a broader survey course in psychopathology or the biologic underpinning of behavior. Students with an interest in the addictions, or the foresight to realize that they will likely encounter many such patients, are left to seek out an elective course, if one is available. It is quite plausible that many, if not most, students graduate from doctoral-level psychology programs with one or two lectures comprising their entire education on SUDs.

Historically, training in the treatment of mental (nonaddictive) disorders has focused on lectures and formal, structured clinical experiences that are found in university-based programs, which are often bastions for scientific research in the diagnosis and treatment of these disorders. In this sense, graduate student training is similar to that received by their counterparts in medicine and allied health. In contrast, training in the treatment of addictive disorders has been traditionally more concentrated on the apprentice model, where practitioners learn by observing model teachers (9,10). This may be, in part, based on the widespread notion within the field of addictions that only former addicts can truly understand and, thus, assist the substance-abusing patient, and this may explain the popularity and endorsement of 12-step programs over other treatments with a stronger base of empirical support.

Although there is no empirical evidence to bear on this question, it also appears to be the case that graduate students

have limited exposure to patients with co-occurring substance abuse disorders during the supervised training in their program’s affiliated training clinic. Such clinics often screen out for referral such patients with co-occurring disorders, as they are deemed too difficult or complex for student therapists just beginning to train in psychotherapy. It may also be the case that a lack of supervisors with proper training, experience, or interest in the addictions would prevent training clinics from accepting such patients for their students, as these patients would then fall outside the professional competence of the responsible supervisor.

As a result, many students reach the internship phase of their training with little, if no, experience with substance-abusing patients, despite the prevalence of such patients in general clinical practice. One suspects that students gain greater exposure to these patients at the internship level, as the internship is considered the capstone clinical experience before the conferral of the doctoral degree with a corresponding emphasis on direct clinical work. The directory of internship programs of the Association of Psychology Postdoctoral and Internship Centers (APPIC) listed 257 predoctoral internship programs offering substance abuse disorders as a “major rotation,” or a primary focus, of training. However, it is unclear whether the nature of these major rotations involves simply the exposure to patients with co-occurring addictive disorders or actual coursework and specific training in empirically based treatment approaches for such patients. The same can be said for postdoctoral placements, which are fewer in number than internships, as they are not a requirement to complete the doctoral degree. It is hard to envision strong, evidence-based training in treating the addictions for students at the internship and postdoctoral levels, except for placements at Veterans Administration Centers and the few specialized substance treatment sites. The limiting factor in providing this training is almost certainly the lack of supervisors at all levels of the graduate school–internship–postdoctoral chain who are properly trained themselves. This dearth of qualified supervisors in the area of addictions not only prevents patients with co-occurring disorders from receiving integrated treatment, but also curtails the training of students who can go on to train others in a “train the trainer” model (11), which will be critical in exponentially increasing the number of competent practitioners needed to meet this clinical demand.

Given this data and the high prevalence of SUDs across patient populations, it is imperative that psychologists be proficient in the assessment and appropriate referral of individuals with SUDs through knowledge obtained about the disease of addiction, the use and interpretation of assessment materials, and clinical training as a requirement to graduate from any institution conferring a degree of doctorate of philosophy or psychology preparing students to practice in the field of psychology.

Box 72.1 is a syllabus outlining an example of the education and training that should be received by psychology students enrolled in any doctoral-level program. This course could be placed in the school curriculum subsequent to or in

Box 72.1 Substance Use Disorders: Education and Training—Sample Syllabus

Course Description

This course introduces and examines basic concepts in the neurobiology, assessment, treatment, and appropriate referral of patients with substance use disorders (SUDs). Lectures, small group discussions, demonstrations, and videos will be incorporated in the presentation of topics. Opportunities for experiential learning—e.g., attendance at an open AA meeting—will be expected. Students will have an opportunity to research a specific topic in the addiction literature and complete a term paper outlining their findings, and explore personal views and biases via electronic submission of weekly one- to two-page essays.

Course Objectives and Philosophy

This course is designed to provide doctoral-level psychology students with a working knowledge of research trends and findings in the treatment of SUDs. Students will be challenged to explore the difference between traditional treatment approaches and current research findings. Emphasis is placed on empirically based or empirically supported treatments.

This course will provide:

1. Cogent and comprehensive coverage of what is now known to be crucial in understanding and treating SUDs
2. Understanding of the trends in pharmacotherapy
3. Assessment of the biologic, psychological, and socio-cultural contributors to the addictive process
4. Understanding and evaluation of the complexities of the addictive processes, including co-occurring disorders and relapse prevention
5. Development of an understanding of commonly used assessment tools in the addiction field and hands-on practice with these instruments
6. Understanding of the key techniques for integrating therapy with 12-step programs and their relevance in addiction counseling today
7. Development of an understanding of the key concepts of Motivational Interviewing and Harm Reduction Therapy models
8. Demonstration of familiarity with appropriate referral sources and the process of effective referral of patients for specialized treatment

Course Requirements

Required texts

Miller WR, Carroll KM. *Rethinking Substance Abuse: What the Science Shows, and What We Should Do About It*. New York: Guilford Press; 2006.

Daley DC, Marlatt GA. *Overcoming Your Alcohol or Drug Problem: Effective Recovery Strategies (Treatments That Work)*. 2nd ed. New York: Oxford University Press; 2006.

Alcoholic Anonymous. *Twelve Steps and Twelve Traditions*. New York: AA World Services, Inc; 2002.

Methods of Evaluation

Weekly essays: The student will submit a one- to two-page essay each week. The essays are to include thoughts regarding class discussions, reading assignments, and personal opinions. The essays will be used as a basis for class discussion and will be submitted via e-mail 2 hours in advance of class time.

Exams: There will be two exams. Each in-class exam will cover the preceding section of the course, including the content of the lectures, discussions, and reading assignments. The format of the exam will include 40 multiple-choice questions and two essay questions.

Term paper: A formal paper is due at the end of the term. The purpose of this assignment is to give the student an opportunity to explore a specific issue/area within the addictions. Suggested paper topics include

- Why do 12-step programs work for some people and not for others?
- What resources are available for young people with an SUD?
- How do we manage countertransference in the assessment of individuals with SUDs?

Term papers will be a minimum of 10 pages to a maximum of 15 pages in length. Topic must be selected by the student and approved by the professor prior to the 11th week of the course.

Alcoholics Anonymous meeting attendance: The student will be provided a list of suggested Big Book and/or Step meetings to attend. The student must be transparent, asking the leaders consent for their presence at the time of the meeting. Students will use the weekly essay to discuss their experience.

Grade Computation:

- Essays and participation = 15%
- Exam I = 35%
- Exam II = 35%
- Term paper = 15%

Course Outline

Week 1: Introduction to SUDs; need for training and education

- Handouts
- Harwood HJ, Kowalski J, Ameen A. The need for substance abuse training among mental health professionals. *Adm Policy Ment Health*. 2004;32:189–205.

(Continued)

Box 72.1 Continue

- Commonly abused drugs: <http://www.drugabuse.gov/PDF/CADChart.pdf>
- Selected prescription drugs with potential for abuse: <http://www.drugabuse.gov/PDF/PrescriptionDrugs.pdf>
- Gifford E, Humphreys K. The psychological science of addiction. *Addiction*. 2006;102:352–361.

Week 2: Neurobiological factors

- Readings:
- Miller WR, Carroll KM. *Rethinking Substance Abuse: What the Science Shows, and What We Should Do About It*. New York: Guilford Press; 2006:1–77.
- Gilpin NW, Koob GF. Neuroscience: pathways to alcohol dependence. Part 1: overview of the neurobiology of dependence. *Alcohol Res Health*. 2008;31(3). Available at: <http://pubs.niaaa.nih.gov/publications/arh313/toc31-3.htm>.

Week 3: Psychological factors

- Readings:
- Miller WR, Carroll KM. *Rethinking Substance Abuse: What the Science Shows, and What We Should Do About It*. New York: Guilford Press; 2006:81–150.
- Bierut LJ, Dinwiddie SH, Begleiter H, et al. Familial transmission of substance dependence: alcohol, marijuana, cocaine, and habitual smoking. *Arch Gen Psychiatry*. 1998;55:982–988. Available at: <http://archpsyc.ama-assn.org/cgi/reprint/55/11/982>.
- Vailiant GE. A 60-year follow-up of alcoholic men. *Addiction*. 2003;98:1043–1051. Available at: <http://www.ncbi.nlm.nih.gov/pubmed/12873238>.

Week 4: Social factors

- Readings:
- Miller WR, Carroll KM. *Rethinking Substance Abuse: What the Science Shows, and What We Should Do About It*. New York: Guilford Press; 2006:153–219.
- Galvan FH, Caetano R. *Alcohol Use and Related Problems among Ethnic Minorities in the United States*; 2003. Available at: <http://pubs.niaaa.nih.gov/publications/arh27-1/87-94.htm>.
- Tonigan JS. Project Match treatment participation and outcomes by self-reported ethnicity. *Alcohol Clin Exp Res*. 2003;27:1340–1344. Available at: <http://www.ncbi.nlm.nih.gov/pubmed/12966335>

Week 5: Assessment; Part I: The face of abuse and withdrawal

- Readings:
- Leshner AI. *The Essence of Drug Addiction*. National Institute of Drug Abuse; 2001. Available at: http://www.nida.nih.gov/Published_Articles/Essence.html.
- TIP 45—Detoxification and Substance Abuse Treatment Executive Summary. Available at: <http://www.ncbi.nlm.nih.gov/books/bv.fcgi?rid=hstat5.section.85311>

Week 6: Assessment; Part II: Application of common assessment measures

- Readings:
- *Substance Abuse Services for Primary Care Clinicians: A Concise Desk Reference Guide—TIP 24*, pp. 1–16. Available at: <http://www.ncbi.nlm.nih.gov/books/bv.fcgi?rid=hstat5.chapter.45293>.
- *Addiction Severity Index (ASI)*. 5th ed. Available at: http://pubs.niaaa.nih.gov/publications/Assesing%20Alcohol/InstrumentPDFs/04_ASI.pdf.
- CRAFT. Available at: http://www.hpssat.org/pdfs_of_cards/CAGE_CRAFT.pdf.
- NET. Available at: <http://www.niaaa.nih.gov/publications/net.htm>.
- Structured Clinical Interview for DSM Disorders-Axis I. Available at: http://www.scid4.org/revisions/download_pdf.html.

Week 7: Pharmacotherapy of SUD

- Readings:
- Miller WR, Carroll KM. *Rethinking Substance Abuse: What the Science Shows, and What We Should Do About It*. New York: Guilford Press; 2006:240–256.
- Sammons MT, Schmidt NB. *Combined Treatments for Mental Disorders: Pharmacological and Psychotherapeutic Strategies for Intervention*. Washington, DC: American Psychological Association Press; 2001.
- Kosten TR, O'Connor PG. Management of drug and alcohol withdrawal. *N Engl J Med*. 2003;348(18):1786–1795.

Week 8: Exam I

Week 9: Behavior therapies

- Readings:
- Miller WR, Carroll KM. *Rethinking Substance Abuse: What the Science Shows, and What We Should Do About It*. New York: Guilford Press; 2006:223–239.
- Carroll KM, Onken LS. Behavioral therapies for drug abuse. *Am J Psychiatry*. 2005;162:1452–1460.
- Griffith JD, Rowan-Szal GA, Roark RR, et al. Contingency management in outpatient methadone treatment: a meta-analysis. *Drug Alcohol Depend*. 2000;58:55–66.

Week 10: Twelve-step programs

- Joan Ellen Zweben demonstrates integrating therapy with 12-step programs. Available at: http://psychotherapy.net/video/Zweben_Addictions (to be viewed in class).
- AA meeting attendance deadline
- Readings:
- Miller WR, Carroll KM. *Rethinking Substance Abuse: What the Science Shows, and What We Should Do About It*. New York: Guilford Press; 2006:257–274.

- Alcoholic Anonymous. *Twelve Steps and Twelve Traditions*. New York: AA World Services, Inc; 2002.
- *What Is a Twelve Step Program?* Available at: <http://www.12step.org>.

Week 11: Motivational interviewing

- William R. Miller demonstrating motivational interviewing techniques. Available at: http://psychotherapy.net/video/miller_motivational_interviewing?gclid=CPqk56aRwJwCFdND5godBi_0mw (to be viewed in class).
- Term paper topic approval due
- Readings:
 - NIDA. *A Cognitive-Behavioral Approach: Treating Cocaine Addiction. Manual 2*. Available at: <http://www.nida.nih.gov/TXManuals/CBT/CBT9.html>.
 - NIDA. *A Brief Encounter with Peer Educator Can Motivate Abstinence*. Available at: http://www.drugabuse.gov/NIDA_notes/NNvol20N3/Brief.html.
 - *What Is Motivational Interviewing?* Available at: <http://www.motivationalinterview.org/clinical/whatismi.html>.
 - Miller WR, Rose GS. Toward a theory of motivational interviewing. *Am Psychol*. 2009;64:527–537.

Week 12: Treatment of co-occurring depression

- Readings:
 - *Managing Depressive Symptoms in Substance Abuse Clients During Early Recovery (TIP 48)*. Available at: <http://www.ncbi.nlm.nih.gov/books/bv.fcgi?rid=hstat5.chapter.91408>.

Week 13: Relapse prevention

- G. Alan Marlatt demonstrating harm reduction techniques. Available at: http://psychotherapy.net/video/marlatt_harm_reduction (to be viewed in class).
- Readings:
 - Daley DC, Marlatt GA. *Overcoming Your Alcohol or Drug Problem: Effective Recovery Strategies (Treatments That Work)*. 2nd ed. New York: Oxford University Press; 2006.
 - Havassy BE, Hall SM, Wasserman DA. Social support and relapse: commonalities among alcoholics, opiate users and cigarette smokers. *Addict Behav*. 1991;16:235–246. Available at: <http://www.ncbi.nlm.nih.gov/pubmed/1663695>.

Week 14: Referrals: What's out there; what's needed?

- Readings:
 - Miller WR, Carroll KM. *Rethinking Substance Abuse: What the Science Shows, and What We Should Do About It*. New York: Guilford Press; 2006:275–292.
 - *Substance Abuse Services for Primary Care Clinicians: A Concise Desk Reference Guide—TIP 24*, pp. 17–22. Available at: <http://www.ncbi.nlm.nih.gov/books/bv.fcgi?rid=hstat5.chapter.45293>.
 - <http://www.drug-rehabs.org/withdrawal-symptoms.htm>.

Week 15: The challenge to psychologists

- Term paper due
- Readings:
 - Miller WR, Carroll KM. *Rethinking Substance Abuse: What the Science Shows, and What We Should Do About It*. New York: Guilford Press; 2006:293–311.
 - Carroll KM, Rounsaville BJ. A vision of the next generation of behavioral therapies research in the addictions. *Addictions*. 2007;102:850–862.
 - *SAMHSA: Implementing Change in Substance Abuse Treatment—TAP 31*. Available at: <http://download.ncadi.samhsa.gov/prevline/pdfs/SMA09-4377.pdf>.

Week 16: Exam II

conjunction with psychopathology, psychopharmacology, and/or the biologic bases of behavior. This information is best presented as a stand-alone course, consisting of two-and-one-half hour, weekly classes, with assigned readings, examinations, and experiential learning opportunities.

Within psychology there is a well-kept secret: post-licensure, the APA's College of Professional Psychology offers a Certificate of Proficiency in the Treatment of Alcohol and Other Psychoactive Substance Use Disorders. The College of

Professional Psychology is a professional certification entity of the APA Practice Organization; it is not involved with graduate or undergraduate education in psychology. They offer a 3-hour exam that consists of 150 multiple-choice questions that can be taken by computer at more than 200 locations. The exam gauges a practitioner's knowledge in such areas as clinical pharmacology and epidemiology of psychoactive substances, causes of substance use disorders, prevention, screening, diagnosis, treatment, ethical concerns, and issues specific

to certain populations. Postcertification, practitioners are required to maintain 18 hours of continuing-education credits every 3 years in order to maintain certification. This certification has been in existence since 1996, and offers the national credentialing necessary for psychologists to practice independently within the field of addiction. Information on this APA certification can be found online at www.apapractice.org/apo/insider/professional/college.html.

The reality of SUD treatment today is that few licensed psychologists qualify to sit for this certification exam due to the lack of education and clinical experience. Implementing the suggested SUD Education and Training course would begin the education process, but clearly, clinical training opportunities need to be made available in order for psychologists to effectively practice in this area. Addiction subspecialties, internships, and postdoctoral positions in the assessment and treatment of SUDs need to be created. Clinical training should be an integral part of the subspecialties, internship, and postdoctoral opportunities in the addictions and could be created via collaborative relationships between psychology programs and local substance abuse treatment centers.

CONCLUSION

The overarching goal of every graduate training program is to provide students with the requisite knowledge, attitudes, and skills to be successful in their professional careers. For the behavioral sciences, as in many other fields of study, this task is complicated by the ever-growing body of knowledge in the discipline. Advances in neuroscience, particularly neuroimaging and neurogenetics, have created new challenges for educators responsible for keeping an up-to-date, relevant curriculum. Given the finite period of time available to train students, difficult decisions must be made on what to teach and what to leave out of the didactic and clinical course of study.

What factors should determine the content of the curriculum covered? It would seem logical that highly prevalent conditions and those with the greatest potential impact on the patient and society should be at the top of the list. Unfortunately, this does not appear to be the case when it comes to addictive disorders. SUDs—including alcohol, tobacco, and other drugs of abuse—are arguably near the top of any list of behavioral problems that create a significant negative impact on a person's life, his or her family, and society. Yet formal training in the etiology, diagnosis, and treatment of these disorders is marginal to virtually nonexistent in most graduate training programs in psychology. The dearth of well-trained addiction mental health professionals worldwide underscores the need to have this be an integral component of all graduate psychology training programs.

The reason for its exclusion may be related to an ongoing prejudice toward patients with SUDs, or merely a lack of trained faculty in the field available to teach this subject. Likely, it is a combination of both. Despite available federal grants for training in the field of addictions, few programs offer comprehensive training. The availability of funds has not translated into better training. As noted above, it's been

our experience that graduate training clinics routinely screen out for referral patients with co-occurring SUDs, deeming these clients too technically complex for beginning psychotherapists. The consequence of this practice is that it virtually eliminates any opportunity for a meaningful clinical exposure to these patients. The federal government, especially NIDA, is keenly aware of this problem and has recommended that SUDs be considered as important as mood and anxiety disorders in terms of public mental health importance.

In this chapter we have reviewed the current state of affairs regarding training of psychology students in SUDs. We have attempted to highlight the critical need for additional well-trained mental health professionals to care for patients and their families with addictive disorders. Finally, we have developed a model curriculum for consideration by training directors at the graduate, internship, or postdoctoral level. We hope that providing the structure of a course on SUDs targeted directly at psychology students will make the provision of such training less daunting.

Given the current available training grants, the problem does not appear to be strictly financial. Whatever the underlying cause, the need to incorporate didactic and clinical training in addictions into all graduate psychology training programs cannot be overstated. In no small way, the future of public mental health demands it.

Betty D. Morgan ■ Donna M. White ■ Colleen T. LaBelle

Nursing as a profession is focused on understanding the patient/person on individual, family, and community levels. The nursing paradigm concerns itself with four constructs: person, environment, health, and nursing. A variety of nursing theories have demonstrated how these concepts interact in health and illness and the role of nursing in caring for persons with potential and actual health problems.

Nursing practice exists on a continuum from preventive care to provision of care in the treatment of specific illnesses. “The essence of nursing practice is the nurse-patient relationship that embodies beliefs about the nature of the person and the nature of nursing” (1). Nursing uses knowledge, theory, and evidence-based practice to guide the delivery of care and to promote change in patients, families, systems, the environment, and the policy arenas, to care for individuals and the health of society (1).

Nurses are educated in a variety of programs in the United States. Registered nurses may complete their initial nursing education in a 2-year community college for an associate degree in nursing, or a 4-year university program for a Bachelor of Science degree in nursing. Three-year hospital-based nursing diploma programs have become rare in the United States. Advanced practice nurses (APNs) are educated in university settings at the graduate level and receive either a Master of Science degree or a Master of Science in Nursing degree. Typically these programs are 2 years in length and prepare nurses to be nurse practitioners, nurse midwives, clinical nurse specialists, or nurse anesthetists. APNs have advanced education in pharmacology, pathophysiology, and physical assessment, as well as courses that are related to their specialty area. Many APNs also have prescriptive authority; requirements for collaboration with medical physicians for prescriptive authority vary from state to state; however, some APNs are able to practice independently. Additionally, many schools have recently begun to educate people with a college degree in another field, allowing them to become nurse practitioners after completing a 3-year intensive program.

In each of these programs, students study the care of adults, children, pregnant women, medical and surgical illnesses, and psychiatric/mental health. Addictions issues are often addressed as part of the mental health course; many schools have integrated mental health concepts throughout the nursing curriculum instead of having a separate course dealing with mental health concepts. Addiction issues may be encountered in any health care setting, and therefore, this

approach may make sense; however, the danger is that the topic may not be discussed in full detail and therefore may not be given the importance needed to prepare nurses to deal with this complicated disease. All nurses use a problem-solving approach to assess patients and identify problems, and plan, implement, and evaluate interventions. Knowledge of generalized nursing care as well as specialized knowledge of addictions is essential to provide effective care for people with addictive disorders.

“Addictions nursing is a distinct specialty practice that integrates the biological, behavioral, environmental, psychological, social, and spiritual aspects of human responses to the illness of addiction into the nursing care provided to those affected by this disorder/disease, regardless of the clinical setting” (2). Addictions nurses provide direct care, consult with other health care providers, shape policy, and advocate for patients. Nurses provide care to individuals, families, communities, or special populations and use evidence-based, holistic strategies to formulate this care. With a point of care that may exist anywhere in the wellness–illness continuum, addictions nurses focus care on specific phenomena of concern as identified in the *Scope and Standards of Addictions Nursing Practice* (2004):

- Conditions that increase vulnerability to or risk for addiction
- Consequences and impairment that occur when people use those substances or behaviors
- Responses of people to dependence on addictive substances or behaviors
- Conditions that affect recovery and rehabilitation (2, p. 16)

Within these concerns the following issues are considered:

- Physiologic effects
- Psychological effects
- Spiritual effects
- Cognitive effects
- Impact on families and community
- Workplace effects
- Legal consequences

This chapter will provide information on the history of addictions nursing and the development of training and education programs in addictions nursing. Nursing licensure and certification will be described in terms of both general and specialty nursing as it relates to addictions treatment. The role of the specialty addictions nurse in a variety of settings will be presented.

Additional topics such as stigma and nursing attitudes toward those with addictive disorders will be included.

HISTORY OF ADDICTIONS NURSING

Although nurses have cared for people with addictions from the early years of nursing, there has been little description of this care in the literature. The first article related to addiction in the *American Journal of Nursing* was published in 1931, and concerned a patient with delirium tremens. Other early articles focused on case reports and discussion of the role of the nurse in caring for people with both alcohol and drug addiction (3). The first example of use of research findings in relation to the nursing care of alcoholic patients occurred in 1956, and this same author was the first in nursing to identify alcoholism as a disease (4).

“Educational preparation for addictions nursing practice has lagged behind education for other nursing specialties” (2, p. 26). Several groups have supported models of curricula for both undergraduate and graduate nursing education, including the National Institute on Alcohol Abuse and Alcoholism (NIAAA), the National Institute on Drug Abuse (NIDA), and the Office for Substance Abuse Prevention (now the Center for Substance Abuse Prevention) (2).

The lack of evidence-based content about addictions in nursing curricula has contributed to the stigma and negative attitudes that have been demonstrated among nursing personnel. Howard and Chung (5) reviewed the literature of the past three decades on nurses’ attitudes toward those with a chemical dependency. They found that there have been some improvements in attitudes in that time period; however, compared to the attitudes of other professional groups (physicians, psychologists, social workers, and addiction providers), nurses were more negative and punitive and had more authoritarian orientations toward those with a problem with addictive disorders. Hutton and Treisman (6) contrasted the personality characteristics of persons with an addictive disorder problem and HIV disease, and the characteristics of health care providers. Persons with an addictive disorder problem were described as being oriented, present focused, impulsive, and engaging in risky behaviors. In contrast, health care professionals were described as having opposite characteristics such as a future orientation, low risk taking, and the ability to make long-range plans rather than act impulsively. These differing ways of operating in the world may heighten the professionals’ negative attitudes toward, and communication with, those with addictive disorders.

Stigma is associated with substance abuse (7–9). Corley and Goren (10) discussed the “dark side of nursing” and examined the effects of stigmatizing, labeling, and stereotyping of patients by nurses, on the quality of patient care and on the nurses, themselves. Nurses have reported psychological stress and feelings of guilt, shame, and grief over their irrational responses and unprofessional judgmental behaviors (10,11). Johnson and Webb (12) found that nurses spent less time with patients that they viewed negatively, providing only physical care and not talking much with the patients.

Nursing Education

Prior to World War II there were no advanced programs in addictions nursing in the United States. The first university-based program was located at Yale University at the Yale Center of Alcohol Studies Summer School. This program was later relocated to Rutgers University. In 1971 the NIAAA provided funding for nursing educational programs on alcoholism, and in 1974 the University of Washington established the first graduate nursing program focused on alcoholism. In 1983 the American Nurses Association Council on Psychiatric and Mental Health Nursing Practice recommended that addictions nursing be recognized as a specialty area of nursing (3). A recent review of existing schools of nursing in the United States that provide a specific curriculum addressing behavioral, genetic, and biopsychosocial components of the disease of addiction revealed a paucity of programs.

Addiction nursing education is currently focused on patients with addiction and their treatment; it is important that all undergraduates have some clinical experiences in caring for patients who have problems related to their addictive disorder. Model curricula have been developed and include content related to neuroanatomy and neurochemistry as it relates to addiction, assessment for early signs of risk behaviors, brief intervention skills, assessment and treatment of withdrawal symptoms, harm reduction, and trauma informed care. All of these topic areas should be included in nursing education about addictive disorders. Pharmacology of addictive substances, etiology of abuse and dependence on substances, care of affected family, and mobilization of community resources should also be included in educational programs. Nursing education should also include information about the risk for addiction among nursing and other health care professionals (3). Ideally, addictions content should be included throughout the nursing curricula since addictions issues occur in all stages of health and disease and throughout all of the different specialties in nursing.

Graduate education for practice in the specialty of addictions nursing needs to include theory and research, evidence-based content on addictions, as well as development of clinical skills such as assessment, differential diagnosis, and interventions or treatment of individuals and families dealing with addictive disorders (3). All APNs need basic skills in assessment of addictive disorders and the need for referral for specialty care.

Addictions Nursing Specialty Organizations

The first U.S. specialty gathering in addictions nursing took place at the 1975 National Council on Alcoholism (NCA). This group was initially known as the National Nurses Society on Alcoholism (NNSA). In 1978 the Drug and Alcohol Nursing Association (DANA) was formed by a group of nurses who objected to the NNSA’s sole focus on alcohol. The NNSA separated from the NCA in 1981 and became the National Nurses Society on Addictions (NNSA) to reflect the broader scope of the practice of its members (3). In 1985 this group

expanded to become the International Nurses Society on Addictions (IntNSA). IntNSA sponsors an annual conference and has published an addiction nursing journal since 1989 and other publications on addictions nursing. It has published a core curriculum on addiction nursing, and has worked with the American Nurses Association (ANA) to develop *Scope and Standards for Addictions Nursing Practice*. Impaired nursing practice and approaches to caring for the impaired nurse have been a major focus of this organization. Development of certification exams on a generalist and specialist level has been undertaken with other nursing organizations (13).

THE ROLE OF THE CERTIFIED PROFESSIONAL ADDICTIONS NURSE

In 1989, the NNSA sought to create a separate specialty of nursing that reflected a specific body of knowledge and related skill sets and competencies (14). In addition, another organization, the National Consortium of Chemical Dependency Nurses (NCCDN), also was developing a similar goal. These organizations shared a common goal recognizing the need to develop a theoretical body of knowledge and promote research in the work of addictions nursing.

Currently, the organizations that have the ability to credential a nurse in the field of addictions nursing are the IntNSA and the Consortium of Behavioral Health Nurses and Associates (CBHNA). IntNSA offers the Certified Addictions Registered Nurse (CARN) at the generalist level and the CARN-AP for the APN. The Consortium of Behavioral Health Nurses Association offers the chemical dependency (CD) credential. Both certifications assure that the nurse is certified as knowledgeable in the field of addictions nursing, and this credential serves as a benchmark of expertise.

The role of the professional nurse providing treatment to individuals who suffer from addictive disorders requires a specialized knowledge base, skill set, and core competencies. Completion of the certification process validates that a nurse has expertise in specific domains of practice and provides a standard that the nurse adheres to as a part of his/her professional ethical mandates in health care (15).

Various agencies emerged to address the interest of nurses who were employed in or interested in this area of clinical practice. Although the ANA recommended that addictions nursing be considered a clinical specialty, several other organizations developed certification processes. The DANA, the NNSA, and the NCCDN were organizations that, by their evolutionary processes, all had similar goals and objectives toward this area. As drug addiction became more problematic as a societal issue in the United States, the role of the nurse addressing critical issues related to care of the person with addiction became increasingly important (16). However, emergence as a specialty evolved through changes in various organizations, and eventually led to a single organization, the IntNSA, that offers certification at the basic and advanced levels of preparation.

In the late 1980s the NCCDN offered an exam to both registered nurses and licensed practical nurses that provided certification as a certified chemical dependency nurse, designated as a CD credential by this organization. NCCDN evolved into the CBHNA and now only recertifies nurses who currently have the credential. Thus, the IntNSA has emerged as the leading professional organization that credentials nurses in the clinical specialty of addictions nursing. In 1989, the IntNSA first offered a certification exam that specifically addressed core areas of chemical addictions and behavioral compulsions leading to the Certified Addictions Registered Nurse (CARN) credential (17). Since that time, the certification process has evolved into a basic generalist and advanced practitioner level. This generalist level credential was the initial comprehensive certification offered in the clinical specialty of addictions nursing practice. The exam is framed in the nursing process format and comprises 200 multiple-choice questions. IntNSA defines two objectives in the CARN examination:

1. "... to determine the nurse's ability to apply knowledge from nursing and related disciplines in the care of persons with problems resulting from patterns of abuse, dependence and addiction, and to determine the nurse's knowledge of principles of prevention of addiction."
2. "... to determine the nurse's ability to synthesize the nursing process in the care of persons with potential or actual problems resulting from patterns of abuse, dependence, and addiction." (18)

Issues addressed in the exam to meet the established objectives are included in Table 73.1. A score of 95 is required to pass the CARN examination (19). One unique advantage to this credential is that in some states, the CARN is recognized as an addiction treatment provider (19).

In 1985, The NNSA changed its name to IntNSA to reflect the broader picture of addictions. This change reflected the broadening awareness of the national and global problem of drug use, abuse, dependence, and related health issues and sequelae. Thus, nurses who were members of this organization viewed the diseases of all drug-related disorders and behavioral compulsions and viewed the problem from an international perspective. These changes reflect the evolution of science-based research that study the neurobiologic etiology of the disease and related terminology used in clinical work. Subsequent to these changes, IntNSA is now considered the leading organization that defines the clinical specialty of addictions nursing (20,21).

Consistent with the organization's commitment to further the role of addictions nursing as a recognized and valued specialty, IntNSA developed the credential for APNs (22). This level of certification is offered to nurses who are prepared at the graduate level. It may encompass the role of a nurse practitioner or a clinical nurse specialist. The advanced level credential offered is a Certified Addictions Registered Nurse—Advanced Practice (CARN-AP). Eligibility to apply and sit for the advanced practice level of certification is built on the completion of the generalist CARN certification process with preparation at the master's level of education in addition to supervised direct patient care contact. The CARN-AP credential certifies

TABLE 73.1 Areas of knowledge included in the CARN certification examination

<i>Diagnostic and Statistical Manual</i> criteria for substance dependence disorders
Definition and characteristics of addictive disorders
Assessment and treatment of physiologic, social, and psychological problems
Application of the nursing process and standards of care
Use of appropriate screening tools
Assessment techniques
Neurobiology of addiction
Acute abstinence syndromes (withdrawal states)
Pharmacologic effects of drugs of abuse
Nursing interventions to ameliorate painful withdrawal states and symptoms associated with addictions
Treatment modalities—pharmacologic and nonpharmacologic
Prevention strategies
Relapse prevention
Outcome evaluation

that the nurse is a recognized professional with a level of expertise that is broadened to consultation, counseling, teaching, and research. The core areas of testing at this level encompasses “biological, psychosocial, cognitive and spiritual problems resulting from concurrent diagnoses: depressant, stimulant and hallucinogenic substances: and process addictions” (20).

Certification in the field of addictions nursing provides the professional credential as a recognized expert in the area of addictions nursing clinical practice. It offers an assurance that states the nurse adheres to parameters of competence and retains a specific knowledge base rooted by a commitment to ethical mandates. Various studies that examine the usefulness as well as the role of certification in health care support the premise that the certified practitioner provides increased accountability with expertise in a specific area of clinical practice (23,24). “The ANA posits that professional self-regulation through certification is important to ensure safe, high-quality services” (3,25). In a White Paper published by IntNSA as part of the *CARN Examination Manual* (19), the association states “Specialty certification also provides advantages to nurses, including self-verification of specialty knowledge, increased self-esteem, and increased pay and job security.” As the profession continues to create uniformity of standards in the clinical practice of addictions nursing, certification ensures the value and worth of the specialty itself and the professional recognition due to those who achieve the credential.

THE ROLE OF THE NURSE IN ADDICTION TREATMENT

Nurses have an important role in providing addiction treatment to patients in both acute care setting and outpatient setting. Patients present in all treatment settings with diagnosed and

undiagnosed disease and fear of disclosure due to concerns of being “labeled,” undertreated, or poorly treated. Nurses have a critical role in engaging the patient in treatment and acknowledging their disease with compassion and empathy. The nurse can obtain a good substance abuse history both with thorough physical exam and with nonjudgmental, thoughtful interviewing. Often the diagnosis of addiction is missed because no one asks the questions, the questions are asked in a judgmental manner, or toxicology testing does not occur. Toxicology testing should be utilized as a tool to assist the nurse and the patient in identifying and addressing substance use. Toxicology screening allows for a dialogue if it is presented in a nonthreatening, nonaccusatory manner.

Professionals often forget to ask the important questions regarding substance use. When seeing a provider, a person may be asked whether they wear a seat belt and whether they smoke cigarettes, but how often are they asked about alcohol or illicit drug use? Medical providers need to begin the dialogue to provide a safe place for patients to discuss these issues and to provide an opportunity for the health care provider to intervene at a place where the patient is willing to begin. Research has shown that screening and brief intervention (SBI) in primary care is effective in reducing hazardous alcohol use, tobacco use, and illicit drug use (26,27). The health care provider can raise awareness about risks of substance use and enhance the patient’s motivation to change unhealthy drinking and/or drug use patterns.

ADDICTION TREATMENT SETTINGS

Addiction treatment has taken place in traditional inpatient detoxification units, self-help meetings such as AA and NA, emergency settings, and inpatient units, but has not typically

been a part of primary care. Methadone maintenance has been in existence since the 1960s. However, it has been and continues to be a separate system from mainstream medical care, other than when a patient is admitted to the hospital and medication and dosage need to be confirmed by the inpatient medical staff and maintained until discharge. In the inpatient setting the nurse is involved in many components of addiction treatment including medical management of withdrawal, detoxification, and maintenance therapy with prescribed medication-assisted treatment, pain management, and patient advocacy for appropriate management of addiction and pain. In the outpatient setting the nurse again may find herself/himself addressing detoxification issues, assisting with placement or referral, and medication-assisted treatment.

NURSING AND METHADONE TREATMENT

Medication-assisted treatment (MAT) is any treatment for opioid dependence that includes a medication (e.g., methadone, buprenorphine, and naltrexone) approved by the U.S. Food and Drug Administration (FDA) for opioid addiction detoxification or maintenance treatment. Methadone is dispensed for opioid dependence under the federal regulations for an outpatient treatment program (OTP) (28).

OTPs must ensure that opioid agonist treatment medications are administered or dispensed only by a practitioner licensed under the appropriate State law and registered under the appropriate State and Federal laws to administer or dispense opioid drugs, or by an agent of such a practitioner, supervised by and under the order of the licensed practitioner. This agent is required to be a pharmacist, registered nurse, or licensed practical nurse, or any other health professional authorized by Federal and State law to administer or dispense opioid drugs. (28)

Since 1971, when this practice was implemented, nurses have been able to dispense methadone, if their state allows them to do so, to patients treated at an OTP (27). Most patients are dosed daily, and others may earn take home doses for between 1 and 28 days of methadone. Nurses play a central role in methadone administration in an OTP: for daily assessments, triage, dosing, dose evaluation, and education, and often as a patient's social support.

NURSING AND BUPRENORPHINE TREATMENT

Major advances in the science of addiction treatment have brought more options to patients and practitioners in caring for patients with addiction. The NIDA and NIAAA have been at the forefront of advances that have brought medication treatment options for tobacco, alcohol, and opioid dependence. All of these medications can be prescribed by physicians, as well as nurse practitioners and physician assistants with prescribing privileges, with the exception of those that fall under the Drug Addiction Treatment Act (DATA, 2000) (29). DATA 2000 allows physicians to prescribe and dispense

scheduled III, IV, and V medications approved by the FDA specifically for the purpose of opioid addiction. At this time this can only be done by an MD or a DO who meets certain requirements and obtains a special DEA number. Nurse practitioners and physician assistants are not allowed to prescribe under DATA 2000 at this time. This regulation has allowed patients to now seek treatment for opioid dependence in traditional medical settings such as a primary care practitioner office, further removing the stigma of addictions treatment and allowing patients to concurrently engage in other medical care. MAT with a scheduled III, IV, or V opioid in an office-based program or an OTP has dramatically changed the management of patients and their addictions by moving treatment into the primary care setting and allowing physicians to manage patients' opioid dependence. Thus far the only licensed medication for this purpose is buprenorphine, which is a partial opioid agonist that treats withdrawal and cravings. Buprenorphine has a ceiling effect, which makes it safer and less likely to be diverted.

MAT has evolved from methadone maintenance in OTPs to office-based treatment for opioid dependence with DATA 2000. Even though nurse practitioners cannot prescribe under DATA 2000, registered nurses and APNs play a critical role in the integration and management of MAT in primary medical care settings. The APNs are often the initial point of contact for many patients seen in a primary care office, and therefore have the unique opportunity to address drug and alcohol use and to educate patients about treatment options, including medications that can be prescribed under DATA 2000. The APN can serve as an educator, an advocate, and a support in engaging someone into treatment. Although the APN cannot prescribe, he/she is often critical in performing the physical exam and lab work and providing referrals and follow-up care.

Having the support of an educated nurse to assist the physician in this process is likely to allow for the seamless integration of MAT in outpatient settings. Models of care utilizing nurses are proving to be an effective strategy in integrating addiction treatment, improving access for patients, and encouraging more physicians to take this on. The Baltimore Buprenorphine Initiative expanded access to treatment by engaging treatment settings, substance abuse agencies, and social service supports. This initiative then built treatment capacity by training physicians to become waivered buprenorphine prescribers (30). The Bureau of Substance Abuse Services in Massachusetts, in conjunction with the Boston Medical Center, piloted a nurse care manager model of care to expand buprenorphine treatment access and then further expanded this with grant-funded models across Massachusetts, utilizing a nurse care manager model of care. This allowed for the expansion of buprenorphine treatment by having nurses working with waivered physicians and taking a primary role in the education, screening, assessment, induction, stabilization, and maintenance of patients requiring MAT. In the first 2 years after the development of this model, over 2000 patients received treatment in community settings awarded grant funding (31).

In the Boston Medical Center treatment model, nurses serve as the initial point of contact for patients seeking treatment, performing a screening assessment, evaluating appropriateness, and then arranging for the patient to come in for a more detailed assessment, education, and plan. Screening and assessment of patients assist in identifying drug, alcohol, mental health, and social issues. On intake the nurse obtains a medical history, assessment, and standard laboratory tests, and provides education on MAT for opioid dependence. A treatment plan is formulated, program expectations are reviewed, and a treatment agreement and consents are signed. Admission lab work includes a CBC; hepatitis A, B, and C serologies; RPR; LFTs; a pregnancy test for women; and a urine toxicology test to include at a minimum opiates, cocaine, benzodiazepines, methadone, buprenorphine, and oxycodone. Additional tests may be added depending on the drug use of the specific region. It is often beneficial to patient's treatment if they wait to start buprenorphine until they screen negative for all substances other than opioids and/or buprenorphine. Some patients may benefit from an inpatient detoxification to assist them in this process. Treatment consents and treatment agreements should be reviewed with the patient so the expectations for treatment are clear, in order to avoid initiating treatment when a patient is not able or willing to adhere to the program requirements.

All patients prescribed buprenorphine must meet *DSM-IV* criteria for opioid dependence prior to initiation of therapy; this must be documented in the patient's chart (32). This information should all be collected and passed along to the approved physician to then further assess and clear for treatment. This treatment model allows physicians to easily integrate complicated patients into their already busy medical practices with the support of a nurse with advanced-level skills. Once the physician sees the patient, agrees with the treatment plan, and confirms the diagnosis of opioid dependence, he/she would communicate with the nurse and generate the prescription, which serves as the induction for the patient about to begin buprenorphine treatment. The patient is then scheduled to follow up with the nurse for induction onto buprenorphine. It is important that the nurse and the patient have established a relationship of trust. Together they schedule a date and time to start the early phase of withdrawal, and dispose of all opioids, paraphernalia, and contacts with active users. This requires a great deal of trust by the patient; however, it is important in helping the patient move forward by eliminating the social components and environmental triggers of his/her addiction.

The induction process has caused many providers to shy away from this treatment because the patient should be in the early stages of withdrawal prior to induction with buprenorphine. Buprenorphine is a partial agonist and therefore will cause a precipitated withdrawal if taken too early after the administration of a short- or long-acting opioid. To avoid this, the patient should come in to see the provider in the early stages of withdrawal. For short-acting opioids, this means 8–12 hours since last use; for long-acting opioids, it is 48–72 hours and sometimes longer. In the Boston Medical Center model, the

nurse does a clinical assessment using the Clinical Opioid Withdrawal Scale (COWS) (32) to ensure the patient is in mild-to-moderate withdrawal and therefore safe for administration of buprenorphine. If the patient meets criteria for withdrawal, they begin with a small dose of buprenorphine with the support of the nurse, who ensures that it is taken sublingually and tolerated without side effects or interactions. Patients usually wait in the waiting room or go outside and return 30–60 minutes later or sooner if in need of further assessment. On return after receiving their first dose, patients often feel much better as withdrawal symptoms begin to resolve. A follow-up plan is arranged, and patients are then monitored with frequent phone contacts until stable, followed by weekly nursing and counseling visits under the direction of the licensed physician. Ongoing visits focus on MAT education, administration techniques, and management of side effects, which might include insomnia, taste perversion, constipation, and headaches.

Follow-up appointments either remain weekly or are adjusted depending on the patient's stability and adherence. This is determined at nursing follow-up, and by negative urine screens, engagement in counseling and psychiatric treatment if warranted, and social stability. Patients need to be scheduled to see the buprenorphine-prescribing physician at a minimum of every 3–6 months for evaluation of their opioid dependence and sooner if needed. In some treatment settings the physician sees the patient more frequently; in other settings the nurse is the point of frequent contact, with the physician involved in treatment planning through verbal and written communication. As patients progress in their treatment to maintenance, it is important to continue to assist them in moving forward in their recovery. Patients should be encouraged to maintain social and psychiatric supports, attend self-help meetings and identify sponsors, and engage in weekly counseling in either a group or an individual setting.

Counseling is an integral component in treating the disease of addiction; the federal guidelines state that "in order to qualify to prescribe Suboxone, physicians must have the capacity to provide or to refer patients for necessary ancillary services such as psychosocial therapy" (28). Many different forms of counseling are available and may be selected or combined based on the patient's needs, including individual counseling, group counseling, self-help, cognitive-behavioral therapy (CBT), and buprenorphine/naloxone (Suboxone) specific groups. Close assessment of the patient's mental health is critical, both at the start of treatment and as the patient reaches a state of abstinence. Often when patients stop using drugs, psychiatric diseases that had been self-medicated may present themselves. Therefore, engagement into services for full evaluation and treatment is essential to the recovery process.

SPECIAL POPULATIONS AND MEDICATION-ASSISTED TREATMENT

Special consideration may be needed in caring for HIV-positive patients, homeless patients, and pregnant women seeking addiction treatment. HIV-positive patients are

frequently treated with antivirals that, like buprenorphine and methadone, are metabolized by the cytochrome P450 inhibitor; fewer drug interactions have been seen with buprenorphine than with methadone (33,34). There have been reports of liver toxicity issues as buprenorphine is metabolized by the liver, so patients with abnormal transaminases or liver complications should be monitored closely (33,34). Pregnancy is a critical time to engage women into care as data have shown that outcomes are greatly improved when pregnant women are managed on medication-MAT. Limited data have shown that treatment with buprenorphine during pregnancy may be safe and efficacious; however, methadone remains the standard of care in pregnancy (35). Use of buprenorphine in pregnancy is off-label and requires careful review, education, and a detailed consent and release of liabilities (35). Methadone should be considered as the first option and has the advantage of daily, observed dosing and assessment, which may be a safer option for some women who may be entering care only due to pregnancy and may benefit from this level of monitoring. Homelessness is another issue that may require special considerations. Treatment utilizing buprenorphine in the homeless population had not been reported until recently. When implemented with additional supports, including more frequent nursing follow-up visits and weekly prescriptions, buprenorphine treatment for this population was as successful as it was for housed, socially stable patients. Methadone is a very effective treatment option for the homeless as there are no concerns regarding storage, administration, or assessment of the medication. A homeless patient would likely benefit from the daily observed dosing offered in an OTP setting by licensed personnel.

Office-based opioid treatment with buprenorphine has opened many doors for patients, allowing them the ability to treat their addiction in a safe, confidential setting with the support of a medical team of providers. Some patients may never have sought out care if it was not for the ability to receive this treatment outside of traditional detoxification settings. Engaging the nurse in this process to further support, educate, treat, and assist patients will allow for further integration, and expansion of treatment to patients who may never have sought the care they needed or had the option to do so.

NURSING AND NICOTINE ADDICTION TREATMENT

Nurses can also play a critical role in treating nicotine dependence. When a patient comes to the hospital and is screened for tobacco dependence, the nurse can educate the patient and offer supportive therapies such as: nicotine replacement therapies, counseling, groups, and CBT. These treatments can begin inpatient and continue on discharge with a follow-up plan. In the outpatient setting when the nurse engages with the patient, he/she can intervene and offer the patient treatment options such as support groups, harm reduction, and nicotine replacement therapy, which comes in patch, gum, tablet, and lozenges.

CONCLUSION

Nurses can play an important role in treatment for addiction to cocaine, alcohol, nicotine, opioids, and other drugs. Screening is a natural fit as nurses are often the providers who spend the most direct, hands-on time with the patient—triaging, screening, assessing, educating, supporting, and assisting with specific service needs. Caring for patients with opioid dependence involves a great deal of hands-on care by the nurse, and treating patients with opioid dependence can have good outcomes with the support of an educated nurse. The nurse can assist the patient in looking at his/her disease, agreeing to an intervention and assisting in this process. Interventions could range from brief motivational interviews to assistance with detoxification, aftercare, or medication-assisted options.

Currently there is no other disease for which less than 2% of patients get treatment (36). Nurses need to address this disparity by educating themselves, talking with patients, and engaging all members of the medical team. In this way nurses can help eliminate the stigma of addiction and its devastating consequences. All nurses should treat with dignity persons with addictions!

Social Worker Education and Training in the Care of Persons with Substance Use Disorders

Michelle Tuten

BACKGROUND

Substance misuse is a common occurrence in the United States and throughout much of the rest of the world. According to the 2008 National Survey on Drug Use and Health, an estimated 20.8% of U.S. residents aged 18 and above met criteria for substance abuse or dependence (1). Competent assessment and treatment of substance use disorders is paramount in the helping professions. Social workers provide services across a range of agencies, populations, and geographic locales; as such, they routinely assess, treat, and refer patients affected by substance use disorders. According to the Bureau of Labor Statistics, 21% of social workers were employed in mental health and substance abuse positions in 2006 (2). The prevalence and wide-reaching effects of substance misuse underscore the importance of specialized education and ongoing training among social workers in the treatment of this vulnerable population.

The historical role in the treatment of substance use disorders by social workers has been described as “reluctant” (3); social workers—along with other helping professionals—have experienced difficulty shedding negativistic and moralistic attitudes about individuals with substance use disorders (4). However, there are notable, important exceptions. This chapter provides a brief history of the treatment of substance use disorders in the field of social work, describes the education and training needs of social workers in addiction treatment, and summarizes recommendations for social work’s role in the treatment of addictions, including the important step of embracing the evidence-based practice movement. Lastly, a summary of some of the available resources on evidence-based practices and interventions is provided.

U.S. HISTORY OF ALCOHOL AND DRUG USE TREATMENT BY SOCIAL WORKERS

Social workers have played a role in the treatment of substance use disorders since the days of Charity Organization Societies (COS) and the settlement house movement of the late 1800s (5). At the time, the prevailing attitude toward addictions was that such disorders represented a moral deficit in the individual. A notable social work figure and prominent COS leader, Mary Richmond, however, rejected the moral

model, and promoted the notion that “inebriety” was a disease in need of early identification and treatment. In her seminal work, *Social Diagnosis*, Ms. Richmond describes the “inebriate” as a patient and not a “culprit” (6), emphasizing the importance of treating rather than blaming patients with substance use disorders. In the early days of the social work profession, assistance was generally offered through educational activities associated with the growing temperance movement; however, few direct services were offered to individuals with substance use disorders. In fact, many individuals with substance use disorders were confined to institutions or incarcerated because of the prevailing moral model and the lack of knowledge regarding substance use disorders on the part of helping professionals, including social workers (7).

Social workers also contributed to the treatment of alcohol use disorders—and to a lesser extent, substance use disorders—following the repeal of prohibition in 1933 and during the Second World War. In the 1940s, Gladys Price, a social worker at the Washingtonian Center for Addictions in Boston, developed the first alcoholism-focused field placement for social work students. Social workers also were represented on the interdisciplinary team of providers at the Yale Plan Clinics founded in 1944. The Yale Clinics included inpatient treatment for alcoholism and served as precursors to modern-day inpatient treatment (6). In 1955, the Yale Summer School of Alcohol Studies organized the first training seminar for social workers focused on alcoholism. In the 1960s, Margaret Bailey, a social worker and author of *Alcoholism and Family Casework*, headed an alcoholism training project that included three family casework agencies. In 1969 she also established the Alcoholism Committee under the New York City Chapter of the National Association of Social Workers (NASW). The committee, now entitled the Addictions Committee, remains in existence and has expanded its scope to include drug use disorders (6).

In the 1970s several factors led to the expansion of the role of social workers in the treatment of substance use disorders. The Hughes Act of 1970 led to the founding of the National Institute on Alcohol Abuse and Alcoholism (NIAAA) and the National Institute on Drug Abuse (NIDA). These agencies provided legitimacy and financial assistance to students pursuing careers focused on substance use disorders (5). During the 1970s, the NIAAA funded several demonstration projects to train students across the helping professions to work in

the area of alcohol use disorders. An important focus of these demonstration projects was to improve practitioners' perceptions of individuals with alcohol use disorders (8). The Hughes Act also provided funding for treatment programs, primarily for alcoholism treatment.

The role of social work in the treatment of drug use has been more limited than the focus on alcoholism (6). From 1935 to 1971 the U.S. government operated large treatment programs, commonly referred to as "federal farms," which were actually federal prisons focused on the treatment of drug use disorders, including detoxification services (6,9). In the late 1950s and 1960s, the therapeutic community (TC) movement grew. TCs espoused a grassroots approach to the treatment of drug addiction, and are very much alive today. It is unclear to what extent social workers were involved in the grassroots movement of the TCs (6). It was not until the 1980s—when media and public attention focused on the crack cocaine "epidemic"—that social workers began to take on more prominent roles in the treatment of substance use disorders as well as roles in program management and administration. The growing attention and awareness of HIV and AIDS also has led social workers to take on more prominent roles in harm reduction strategies and prevention programs, many of which focus on substance use disorders (6). The founding of the Substance Abuse and Mental Health Services Administration (SAMHSA) in 1994 also has increased the pool of federal funds—along with funding provided by NIAAA and NIDA—to prepare students, including social workers, for work in the substance abuse field. See Figure 74.1 for a timeline of factors affecting social work involvement in the treatment of substance use disorders.

LICENSURE AND CERTIFICATION OF SOCIAL WORKERS

All states have licensing, certification, or registration requirements for the practice of social work. Typically, there are four categories of practice that jurisdictions may legally regulate: (a) *bachelor's*: the baccalaureate social work degree, which is granted upon completion of a 4-year degree, (b) *master's*: the MSW degree in social work without post-MSW experience, (c) *advanced generalist*: the MSW degree with 2 years of supervised post-master's work experience, and (d) *clinical*: MSW with 2 years of post-master's clinical social work practice. State Boards of Social Work require that social work degrees are granted by programs accredited by the Council on Social Work Education (CSWE) (from the Association of Social Work Boards [ASWB] website: <http://www.aswb.org/SWL/licensingbasics.asp>).

GENERAL EDUCATION AND TRAINING

A bachelor's degree in social work (BSW) is typically the minimum requirement for entry-level social work positions; however, the MSW degree has become the standard for many positions and is required for independent clinical practice. As of 2006, the CSWE accredited 458 bachelor's programs and 181 master's programs (2). Doctoral education in the United States has grown considerably in recent years (10). In 1957 there were only 10 social work doctoral programs, in 1990 there were 47, and in 2003 there were 72. The growth in doctoral programs is largely the result of a growing emphasis on research, publication, and grant funding (11).

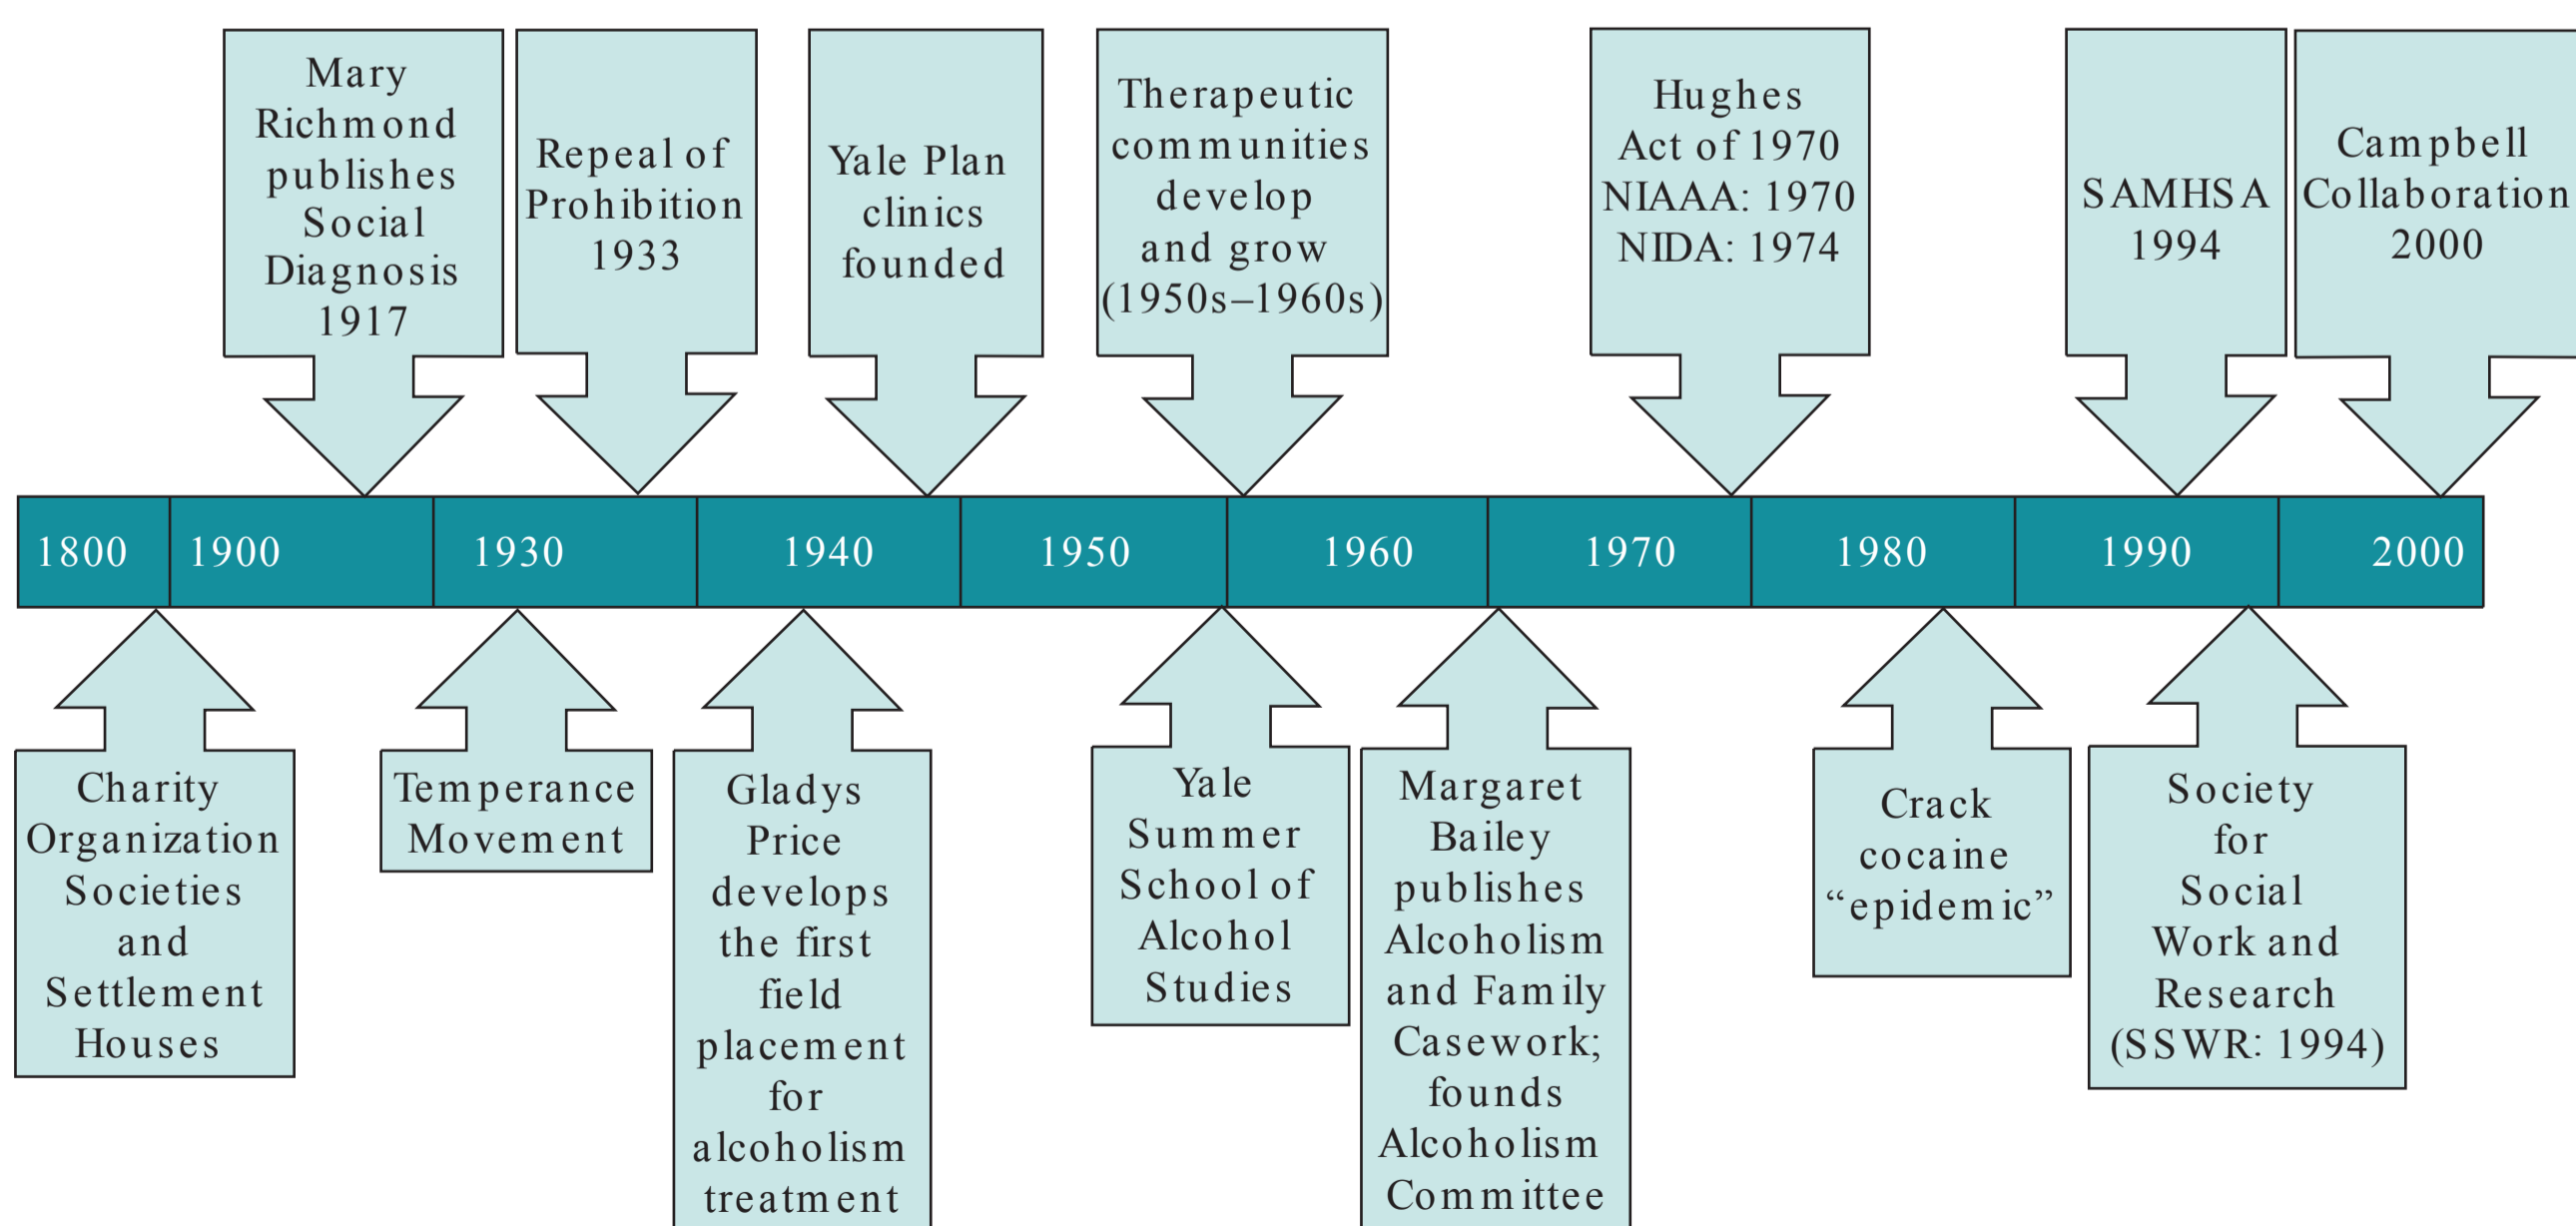

Figure 74.1. Brief history of social work in addictions treatment. (Adapted, in part, from Straussner S. The role of social workers in the treatment of addictions: a brief history. *J Soc Work Pract Addict.* 2001;1:3–9.)

SUBSTANCE ABUSE TREATMENT SERVICES PROVIDED BY SOCIAL WORKERS

According to a 2000 survey of NASW members, 71% of respondents reported activities related to the diagnosis or treatment of patients with substance use disorders in the past 12 months; however, only 2% of the sample identified substance abuse as their primary area of practice (12). The sample reported a mean of 35.4 hours spent in professional development training during the past year; however, the number of hours spent in substance abuse–related training was only 4.4 hours for the same 12-month period. Although the majority of the respondents (81%) reported lifetime training in substance abuse (primarily through continuing education courses), only 1% of the sample had completed a substance abuse certification program (12). The findings from the NASW survey seem to suggest that although social workers routinely assess and treat substance use disorders, only a few treatment agencies and/or practitioners have embraced substance use disorders as a specialty area of primary practice. There also appears to be disproportionate availability and/or interest in training related to substance abuse disorders. Given the high prevalence of substance use disorders among patients treated by social workers, the survey highlights the need for increased coursework focused on substance abuse in social work programs, as well as increased continuing education opportunities related to substance abuse (12).

EDUCATION AND TRAINING IN SUBSTANCE USE DISORDERS

It has been long agreed that social work programs are primarily responsible for training social workers to effectively treat substance use disorders (3). However, there is a large gap between science and practice in the addiction field. This gap may be the result of values and models gained through professional training (13). However, despite the prevalence of substance use disorders among patients being treated by social workers, substance abuse specialties and coursework is limited in schools of social work. Consequently, social workers enter the field with little or no training in the area of substance use and related issues. Bina et al. (14) conducted a survey of a random sample of social work programs (30% of the 187 accredited programs in 2007 to 2008) and found that none of the programs surveyed offered a substance abuse specialization. Furthermore, 52% did not offer a single substance abuse–specific course. Not surprisingly, the majority of social workers (54%) report the need for more training in the area of substance abuse assessment and treatment (15). The paucity of training provided to social workers is associated with a lack of practitioner knowledge of substance use disorders, more negative attitudes toward patients with substance use problems, and decreased effectiveness and quality of treatment provided (16).

Substance abuse training and education, on the other hand, has been shown to have a positive impact on social

work practice. Lemieux and Schroeder (3), in a sample of foundation and advanced year MSW students, showed that training curricula in substance abuse resulted in greater knowledge of substance use disorders, fewer negative experiences in substance abuse–related internships, and more proactive assessment of patients for substance use disorders. Amodeo, Fassler, and Griffin (4) compared the behavioral outcomes of MSW-level practitioners who completed postgraduate substance abuse training to a comparison group of MSW practitioners without postgraduate substance abuse training. They found that social workers with specialized training were more likely to provide substance abuse training in their own agencies, to receive training and supervision in substance abuse outside of their agency settings, to engage in substance abuse community service, to present at conferences on substance abuse topics, and to treat significant others with substance use disorders.

EVIDENCE-BASED PRACTICE (EBP) IN ADDICTIONS

There is growing emphasis on the use of EBP in the field of social work (10), as researchers and practitioners alike advocate for the highest quality care for patients. This increased momentum is underscored by the growing number of publications on EBP across social work disciplines, including mental health services, health, and social welfare. There also has been an increase in the number of social work textbooks dedicated to the topic of EBP, as well as meta-analyses and systematic reviews of EBPs—all of which make EBPs more accessible to academicians and practitioners (17). Although EBPs are becoming more widely advertised and disseminated, practitioners remain ambivalent about embracing EBPs. There remains a large gap between processes that are supported by science and the processes used by social work practitioners. The translation time from the scientific world to the “real world” of practice, in fact, is estimated at between 15 and 20 years, and some empirically supported practices never translate into community practice (Balas and Boren, as cited in Ref. (18)). Given the large body of literature in substance abuse treatment, including the growth of several evidence-based interventions, social workers need to remain abreast of the current treatments to ethically and most effectively treat their patients.

Social work is in a good position to embrace the EBP movement, rather than continue to lag behind scientific advances, and to increase the profession’s credibility in the process (10). For this reason, academicians have suggested a new pedagogy for social work education that focuses on a framework of EBP (19). Howard et al. (19) suggest social work education curricula for MSW students that focus on seven key objectives. According to these curricula, graduates should be able to

- a. Understand and value the evidence-based perspective;
- b. Select empirically tested interventions or practice methods supported by the best available scientific evidence;

- c. Appreciate the degree to which leading social work theories and polices are research based;
- d. Effectively deliver micro-, mezzo-, and macropractice interventions with the strongest empirical support in their fields of practice;
- e. Adapt the recommendations of practice guidelines, treatment manuals, and systematic reviews for use with specific client populations and in diverse agency settings;
- f. Evaluate the effectiveness of their own practice efforts; and
- g. Identify their information needs as they arise in varied practice settings, define searchable questions with which to query relevant scientific databases, and locate, critically appraise, and apply interventions based on the evidence they judge valid and pertinent (19, p. 242).

Woody, D'Souza, and Dartman (20), in a survey of deans and directors of 66 MSW programs, found that informal faculty commitment to the teaching of evidence-supported interventions (ESIs), a term often used interchangeably with evidence-based practices, was significantly greater than that of program commitment. Only 31 of the programs surveyed endorsed teaching specific ESIs, and only 26 had designated courses to teach ESI content. Further research is needed to evaluate the manner in which social work programs are responding to the growing emphasis on science as a guide for practice decisions in social work.

Although EBP has received increased attention in the helping professions, there remain considerable barriers to defining these practices and encouraging practitioners and programs to adopt them. There are many, often divergent, definitions of EBP, making consensus regarding what constitutes EBP elusive. Some researchers define EBP as a set of processes that the practitioner uses when providing clinical care. Sackett et al. (21) define EBP as “the conscientious, explicit, and judicious use of current evidence in making decisions about the care of individual patients” (21, p. 71). The EBP process is further described by a set of activities, including posing relevant searchable questions, accessing and critically analyzing evidence, evaluating the applicability of the evidence to the client, and evaluating outcomes (22,23).

In other research, EBP is defined as the use of specific empirically validated *interventions* (e.g., use of cognitive-behavioral treatment) rather than the use of processes. The implementation of these interventions is more accurately described as *evidence-based interventions*. However, the terms *evidence-based practice*, *evidence-based treatment*, and *evidence-based interventions* are often used interchangeably, a methodological flaw in the literature that makes comparisons across the studies using process activities versus specific interventions difficult. Research is needed to evaluate to what extent process activities, such as posing questions and searching the literature, actually lead to the implementation of specific recommended interventions. In other words, it is unclear whether engaging in the process of looking up information, for example, actually leads to the implementation of the empirically validated interventions suggested in the literature. It is also unclear what factors may

impede the use of EBP when process-oriented activities are utilized by practitioners. For example, the practitioner may have difficulty accessing information on EBPs, either because information is not readily available for a particular population/problem area or because the practitioner does not have the knowledge about how best to access them. It may also be that the practitioner is able to access the information but does not implement the intervention because he/she does not agree with the interventions suggested. In fact, personal attitudes about EBI—including perceived flexibility and the perceived requirements of the practice—may have greater influence on practitioner behavior than the weight of scientific evidence (18).

RESOURCES AVAILABLE ON EBPs AND EBIs

Fortunately, there are a growing number of resources available to aid practitioners in identifying EBPs and interventions for mental health and substance abuse prevention and treatment. The SAMHSA maintains the National Registry of Evidence-Based Programs and Practices (NREPP, <http://www.nrepp.samhsa.gov>). Practitioners can enter search terms to determine which programs and/or practices are effective for particular populations (e.g., gender, age, and problem area). Another SAMHSA resource is the Addiction Technology Transfer Centers (ATTCs), which provide valuable information on EBPs as well as videos, pamphlets, and other instructional tools on how to implement these practices (see <http://www.attcnetwork.org/aboutus/index.asp>).

The NIDA is another useful resource for accessing information on EBPs. NIDA published a guide to effective treatment entitled “Principles of Drug Addiction Treatment: A Research Based Guide” to disseminate information on basic principles of the treatment of substance use disorders and to identify research-based treatments (NIH Publication No. 09-4180, 2009; see <http://www.nida.nih.gov/podat/Evidence.html>). The interventions identified by NIDA include two main categories: (a) pharmacologic treatments for opiate, nicotine, and alcohol abuse and (b) behavioral treatments for a range of substance use disorders. A number of comprehensive treatment manuals specific to cocaine addiction also are available online.

The Campbell Collaboration, a sibling organization to the Cochrane Collaboration, was founded in 2000 to promote access to systematic reviews in the areas of education, crime and justice, and social welfare. The Campbell Collaboration website provides a keyword search for systematic reviews at <http://www.campbellcollaboration.org/>.

RESOURCES ON SUBSTANCE USE DISORDERS

Journals

The first social work journal dedicated to the topic of alcohol and drug abuse, *Social Work Practice in the Addictions*, was published in 2001 (5). Today, there are a growing number of

journals in social work and related disciplines devoted to the topic of substance use disorders, including *Addiction*, *Addictive Behaviors*, *Addictive Disorders and Their Treatment*, *Alcohol and Alcoholism*, *The American Journal on Addictions*, *The American Journal of Drug and Alcohol Abuse*, *Drug and Alcohol Dependence*, *Journal of Child and Adolescent Substance Abuse*, *Journal of Groups in Addiction and Recovery*, and *Journal of Substance Abuse Treatment*.

Websites

Online resources also are available to educate and assist practitioners working in the field of addictions. SAMHSA's *The National Clearinghouse for Alcohol and Drug Information* is a repository of information on a wide range of topics related to substance use disorders. Information on drug classes and other addiction-related educational materials, including fact sheets, posters, statistics, and videos/DVDs is available to practitioners and their patients. The ATTCs, NIAAA, NIDA, and the Center for Substance Abuse Treatment (CSAT; <http://csat.samhsa.gov/>) websites (see also the section "Resources Available on EBPs and EBIs") also serve as repositories of information and educational materials for patients and practitioners alike.

The NASW is the largest organization for social workers, with a current membership of approximately 150,000 (from <http://www.socialworkers.org/nasw/default.asp>). The NASW website provides information on NASW-approved continuing education courses, including those related to substance use disorders. For NASW members at the MSW level specializing in alcohol, tobacco, and other drug use disorders, the NASW offers a specialty credential, the Certified Clinical Alcohol, Tobacco, and Other Drugs Social Worker (C-CATODSW).

SUMMARY

Historically, social workers have played key roles in the assessment, treatment, and understanding of substance use disorders. Given the large numbers of individuals impacted by substance use disorders, and the growth of programs to treat them, social workers will continue to be among frontline staff in addictions treatment. As such, social workers have considerable influence on the prevailing attitudes toward individuals with substance use disorders and the type and quality of treatments available to them. There is promising momentum for an increased emphasis in the field of social work on the use of evidence-based and best practices to more effectively treat patients. To the extent that social workers embrace this movement, the field as a whole serves to gain tremendous credibility as an equal partner in the helping professions. Social work programs can facilitate the adoption of an EBP framework by teaching future practitioners, academicians, and administrators about how to critically analyze research literature, how to implement evidence-based practices, and how to disseminate practices in community agencies.

INTRODUCTION

The majority of substance abuse treatment in the United States is provided in addiction specialty care centers. Counselors comprise the greater part of the work force in these centers and they provide most of the behavioral treatments (1). In the broader context of behavioral health care, counselors are a distinct professional group with a defined academic and training curriculum, competency, and licensure standards. In the addiction treatment field, the term counselor is used as a job title for individuals with a wide range of backgrounds who provide counseling services. These counseling positions are occupied by individuals with a variety of backgrounds including professional counselors, social workers, or individuals who enter the addiction workforce due to life experiences rather than academic and professional training. Historically, many of the counselors working in addictions are themselves recovering from alcohol and/or drug dependence. Proponents of a recovering addiction treatment workforce suggest that recovering persons may possess a special empathy for drug-dependent patients that makes them particularly effective in working with this population. Critics of this view claim that many of these “recovering” professionals may hold strong bias as a result of their own experience, insisting that their approach is the only or the best, which may limit their effectiveness. Just as the patients presenting for addiction treatment are a diverse population so are the environments in which treatment is provided and so also is the counseling workforce that provides a great deal of that treatment.

Training and development of addiction counselors has traditionally favored an apprentice model over the more common academic model for professional counselors. The “on-the-job training” approach presents some unique challenges for the dissemination of new information to the workforce. The science of addiction treatment has made numerous advances in the development of both behavioral therapies and medications for the treatment of addiction. While these advances have made some impact in the treatment delivery system, there remains a gap between the state of addiction science and the treatment services that patients are likely to receive (2). In addition to the gap in knowledge between scientists and practitioners, due in part to the prevalence of the on-the-job training model, the addiction treatment system itself has been chronically underfunded and suffers from numerous barriers to its advancement including the vulnerability of treatment

facilities to closure due to fiscal problems and the large staff turnover in centers that remain open (3). The prevalence of the apprentice training model for addiction counselors, the gap between addiction treatment science and practice, and the unreliable resources supporting addiction treatment all have significant implications for the training of the addictions counseling workforce.

HISTORY

The addiction counselor workforce has long been thought of as a dichotomy consisting of recovering counselors on the one hand and counselors who have come into the field of addictions through academic training on the other. In his 1996 review of the addiction treatment workforce, Barry Brown (4) noted that while the educational qualifications of drug abuse counselors were increasing, the majority were paraprofessionals who relied heavily on their personal experiences. While this dichotomous view is somewhat outdated, it represents an important historical trend in addictions counseling. We say this view is outdated because the trend toward increasing educational qualifications noted by Brown has continued and, recovering individuals themselves often possess graduate level training in counseling and both state and national certifications, as well as licensing efforts, have progressively professionalized the counseling workforce. In a 2003 report, Mulvey et al. (5) described the addiction treatment workforce based on surveys and interviews of 3267 respondents, of whom 37% were counselors, 31% were program directors, and 30% were clinical supervisors. They found that counselors in the sample were well educated: 74% held at least a bachelor’s degree, 42% held graduate degrees, and 72% were certified or licensed as substance abuse/mental health professionals.

The development of substance abuse counselor certification and licensure is closely linked to the history of the substance abuse treatment system. Federal funds for community-based alcoholism treatment were first authorized in 1967. In the following year, the Alcoholic Rehabilitation Act of 1968 described alcoholism as a major community health problem, encouraged community-based treatment and prevention, and authorized federal funds for construction and staffing of services in community mental health centers. With the availability of federal funding and state legislative action pressuring many insurance companies to offer substance abuse treatment in their policies, states began to

license both the facilities and the individuals that could provide care for persons with substance use disorders (6).

In the late 1970s and early 1980s, three states in the Midwest of the United States established a small consortium to develop some common standards for certification of alcoholism or addiction counselors. Using the Birch and Davis Report (7), based on a survey of critical job functions and skills of active alcoholism counselors, the first national competencies for alcoholism and drug abuse counselors were developed. The *twelve core functions of the addiction counselor* were defined as consisting of screening, intake, orientation, assessment, treatment planning, counseling, case management, crisis intervention, client education, referral, report and record keeping, and consultation with other professionals. Many certification and licensure boards now require that applicants seeking substance abuse counseling credentials document that they have at least the minimum number of hours of experience required in each of the core functions. Boards requiring oral examination, in

addition to written examination, may use the core functions in a Case Presentation Method (CPM) in which the candidates must present a case that demonstrates their competence in each of these core functions. Competence in each of these areas is evaluated using a set of criteria referred to as the “Global Criteria.” John Herdman (8) provides a detailed history of the development of substance abuse certification and the CPM. Table 75.1 provides definitions of the Twelve Core Functions and the respective Global Criteria used to evaluate a certification or licensure candidate’s competence in them.

In 1993, the Addiction Technology Transfer Center (ATTC) Network created by the Center for Substance Abuse Treatment (CSAT) of the Substance Abuse and Mental Health Services Administration (SAMHSA) set out to improve the preparation of addiction counselors. The ATTC established the National Curriculum Committee to evaluate criteria and establish priorities for curriculum development. From these efforts, the Addiction Counseling Competencies

TABLE 75.1 The 12 core functions and global criteria

Core function	Definition	Global criteria
Screening	The process by which the client is determined appropriate and eligible for admission to a particular program	<ol style="list-style-type: none"> 1) Evaluate psychological, social, and physiological signs and symptoms of alcohol and other drug use and abuse 2) Determine the client’s appropriateness for admission or referral 3) Determine the client’s eligibility for admission or referral 4) Identify any coexisting conditions (medical, psychiatric, physical, etc.) that indicate need for additional professional assessment and/or services 5) Adhere to applicable laws, regulations, and agency policies governing alcohol and other drug abuse services
Intake	The administrative and initial assessment procedures for admission to a program	<ol style="list-style-type: none"> 6) Complete required documents for admission to the program 7) Complete required documents for program eligibility and appropriateness 8) Obtain appropriately signed consents when soliciting from or providing information to outside sources to protect client confidentiality and rights
Orientation	Describing to the client the general nature and goals of the program; rules governing client conduct and infractions that can lead to disciplinary action or discharge from the program; the hours during which services are available; costs to be borne by the client, and client rights	<ol style="list-style-type: none"> 9) Provide an overview to the client by describing program goals and objectives for client care 10) Provide an overview to the client by describing program rules, and client obligations and rights 11) Provide an overview to the client of program operations

Core function	Definition	Global criteria
Assessment	The procedures by which a counselor/program identifies and evaluates an individual's strengths, weaknesses, problems, and needs for the development of a treatment plan	12) Gather relevant history from client including, but not limited to, alcohol and other drug abuse using appropriate interview techniques 13) Identify methods and procedures for obtaining corroborative information from significant secondary sources regarding clients' alcohol and other drug abuse and psychosocial history 14) Identify appropriate assessment tools 15) Explain to the client the rationale for the use of assessment techniques in order to facilitate understanding 16) Develop a diagnostic evaluation of the client's substance abuse and any coexisting conditions based on the results of all assessments in order to provide an integrated approach to treatment planning based on the client's strengths, weaknesses, and identified problems and needs
Treatment planning	Process by which the counselor and the client identify and rank problems needing resolution; establish agreed upon immediate and long-term goals; and decide upon a treatment process and the resources to be utilized	17) Explain assessment results to the client in an understandable manner 18) Identify and rank problems based on individual client needs in the written treatment plan 19) Formulate agreed upon immediate and long-term goals using behavioral terms in the written treatment plan 20) Identify the treatment methods and resources to be utilized as appropriate for the individual client
Counseling	(Individual, group, and significant others): The utilization of special skills to assist individuals, families, or groups in achieving objectives through exploration of a problem and its ramifications; examination of attitudes and feelings; consideration of alternative solutions; and decision making	21) Select the counseling theory(ies) that apply(ies) 22) Apply technique(s) to assist the client, group, and/or family in exploring problems and ramifications 23) Apply technique(s) to assist the client, group, and/or family in examining the client's behavior, attitudes, and/or feelings if appropriate in the treatment setting 24) Individualize counseling in accordance with cultural, gender, and lifestyle differences 25) Interact with the client in an appropriate therapeutic manner 26) Elicit solutions and decisions from the client 27) Implement the treatment plan
Case management	Activities that bring services, agencies, resource, or people together within a planned framework of action toward the achievement of established goals	28) Coordinate services for client care 29) Explain the rationale of case management activities to the client
Crisis intervention	Those services that respond to an alcohol and/or other drug abuser's needs during acute emotional and/or physical distress	30) Recognize the elements of the client crisis 31) Implement an immediate course of action appropriate to the crisis 32) Enhance overall treatment by utilizing crisis events

Continued

TABLE 75.1 The 12 core functions and global criteria (*Continued*)

Core function	Definition	Global criteria
Client education	Provision of information to individuals and groups concerning alcohol and other drug abuse and the available services and resources	33) Present relevant alcohol and other drug use/abuse information to the client through formal and/or informal processes 34) Present information about available alcohol and other drug services and resources
Referral	Identifying the needs of a client that cannot be met by the counselor or agency and assisting the client to utilize the support systems and community resources available	35) Identify need(s) and/or problem(s) that the agency and/or counselor cannot meet 36) Explain the rationale for the referral to the client 37) Match client needs and/or problems to appropriate resources 38) Adhere to applicable laws, regulations, and agency policies governing procedures related to the protection of the client's confidentiality 39) Assist the client in utilizing the support systems and community resources available
Reports and recordkeeping	Charting the results of the assessment and treatment plan, writing reports, progress notes, discharge summaries, and other client-related data	40) Prepare reports and relevant records integrating available information to facilitate the continuum of care 41) Chart pertinent ongoing information pertaining to the client 42) Utilize relevant information from written documents for client care
Consultation with other professionals in regard to client treatment/services	Relating with in-house staff or outside professionals to assure comprehensive, quality care for the client	43) Recognize issues that are beyond the counselor's base of knowledge and/or skill 44) Consult with appropriate resources to ensure the provision of effective treatment services 45) Adhere to applicable laws, regulations, and agency policies governing the disclosure of client-identifying data 46) Explain the rationale for the consultation to the client, if appropriate

(ACC), covering 121 specific areas of competency, were established. In 1998, SAMHSA published the ACC as Technical Assistance Publication 21 (TAP 21), which was reviewed and updated in 2005 (9). The ACC is divided into two sections. The first contains Transdisciplinary Foundations organized into four dimensions covering the *basic knowledge and attitudes* necessary for caregivers in the addiction field. These include understanding addictions, treatment knowledge, application to practice, and professional readiness. The eight dimensions of the second section focus on the *practice* of addiction counseling and include clinical evaluation; treatment planning; referral; counseling; client, family, and community education; documentation; and professional and ethical responsibilities.

LICENSURE AND CERTIFICATION ISSUES

While legal requirements and standards for credentialing of substance abuse and mental health counselors in the United States are established at the individual state government level, there are national and international efforts to support the adoption of ACC and to standardize certification testing for substance abuse counselors. The International Certification and Reciprocity Consortium (IC&RC) was formed in 1981, with a mission to advance reciprocal competency standards for substance abuse professionals and to support the member certification/licensure boards. The IC&RC currently reports that over 37,000 alcohol and drug abuse counselors are certified by over 73 member certification boards (10). In 2007, the

IC&RC board voted to stop using the oral Case Presentation Method and instead revised the written examination to cover questions of competency in the core functions, which were previously addressed in the CPM.

The National Association for Addiction Professionals was founded in 1972, as the National Association of Alcoholism Counselors and Trainers (NAACT), and later became the National Association for Alcoholism and Drug Abuse Counselors (NAADAC) in 1982. The primary objective of NAADAC is to develop a field of counselors with professional qualifications and backgrounds. In 1990, concerned with the lack of national standards and the confusion caused by numerous acronyms used by state certification boards, NAADAC developed a national certification that required applicants to be certified at the state level, pass a national examination, and have an academic degree. This was the first time in the addiction counselor credentialing process that academic degrees were paired with competencies as a basis for certification. They now offer three levels of national certification for addiction counselors, which are commensurate with education, hours of work experience, contact hours, and length of supervised experience. They also offer a Tobacco Addiction Specialist (TAS) certification (11).

While the efforts to define core functions, describe competencies, and develop common minimum certification/licensure requirements have served to advance the professionalism of substance abuse counselors, there remains a lower academic standard for substance abuse counselors when compared with counselors working in other areas of behavioral health. For example, there are notable differences in the requirements for credentialing of substance abuse treatment counselors versus those for mental health professionals. These differences reflect a continuation of the historical trend of a reliance on personal experience and an apprentice model of professional development for addiction counselors. According to a 2006 report by Kerwin et al. (12), only 67% of state governments either offered or required certification or licensure for substance abuse counselors, while 96% offered or required the same for mental health counselors. Of the 48 states with a minimum degree requirement for mental health counselors, 98% required a graduate degree. Of the 31 states with a minimum degree requirement, only 10% require graduate degrees for substance abuse counselors. While these states have lower degree requirements for substance abuse counselors compared with mental health counselors, they tend to require more hours of supervised work experience for substance abuse counselors. For substance abuse counselors, the mean minimum required supervised work experience was 3819 hours, whereas that for mental health counselors was 2801 hours.

The primary function of certification and licensing boards is to protect the public by ensuring providers of substance abuse counseling services meet at least a minimum standard of training and competence. Most states license behavioral health-related professionals such as psychologists, counselors, and social workers, and in many states, these professionals may provide substance abuse treatment services within the scope of those licenses. Specialized addiction certifications or licen-

sure provide an avenue for addiction counselors, who do not have a general license, to practice in a restricted fashion with substance abuse related patients only. Addiction certifications or licenses may also be held by professionals with other behavioral health licenses in order to demonstrate addiction-specific expertise or to privilege themselves to perform functions that have been restricted to those who hold addiction-specific certification or licensure. For instance, in some states, only individuals with an addiction-specific licensure or certification can supervise addiction counselors.

APPROACHES TO TRAINING AND EDUCATION

Given the widely acknowledged gap between empirically supported substance abuse treatment interventions and community-based practice, research efforts are beginning to focus on identifying successful methods of dissemination (2,13,14). In the field of behavioral substance abuse treatment, this is a relatively nascent area of study. Compared to Oxman et al.'s (15) review conducted 15 years ago, which identified 102 randomized clinical trials focused on improving aspects of professional medical practice, Walters et al. (16) identified only 17 studies focused on evaluating behavioral treatment training methods for community-based practitioners. The pharmaceutical industry employs several strategies to disseminate information about new pharmacologic treatments including training sessions, promotional materials, and incentives offered to health care providers (17). Effective mechanisms for disseminating behavioral treatments, which often require more complex skill acquisition, are not yet identified. However, studies offer preliminary information to guide future efforts in this area.

Currently, Motivational Interviewing (MI) is the most frequently taught method, followed by Cognitive-Behavioral Treatment (CBT), network therapy, and other brief interventions (16). While these manualized treatments are evidence based, a small cadre of literature also indicates that subsequent patient outcomes for treatment as usual, as provided by community substance abuse treatment programs, can perform similarly to the intervention approaches developed in randomized controlled trials (18,19). As the primary goal of training clinicians in empirically supported interventions is to improve patient outcomes above that of treatment as usual, it is important to ensure that the intervention has not only proven efficacious in a controlled environment but that it has also proven to be more powerful than interventions currently used by the community agencies (i.e., proven effective). Otherwise, training efforts are premature. Even so, Miller and Wilbourne (20) identified several treatment approaches utilized by many community-based substance abuse treatment programs, which lack evidence for their effectiveness. These approaches include educational lectures and films, general counseling, confrontational approaches, and milieu therapy.

Some have suggested that community-based substance abuse counselors prefer 12-step interventions over other empirically based interventions such as CBT, since most community treatment programs are based upon a 12-step

approach (18). Also, manualized-based treatments might be less acceptable to community providers, given the perceived inflexibility of manualized intervention components. These assumptions have not been supported by research. In particular, Morgenstern et al. (18) concluded the opposite, that many counselors actively seek new skills to improve patient outcomes and that counselors appreciate the structure and specificity of manuals. However, unmotivated clinicians, or those mandated to trainings (vs. actively seeking training), might benefit from a focus on increasing their motivation to learn and apply new clinical skills (13).

Training procedures used in clinical trials differ from those used to train frontline clinicians. Among trials, therapist training often involves (a) selecting experienced therapists committed to the treatment approach, (b) a 2- to 3-day didactic seminar with role play and practice, and (c) ongoing supervision (usually audio- or videotape) of cases until the clinician shows adequate skill and fidelity with the intervention (17). In contrast to the rigorous therapist training procedures used in controlled trials, the most frequently used methods for dissemination of treatments to community-based clinicians, who have a range of education and practice experience, include distribution of treatment manuals and/or a brief didactic training without ongoing supervision (16,17). As noted below, the most commonly used strategy to train clinicians has shown limited success in translating to changes in patient behavior.

Although the extant training studies report changes in therapist behavior, attitude, and/or skills associated with many training procedures, concomitant change in patient outcomes is less studied. The exception has been the work conducted by Miller and colleagues. Miller and Mount (21) found that clinicians' practice behaviors significantly changed subsequent to a 2-day training workshop (without ongoing supervision), but in-session patient behavior did not change. Miller et al. (13) suggested that more intensive, ongoing training that includes empirically grounded learning aids—systematic feedback and reinforced practice—was needed in order to impact complex clinician behaviors, and that this would positively impact patient behavior. As such, a follow-up study (13) evaluated MI training in five formats with clinicians randomly assigned to (a) workshop alone, (b) workshop plus telephone coaching, (c) workshop plus feedback on audio-recorded sessions, (d) workshop plus individual feedback and coaching, or (e) a wait-list control. The findings support a “more is better” hypothesis. Those receiving feedback and/or coaching more fully retained their clinical proficiency in MI than those who received the workshop alone. However, only patients whose clinicians received the workshop, feedback, and coaching sessions showed in-session changes in behavior.

Clinicians in the workshop-only condition showed initial gains in skill but these degraded over time, which is consistent with other research findings (17,22). That is, a discrete training workshop is associated with a short-term increase in knowledge and skills, but these gains do not lead to long-term changes in clinician skills (16). Similarly, self-guided training using the MI book and training videotapes produced no increase in clinician skill. Self-study and one-time

workshops are common methods that clinicians seek to acquire new skills (13). Although adding additional contact to workshop training appears to improve clinician skill, the length and amount of training needed to sustain clinician improvement, as well as concomitant patient improvement, is not known.

To date, training methods target the clinician alone without consideration of institutional barriers, which could impact the clinician's utilization of new found skills. Incompatibility of the new treatment approach with the underlying philosophy of the program is a potential barrier to the widespread adoption of empirically supported treatments. For example, Miller et al. (13) reported that several newly trained clinicians in their research study left their positions of employment because the collaborative, autonomy-respecting style of MI was incompatible with their practice setting. These clinicians sought practice settings more compatible with their new found skills and therapeutic approach. Possibly, clinicians unable to secure alternative employment may not be supported to implement new found techniques if those techniques are incompatible with the agency's overall philosophy.

Another institutional barrier is that the intensive clinician training, which has a mounting evidence suggesting its superiority over less intensive methods, requires expert trainers' time, clinician time, and concomitant expense. The financial burden can be a significant barrier for many agencies that struggle to maintain their programs and staff in an economy of dwindling resources. Overall, institutional factors that affect the successful adoption of new intervention practices require more attention (13,16). An important consideration is that the clinician is not an isolated organism within a systemic vacuum but instead is powerful in his/her ability to influence and be influenced by his/her social ecology.

Innovative and practical solutions to high training costs are under investigation. For example, computer and web-based training can be a less expensive method for training large numbers of clinicians and might be more feasible than face-to-face training (17). In fact, preliminary support for teleconferencing supervision (23) and web-based training methods (17,24) has begun to appear in the literature. The use of technology in new and creative ways has the potential to overcome logistical barriers such as physical distance between expert trainers and clinicians, as well as reduce the costs associated with trainer time.

Overall, the necessary components of clinician training, which translate into improved patient outcomes, have not been identified. Research has not deciphered whether training methods need to focus on diminishing old habits rather than simply teaching new behaviors as suggested by Miller et al. (13), and which principles of learning are most salient for different therapeutic techniques. Some of the more complicated techniques such as complex reflections used in MI or family-systems-based techniques might require a range of strategies to ensure clinician skill including systematic shaping of behaviors, role play practice, modeling, immediacy of feedback, and even cognitive shifts among clinicians themselves. Alternatively, clinical techniques such as contingency management might only require an initial workshop with follow-up phone

consultation. However, some tentative conclusions are possible based upon the small number of studies conducted to date. It appears that a workshop training alone can improve clinician skill, but without continued supervision or support, skills degrade with time. Studies suggest that a core training workshop, manuals, and ongoing video or audiotaped supervision appear to be the current “gold standard” of training methods. However, the context of training (face-to-face vs. technology-based, tape review vs. live supervision), its intensity and duration, and how to engage institutional supports to maintain change are among the areas requiring more research. This information will certainly be integral for narrowing the research–practice gap.

ROLE OF THE SPECIALTY IN ADDICTION TREATMENT AND TRAINING WITHIN AND ACROSS SPECIALTIES

As the addiction treatment delivery system changes, the roles, skills, and knowledge required by counselors will also change. There are current efforts focused on broadening the availability of addiction treatment services beyond the specialty care settings. Primary care physicians have a unique opportunity to identify substance abuse in individuals who are seeking care for other medical problems. Traditionally, physicians have been reluctant to address these issues due in part to the lack of resources to treat substance abuse problems once they are identified. Increasingly substance abuse services such as identification, referral, and monitoring are being addressed in primary care settings by having counselors available in the primary care setting or by developing close collaborative relationships to provide linkage to those services off-site. These settings require new knowledge and skills to address early detection and motivating nontreatment-seeking individuals. These practices are significant because they show considerable promise for extending the benefits of substance abuse treatment to populations that currently do not access treatment (25).

SPECIAL CONSIDERATIONS

There are numerous subpopulations of individuals with substance dependence problems for which counselors may require specialized training to achieve competence. The subpopulations may be based on demographic characteristics such as gender, cultural background, or developmental stages as in adolescents, or they may be based on clinical characteristics such as criminal justice populations or co-occurring substance abuse with other psychiatric disorders.

Women generally have more barriers to seeking treatment and are more likely to seek treatment in gender-specific settings or primary care medical settings. In general, although women face more difficulties accessing treatment and have more complications to cope with in comparison with men, they tend to have better treatment outcomes than men. Even though women are more likely to seek treatment in gender-specific programs, there is no clear evidence that gender-specific programs are

more effective than mixed-gender treatment. Although there are no specific training curriculums for counselors to specialize in the treatment of women, the interventions that are considered useful would suggest that additional competencies in assessment of victims of sexual and violent trauma, and arranging comprehensive services such as housing, transportation, education, and income support (26) are desirable.

Individuals presenting for the treatment of substance use disorders are culturally diverse and this diversity has implications for treatment. Cultural competence is increasingly viewed as an important aspect of substance abuse counselor competence. While no single approach to developing cultural competence has emerged as superior, it is generally accepted that cultural competence should be addressed as an important component in any addiction professional training curriculum.

Treating adolescents with substance abuse problems requires knowledge and skills unique to the treatment of this population. Adolescents who present for treatment are often involved in multiple medical and social systems reflecting their diverse health, legal, and social problems. In addition, the reasons adolescents use substances may differ from adults and require unique counselor competencies to address them (27). The most effective treatments for this population often involve systems approaches that require specialized training and supervision.

The incidence of other mental disorders co-occurring with substance use disorders is high in both adult and adolescent populations. There is general consensus that the best practice is to provide concurrent treatment for both the mental health diagnosis and the substance use disorder. This type of treatment requires specialized training for the recognition, diagnosis, and treatment of mental disorders. Numerous counselor-training curriculums have been developed to provide this specialized training. CSAT develops treatment improvement protocols (TIPs), which are best-practice guidelines for the treatment of substance use disorders. CSAT’s TIP 42 focuses on substance abuse treatment for persons with co-occurring disorders, and an in-service training protocol has been developed to accompany the TIP (28).

CONCLUSIONS

Counselors play a critical role in the delivery of addiction care. The distinction *counselor* has developed more as a job than as a profession within the substance abuse field and the training and certification standards reflect this vocational emphasis. Much of the required training for substance abuse counselors is based on a job analysis of the functions performed by individuals in these positions and historically less emphasis has been placed on specialized knowledge. While the SAMHSA TIP 21 provides a comprehensive guide to the development of training for addiction counselors, it also documents the substantial gap between these standards and the actual and needed competencies of addiction professionals in the field. State, national, and international efforts to develop and evaluate uniform minimum competency standards have helped the addiction counselor job progress into a

profession. However, the gap between science and practice in addiction care highlights a critical challenge presented by the lingering apprentice model of addiction counselor development. Academic preparation and professional training activities for addiction counselors will need to become more comprehensive and provide greater continuity to develop the capacity to integrate science-based improvements into the treatment of addiction (29).

INTRODUCTION

In general when we think of treatment of individuals with substance use disorders (SUDs), the primary focus is on the role of physicians. However, the treatment of individuals with SUDs requires a complex coordinated team, a multidisciplinary group. This team includes a significant number of non-physicians. Psychologists, counselors, social workers, nurses, and other allied health care providers play essential roles in promoting the biopsychosocial well-being of individuals with SUDs. In order to maximize the professional team's efficiency and efficacy, it is vital that the role of each member of the group is structured and understood.

There is minimal research literature on the role of non-physician professionals in the substance abuse treatment team. Addressing their role requires an in-depth understanding of the type of standardized training that exists for these professionals. Only then is it possible to suggest modalities for improving the contribution of individual professional groups and that of the overall team. The range of settings in which treatment is provided further complicates the professional roles. These range from the emergency room, acute inpatient detoxification, to 2-year treatment facilities in therapeutic communities. Furthermore, the role of these non-physician health professionals may vary with setting. They probably play a major role in community settings. This is likely due to the difficulty of recruiting physicians in community clinics (1). It is important that all members of these professional groups are provided with the right balance of mental health and substance abuse training for their level and range of practice. Therefore, the field must provide high-quality appropriate training within each profession. The role of these professionals is not limited to treatment and a number of them, especially psychologists, contribute to the development of biological and behavioral interventions for SUDs. For example, psychologists play a major role in medication development from basic science to clinical trials. However, it is beyond the scope of this chapter to address the research role of other professionals.

There is no standard homogeneous education/training available to educate and train other addiction health professionals. However, there are limited fellowship, workshops, and training available for the other professionals in the field of addiction. Some of this training or certification are recommended or approved by specific state or professional organizations. Some institutes offer fellowship or other training for

all other professionals—psychologists, social workers, occupational therapists, nurses, and chaplains. For example, the Veterans Affairs Medical Center at Seattle developed an interdisciplinary program (2), which trains professionals in details of substance abuse treatment using biopsychosocial model. Other institutions offer 1-year advanced fellowship training in substance abuse treatment for psychologists, social workers, occupational therapists, nurses, and chaplains.

In this chapter, we attempt to review the existing data on nonphysician providers' roles in substance abuse treatment. We will present each professional group, define each scope of practice, and examine the current roles in treatment. Lastly, we will address future directions within each professional group.

PSYCHOLOGISTS

Definitions

The American Psychological Association (APA) policy on the use of the title “psychologist” is contained in the General Guidelines for Providers of Psychological Services, which define the term “Professional Psychologist” as “Psychologists have a doctoral degree in psychology from an organized, sequential program in a regionally accredited university or professional school.” There are many different types of psychologists, as reflected by the 56 different divisions of the APA. Psychologists are generally described as being either “applied” or “research” oriented. This major division is also described as the difference between scientists and practitioners or scholars and professionals. The training models endorsed by the APA require that practitioners be trained as both scholars and professionals and to possess advanced degrees.

A *clinical psychologist* has a Ph.D. or a Psy.D., and has successfully completed an internship in clinical psychology. Clinical psychologists are qualified to diagnose and treat psychological disorders and perform psychological testing. In some cases, after additional training, they may prescribe medication in some medical settings.

A *counseling psychologist* has either a Ph.D. or an Ed.D., and has completed an internship in counseling psychology. Like a clinical psychologist, a counseling psychologist can perform psychological testing. In addition, he or she may assess and provide therapy for routine problems of life.

A *school psychologist* may have a Ph.D., an Ed.D., or a master's degree, in addition to an internship in school psychology.

Along with psychological testing, a school psychologist can assess and treat school (and other related) problems in children and adolescents.

Education and Training

The APA has certification program in addiction proficiency (3). The *Certificate of Proficiency* (Certification for Licensed Psychologists in Substance Abuse Treatment) is a uniform national credential offered exclusively to licensed psychologists who meet the following criteria:

- Possess a current state or provincial license in good standing to engage in the independent practice of psychology.
- Have treated alcohol and other psychoactive SUDs as a licensed psychologist for at least 1 year during the last 3 years.

- Have provided health services in psychology.

- Have successfully completed the *College of Professional Psychology* examination in the treatment of alcohol and other psychoactive SUDs.

- Have provided alcohol- or substance abuse treatment for at least 5 of the last 8 years.

Following the above criteria, a psychologist must take a 3-hour computerized examination of 150 multiple-choice questions. This exam measures the psychologist's knowledge in several areas including epidemiology of psychoactive substances, etiologies of SUDs, prevention, screening, diagnosis, treatment, ethical concerns, and matters specific to certain populations

The APA Practice Organization, College of Professional Psychology's Certificate of Proficiency provides certification for 3 years. To maintain certification, recipients must then take 18 hours of continuing education during each 3-year period of Certification and to submit verification that his/her state or provincial license continues in good standing (4).

The *Certificate of Proficiency* assists the public in identifying licensed psychologists whose scope of practice includes the treatment of patients with alcohol and SUDs. A growing number of state agencies (Georgia, Hawaii, Indiana, New Hampshire, North Carolina, Vermont, Wisconsin) have encouraged addiction psychologists to obtain the *Certificate of Proficiency*.

Other psychology program like internships and fellowships (clinical and research) make psychologist work with credential in the field of addiction offered by many institutions and Universities (5,6). Many graduate and postdoctoral programs have concentration on addiction. There are also graduate and postdoctoral fellowships available for the psychologist in different institutes (7). However, there are no mandatory requirements for a psychologist to fulfill to work in the field of addiction.

Role and Scope of Practice

Scope of Practice is a terminology used by state licensing boards for various professions that define the procedures,

actions, and processes that are permitted for the licensed individual. The scope of practice is limited to that which the law allows for specific education and experience, and specific demonstrated competency. Each state has laws, licensing bodies, and regulations that describe requirements for education and training, and define scope of practice.

Psychologists work in teaching, research, social service in schools, clinics, government agencies, and private industry. About 34% of psychologists were self-employed in 2006 among 166,000 psychologist jobs (8). Educational institutions employed about 29% of psychologists in positions other than teaching, such as counseling, testing, research, and administration. About 21% were employed in health care, primarily in offices of mental health practitioners, hospitals, physicians' offices, and outpatient mental health and substance abuse centers. Advancement depends on many factors, including education, experience, and other personal qualities. Psychologists can expand their private practices or move into high-level jobs in research, teaching, counseling, or administration. Some psychologists advance by serving as consultants to government or industry or by writing about their special fields.

There is increasing emphasis by psychologist educators and advocates to involve psychologists in the treatment of addiction-related disorder (9) over the past decade. According to advocates, psychologists should treat SUDs by recognizing that these disorders are fundamentally behavioral and psychological in nature (10). They argue that SUDs respond to many of the same psychotherapeutic principles and interventions that apply to other mental health problems. The efficacy of addiction treatment approaches based on behavioral and other psychotherapeutic techniques is well documented. Included among these are motivation-enhancement strategies based on Rogerian principles of client-centered therapy (11); relapse prevention strategies based on principles of cognitive-behavioral therapy (12); solution-oriented and other brief therapy techniques (13); and harm reduction approaches (14). Miller and Brown et al. (10) assert that practicing psychologists are particularly well qualified by their training and expertise to treat SUDs.

NURSES/NURSE PRACTITIONERS

Definition

Registered nurses provide care in hospitals, private clinics, long-term health care centers and other medical facilities. A registered nurse is qualified to administer medication, provide therapies and treatments to patients, and consult with practicing physicians on patient care. Registered nurses also provide patients with explanations of test results and treatment options.

Nursing practice involves autonomous and collaborative care of individuals of all ages, families, groups, and communities, in many settings. Nurses also promote health and disease screening, prevention of illness. Furthermore, some nurses have roles in patient advocacy, promotion of a safe

environment, research, health policy, health systems management, and education. Addiction nurses need an understanding of both general nursing along with a specialized knowledge of addictions in order to provide effective care.

Education and Training

Subsequent to high school graduation, an individual may apply to nursing programs at accredited colleges and universities. Some individuals first earn an associate's degree in nursing (an AND). Bachelor's degree programs in nursing (BSN) are granted only from accredited 4-year universities. These programs often combine nursing course work with several hours of clinical experience. BSN students have 2 years of general college courses before entering the nursing major, including behavioral and physical science courses. In each program, nursing students study the care of adults, children, pregnant women, mental health nursing and community health nursing. Although addiction issues are addressed in all nursing specialty areas, basic knowledge in addiction nursing is often taught as part of the mental health course. Addiction nurses can gain advanced education through workshops, specialty journals, and graduate programs.

There is little data about nursing education and training in the field of addiction. Pilon et al. (15) conducted a study on nurses in Brazil and demonstrated that 70% of the participants had received little or no information on physical, family, and social problems related to alcohol use. Furthermore, 87% of participants had received little or no information on high-risk behaviors in specific populations and 95% of participants had received little or no information on nursing procedures for alcohol-abuse patients.

The National Nurses Society on Addictions (NNSA) sponsors an annual conference on addiction nursing, an addiction nursing journal, and other publications on addiction nursing. NNSA is currently the largest professional nursing organization representing addiction nursing. It has published a core curriculum on addiction nursing, and has worked with the American Nurses Association to define the dimensions of addiction nursing and develop standards. Advance Practice Nurses (APNs) are prepared at the graduate level and receive a Master of Science Degree in Nursing (MS or MSN) as either nurse practitioners or clinical nurse specialists. APNs have advanced education in pharmacology, pathophysiology, and courses related to their area of specialization. In many states, APNs also have prescriptive privileges. There are several graduate nursing programs with a specialty in addictions nursing; other programs include addiction nursing as a subspecialty of mental health nursing.

Over the last decade there have been some initiatives (government and nongovernment) and advocacy for training and education of nurses in the field of addiction that emphasizes the skills that the nurse must possess to intervene effectively with the substance abuser (16–22). The International Nurses Society on Addictions (IntNSA) publishes *Journal of Addictions Nursing*; this journal offers continuing education credits for nursing addiction professionals.

Certification as an Addiction Nurse

In 1989, the *Addictions Nursing Certification Board* (ANCB) offered the first certification for addictions Registered Nurses (CARNs). A similar certification became available for advanced practice nurses in the year 2000 (the CARN-NP) (23). These certifications ensure consistent basic training in addiction nursing among certified nurses. The applicant for the CARN-AP must be an RN holding a master's degree or higher degree with documented clinical practice hours at the advanced practice level. The American Nurses Association describes that professional certification helps ensure delivery of safe, high-quality services (24). Nurses generally must complete the following requirements to become an addiction nurse (CARN or CARN-NP):

- State's guidelines for becoming an addictions nurse.
- Mental health nursing curriculum
- Attending conferences for addiction rehabilitation and counseling
- Postgraduate nursing programs. Many certifications require a minimum of a bachelor's degree and some require up to a doctorate.
- Volunteer in rehabilitation centers or clinics.
- Familiarize with the current trends in substance abuse by visiting sites such as the one ran by the National Association for Addiction Professionals.
- At least 3 years of work as an RN, and a minimum of 4000 hours (2 years) of nursing related to addictions (for instance on a dual diagnosis unit).

Specialty certification in addiction nursing provides several advantages to nurses including self-verification of specialty knowledge, increased self-esteem, increased pay and job security, and increased confidence (25). Furthermore, certification may help reduce health care errors, demonstrate nurses' commitment to state-of-the-art care, and improve retention of nurses in the workforce.

Some nursing programs offer nurses roles in addiction research. The University of Washington School of Nursing has been awarded funding by the National Institute on Drug Abuse (NIDA) for nursing research training in substance abuse (26).

Role and Scope of Practice

Nurses with advanced training in addiction have several skill sets including knowledge of general nursing and details of common addiction behaviors. Because behavioral health units in hospital settings often combine addiction and mental health programs, many addiction nurses routinely use both skill sets. Specific nursing activities include counseling patients, educating patients and their families, facilitating group therapy sessions, and working closely with other staff members.

Nurses may choose to work in hospitals, outpatient facilities, and community care centers. Some nurses pursue managing interests and may develop skills to serve as a nurse case

manager (27). The addiction nurse's role depends on the setting as well as the expertise and interests of the nurse. On an inpatient unit, addiction nurses are involved in the full range of patient care. They are involved in the detoxification phase of treatment and maintain ongoing monitoring of the patient's health status using protocols such as the Clinical Institute Withdrawal Assessment (CIWA) scale. Some outpatient settings are experimenting with outpatient detoxification based on nursing assessment and monitoring via intermittent contact and a paging system.

Addiction nurses provide a variety of therapeutic modalities. Nurses often develop and maintain a therapeutic environment to promote recovery and both personal and interpersonal growth. Nurses also facilitate group activities, talk with patients' family members, and contribute observations to the interdisciplinary treatment team. Furthermore, nurses directly observe patients around the clock and may gather an in-depth view of the patient's behavior and relationships.

The addiction nurse's role in outpatient settings also includes telephone consultations with patients. Nurses may also be involved in intake evaluations of new patients. Some participate in administrative activities in the role of nurse supervisor or manager within the nursing department or within an organizational environment. Nursing roles also exist outside of traditional treatment settings. Occupational health nursing, school nursing, and community and home health nursing are all areas in which a substantial amount of addiction nursing is practiced. Some general hospitals employ nurses to assist in substance use screening for all hospitalized patients. These nurses help determine which patient would benefit from further evaluation of substance use.

Addiction nurses, particularly those with advanced degrees, are often involved in addiction research. This may occur through individual or group research projects. Several university schools of nursing currently receive grants to fund postdoctoral study in addiction research.

Nursing emphasizes disease prevention and health promotion through education and other appropriate means, and also recognizes the importance of the patient's family as part of recovery. Individualized care plans are developed collaboratively between the patient and the nurse.

PHYSICIAN ASSISTANTS

Definition

A physician assistant (PA) is a midlevel medical practitioner who works under the supervision of a licensed physician. The PA came about in the 1960s as a response to the need for more clinicians (there was a shortage of family physicians) and to improve access to care. The first PA program was developed by Dr. Eugene Stead, chairman of the Department of Medicine at Duke University, to train PAs for rural areas with dwindling numbers of physicians and nurses. Although there is not yet a requirement to hold a degree beyond the bachelor's level, most PAs have a master's degree.

Education and Training

The National Commission on Certification of Physician Assistants accredits PA training programs. Each state in the United States has its own specific licensing and practicing restrictions for PAs. Most states require PAs to pass the certification examination of the National Commission on Certification of Physician Assistants.

To practice as a PA, most states require a master's degree and a degree from an accredited PA program. Candidates must meet state requirements pertaining to a PA.

Most PA programs have little training in the area of addiction. During their clinical rotation series, students usually train for 6 to 10 weeks in the area of behavioral science, which may or may not include addiction medicine. PA students must often use elective time during school to obtain training in addiction principles. PAs interested in addiction medicine may require extra training in addiction prior to encountering patients. Few PA programs offer specific postgraduate training in addiction medicine, complicating a PA's path to becoming involved in addiction treatment. Some national courses exist to train PAs in addiction principles (28). A national society for PAs involved in addiction medicine offers opportunities for continuing education and networking (29).

Role and Scope

PAs evaluate patients under the supervision of a licensed physician. Although the physician need not be present during the time the PA performs his or her duties, there must be a method of contact between the supervising physician and the PA at all times. The PA must be competent in the duties he or she is performing and the physician for whom the PA is working must also be licensed and trained to perform the relevant duties.

Examples of the duties of a general PA include:

Medical histories and physical examinations: a PA can usually perform histories and physical examinations that do not go beyond a particular level.

Laboratory tests: a PA can order any test which he or she is competent to interpret and provide the appropriate treatment.

Follow-up: PAs follow patients through their hospital course, their course of treatment in a clinic setting, and so on.

Many private insurers and health plans sometimes require advanced degrees and/or certifications for PA specifically in behavioral health as a prerequisite for payment. Some companies do not pay for services delegated to PAs, even if the delegated service is within the PA's legal scope of practice (30).

SOCIAL WORKERS

Definition

The International Federation of Social Workers states, "social work bases its methodology on a systematic body of evidence-based knowledge derived from research and

practice evaluation, including local and indigenous knowledge specific to its context. It recognizes the complexity of interactions between human beings and their environment, and the capacity of people both to be affected by and to alter the multiple influences upon them including biopsychosocial factors. The social work profession draws upon theories of human development and behavior and social systems to analyze complex situations and to facilitate individual, organizational, social and cultural changes.”

Training in psychotherapy and techniques of managing various mental health and daily living problems to improve overall functioning are necessary to qualify as a licensed clinical social worker. Furthermore, social workers hold a masters degree in social work and have studied sociology, growth and development, mental health theory and practice, human behavior/social environment, psychology, and research methods. In addition to a minimum of a master’s degree in social work (M.S.W), additional course work and training to pass accreditation tests as a licensed clinical social worker (L.C.S.W.) is necessary. Social workers may diagnose and treat psychological disorders. They often assist with the identification of supportive community services frequently working in conjunction with institutions such as hospitals.

A licensed professional counselor (L.P.C.) also has a master’s degree, as does a marriage and family therapist. They focus primarily on private practice and may specialize in relationships, day-to-day life problems, and/or psychological disorders.

Generally, those who hold a professional degree in social work are considered professional workers. They usually have a license or some other professional registration.

Education and Training

Social work education programs usually award a bachelor of social work (BA, BSc, or BSW) degree. However, some also offer postgraduate degrees such as masters (MA, MSc, or MSW) or doctorates (PhD or DSW).

Despite the long history and importance of social service in the field of addiction, there is no uniform standard curriculum in addiction social worker education. Some states make recommendations and regulations regarding the training of social workers in the addiction field; however, no nationwide standards exist.

SUDs may be overlooked in many social worker training programs. In 1989, all Certificate of Qualification in Social Work (CQSW) courses in the British Isles were included in a survey of the training offered to social work students on responding to psychoactive substance misuse (31). There was a 74% response rate. Eleven percent of the courses that responded provided no formal substance misuse training. Those that offered training provided a median of 8 hours, with over 70% of students receiving less than 11 hours, indicating that many students were being given the briefest of overviews. Outside of four or five centers of excellence, social workers received less than the recommended amount of

preparation to work with people with alcohol- and drug-related problems, despite evidence that these patients account for a large and growing proportion of their caseloads.

Social workers may receive little training in addiction in the United States as well. In 2000, the results by Hall et al. (32) of an assessment of the substance abuse treatment training needs of social workers working in randomly selected substance abuse treatment facilities in New England revealed that clinical supervision related to substance abuse treatment had not been available to a significant percentage of the respondents throughout their careers. Despite limited previous training experience and considerable barriers to current training, social workers surveyed in this study reported considerable interest in additional substance abuse treatment training.

In 2006, Smith et al. (33) studied the results of the first Practice Research Network (PRN) survey conducted by the National Association of Social Workers, a collaborative project funded by the Center for Substance Abuse Treatment. The objectives of the PRN survey were to develop broad knowledge about social work practices and more specific knowledge about social workers’ involvement with substance abuse services. Although 71% of the employed social workers reported taking some action related to substance abuse diagnosis and treatment in the preceding 12 months, 53% reported receiving no training in substance abuse during the same period. More than 25% of the clients seen by the sample were reported to have either a primary or a secondary SUD, yet only 2% of the respondents reported addictions as their primary practice area. The results of the survey indicate a need to further assess social workers’ role in substance abuse services and to identify training opportunities for the profession.

Recent initiatives aim to increase interest in the field of addiction (34–37). Various organizations provide different programs available in several states. Interested social workers may take courses in addiction and substance use to obtain advances certification. These programs generally require graduate level education prior to enrollment.

The Department of Social Work at the University of North Dakota provides an Addiction Counselor Training Program sponsored by the North Dakota Board of Addiction Counseling Examiners. Students successfully completing the course of study, the clinical training requirements, and the licensure examination are eligible for licensing as addiction counselors in the State of North Dakota. Students are admitted to this training on two levels. The first level includes social work majors who also complete the minor in Chemical Use/Abuse Awareness (required courses for licensing in addiction counseling, or their equivalent) and the 9-month practicum in a certified addiction facility. Students must meet all requirements for a social work major in addition to the minor requirements and the addiction practicum requirement. This generally involves a 5-year program of study. The second level relates to graduate students in counseling who must meet the required graduate program of study, the required addiction courses, and the 9-month practicum (38).

The National Institute on Alcohol Abuse and Alcoholism (NIAAA) has developed a social worker training program for those seeking a career in the service of patients with alcohol and other SUDs. The program's main goals are to teach motivational interviewing skills in managing coordinated care systems and the techniques for assisting special populations.

Role and Scope of Practice

Social workers play a significant role in serving individuals with SUDs (39). The data suggest that adding social services to public sector programs significantly improves the treatment outcomes in addiction (40).

Professional social workers provide a variety of services that include case management (linking clients with agencies and programs that will meet their psychological needs), counseling, medical social work, human services management, social welfare policy analysis, policy and practice development, community organizing, advocacy, teaching (in schools of social work), and social science research. Other settings in which professional social workers are active include advocacy organizations, hospices, community health agencies, schools, international organizations, employee assistance, philanthropy, and the military. Social workers also assist in a number of therapeutic groups, playing a key role in the interdisciplinary management of individuals with SUDs.

COUNSELORS

Definition

A *licensed chemical dependency counselor* (L.C.D.C.) provides counseling and education for substance abuse problems, but may not diagnose or provide official treatment.

Education and Training Requirements

A high school diploma is usually required to work in this field. Counselors generally are trained on the job. Training programs vary in length from 6 weeks to 2 years. Some colleges also offer training programs for counselors. These programs usually last 2 years and include courses on the effects of alcohol and other drugs. Students may also learn crisis intervention—a way of handling emergency situations. Graduates are usually awarded an associate's degree. Students may also obtain certification from the National Board for Certified Counselors. For some positions, a bachelor's degree or higher in sociology, psychology, or a related field may be required. An increasing number of substance abuse counselors are obtaining master's degrees in mental health counseling.

OASAS-CASAC Credentialing

The New York State Office of Alcoholism and Substance Abuse (OASAS) offers CASAC (Credentialed Alcoholism and Substance Abuse Counselor certification), which is intended

for individuals who provide alcoholism and substance abuse COUNSELING services in approved work settings.

In order to become certified as a CASAC, the individual must have specific ethical and competency, work experience, education, and training and pass the International Certification and Reciprocity Consortium/Alcohol Drug Abuse (ICRC/AODA) written examination. Furthermore, the individual must be at least 18 years old, have earned either a high school diploma or a General Equivalency Diploma (GED), have lived or worked in New York at least 51% of the time.

Evaluation of Competency and Ethical Conduct

The individual signs an affidavit to abide by the Canon of Ethical Principles and arranges to have three individuals complete an Evaluation of Competency and Ethical Conduct on his/her behalf. All evaluators must have direct knowledge of his/her work experience observed for a minimum of 6 months. One evaluator must be the individual's current clinical supervisor, one must be a CASAC or hold reciprocal-level credential issued by another member of the ICRC/AODA. The third evaluator must be a Qualified Health Professional with at least 1 year of experience in substance abuse treatment.

Work Experience

The individual must document a minimum of 6000 hours (approximately 3 years) of supervised, full-time equivalent experience in an approved work setting as a provider or supervisor of direct patient services. A minimum of 2000 hours must be paid. The work experience must have been obtained within 10 years prior to submission of application and include 18 consecutive months during the 5 years leading up to the application. The individual must have performed professional tasks including but not limited to, diagnostic assessment, evaluation, intervention, referral, substance abuse counseling in both individual and group setting. Furthermore, there is a need for a minimum weekly, on-site, and documented clinical supervision by a Qualified Health Professional; must include a minimum of 300 hours of supervised practical training in 12 core functions performed for a minimum of 10 hours, under the supervision of a Qualified Health Professional. OASAS strongly recommends the majority of your work experience be devoted to the practice of substance abuse counseling.

In addition, the following academic degree substitutions may be claimed toward satisfying the 6000 hour work experience requirement:

- A master's (or higher) degree in an approved Human Services field from an accredited college or institution may be substituted for the remaining 4000 hours of work experience, provided that the 2000 hours of paid work experience occurred within 5 years prior to submission of the application.
- A Bachelor's Degree in an approved Human Services field from an accredited college or institution may be substituted for 2000 hours of work experience. A maximum of 2000 hours of full-time equivalent voluntary or other

nonpaid work experience (including a formal internship or formal field placement) that occurred within 5 years prior to submission of the application may also be claimed, providing it involved appropriately supervised direct patient services in an approved work setting.

If an academic degree substitution is not being claimed toward satisfying the 6000 hour work experience requirement, a maximum of 2000 hours of full-time equivalent voluntary or other nonpaid work experience (including a formal internship or formal field placement) that occurred within 5 years prior to submission of the application may be claimed, providing it involved appropriately supervised direct patient services in an approved work setting. A formal internship or formal field placement may be claimed as work experience OR education and training, but not both. You should calculate the need to claim a formal internship or formal field placement as either work experience or education and training. Work experience claimed may not include any experience gained as part of, or required under, participation as a patient in a formal alcoholism and/or substance abuse treatment/aftercare program and/or plan.

Education and Training

The individual must document education and a total of 350 hours of training. The minimum requirements include hours ranging from 45 to 150 in Knowledge of Alcoholism and Substance Abuse; training with focus on Alcoholism and Substance Abuse Counseling, Assessment; Clinical Evaluation; Treatment Planning; Case Management; and Patient, Family and Community Education; and Professional and Ethical Responsibilities. All these must have occurred within 10 years prior to date of submission of the application. Long-distance learning is acceptable as long as the institution is OASAS approved. However, no more than 30 hours of training through participation in conferences by professional organizations is acceptable. A formal internship or formal field placement may be claimed as work experience or education and training based on the academic credit associated with completion, but not both. One should calculate the need to claim a formal internship or formal field placement as either work experience or education and training.

Addiction counselor students may obtain training and certification from the National Association of Addiction Counselor (NAADAC). NAADAC certifications vary by amount and type of clinical experience and are graded as follows: National Certified Addiction Counselor (NCAC) Level 1, NCAC Level 2, and Master Addiction Counselor (MAC). Other training exists in age-group specific areas (such as the Adolescent Specialist Endorsement) and spiritual-belief areas (Certificate in Spiritual Caregiving to Help Addicted Persons and Families).

The NCAC I certificate requires 6000 hours of supervised experience in counseling, current licensure as a counselor, and 270 hours of education in SUD counseling subjects. The NCAC II certificate requires a bachelor's degree in a subject emphasizing counseling, 10,000 hours of supervised

experience, and 450 hours of education in SUD counseling. The MAC certificate requires a master's degree in an area emphasizing counseling, current state licensure, 6000 hours of supervised experience, and 500 hours of education in substance use topics.

California also provides a Training Institute for Addiction Counselors (TIAC). This provides training in addiction counseling to meet state requirements for certification in drug and alcohol counseling. Students completing the TIAC program will be prepared to apply for the Certified Alcohol and Drug Abuse Counselor (CADAC) certification and others. This is a CAADAC and a CAADE Continued Education Unit (CEU) Provider (41).

Role and Scope of Practice

Substance abuse counselors help people who have problems related to alcohol and other drugs. They counsel patients with SUDs. Counselors also help the families, friends, and loved ones of patients.

Addiction counselors usually help with practical problems. For example, a counselor might help a former addicted person find a job. Counselors do not prescribe medicine or provide medical or psychological therapy. Doctors, psychologists, or social workers often supervise substance abuse counselors.

Some counselors work in halfway houses. Counselors may also work in outpatient clinics where people come in on a regular basis for treatment. Other counselors work in hospitals, treatment centers, or human service agencies. Sometimes counselors have personal histories of substance misuse and use their experiences to help others. Many counselors host group meetings to discuss the common complications involved in managing SUDs.

CONCLUSION AND FUTURE DIRECTION

Many disciplines serve within the substance use field; however, no standard/uniform curriculum, policies, or strategies exist to train professionals in the field of addiction. Fellowships and certification trainings are available; however, these programs do not necessarily follow any standard. These uncertain credentialing practices may contribute to the variable practice standards in addiction.

The APA has developed a nationwide certification program. This program assists clinical and research psychologists in pursuing advanced training in SUDs and research methods. Social workers commonly assist in the management of patients with SUDs. Not all social workers working in the addiction field have specialized training in addiction. Perhaps a standardized training program can be developed to provide more structured and nationally standardized addiction training for social workers during their undergraduate years. PA training in addiction is limited, although the potential for PA service in the field is large. As is common among physician-extenders, PAs usually gain experience in this field through their regular encounter with addiction

population. The in-school training in addiction for PAs and the opportunities for postgraduate training could be expanded and standardized to prepare PAs to work in the addiction field. Some addiction counselors receive education and training; however, standards vary from state to state in credentialing. Some standardized certificates exist, but most counselors remain uncertified. Statewide or nationwide certification practices could ensure that addiction counselors receive adequate basic training in counseling before encountering individuals with SUDs.

The primary concern across all fields is that there is no requirement for addiction education prior to entering the field. There is a dearth of outcome data on the services these professionals provide, further complicating picture. Inefficient or potentially dangerous practices may continue within if most professionals remain without adequate training and education, and the field requires regulation and quality control measures. Considering the staggering social and economic costs of addiction and the great concern to society, increasing and developing other professionals' involvement could improve the effectiveness and decrease the cost of addiction treatment. Furthermore, ongoing patient supervision during acute and maintenance phases of treatment could be provided by well-trained nonphysician professionals. Developing standardized policies and training curriculum could improve the quality and contribution of these professionals to the field of addiction treatment.

Drug Policy: A Biological Science Perspective

Robert L DuPont ■ Bertha K Madras ■ Per Johansson

INTRODUCTION

Drug policy is often politicized, sometimes passionately. This reflects the fact that drug use can be interpreted as derivative of other contentious issues, from poverty and racism to mental illness and crime. Moreover, the phrase *the war on drugs* can be seen as a dehumanizing assault on drug users. The reality is simpler. The root of the drug problem is found in the human brain, specifically the brain's reward centers that control behavior. Humans, in a relentless exploration of our environments, have discovered—and more recently invented—a variety of chemicals that hijack the brain's reward system, thus *rewarding* drug-taking behavior. The negative behavioral consequences of drug use—including intoxication and addiction—are collateral damage from the powerful brain reward that results from the use of these chemicals.

The goal of drug policy is to limit drug use and the damage to individuals and society from the negative effects of drug use by taking actions that recognize the serious consequences of drug use while remaining consistent with the society's values and laws. The drug policy debate is how best to achieve this goal. Although drug addiction is rooted in biology, the drug problem reflects a wide range of issues from economic to cultural, all of which determine the level of exposure of people to drugs and the environments in which they make decisions to use or not to use them. There are few issues more complex and fascinating than drug policy, and not many that are more important to human health and welfare.

A *policy* is a course of action selected from among alternatives to guide present and future decisions regarding goals and procedures. Public policy usually refers to government actions, and in particular plans at the highest level of government. Policy is closely related to politics which also focuses on the actions of governments but often on issues of broader impact than specific policies. Most drug policy issues are not captured by partisan politics but a few are, if only briefly. For example, it is not easy to define a Democratic or a Republican drug abuse policy, nor is it possible to identify methadone maintenance or Alcoholics Anonymous as liberal or conservative. Nevertheless when drug issues come up in legislatures, partisan conflicts are often evident. Rather than seeing drug policies as consistently partisan it is more accurate to note that parties in a democracy often disagree. The positions of

the two parties in the United States on drug policies are often more easily distinguished by which party is in power than by which one is conservative or liberal.

When considering drug policies the question is not only, what is a policy, but also, what is a *drug*? In this chapter, we define a drug as a dependence-producing illegal drug of abuse, or the nonmedical sale or use of a legal dependence-producing drug, such as oxycodone. The focus on brain reward which is at the heart of the modern science of drug abuse has identified a wide range of behaviors and substances that produce brain reward. This perspective leads to a wider definition of a drug including not only alcohol and tobacco but also addicting behaviors such as gambling, playing video games, and unhealthy eating (1). In this chapter, we stick to the most restrictive definition of a drug, namely dependence-producing drugs—which mostly means *controlled substances* listed in the Controlled Substances Act as administered by the Food and Drug Administration (FDA) and the Drug Enforcement Administration (DEA). In short, this definition means illegal drugs used nonmedically, such as smoking marijuana, snorting cocaine, shooting heroin, or illegally using a prescribed controlled substance such as an opiate, stimulant, or sedative-hypnotic.

In response to the dramatic increase in heroin addiction, the drug policy response resulted in the approval of methadone as a treatment for heroin addiction in December 1972 (37 FR 26790) by the FDA and the DEA. This approval became effective in March 1973 (2). In 1987, another policy decision created more severe criminal penalties for crack cocaine compared to powdered cocaine in response to the emergent crack epidemic. An even larger drug policy decision came in 1971 when for the first time the federal government made massive investments in treatment, prevention, and research on a level similar to the investments in law enforcement that had characterized the federal government's approach to drug policy for the previous half century (3).

Drug policy is sometimes debated in the mass media and may engage the political processes, as did these three policies. Many drug policies can be considered as either relatively permissive of drug use or relatively restrictive (4).

Drug abuse is the only health issue, and one of few problems of any kind, to which a White House Office is devoted. The United States federal government has had a White House

drug czar since June 17, 1971 when President Richard M. Nixon appointed research psychiatrist, Jerome H. Jaffe as the nation's first drug czar and declared drug abuse to be the nation's *public enemy number one*. Each year since 1973 this office has published a National Strategy detailing the government's drug policies. Since 1988 the White House drug office has been called the Office of National Drug Control Policy (ONDCP) making clear in its name that this agency leads the federal government's drug policy. Year-in and year-out Congress has supported retaining the White House drug policy office with its director held responsible for the Executive Branch's multifaceted drug control efforts (5).

Over the past four decades, 12 separate drug czars have served 8 presidents. These drug czars all have testified at hearings held by the United States House of Representatives and the United States Senate. Both of these houses of Congress have changed hands between political parties many times over these decades. While there have been a few truly partisan disputes, the drug policies of the federal government have evolved with striking stability and bipartisanship over this prolonged period of time. In this chapter, we explore why drug abuse policy has occupied this uniquely prominent position in the federal government and what the major evolving drug policies have been. To better inform drug policy decisions, the federal government's investment in research has created the explosive increase in understanding of the biology of brain reward, the biology that creates the public health and public safety consequences of drug use.

Sometimes, both in the United States and around the world, the high priority given over the last four decades to policies dealing with illegal drugs is criticized as misguided. To understand why drug abuse has sustained a unique position of prominence in the public policy debate of recent decades, it is helpful to understand why the modern drug abuse epidemic is different from the ancient use of these same substances. It has been argued that drug use is both old, and relatively trivial, and that the intense focus on drug policy in recent decades is *A Signal of Misunderstanding*, the title of the 1972 initial report of the National Commission on Marijuana. The Commission's second, and final, report in 1973 was titled *Drug Use in America: Problem in Perspective* to show that the Commission thought the politicians, and the voting public, did not have the drug problem "in perspective" (6,7).

Both within the domestic policy debate in the United States and in the world there are abundant and enduring policy conflicts. Many commentaries on drug policy have failed to recognize that the modern drug abuse epidemic is profoundly different from earlier skirmishes. Four characteristics distinguish the modern drug abuse epidemic even though many of the drugs themselves are truly ancient (8–10).

First, the modern drug abuse epidemic is not limited to the oral route of administration. For example, smoked cocaine is not to be confused with chewing coca leaves. Smoked marijuana is not similar to the earlier cannabis remedies that were low dose oral preparations. Even smoking opium, a terrible health problem which first emerged in the 16th century when smoking was introduced as a route of drug administra-

tion with the introduction of tobacco outside the Western hemisphere, is not comparable to intravenous heroin use. To make this same point with another old drug, it was the invention of the cigarette at the end of the 19th century that created a health crisis as a result of tobacco use. Changing the route of administration and the dose profoundly changed the health consequences of nicotine, just as shifting from snorting to smoking changed the health consequences of cocaine use in the late 1980s. The preferred routes of administration of modern drug users are smoking, snorting, and intravenous injection, all of which produce dramatically enhanced brain reward. It is no accident that once adopted, these new routes of administration become the preferred methods of illegal drug use. New brain science has shown that these routes of administration produce far more intense brain reward than do the old methods that fail to deliver rapidly rising high levels of drugs to the brain.

Secondly, the modern drug epidemic involves multiple, often simultaneous drug use often at far higher doses than did the earlier, single use of some of these same drugs. Third, for the most part in earlier exposures to drugs, the drug-using populations were relatively small segments of total populations. Today drug use involves large populations exposed to a wide range of potent drugs by intensely rewarding routes of administration. Fourth, the modern drug epidemic is characterized by initiation to drug use at very young ages when the human brain is especially vulnerable to addiction.

Not only are these four characteristics of drug use new in the world, but also there is a compounding factor in the growth of new sophisticated, globalized drug distribution networks. Moreover, the use of drugs of abuse, for example marijuana and heroin, has been justified by significant political and cultural movements as consciousness expansion, self-medication, and as a legitimate legally protected expression of individual choice. The modern drug epidemic, as new as the computer, is continuing to evolve. This evolution, facilitated by the Internet and increasingly sophisticated and globalized drug trafficking, is moving toward higher doses and wider access to drugs.

This new epidemic began in the United States and quickly became worldwide. Previously isolated cultures and peoples saw a dramatic shift in values with a decline in traditional controls over behavior and a correspondingly sharp increase in the perceived value of personal control over behavior and the importance of immediate pleasure. Delayed gratification, restraint, and traditional controls over behavior, whether from religion or law, became passé, especially for the young. The modern drug abuse epidemic first took hold in youth because young people are disproportionately affected by these changed values and because the adolescent brain is uniquely vulnerable to brain reward. While there remains much debate about the reasons for and the meaning of the cultural change that ushered in the world's modern drug abuse epidemic, one fact is clear: it occurred when the baby boom generation entered adolescence. Suddenly with this demographic shift, a heretofore stable cultural balance shifted as well (11). The baby boom was a global phenomenon, resulting from delayed

fertility in the developed world due to first the great depression then to World War II, and in the developing world to the dramatic fall in infant mortality.

To understand the potential health impact of this epidemic of illegal drug use it is important to recognize the unprecedented investments that have been made over the past four decades in the United States and abroad to curtail illegal drug traffic and limit illegal drug use. In addition, powerful cultural forces have been marshaled to curb illegal drug use. As a result of these twin efforts, the current levels of illegal drug use have been kept relatively low. In contrast, alcohol and tobacco are relatively unrestricted legally and culturally, with resulting relatively high levels of use compared to the illegal drugs. In 2007, the most recent year for which data is available, there were 126.8 million Americans who drank alcohol in the prior 30 days (defined by epidemiologists as “current use”), 60.1 million who smoked cigarettes, and only 19.9 million who used any illegal drug (12). The social costs of either alcohol use (\$166.5 billion) (13) or tobacco use (\$193 billion) (14) alone exceed the social costs of all of the illegal drugs combined (\$109.8 billion) (13). Another useful comparison is that in 2006, the number of illegal drug-induced deaths totaled 38,396 in the United States, while alcohol-induced deaths totaled 22,073 and tobacco-related deaths topped 400,000. The proportion of health-related costs is far greater for legal drugs and the criminal justice costs are far greater for illegal drugs. These data lead to an important policy conclusion: while making drugs illegal reduces the levels of use of those drugs and reduces resulting health costs, it increases criminal justice costs. However, making drugs illegal leads to smaller combined social costs. Regardless, the currently illegal drugs are today a major cause of preventable illness and death. The impact of the currently illegal drugs on the developing world is profound, and rapidly growing.

There are few public policy issues on which almost everyone has an opinion. Drug policy is one of those issues. In discussions about drug policy, sometimes heated and politically cast, the contrasting positions are often reduced to the simplest terms as either being pro- or antidrug. According to David Musto, an eminent historian of drug abuse, national and even global drug policy has swung between periods of permissiveness and restriction over the past century (4). Such simplification of often complex and finely nuanced policy conflicts is common in political discourse because complex issues need to be reduced to simple terms to be transmitted in the modern media and to find resonance in partisan politics. The same simplification—and regrettable but inevitable distortion—takes place in other significant public policy disputes for the same reasons.

The two poles of contemporary drug policy can be variously described. For example, the current United States *balanced policy* is made up of supply reduction (or law enforcement) and demand reduction (either prevention, treatment, or a combination of the two). This balanced policy can be described as a *restrictive drug policy*. The objective of a balanced and restrictive policy is the reduction of illegal drug use. When it is demeaned, it is usually called *prohibition* to

conjure up the image of alcohol prohibition which is widely seen to have failed. In contrast to the balanced and restrictive policy, the other pole of drug policy can be called *harm reduction or a permissive policy*. A policy of harm reduction accepts illegal drug use as inevitable and seeks to reduce the “harms” caused both by drug use and by the policies designed to reduce drug use (especially those involving the criminal justice system). In reality most drug policies have features of both approaches and many serious issues (such as setting the legal drinking age for alcohol at 18 or 21, or establishing parity for substance abuse treatment) are not easily characterized in this politicized and caricatured drug policy dichotomy (15).

Influencing drug policy, which many people want to do, is a bit like trying to change the direction of a slow-moving aircraft carrier by nudging it with a rowboat. While no single rowboat can have any measurable effect there is no doubt that millions of rowboats can nudge the biggest aircraft carriers. From time to time the change of course of major national drug abuse policy is dramatic and sudden. As an example, the course of American drug policy took a dramatic new turn in the early 1970s when the national drug policy which had been focused almost exclusively on law enforcement for half a century was suddenly balanced by a huge new investment in treatment, research, prevention, and training (3). This policy change balanced traditional supply reduction by a similar-sized investment in demand reduction.

To have an impact on national or even local drug policies, first it is necessary to team up with lots of other rowboats to do the nudging. Second, it is easier to slightly change the direction of the moving aircraft carrier than it is to start it moving in an entirely new direction. So, as practical steps, drug policy advocates need to find individuals and organizations that share their views. They are most likely to have success when they are able to catch a strong policy momentum that is either growing or already established on specific drug policies.

A good place to start learning about drug policy is the annual report of the ONDCP which can be found on its web site <http://www.whitehousedrugpolicy.gov>. Good resources also can be found on the web sites of nongovernmental organizations (NGOs) dealing with substance abuse problems. An example of an NGO is the American Society of Addiction Medicine (<http://www.asam.org>) with 165 published policy positions on its web site ranging from statements on underage drinking to drugged driving and from parity to buprenorphine. Most other organizations in the substance abuse field take active positions to influence drug policy that often focus on areas of their own self-interest, for example supporting greater funding for their activities. But all organizations also focus on less obviously self-interested aspects of drug policy. (For a recent scholarly review of drug policy see *An Analytic Assessment of US Drug Policy* by David Boyum and Peter Reuter.) (16).

With this overview in mind, we turn to a review of the history of drug policy initially in the context of an earlier drug epidemic in the United States at the end of the 19th century and the response to it both in the United States and around

the world. We then look at the modern epidemic and the major drug policies of the past four decades.

Following that discussion, the chapter next explores the science of drug abuse and the central place of brain reward in this story, looking closely at lessons that can be taken from rapidly evolving and very promising research to inform drug policy.

Following after the information about brain science and policy, the chapter describes the public health and safety dimensions of drug policy from an international perspective.

The chapter concludes with a description of the major drug policy issues facing the United States and other countries today, and speculates about issues likely to be confronted in the decades ahead.

THE CONTEXT OF DRUG POLICY

While drug policy, like drug use, can be traced back to the beginning of history when alcohol use already was widespread, the modern era of drug policy started in the 19th century when the chemicals responsible for drug effects were first identified and when injection became an available route of administration. Although global distribution of drugs was a factor for centuries, in the 19th century the global supply of all commodities, including the drugs that are now illegal, become far more common. By the end of the 19th century there was a significant drug epidemic in the United States and in some other areas of the world, especially in Asia where opium consumption had created havoc ever since the Opium War in 1842. As a result of losing that war China was forced, along with other Asian countries, to open their markets to opium brought mostly from India by the British. Compounding world drug problems, in 1898 the Bayer Company introduced a semisynthetic opiate, heroin, to the global market as a cough medicine. It was especially popular in that era because of the high prevalence of tuberculosis. This was the era in which patent medicines in the United States often contained alcohol, morphine, and cocaine and when a popular soft drink introduced in a pharmacy in Atlanta adopted the trade name “Coke” to make unmistakable the origin of its stimulating effects.

Most of these preparations, including Coca-Cola, were sold with medicinal claims. In reaction to this open market in what now are known to be addicting drugs, there was a powerful grassroots progressive backlash that urged new legislation to restrict access to these substances. The first of several laws passed during this infant era of modern drug policy, the Food and Drug Act of 1906, did not prohibit the sale of these drugs but required them to be clearly labeled. The next legislation was the Harrison Narcotics Act of 1914 which restricted the use of opiates through the federal government’s power of taxation. In 1919, using a similar mechanism to restrict the sale of alcohol, the Volstead Act, also known as the *18th amendment*, became law. These laws were not only bipartisan but they were central parts of the agenda of the then triumphant progressive era. From a drug policy perspective, it is important to recognize that these were all restrictive laws.

They all were passed in response to the rapidly escalating and serious problems created by the open market in addicting drugs.

This progressive movement’s focus on addicting drugs was not limited to domestic policy within the United States. In 1909, the Shanghai Conference targeted the global opium trade by invoking international cooperation. The United States played a key role at this international meeting. It brought to the table experience with its polyglot population made up of immigrants with drug-using habits from every part of the globe, its distinctive culture and laws that promoted individual freedom and limited government interventions on behavior, and its recent legislative measures restricting the availability of abused substances.

These events, in this first drug abuse epidemic, are well described in many fascinating histories of drug abuse and drug policy (4,8–10,17,18). Even in this short review it is important to notice the origins and characteristics of the responses to this epidemic. While there was little government investment in treatment during that time, William White has shown that in the early years of the 20th century there were significant nongovernmental developments in substance abuse treatment even though they were small by comparison with what was to follow half a century later (19).

The initial law enforcement effort to restrict access to drugs of abuse was backed by the strong support of large majorities in the United States. At the time there were few voices from any part of the political spectrum raised to support drug use or individual rights to use drugs, including privacy rights. These early efforts to contain drug abuse with near exclusive reliance on law enforcement were remarkably effective, but not without problems. They did not end drug or alcohol use although from today’s perspective it is remarkable how successful they were in reducing drug use and reducing the negative consequences of that use—despite their modest size.

Following these events, there was a flurry of interest in what happened to the drug addicts themselves, leading in 1925 to Congressional hearings and ultimately in 1935 to the first investment of the federal government in what would today be called *demand reduction*—the science of addiction and treatment of addicted individuals. The Narcotics Farm and later the Addiction Research Center (ARC) in Lexington Kentucky were born, the organizations that would later spawn both the National Institute for Mental Health (NIMH) in 1946 and the National Institute on Drug Abuse (NIDA) in 1973.

In the first half of the 20th century, some voices were raised against the government’s balanced and restrictive drug policy. Some concerns were heard from the medical community, but the medical establishment, led by the American Medical Association, was strongly supportive of this approach. The results spoke for themselves as these decades were remarkable for a generally low level of drug and alcohol use (20). In contrast to the continuing support for restrictive drug laws, the 18th amendment to the Constitution was repealed in the 21st amendment as one of the first acts of economic stimulation by Franklin Roosevelt in 1933. Prohibition of alcohol sale

was the only Constitutional amendment to be repealed. President Roosevelt explained his dramatic action mainly as an effort to promote jobs in the alcohol industry but also as a way of helping working people cope with the suffering of the depression. The rationale of curbing organized crime was later offered as a significant factor, but in 1933 this was far down the list of reasons for repeal. While repeal did deprive organized crime of one source of revenue, few claimed in the 1930s that the repeal of alcohol prohibition reduced the serious threats posed by organized crime.

Prohibition dramatically reduced drinking and many of the most serious effects of excessive drinking (21). Nevertheless as the years went by the support for alcohol prohibition waned until the Depression shifted the political balance in favor of repeal. After the end of alcohol prohibition, the *per capita* consumption of alcohol in the United States rose steadily from the lowest levels in the nation's history during prohibition until the mid-1980s. Since that time it has declined modestly. The highest level of *per capita* consumption of alcohol occurred in the early years of the 19th century, creating the push for prohibition which by the later half of the 19th century had become one of the three major popular movements in the country. (The others were the abolition of slavery and women's suffrage.) Today few people know that in the 19th century, the *temperance movement* attracted more support than either of the other two big policy ideas or that Maine in 1851 was the first state to prohibit alcohol. By the time the 18th Amendment became federal law, most states were already *dry*. When alcohol prohibition in the United States ended in 1933, there was no interest in removing the restrictive laws on illegal drugs.

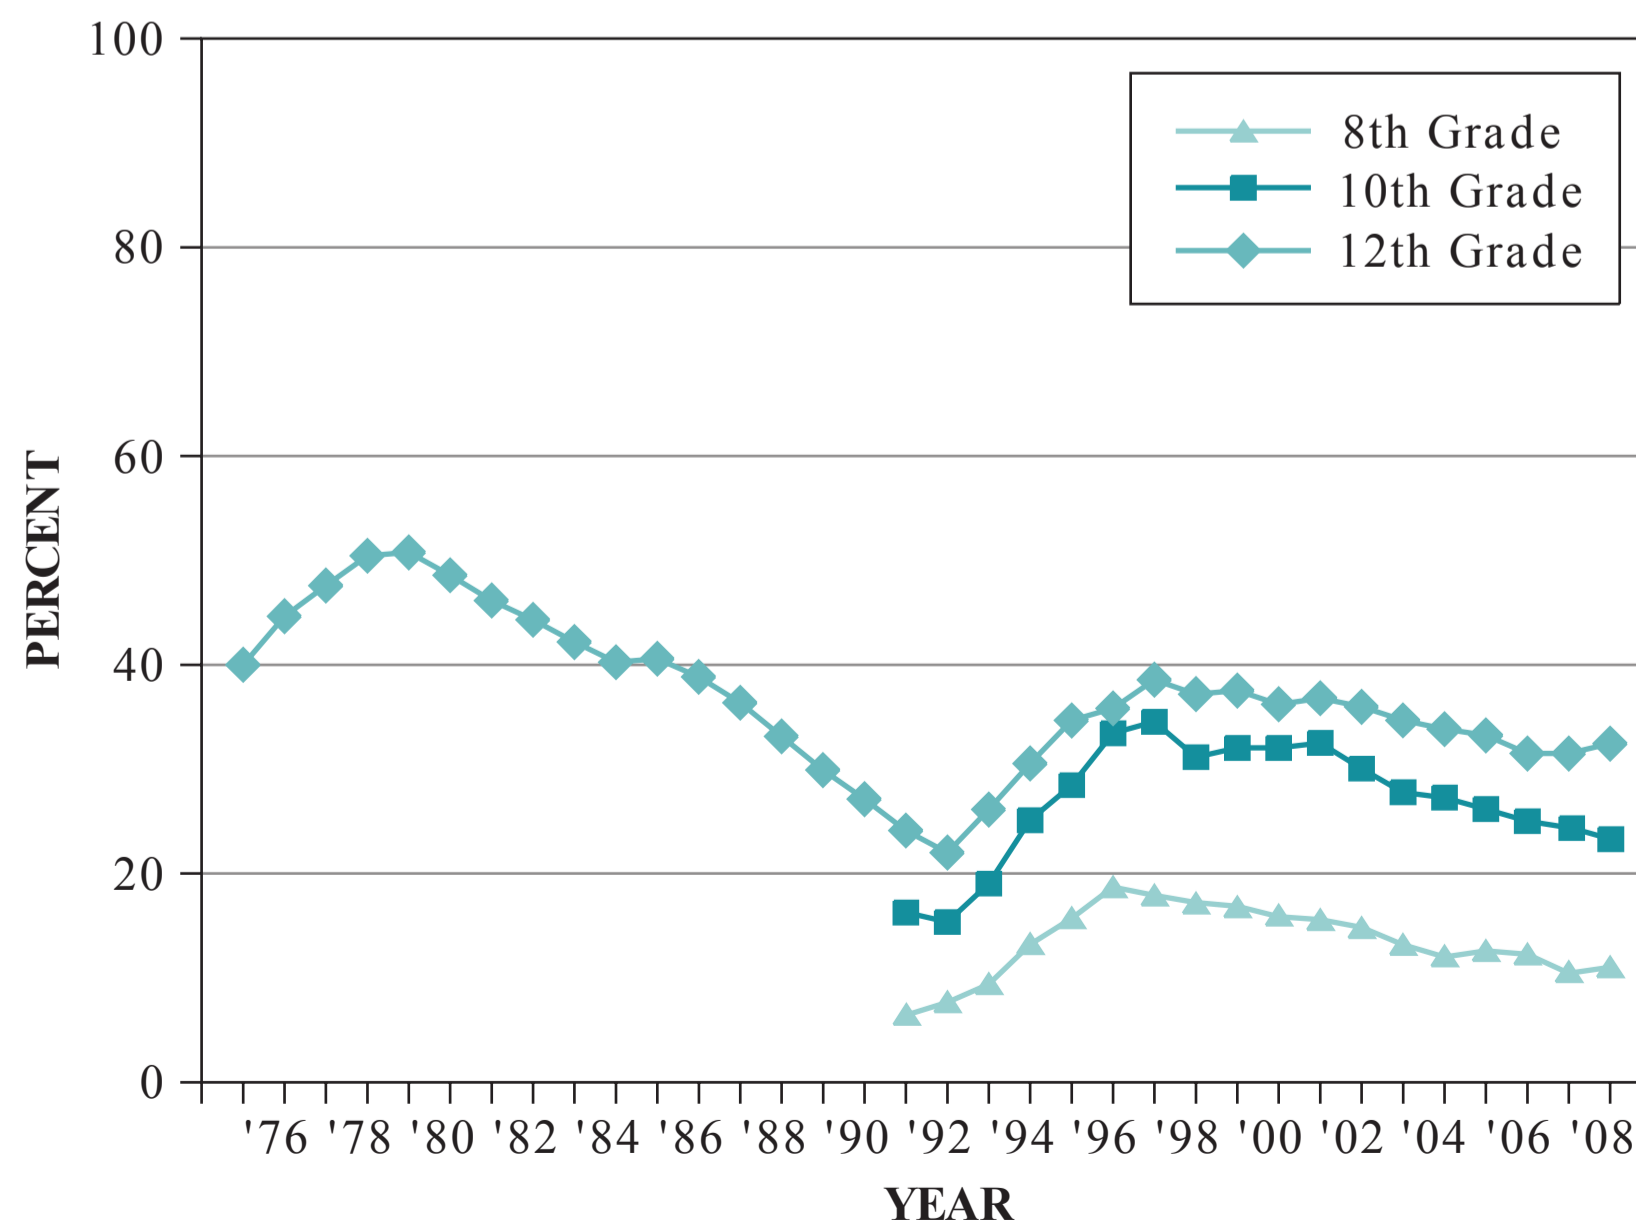

The second drug epidemic in the United States, the modern drug abuse epidemic, began with an increase in illegal drug use that had incubated in the late 1940s and throughout the 1950s only to spring to life as a major national threat to public health and public safety in the late 1960s.

In 1962, only 4% of Americans 18 to 25 years old had ever used an illegal drug. That number rose to a peak of 68% in 1979. That is evidence of the massive impact of the modern drug abuse epidemic. Since that time the levels of illegal drug use have changed profoundly over relatively short periods of time. This is in contrast to the smoother, more consistent trend lines showing the use of alcohol and tobacco, both of which have declined from recent peaks and show signs of continuing to do so, with drops in alcohol use being much more modest than those of tobacco in recent decades.

Figure 77.1 shows the national rates of use of marijuana over the past three decades for students in the 8th, 10th, and 12th grades. While data on individual drugs show some variability, over this long period of time marijuana has remained the most commonly used illegal drug. Most other illegal drugs have shown trends similar to those shown here for marijuana. The dramatic escalation of illegal drug use that started in the mid-1960s peaked in 1978 when the highest levels of illegal drug use in the United States were recorded. Between 1973 and 1978, ten states signaled a change in drug policy when they *decriminalized* marijuana. This drug policy activity was associated with the more permissive side of the drug policy debate. The long decline in illegal drug use between 1978 and 1991 was widely attributed to the impact of the *Parents Movement* and other efforts to restrict drug use, all of which were clearly reactions to the dramatic increase in drug use in the prior decade. After 1978 no state decriminalized marijuana and two states rescinded their earlier decriminalization efforts.

Both the rise in drug use from the 1960s to 1978 and the subsequent drop from that high point to the low in 1991 cannot be explained by changes in brain biology or any change in the drugs that generally were in use during those years. Instead these changes are most plausibly explained by shifts in the environment in which drugs and human brains come in contact. The upsurge in illegal drug use was the result of an

Figure 77.1. Marijuana: trends in annual use, grades 8, 10, and 12. Percentage who used in the last 12 months. (Data from Johnston LD, O'Malley PM, Bachman JG, et al. *Teen Marijuana Use Tilts Up, While Some Drugs Decline in Use*. Ann Arbor, MI: University of Michigan News Service; 2009. Retrieved 04/27/2010 from <http://www.monitoringthefuture.org>.)

attitude of permissiveness and even a widespread appreciation for the positive effects of illegal drugs, especially marijuana and the hallucinogens. The subsequent fall in national levels of illegal drug use is explained by the widespread counterreaction to this sharp rise. In both cases marijuana use and perceptions regarding that use were at the center of the trends. This is clearly seen in the data from *Monitoring the Future* (22) which has shown the inverse relationship between perceived risk and drug use: The more the perceived risk the less the use, the less the perceived risk the more the use. On the other hand perceived availability showed a less dramatic correlation with levels of marijuana use over time.

Since 1991 the battles over drug policy have intensified. The critics of the balanced and restrictive strategy of national drug policy received an infusion of new funding in the early 1990s, fueling a resurgence of the debate. This debate over drug policy had been largely muted if not absent from 1978 to 1991, the era of declining drug use. The renewed battlegrounds include medical marijuana, needle exchange programs, and the cultivation of hemp on the one hand and random student drug testing and tough enforcement of drugged driving laws on the other. Central to this drug policy debate have been issues such as the health risks versus the safety of marijuana use and the role of the criminal justice system. This critique of the restrictive drug policy has been widely labeled *reform*, a word that has become a code word for the more permissive drug policies of harm reduction.

While Figure 77.1 shows the trends in marijuana use over recent decades, with the current level far below the peak level in 1979, note in Figure 77.2 that the drug overdose deaths have shown no decline over that time. Instead the drug-related deaths indicate a dramatic and continuing escalation. How can those two trends be rationalized? Why does drug use show powerful changes over relatively short periods of time while deaths show a steady escalation? This is one of the many mysteries of current drug epidemiology, mysteries that are important for the development of better drug policies (23).

Figure 77.1 suggests that the balanced drug policies have contained the use of illegal drugs and that the level of use of illegal drugs in the United States has declined since the peak in 1978. In contrast, Figure 77.2 implies that the illegal drug problem is continuing to escalate.

One of the foci of political discussions of drug policy is the role of the criminal justice system. Critics of the current balanced and restrictive strategy of drug abuse prevention contend that law enforcement is abusive, counterproductive, and not *evidence based*. Supporters of the current balanced policies are more likely to defend the role of the criminal justice system. Similarly, critics of current balanced drug policies point to evidence that *the war on drugs* has failed, while defenders of this policy see progress in drug prevention. In sorting out these conflicting views it is helpful to ask, “compared to what?” As stated earlier in this chapter, the criminal justice costs of illegal drugs exceed the criminal justice costs of alcohol and tobacco, for example but the health costs of alcohol and tobacco (and their rates of use) are far larger than the costs of all the illegal drugs combined. What would be the potential rate of use of the currently illegal drugs if they were legalized? Opponents of current policies generally perceive the United States to be saturated already with drug availability and doubt there would be an increase in use if the drugs were legalized. Supporters of the current policies expect increases in use of the currently illegal drugs to levels now seen for alcohol and tobacco were these drugs to be legalized. Many critics of current policies focus only on the criminal justice costs of the currently illegal drugs ignoring the health and other social costs related to their use, while supporters of current policies are more apt to emphasize these costs. As an example, they point to the vastly larger health costs from the currently legal drugs, alcohol, and tobacco.

An ominous new trend in drug use confounds many of these formerly common policy conflicts. The rise in the abuse of prescription drugs such as oxycodone (OxyContin), alprazolam (Xanax), and dextroamphetamine (Adderall) has

Figure 77.2. Drug- and alcohol-induced deaths, 1979–2006. (Data from CDC National Vital Statistics Report, Vol. 58, No. 14.)

provided useful evidence about the fundamental nature of the public health problems of drug abuse and addiction. Since 2005 more Americans have first used a prescription opiate nonmedically each year than have first used marijuana, the most popular of the illegal drugs. There now is more death in the United States from the nonmedical use of prescribed opiates than from heroin and cocaine combined. These tough facts impact the drug policy debate. In prescription drug abuse, there is no Mafia and no actively enforced prohibition. Instead the vast majority of the prescription drug supply flows directly from physician prescriptions to medical patients at which point they are diverted and/or used in a nonmedical pattern of abuse. The old-fashioned debates on drug policy are moot when it comes to this growing problem, a problem that leads back to the brain and the uniquely powerful reinforcing effect of these drugs, whatever their source. The recent dramatic rise in prescription drug abuse not only reflects the huge increase in the use of controlled substances in medical treatments over the past decade (and thus the increasing availability of these drugs), but it also shifts the policy picture from a focus on global drug traffic as the force driving drug use to a focus on the role of a unique group of chemicals in brain reward. Prescription drug abuse is pushing the perspective back to brain biology as the fundamental problem to be addressed by future drug policies.

A valuable, and often overlooked, source of evidence that can inform drug policy is found in the common experiences of families confronting drug problems. Just as whole societies are often taken aback by drug problems and come to recognize them long after they are firmly entrenched, so it is with most families. Drug addiction has two salient features. The first is dishonesty. Most drug users hide their use from those who care about them, and they lie about it if confronted. Moreover, the drug user does not want to stop using. The second characteristic feature of drug use is its continuation despite the serious and even devastating problems flowing from it. Such paradoxical behavior can be compared to that of an abusive love affair. In this case, the lover is the drug in the user's brain. Those associated with the addicted individual try to discourage return to the chemical lover but the drug user repeatedly believes the next time will be different and will not lead to painful consequences. The distortion in the thinking of the drug-dependent person is striking. This individual's brain has been hijacked by the chemical lover.

Many families reluctantly emerge from a long period of not knowing about the drug use to face the problem initially with compassion and love, expressed by tolerant behaviors that are widely seen in the drug treatment community to be *enabling*. Only when this initial approach fails do most families turn to *tough love*. Tough love is characterized by determined efforts to make continued participation in the benefits of the family conditional on stopping drug use, sometimes by getting into and sticking with substance abuse treatment. The seductive pull of the chemical lover is intense. The challenge of recovery is great. But with help, and often that includes the 12-step programs of Alcoholics Anonymous and Narcotics Anonymous, it can be achieved and maintained. This is a

joyous outcome for all involved. Addiction is modern, chemical slavery. Recovery is emancipation (24).

Analogous to this common experience, communities and entire nations confront the problems flowing from nonmedical drug use first with denial, then with enabling, and typically only belatedly with tough love. It is vital to maintain compassion and respect in the context of such a struggle.

THE SCIENCE OF DRUG USE AND ADDICTION

The Magnitude of the Public Health Problem

The brain science of addiction is rooted in public health. Individuals, families, societies, and nations bear a heavy burden from the use of drugs for nonmedical purposes. Potentially life-changing consequences range from accidents, trauma, compromised health, cognition and education, unplanned pregnancies, failure to meet commitments, high job turnover, psychotic reactions, and drug-induced violence. The devastating end point of nonmedical drug use—addiction—has the dubious distinction of being among the leading causes of preventable deaths and chronic illness during the prime of life, and among the most prevalent, most costly, and deadliest of neuropsychiatric disorders (23,25). In the United States, over 22 million people (8.9% of the population over 12 years) are estimated to harbor a medical diagnosis of alcohol or illicit drug abuse/addiction (26). More than double this number (estimated at 46 million) are engaged in risky, problematic alcohol, and other drug use and are at risk for addiction with medical, psychiatric, social, and emotional consequences of substance abuse (27). An emerging concern is the blurred boundaries between illicit and prescription drug abuse. Prescription drug abuse now ranks second, after marijuana in number of users, first among new initiates of drug use (numerically, but not statistically), second among those dependent on illicit drugs, and first among causes of drug-related deaths (26).

Advocates for decriminalization or legalization of drugs frequently argue that as a victimless activity, drug use should not be regulated. Numerous medical, social, and economic reasons argue against this stance. Consider that 8.3 million children (11.9% of all children) live in the United States with at least one parent who is dependent on, or abuses alcohol or an illicit drug during the past year, with an estimated 70% of child abuse/neglect cases involving parental use of drugs (28,29).

Biological research of drug use and addiction has clarified specific events that can compromise the function of our brains, the repository of our humanity. We have learned that certain drugs, such as cocaine, methamphetamine, ecstasy, inhalants, and alcohol, can be toxic to the brain, destroying nerve cells or nerve endings and interrupting normal blood supply (30,31). Even without inducing frank toxicity, drugs can promulgate adaptive changes in cell structure, metabolism, brain signals, and circuitry, leading to behavior consistent with addiction (31–33). As addiction sets in, survival behaviors (waking up, washing, eating, dressing, attending

work or school, and focusing on personal and work commitments and goals) become secondary, as the brain increasingly focuses on a narrow set of compulsive, uncontrollable goals—to seek and consume drugs despite adverse consequences. The addicted brain converts normal behavior into a drug-centered existence. Those motivated to become and sustain abstinence can endure drug cravings months or years after withdrawal symptoms have ceased, cravings that can trigger relapse at vulnerable periods. A number of treatment approaches (cognitive-behavioral therapy, medication-assisted therapy) effectively assist people in overriding these biological changes (34).

The biological science of drug use and addiction provides an essential framework for shaping clinical, social policies and programs for prevention, intervention, and treatment. Yet, biological understanding is a daunting quest: how can a simple ingested chemical imprint itself on the brain, create sensations that surpass, suppress, or supplant natural rewards, transform personality, and usurp the pursuit of fundamental human priorities: survival, food, safety, shelter, family, and health? What brain systems does it invade? What brain systems does it change? How does this chemical enable the addicted brain to tolerate doses that, in a drug-naïve person, would be lethal? How can a simple molecule leave such a strong imprint on the brain and body that when it clears the system dysphoria or severe withdrawal symptoms surface? How can drug craving reoccur years after the last dose of the drug? These questions drive neuroscientists to create a biological roadmap, the starting point a simple chemical, the end points being hedonistic sensations, powerful memories, behavioral and personality changes, addiction, craving, and relapse. Within the triad of risk factors—the environment, the individual, and the drug—most environmental and individual factors cannot be faithfully replicated in preclinical laboratory settings as models and for further scrutiny at a molecular level. By and large, our knowledge relies on incomplete human studies using a paucity of noninvasive techniques, or imperfect animal research. Despite these limitations, evidence-based risk factors and the underlying biology that influence the behavioral trajectories of new drug initiates and susceptibility to addiction are increasingly understood.

Risk Factors: The Environment

Chaotic homes with ineffective parents, inadequate bonding with parents, parent or sibling drug use or acceptance of drug use as a rite of passage, stress, sexual and physical abuse, post-traumatic stress disorder, the need for social acceptability, peer pressure, initiation of alcohol and smoking, and the media are all recognized as risk factors for initiation and sustaining drug use. Public misinformation or no information on the physical and mental health risks of specific drugs (e.g., prescription drugs are harmless or safer than street drugs) is another risk factor, highlighting the need to survey the knowledge base of the public and address these voids. Countering these influences are unequivocal negative attitudes and stances on drugs conveyed by parents and communities. Other factors countering the pressure to use drugs are views

of friends, schools, religious authorities, the media, affiliations and participation in social and religious organizations, and laws enforced by the criminal justice system. Evidence-based risk factors need adequate representation in prevention programs.

Risk Factors: The Individual, Genetics

As with other neuropsychiatric disorders, certain individuals are more vulnerable to addiction, with genetic influences penetrating every dimension of human drug response. Strong evidence from family, twin, and adoption studies indicate that genetic and environmental factors play equally important roles in the development of addiction. For example, siblings of abusers are more likely to use drugs. Likewise, adopted children with histories of substance abuse in their biological families are more likely to become abusers themselves, even if the current environment is devoid of drugs. Identical twins have a higher propensity to share drug histories than fraternal twins, with a genetic component greater for drugs with higher addictive potential (e.g., heroin). It is now feasible to scan multiple genes at the same time—500,000 gene snippets (SNPs or single nucleotide polymorphisms) simultaneously—to seek genetic differences between nonaddicted and addicted populations. More than 100 candidate genes for addiction susceptibility have emerged from this approach, indicating that genetic influences are complex and arise, not as a result of a single anomaly, but of convergence of multiple genes. Genome-wide association studies reveal a complex polygenic (multiple genes) influence on addiction vulnerability, which distinguish addicts of different ethnicities from matched controls. Intriguingly, susceptibility genes overlap for different drugs (36). Scientists can infer from these findings that addictive processes are likely to converge on common molecular events and neural networks in the brain, even though the starting point of addiction, activation of diverse brain receptors is unique to each drug class. Molecular, anatomical, and brain imaging research lends credence to this model of “biological convergence of addictive processes” (see below). Prominent among susceptibility genes are those encoding cell adhesion molecules and other genes involved in learning, memory, and cognition, implying that memory/salience play a critical role in compulsive drug seeking and drug craving (35). Also, inherited traits for vulnerability to addiction are shared with other common heritable neuropsychiatric disorders (e.g., bipolar disorder, cognitive ability, Alzheimer disease). Accordingly, prevention, diagnosis, and treatment of addictions should be viewed in the context of the neuropsychiatric profile of people at risk for addiction. The promising genetic approach portends a future of genetically based personalized prevention and treatment approaches (35).

Other individual factors with high predictive value for drug abuse are psychiatric comorbidity, personality disorders, poor school performance, inappropriate school behavior, or early drug use. For those enduring posttraumatic stress disorder, anxiety and depression, drug use has been interpreted as a form of maladaptive chemical coping. Severe emotional

shocks, such as child abuse, the death of a parent, or alcoholic or drug-addicted parents, can increase drug use. Age of onset of first drug use is the most significant risk factor for progressing to addiction, another important rationale for promoting prevention in youthful populations. All of these risk factors have one thing in common, they make individuals more willing to try drugs and they make individuals more willing to ignore the risks, and the warning of risks, from escalating drug use. In other words, these risk factors generally make individuals more vulnerable to the biology of brain reward which itself is ubiquitous in the human brain.

Risk Factors: The Developing Brain in the Adolescent

Adolescent drug use is a unique public health challenge, warranting aggressive prevention and intervention policies in this population: (a) age of onset of drug use is declining; (b) during adolescence, initiation of one drug accelerates the use of other drugs; (c) the younger the drug initiation, the higher the probability of progressing to addiction; (d) psychiatric symptoms are higher in adolescent users; (e) drug use is associated with risk-seeking behavior, delinquency, and criminal behavior; (f) adolescent drug use is associated with a higher likelihood of injury or death; (g) adolescent use is associated with lowered academic performance, absenteeism, higher school drop-out rates, gang membership, and later involvement in criminal behaviors.

Initiation of drug use is largely an adolescent phenomenon, with at least 60% of new initiates falling below the age of 18, and even a higher percentage for tobacco and alcohol use (26). Onset of prescription drug abuse is later and more likely to emerge in the third decade of life often in association with earlier use of alcohol and other drugs. Drug initiation during the early phase of adolescence, in contrast with adult onset of use, confers a much higher risk for developing addiction during adolescence or later in adulthood. Risk analyses demonstrate considerably higher rates of addiction with early onset of use of marijuana, cocaine, other psychostimulants (e.g., amphetamines), hallucinogens, opioids, inhalants, alcohol use, smoking, prescription drugs (stimulants, opioid analgesics, sedatives, tranquilizers, anxiolytics) (36–41). Progression to addiction is higher, if involvement with drugs occurs prior to 18 years of age (36,42,43). With each year of delay of onset of use, the likelihood of lifetime drug abuse and dependence is reduced significantly (36), and the odds of developing prescription drug abuse decreases 5% with each year of delay of nonmedical use (44).

The alarmingly high risk of the adolescent becoming addicted can be attributed to the underdeveloped adolescent brain which is uniquely vulnerable to addiction. The adolescent brain undergoes extensive linear (age-dependent) neurodevelopment, primarily in regions associated with motivation, impulsivity, and addiction (45). Brain regions that serve attention, reward evaluation, emotional responses, and goal-directed behaviors undergo structural and functional reorganization throughout late childhood and early adulthood (46–48). Magnetic resonance imaging of living brain reveals critical anatomical and functional changes in

brain development, beginning in utero and *ending at age 24* (47,48). The most robust changes are a linear increase in white matter volume as a function of age, and peak increases in grey matter volume during late childhood or early adolescence. The back of the brain, evolutionarily the oldest part of brain, matures more quickly than the frontal cortex, the most recent addition to mammalian brain. The higher-order cortices, involved in decision-making, inhibiting impulses are developmentally immature in the adolescent compared with adult brains and reach adult form only after brain regions involved in interpreting sensory and visual stimuli are formed. This may account for the activities favored by adolescents, the sensory, physical, impulsive, risk-seeking over cognitive, impulse control, and executive functions of the adult brain. The later maturation of the prefrontal cortex is paralleled by increased abilities in abstract reasoning, attentional shifting, response inhibition, and processing speed (46).

At the cellular and molecular level, brain development is an exquisitely regulated progression of formation of circuits and connections. Consider that the brain contains over 100 billion nerve cells and each cell may have a few or more of 10,000 connections with other cells. With meticulous precision, a family of proteins designated axonal guidance molecules, steers the complex formation of neural circuits, some by lengthening, others by stopping or directing the wires (axons) that connect nerve cells. In the adult brain, these proteins also regulate neuroadaptive changes, by shaping the morphology of nerve cells (dendrites), modulating the strength of memory processing, and regulating the genesis of nerve cells. Drugs can modulate the expression of neurodevelopmental proteins in brain and in cell cultures, resulting in altered levels or ratios of expression (49,50). Conceivably, the introduction of drugs during adolescence, a period of rapid neurodevelopment, may change the concentrations of axon guidance molecules, modifying neural circuitry, signaling, and neurogenesis. These processes may alter the normal trajectory of adolescent brain development, leading to a much higher vulnerability to addiction.

Risk Factors: The Drug

Addictive drugs can elicit powerful, subjective responses, embedded in their unique chemistry and chemical formulation (e.g., salt, free base). The impact of the drug is partly engineered by the dose, dosing regimen, route of administration (intravenous, inhalation–smoking, insufflation, subcutaneous, oral), how fast it combines with its brain targets, and user response. Self-reports of “high” are greater when heroin or cocaine is administered intravenously compared with insufflation, potentially increasing the desire for more drug and heightening addictive potential (51).

Are some drugs more addictive than others? Overall, drugs directly targeting brain dopamine or opioid systems (e.g., cocaine, heroin) have higher addictive potential, progress from initial use to addiction. The prevalence of addiction among users of cocaine, heroin, amphetamines, or marijuana is higher than for 3,4-methylenedioxy-methamphetamine (MDMA), or inhalants (52). Higher still is the percent of smokers who

manifest addictive symptoms, but this is a questionable comparison, as nicotine delivery systems are legal, inexpensive, socially acceptable in certain domains, and widely available. Predicting the relative addiction potential of drugs on an individual basis is even more daunting, considering the unique individual experiences of environment, genetics, and psychiatric comorbidity.

These variables are of minimal significance in a homogeneous population of laboratory animals matched for genetic backgrounds, environment, and stress levels. Animals self-administer all the same drugs that humans compulsively seek, including marijuana, cocaine, heroin, ecstasy (MDMA), amphetamine, methamphetamine, phencyclidine (PCP), nicotine, and alcohol. These findings reflect a fundamental property of the mammalian, and even the bird brain. (Pigeons will consistently poke at a lever to receive cocaine.) Drugs elicit hedonic, rewarding responses in mammalian brain; the responses are not unique to a few susceptible individuals or to humans. This fundamental observation implicates drugs and associated drug addiction as a universal risk and support the limitations on drug availability as a sound public health response.

Mammalian species, from mice to monkeys, rapidly learn to self-administer cocaine and opioids, with cocaine reportedly causing inevitable death in primates that are given free, uncontrolled access to it. The relative addiction potential of the majority of drugs can be measured by various tests; the rate at which they acquire self-administration, whether the drug requires coupling with another re-enforcer or a priming agent to initiate drug-taking behavior (e.g., adding sugar to alcohol), the amount of effort expended to acquire a single dose, and how much effort is exerted before subjects give up, whether self-administration persists despite an adverse consequence, and how quickly a single dose, stress, or environmental cue reinstates drug administration during abstinence. These procedures have not been systematically applied in uniform experiments to assess the relative addictive potential of a wide range of drugs.

Brain Biology

Addiction biology refers to complex biological adaptations in the brain that reflect a sequence of progressive behaviors manifest as addiction: initial use, escalation of dose and frequency, transition to loss of control and compulsive use, withdrawal, craving, and relapse (31). Current models, although rudimentary, provide important insights that are crucial for infusing prevention programs with sound scientific discoveries and for providing biochemical leads to develop effective medications and other treatment strategies.

The Immediate Targets of Drugs in the Brain: Receptors

In complex organisms, communication within the brain is the key to survival. It is intriguing to consider the value of communication to human survival, as at least 15% of the human genome encodes proteins involved in communication. All addictive drugs target proteins that are critical for the complex communication system of the brain. From the

instant a drug encounters its protein target, it inserts itself into the communication system of the brain, triggering a prodigious array of molecular and cellular changes to affect brain function and behavior. At the core of this communication system are an estimated 100 billion nerve cells (neurons) and even higher numbers of infrastructural cells, glia, which are also implicated in facilitating communication. Neurons accumulate information from sensory systems in the body, from other brain regions and from the environment, attribute a priority and salience (value) to this information, develop a response, communicate the response, and memorize the sequence of events for future use. Reduced to the molecular level, when a sensation originates, for example, from visual, auditory, tactile, pain, temperature sensors, or drugs, it is propagated through the axons (wires) of nerve cells to target cells that receive and interpret the signal, to generate a response. Neurons communicate this signal with their neighboring cells by releasing quantal amounts of chemical messengers, *neurotransmitters* (over 100 different types), into a gap. The transmitter diffuses across the space to adjacent neurons to convey the message. On these adjacent neurons, transmitters bind to interpreters (receptors) which not only decipher the chemical signal but propagate it, by an elegantly regulated sequence of events. This reflects the critical role of communication in maintaining homeostasis and the viability of an organism.

Transmitters and their receptors are made by specific neurons in specific brain regions. The transmitter/receptor signaling partners can initiate movement (dopamine), suppress pain (opioids), engender tranquility or fear (serotonin), imprint or erase memories (dopamine, glutamate, acetylcholine, anandamide), produce arousal, pleasurable or unpleasant sensations (dopamine, endorphins, norepinephrine, serotonin, dynorphin), induce paranoia, regulate heart rate (catecholamines), respiration (opioids), and a myriad of other functions. Of core relevance to addiction, specific signaling systems and circuits alert the brain to natural rewards that are necessary for human survival, for example, food, water, safety, relationships, and sex. Drug structures resemble, but are not identical to the structures of endogenous transmitters produced by the brain. The “imposters” (cocaine, amphetamine, and ecstasy) have structural similarities to dopamine, serotonin, and norepinephrine; Δ^9 -tetrahydrocannabinol (THC) the major psychoactive constituent of the marijuana plant resembles the brain’s cannabinoids (anandamide, 2-arachidonylglycerol); heroin shares structural overlap with the brain’s opioids (endorphins, enkephalins); lysergic acid diethylamide (LSD) resembles the neurotransmitter serotonin. As structural analogs of neurotransmitters, the drugs become embedded in the communication system and they trigger signals. But the similarities end here: drugs do not replicate, with fidelity, communication by brain neurons. Communication is an exquisitely regulated series of events, designed for chemicals produced by the brain and not for drugs. Normal brain transmitters are produced in highly circumscribed brain regions by specialized nerve cells, and released in carefully controlled amounts. In contrast, drugs

access all brain regions at concentrations the brain cannot regulate. Drugs may activate multiple receptor targets simultaneously, with receptor activation differing from natural transmitters. Drugs may generate signals of unusually long duration, that are irregular, and that change the rhythm of normal tonic or phasic signals which maintain homeostasis or alert the brain to a natural reward. Termination of signals, an essential step in normal communication and to maintain homeostasis, is also affected by drugs. A critical step in terminating communication and resetting the system is removal of the transmitter by rapid transport and storage in storage vessels (vesicles). Most transporters cannot accommodate the unusual structures (shapes and charges) of psychoactive drugs (e.g., LSD, morphine, cocaine, marijuana), again enabling drugs to trigger persistent signals, at abnormally high strength for abnormally prolonged periods of time, and in inappropriate brain regions.

Researchers have identified the immediate target proteins of most drugs of abuse in the brain (31), isolated and expressed (cloning) the genes that encode these proteins, and documented a prodigious array of molecular and cellular adaptive events triggered from the moment the drug and its receptor target in the brain meet and bond.

The effects of all drugs are unique, with each binding to a unique spectrum of receptors, which under normal conditions, are activated by the transmitters that drugs resemble. LSD produces hallucinations via serotonin receptors; marijuana magnifies sensory perception, distorts time, reduces coordination, and interferes with working memory through cannabinoid receptors. Cocaine indirectly activates dopamine receptors to produce powerful stimulant and euphoriant sensations. Heroin induces a measure of tranquility combined with euphoria by activating opioid receptors. All drugs have highly distinctive sensory effects on the body that contribute to their emotional value. With repeated use, the brain and body adapt, which is manifested dramatically during withdrawal. Yet as complex, unique, and diverse as these acute and adaptive responses may be, addictive drugs also activate convergent neuronal circuits, circuits that signal changes in homeostasis.

The Brain Reward System

Although drugs elicit a wide spectrum of sensations, through multiple circuits in the brain, they all propagate one common biological response: the release of dopamine in the nucleus accumbens. Dopamine is not a hedonic signal, but a signal for learning and motivated behavior. Dopamine is also released in anticipation of, or during, natural rewards (e.g., food) and even in response to aversive stimuli, serving as the brain's "adrenaline," to alert the body of novel, meaningful rewarding or aversive stimuli and of pending appearances of a stimulus associated with a hedonic reward. Signals that alert the brain of natural rewards differ from drug-induced rewards. Drugs release dopamine at concentrations and for periods of time grossly exceeding dopamine release and clearance times triggered by natural rewards. This focal, unregulated dopamine signal fans out to brain circuits, alerting other regions of a novel, motivating, positive experience,

recruiting other transmitter systems, primarily glutamate, along the way. Glutamate, one of the transmitters implicated in mediating short- and long-term memory, most likely encodes the specific details of the drug experience and stores these details (53). These complex signals carry the message to specialized circuits and brain regions (54) that interpret and consolidate memories of the liking and cued associations of the experience (hippocampus, amygdala), that learn to repeat the behaviors involved in acquiring these rewards (dorsal striatum, nucleus accumbens), that assign a priority or relative value for response to these awards (orbital prefrontal cortex), and that imprint cognitive control over rewarding behaviors (prefrontal cortex, striatum, thalamus). Although natural rewards and drugs share some common alerting circuits and memory processes, the natural rewards benefit the individual by rousing conscious and unconscious behaviors for survival and reproduction. In contrast, the extraordinary hedonic signals propagated by drugs overpower signals of natural rewards, suppress the salience (value) of essential rewards, and eventually supplant the drive for essential, natural, rewarding behavior, and draws the person into a deleterious state. Drug craving and drug seeking evolves into a compulsion that can persist for months or years after the last dose of a drug (55).

With repeated abnormal signaling, other transmitters are recruited. Adaptive processes at the molecular level trigger biological sequences to change the structure of nerve cells and reconfigure neural circuitry. This may result in a biochemical and functional disease of the brain. Understanding these processes is of fundamental relevance for identifying objective biological criteria for the disease of addiction and the state of recovery, for defining reversibility or irreversibility of adaptive states, for identifying genetic susceptibility, and developing leads for psychological or pharmacological treatment of addiction. Equally fascinating and ultimately practical is the development of a comprehensive view of how the brain assigns value for competing rewards and rewarding behaviors, how it learns and stores reward-related experiences to motivate behavior, how environmental stressors and the developing brain heighten susceptibility for addiction, and whether the transition or "switch" to addictive behavior is discernable at a biological level. We remain at a rudimentary stage in resolving these questions.

Transition to the Disease of Addiction

DSM-IV criteria separate abuse (adverse consequences) from addiction (adverse consequences coupled with loss of control, compulsive use, neuroadaptation), but objective data increasingly do not sustain a clear division between abuse and addiction. On a population basis, the transition from use to addiction is time, age of onset, and drug specific. Approximately 23% of heroin users meet the criteria for lifetime dependence. Corresponding values for cocaine (16.7%), other stimulants (11%), marijuana (9%), hallucinogens (4.9%), and inhalants (3.7%) are lower, with alcohol and tobacco dependence (15% and 32%) possibly reflecting their legal, acceptable social status, and availability (38). A subpopulation progresses

rapidly to addiction; 4% to 6% of recent onset users of cocaine or other stimulants (methamphetamine, amphetamines, methylphenidate) become addicted within 24 months, a lower level with marijuana. In general, marijuana and alcohol display a slower, more insidious onset of addiction (38,52,56–58). Is there biological evidence of a brain switch, one that propels a user from controllable use to compulsive, involuntary drug-seeking and -using behavior? (59).

With repeated and frequent use, the brain adapts to and compensates for abnormal reward signals by altering production of gene copies and proteins, leading to profound changes in every dimension of brain biology and function. Some adaptive changes, of unpredictable reversibility, can be visualized in human brain, and are manifest as suppressed glucose metabolism, dopamine release, and altered blood supply. Activation or suppression of unique brain regions, particularly those involved in judgment and impulse control, follow exposure to drugs or drug cues and during abstinence. The insula, a brain region ignored for years, has recently been designated the “hidden island of addiction,” as it may play a crucial role in the conscious urge to take drugs (60). Uniquely, this brain region alone is activated in human subjects during urges to use a large array of drugs (cocaine, heroin, alcohol, and cigarettes). Intriguingly, addicted smokers with lesioned or destroyed insula (but not populations with other damaged brain regions) readily quit smoking without relapse, and lose the urge to smoke (61). This brain region is viewed as a key location for integrating stimuli arising from the body, arousing conscious awareness of these feelings, attributing a value to them, and integrating a response to them. Accordingly, signals from the insula may override the prefrontal cortex, subverting its function as a reasoning center for impulse control. Conversely, the impaired insula may permit the prefrontal cortex to reassume impulse control, executive function, and judgment. Conceivably, medications that interrupt insula function may dampen the conscious urge to seek and consume drugs during the abstinence phase.

In experimental animals, repeated administration of a drug leads to an excess of, and diminished expression of many genes in various brain regions, in conjunction with abnormal production of proteins. The findings provide powerful clues for clarifying how the brain adapts to drug-induced activity and sensations, as well as leads for designing drug therapies to treat addiction. In brains of animals exposed to repeated cocaine, a restructuring of neural circuitry is visible, and correlates with altered behavior and motor function (33). Brain signaling systems, gene function and expression (62), protein production (49), cell structure (32) change. But do these changes constitute a molecular switch, a biochemical process that switches behavior from controllable to uncontrollable use? (63) Theoretically, this switch would have to persist for months or years after the drug is withdrawn, to sustain and reinstate drug-seeking behavior on a whim, a cue, stress, or re-exposure to the drug. The transcription factor deltaFosB is one candidate for this molecular switch. Transcription factors turn on or off genes that encode proteins, the critical drivers of brain function. Intriguingly, deltaFosB accumulates

within the nucleus accumbens and dorsal striatum (brain regions highlighted above as relevant to addiction), not immediately, but after repeated administration of many kinds of drugs of abuse. Once induced, it is stable and remains in these brain regions for long periods of time, possibly triggering the expression of a panoply of genes/proteins implicated in addiction, long after the drug has cleared the body. Accordingly, Nestler et al. (59) have designated deltaFosB as a sustained “molecular switch” that functions as a transducer to convert sustained drug exposure into complex adaptive responses. It is premature to conclude that deltaFosB is the critical or only molecular switch responsible for changes in brain and behavior that characterize addiction.

The Toxic Effects of Specific Drugs

Certain drugs are frankly toxic to the brain and cause cell damage or death, either directly or by interrupting blood supply. Cocaine promotes vasospasm and loss of normal blood flow in human brain (30). Frequent exposure to amphetamine, methamphetamine, and ecstasy produce cell-specific toxicity and damage. Heavy alcohol or inhalant use (e.g., toluene) can produce profound irreversible toxic effects that are manifest as shrinkage of brain grey matter and enlargement of the fluid-filled spaces of the brain’s drainage system.

Withdrawal

Upon withdrawal from the drug, the adapted brain is no longer at the original set point as in the predrug state, requiring the drug for “normal function.” During drug withdrawal, anxiety, irritability, dysphoria, stress, and other psychological or physical (tremors, flu-like symptoms) discomforts emerge. Abrupt withdrawal from drugs such as alcohol and heroin unmask the adapted brain and produce wrenching physical symptoms. Withdrawal from marijuana, nicotine, cocaine, amphetamine generate a spectrum of symptoms, including anxiety, irritability, dysphoria, insomnia or hypersomnia, aches, craving, and other drug-specific effects.

Craving and Relapse

With prolonged abstinence, the addicted brain can generate intense craving and suppress efforts to control compulsive drug seeking. Craving leads to relapse, and the addict can rotate through compulsive use, withdrawal, and relapse several times, unless the cycle is finally broken. Yet craving can persist for months or decades, causing vulnerable people to relapse and revert to addictive behavior, especially if they encounter stress, drug cues, or are primed by a single dose of the addicting drug or another drug.

Policy Lessons from Modern Brain Biology

The science of drug use and addiction can inform and shape drug policies, in the realm of demand reduction and supply reduction. Without agreed upon biological markers for addiction in humans, the science remains at a rudimentary state. Nevertheless, research has yielded a number of fundamental principles with core relevance to drug policy. (a) The

rewarding effects of drugs of abuse are universally sensed by mammalian brain (even the fruit fly!) and not only by small subpopulations of humans. Control of drugs is a necessary public health measure, to prevent an array of adverse consequences with the potential to derail individual lives, from in utero to old age. (b) Drugs produce a cluster of biochemical, cellular, physiological, behavioral, and psychological effects that can propel individuals into the detrimental state of addiction. A disease model of the brain is justified, on the basis of these findings and so is the shift to a public health domain. A disease model should also motivate medical professionals to contribute to diagnosis and treatment of substance use disorders. (c) Adolescents and persons with psychiatric disorders are at high risk for use and addiction, and warrant specific prevention and intervention policies and programs. (d) All drugs of abuse produce psychological or physiological withdrawal signs, indicative of altered, adapted brain and body biochemistry. The availability of medications to provide assistance to suppress or reverse adaptive responses that trigger drug craving should be an integral component of research and treatment.

Prevention

Federal funding for national drug control policies expended on prevention in the United States falls into several categories. State Prevention block grants provide states with discretionary funds for prevention, while other grant programs are designed to create community coalitions to formulate local solutions to local drug problems. The Department of Education issues grants for safe and drug-free schools, and the national Media Anti-drug Campaign is targeted primarily to youth. Adolescence is a critical risk factor for progression to addiction to all drugs and prevention in this population is of paramount importance. Evidence-based prevention programs targeted to parents, a critical factor in youth drug use, and to youth are likely to be among the most effective and cost-effective use of public funds. As indicated above, each year delay in onset of drug use can reduce addiction potential by a significant percent, notwithstanding a host of other adverse consequences that can accumulate in the drug-using adolescent population. This is not to suggest that 18 to 25 year olds, the highest consumers of all drugs, are immune to the adverse consequences of drug use or to addiction. On the contrary, it is necessary to address this population of users within their unique environments, including colleges, workplace and specific jobs at higher risk for use, as well as the unemployed and the homeless.

Intervention

The goals of prevention are to stop the initiation to drug use, while the goals of intervention are to prevent progression to addiction or to reverse the behavioral patterns associated with risky, problematic use. Interventions to prevent progression to addiction, improve health and parenting, reduce medical costs, reduce transmission of infectious diseases such as AIDS, and to reduce crime, will benefit the health and welfare of individuals (27). It is estimated that over 46 million people

engage in risky, problematic drug use. Paradoxically, the health care system does not address this issue aggressively, which leads to burgeoning health problems (e.g., trauma, injuries, infections, depression) and escalating health care costs.

Substantial evidence indicates that brief behavioral interventions are effective when used by clinicians who are not specialists in substance abuse treatment, especially when enhancing entry to more intensive substance abuse treatment. Equally relevant, a significant proportion of drug users (as many as 50%) have underlying psychiatric problems that should be diagnosed and treated concurrently with drug treatment. For adolescents, brief interventions that include feedback on risks, an emphasis on personal responsibility, and alternatives for change have proven effectiveness. Calls for universal screening (verbal, written, electronic) for a full spectrum of drug use and providing brief interventions or referrals to specialty treatment constitutes an exquisite convergence of prevention, intervention, and treatment policies (27).

Why screen universally for risky use in health care settings? (a) Early detection among youth is crucial, especially as early onset of use is among the highest risk factors for progression to addiction. (b) Screening of pregnant women can identify at-risk fetuses: exposure to heavy alcohol, drugs in utero can cause harmful developmental, behavioral, and physical effects. (c) It is routine for physicians to inquire about all patients' medications (drugs), to prevent drug interactions and compromised effectiveness of prescribed medications, yet physicians do not routinely inquire about all nonmedical substance use. (d) Prescription drug misuse and abuse is a growing problem. (e) Prescription drug abuse is considerably more common in alcohol and illicit drug abusers, justifying universal screening for all drugs. (f) Overdose deaths due to prescription drug misuse are higher than at any time period in recent history, and far exceed deaths due to heroin or cocaine. (g) Drug intoxication is associated with higher Emergency Room and Trauma Center use. (h) Injuries are more common and clinical outcomes are worse in the alcohol and drug-abusing population. (i) Substance use disorders increase health care costs (e.g., HIV-AIDS, injuries, and trauma).

Treatment

A fundamental premise of neuroscience is the view of addiction as a brain disease (64). The biological evidence that drugs forge a diseased state of the brain is based primarily on drug-induced brain remodeling, visualized in living human brain by imaging, and in preclinical research by a variety of techniques. Dictionaries define disease as: "an alteration in the state of the body or of some of its organs, interrupting or disturbing the performance of the vital functions, and causing or threatening pain and weakness and characterized by an identifiable group of signs or symptoms"; "a pathological condition of a part, organ, or system of an organism resulting from various causes, such as infection, genetic defect, or environmental stress." Drug addiction can be viewed as a chronic, relapsing disease, characterized

by compulsive, uncontrollable use despite adverse consequences. The neurobiology, however, should not supplant the role of personal responsibility in propagating this behavior. Within the construct of a disease model, patients are urged to assume responsibility for compliance with treatment, comparable to patients with asthma, hypertension, and diabetes.

Notwithstanding the progress in the biology of addiction, the DSM-IV criteria for addiction—compulsive, uncontrollable use despite adverse consequences—appear retrogressive, based as they are on loss of voluntary control (65). The medical diagnostic criteria not only eschew the mountain of biological evidence but minimize older definitions that highlight symptoms of biological adaptation, namely drug tolerance and withdrawal. Based primarily on alcohol and heroin, early biological hallmarks of addiction were thought to be reflected by diminished pharmacological effects of a fixed drug dose (tolerance) and frank physical signs of withdrawal during initial abstinence. In DSM-IV, these traditional criteria were retained but diluted by the preponderance of other criteria emphasizing loss of behavioral control and adverse consequences. The diminishing value of these specific physical signs is justified, as they are not uniformly relevant to all addictive drugs. For example, withdrawal from cocaine and nicotine is not manifest by physical signs (e.g., vomiting, pain, diarrhea, tremors, piloerection, hand tremor, fever, or convulsions). Patients treated with high doses of opioids for acute pain, can, upon drug cessation, display profuse sweating, nausea and vomiting, similar to moderate withdrawal from heroin without manifesting the signs of the disease of addiction. Prescription drugs with low abuse potential also can engender tolerance and withdrawal symptoms. Taken together, neuroadaptation that is manifest as withdrawal or tolerance is not a hallmark of addiction but one of many components that drive behavioral change for addictive drugs. Unfortunately, as there is no consensus on valid biological markers for the disease of addiction, behavioral terminology prevails. Nevertheless, positioning addiction in the category of a biological disease offers a framework to accelerate treatment research, reduce stigmatization by professionals, focus on problem solving, increase treatment availability for the populations in general and those involved in the criminal justice system, and medicalize this public health challenge. According to the latest National Survey on Drug Use and Health, over 20 million people in the United States harbor a medical diagnosis of abuse/addiction yet do not seek treatment and remain unidentified (28).

Treatment effectiveness can be measured by a range of outcome measures including reduced drug use, improved physical and mental health, employment, family relationships, reduced mortality, crime, and diminished medical, legal, social services, employment, and educational costs to society. By all these measures, numerous studies have demonstrated positive outcomes of treatment (34,66). A variety of treatment approaches is necessary to accommodate the needs of substance abusers, who present with varying social skills, economic status, underlying psychiatric disorders, criminal

activity, age, and family support systems. The majority of residents of the United States who had an alcohol or illicit drug problem in 2002 did not receive treatment. Nearly all who needed treatment (dependent on or abuse of drugs or alcohol) but did not receive it, reported they did not feel a need for treatment. This may partially reflect a conscious or biologically based loss of judgment that gradually prevents drug users from understanding their predicament and supports the need for external intervention. Outpatient drug-free, outpatient methadone, long-term residential, and short-term inpatient programs reduce drug use. The cost-effectiveness for treating compared with the cost of not treating is variable. Some reports indicate a cost savings equivalent to a 1:3 ratio, whereas others report much higher ratios. Medications development offers a powerful rationale for clarifying the mechanisms underlying drug rewards and the progression to addiction.

Yet there is a dearth of effective medications to reduce drug cravings, prevent relapse, and facilitate recovery, one of several reasons why health care professionals do not universally screen for addiction. Although not universally effective or enduring, over 25 different medication formulations are available for smoking cessation and more than 3 for alcoholism. In contrast, approved medications to treat addictions to illicit drugs are available to less than 30% of the estimated 6.8 million people addicted to any illicit drug. Only those addicted to heroin or prescription opioids can avail themselves of approved medications (methadone, buprenorphine, naltrexone, and naloxone) to assist in recovery. Treatment of prescription opioid abuse/addiction (25% of total) with medications traditionally used for heroin addiction, is still in the experimental phase. Yet the heroin-addicted population is but a fraction, 3%, of the population estimated to harbor DSM-IV signs of abuse/addiction to illicit drugs. The remaining populations (marijuana: 57%; cocaine: 24%; other stimulants: 6%) do not have the benefit of medications-assisted recovery (28). The dearth of medications alone justifies the quest to understand the underlying biological processes of addiction and relapse and identify novel leads for medications development.

INTERNATIONAL PERSPECTIVE

On June 24, 2009 in Washington DC the Executive Director of drug abuse prevention efforts for the United Nations, Antonio Maria Costa, released The World Drug Report in collaboration with R. Gil Kerlikowske, the newly appointed Director of the White House ONDCP (67). The report concluded that global markets for cocaine, opiates, and cannabis were in “steady decline, while production and use of synthetic drugs is feared to be increasing in the developing world.” Further, the report “offers several recommendations on how to improve drug control. These include universal access to drug treatment, international agreements against organized crime and greater efficacy in law enforcement.”

A decade earlier, the United National General Assembly Special Session (UNGASS) had called on governments to

reduce drug production and consumption greatly within 10 years. The World Drug Report, representing an independent and scholarly study of that decade-long effort concluded that “the demand for drugs in the world has stabilized mainly as a result of the interaction of epidemic forces, culture and economic development.” This study found that the supply of drugs “has become more concentrated and the menu of drugs has changed surprisingly slowly.” Further, the study reported that “The most prominent innovations under discussion have limited potential effects (heroin maintenance), have been unproductive policy interventions (“addiction is a brain disease”) or have no political appeal (legalization).” On a more optimistic note this report concluded that “The option with the most scope is increased effort at diverting arrested drug users out of the criminal justice systems.”

In commenting on the report, ONDCP Director Kerlikowske summarized his approach to the drug problem. He stated, “In the United States, we are moving away from divisive drug war rhetoric and focusing on employing all the tools at our disposal to get help to those who need it. We recognize that addiction is a disease and are seeking public health solutions. My top priority is to intensify efforts to reduce the demand for drugs which fuels crime and violence around the world.”

While there are widely varied rates of drug use in the world, there are no populations without drug problems. Most, if not all, countries have seen significant increases in drug use in recent decades, despite the most recent stabilization of drug use rates in some countries. Those populations most exposed to modern values which emphasize individual freedom and pursuit of pleasure and which have correspondingly lower levels of traditional or religious control over behavior have higher rates of drug use. Since these values are characteristic of much of the modern world, it is easy to see why the vulnerability to drug abuse has increased worldwide since the 1960s.

The drug problem was recognized as global in the early years of the 20th century when the first international efforts were made to curtail drug supply. The modern drug epidemic beginning in the 1960s has become truly global and is a major threat not only in developed nations but also in developing nations.

The United States was early in experiencing a serious drug problem for many reasons including the fact that the country is made up of people from all parts of the globe who brought with them to their new homes their drug-using behaviors related to religion and ritual, but not their cultural intolerance of these behaviors for pleasure and in excess. The United States has been characterized by diversity of values and behaviors and by a tolerance for this diversity that has been unique in the world. This vulnerability led to serious alcohol abuse problems that peaked in the first two decades of the 19th century. There was a strong grassroots reaction in the United States to this problem, made more cohesive and effective by newly emerging indigenous religious movements that were strongly opposed to alcohol use. The temperance movement was a powerful influence against alcohol as well. By the

close of the 19th century other drugs of abuse emerged in the United States, including cocaine and heroin, resulting in a correspondingly strong antidrug movement focused on law enforcement, and new legislation passed by the United States Congress, as described in the first section of this chapter. In both the 19th and 20th centuries the American drug experience led to significant worldwide efforts to reduce alcohol and drug problems.

These efforts culminated in a series of international treaties that codified the commitment to curbing illegal drug use worldwide. Through leadership by the United Nations, the Single Convention on Narcotic Drugs in 1961 focused on the agriculturally produced drugs specifically cocaine and opiates (especially the semisynthetic heroin). In 1971, the Convention on Psychotropic Drugs focused on the completely synthetic newer drugs of abuse including the synthetic opiates, the stimulants, the depressants, and others. These meetings resulted in treaties that were widely ratified and managed effectively by the United Nations. The United Nations system of drug control includes the Office of Drugs and Crime (UNODC) established in 1997, the International Narcotics Control Board (INCB) established in 1968, and the Commission on Narcotic Drugs (CND) established in 1946. In the United States, the drug laws were updated in the Controlled Substance Act of the 1970s as amended over time (68).

Among the dramatic differences in drug use rates globally, those in Europe are noteworthy because of the wide differences between similar countries and the generally high quality of data available about drug use in these countries. Some countries can be characterized as having low drug use while others have higher drug use. The former countries generally have more restrictive drug policies (see the first part of this chapter) and the latter more tolerant, permissive drug policies. According to a recent UN report, for example, the percentage of students in the low use European countries that reported use of marijuana or hashish in the prior 30 days was: Sweden 1%, Turkey 2%, Greece 2%, and Iceland 4%, while the percentage of students reporting prior 30-day use in the more tolerant countries was: Spain 23%, France 22%, United Kingdom 20%, and the Netherlands 13% (69). More striking still is the contrast in student drug use in Malmo, Sweden, and Copenhagen, Denmark, twin cities across a bridge in the Baltic Sea. The rates of ever use in Copenhagen are three times higher than those in Malmo, and the rates of use in the last 30 days are five times higher in Copenhagen than in Malmo.

While the future of drug policy is increasingly being debated in Europe and elsewhere in the world, the experience in Sweden offers an especially instructive lesson.

THE SWEDISH DRUG POLICY EXPERIENCE

In the early 1960s, Sweden was among the first countries in Western Europe to experience a large-scale drug problem among young people. The origins of the Swedish drug epidemic date back to the late 1940s when abuse was limited to

tiny bohemian circles in Stockholm and only later spread to individuals with criminal lifestyles. Gradually, a wider segment of young people was introduced to nonmedical drug use at which time the media began reporting the Swedish drug epidemic.

Central nervous system stimulants of the amphetamine-type then dominated the illegal drug market in Sweden. Because these drugs were seen as nonaddicting and had widespread clinical use at the time, it is not hard to understand why many Swedish physicians were attracted to the idea of prescribing drugs in order to keep individuals from obtaining them through illegal sources. This idea was quickly adopted by some health and law enforcement authorities. Between 1965 and 1967 nonmedical drug users in Stockholm could obtain their favorite drugs including not only stimulants, but also opiates, with a prescription from a handful of doctors who took part in a special program sanctioned by the National Board of Health. Initially, around 110 drug-addicted patients were enrolled in the program for whom more than 4 million doses were prescribed. Out of those, about 3.4 million doses were stimulants; most of the rest were opiates. Unsurprisingly, a large percentage of these legally prescribed drugs were resold or given away, flooding the city with drugs and spreading the drug epidemic in Sweden rather than limiting it as the program's sponsors naively expected. This legal prescription experiment came to an abrupt end in June of 1967 2 years after it started, following the tragic and widely publicized death of a 17-year-old girl who had been offered drugs by one of the patients in the prescription program.

As a psychiatrist working with the Stockholm police, Nils Bejerot was one of the few physicians in Sweden at this time with firsthand experience of drug addiction. Bejerot's work with criminals since the 1950s in Stockholm gave him a unique perspective with regard to the National Board of Health's drug policy experiment. He tried in vain to stop this legal prescription experiment by offering his expertise and experience to the authorities. Out of frustration and in the hope that this initial experiment would never be restarted, in 1965 he initiated a study of drug injection marks among arrestees at the Remand Prison in Stockholm. He later linked the changes in the frequency of injection marks to the changes in the Swedish drug policy (70). In 1969 he founded the National Association for a Drug-free Society (abbreviated RNS in Swedish) in order to promote the idea of restrictive drug policy by educating both the public and his medical colleagues.

In 1968 Bejerot published his first book—later to become a series of books—about the drug problem under the title, *The Drug Issue and Society* (71). He presented his analysis of the drug problem as a response to the diametrically opposed, and widely influential, analysis of drug policy that had been presented a few years earlier by the American sociologist Alfred Lindesmith in his book, *The Addict and The Law* (72).

One of Bejerot's major contributions to the understanding of the drug problem was his classification of dif-

ferent types of drug abuse, presented in his 1968 book. At that time most classifications were focused on the various drugs or types of drugs that people used nonmedically. Bejerot took a different approach to classification in which he categorized the various patterns of abuse based on how the drug was introduced to individual drug users. In his early models he described six different patterns of drug abuse. Over the next two decades he refined his model, settling on three main types: therapeutic, cultural or endemic, and epidemic types.

The therapeutic type of illicit drug use occurs when a patient in medical care becomes addicted to drugs, knowingly or unknowingly, when using the drugs prescribed by a physician. Medical staff who become addicted because drugs are available to them at work are also included in this group. Addicts of this type differ from other types because women dominate the group. They are relatively old when first introduced to drugs and use them initially for medical purposes. Bejerot found that these addicts tended to be secretive about their addiction and very seldom introduced others to drug abuse.

The cultural type of drug use occurs when the drug use/abuse is culturally accepted in society, for example, alcohol use/alcoholism in the Western world. This pattern of drug use is more or less part of becoming an adult in most parts of the world. It can even be considered antisocial behavior not to use alcohol in certain settings. Cigarette smoking is similar in that it is culturally and legally accepted in many societies not only to use but even to be addicted to nicotine. Other endemic drugs are the chewing of coca leaves among native Bolivians and khat leaves in Somalia and Yemen.

The epidemic type of drug addict was described by Bejerot as a type of substance use which is not socially accepted generally in the society at large and is often illegal. Novices are introduced through intimate contact with someone, usually a close friend, who recently has been introduced to nonmedical, prohibited drug use. These relatively new drug users have enough experience to pass on to initiate other new drug users, while they do not yet exhibit the negative consequences of the drug use that might protect a nonuser from trying the drug. Bejerot had observed that early in the epidemic, especially vulnerable individuals were overrepresented among drug users of this type. However, as the drug epidemic grew in Sweden, people with little or no social or psychological problems became active drug abusers.

Based on his analysis Bejerot wrote many articles and books (71,73–76) and acted through RNS to promote a drug policy that focused for two reasons on small-scale drug crimes and early intervention to reduce the epidemic type of drug use:

1. The spread of drug abuse from person to person usually occurs early after onset of the illicit drug use. Bejerot described this period as the honeymoon of drug abuse, when almost everything is positive about the drug use, encouraging the

newcomer to introduce his friends as a generous gesture of friendship. Bejerot concluded that if society wants to stop drug abuse from spreading it must intervene early to interrupt this malignant and rapid spread of nonmedical drug use.

2. Once addiction is established the prognosis for the individual to become drug free is substantially worsened. Drug addiction, once entrenched in an individual and in society, is difficult to stop. The willingness of drug addicts to go into treatment usually occurs only after many years of abuse and after an accumulation of many painful experiences and losses. For this reason, for a policy to be effective in reducing the prevalence levels of drug use in a society, Bejerot concluded that the society must prevent young people from starting to use drugs altogether.

While evidence-based and persistently expressed, Professor Bejerot's views on drug policy initially were not universally accepted in Sweden. There was a strong counter argument based on the belief that medicalizing nonmedical drug use would reduce not only drug use but also the many serious and even fatal problems that drug use created. This view was attractive to many Swedish health officials because it appeared to be more compassionate and humane. During the 1970s the debate about drug policy in Sweden picked up momentum gradually. Official drug prevention policy at that time directed the police to concentrate on trafficking and smuggling and not arrest the drug users for drug possession and street peddling on the presumption that this would make it more attractive for them to voluntarily seek treatment and other help from social services providers or hospitals. During those years in Sweden it was legally safe for drug users to possess up to 20 g of hashish for personal use. Naturally the street pushers never had more than this legal limit. This legal practice was criticized by Bejerot and RNS for several years. Public debates, demonstrations, and media debates were organized and finally achieved results. The Swedish Prosecutor General issued a directive to all prosecutors in January 1980 that waivers of prosecution for small amounts of narcotic drugs would not be allowed any longer. Overnight, this announcement changed Swedish drug policy as a practical matter. It was the tipping point, when Swedish drug policy swung from being a permissive to a restrictive drug policy. The restrictive policy has continued to the present time.

Based on this newly articulated drug policy, the Swedish police changed its priorities to focus on small crimes of possession, making small-scale trafficking of drugs a much riskier business. Unsurprisingly, the number of drug crimes rose initially while at the same time drug use surveys showed a consistent decline all through the 1980s. In those years, the economy in Sweden was good. The city councils were generally willing to fund drug treatment and antidrug prevention activities in schools. The general debate in society about drug policy receded as all parties adopted the restrictive policy, which was an important inspiration to everyone working professionally with the drug problem.

In 1983, the Supreme Court of Sweden ruled that the Narcotic Drugs Act did not cover the act of consuming illegal drugs. Simply speaking, it was forbidden to have any drug of abuse in your pocket or in your possession in any other way, but to smoke, eat, inhale, or inject drugs was not illegal. The following year RNS began campaigning to make the consumption of illegal drugs itself a crime. An opinion poll in 1984 showed that 95% of the public were in favor of this change in the law. The debate went on for several years, engaging all of Sweden's political parties in the Parliament. In 1988, the Swedish law was changed so that consumption of narcotic drugs was made illegal. Initially the law did not allow the police to take a urine or blood test as evidence of use. The law was rewritten in 1993 so that the police could use drug tests for evidence of drug consumption.

During 2008 approximately 35,000 drug tests were taken by Swedish police based on suspicion of illegal consumption. Over 10,000 tests were taken on suspicion of drugged driving. The punishment for illegal consumption is a monetary fine related to the offender's income. Drugged driving can lead to imprisonment, depending on the circumstances.

If the 1980s were the Golden Age of drug prevention in Sweden, then the 1990s were the Dark Age. Sweden was hit by a severe economic crisis in the early part of the decade, a crisis that took the rest of the decade to sort out. Virtually all segments of Swedish society experienced an economic decline, or ground to a halt. Since the drug problem, especially among the young, was at such a low level at the beginning of the 1990s, drug policy did not receive much attention from those with political power. As a consequence, antidrug efforts declined in the 1990s, and drug treatment became much harder to obtain. For these same economic reasons, schools did not focus on the drug problem in the 1990s. It is not surprising that drug abuse levels in Sweden went up during this decade, although they never again reached the levels seen in the late 1960s and early 1970s. However by the end of the 1990s, drug abuse was again serious enough for the government to take action to rectify this trend.

In 1998, the Government appointed a Narcotics Commission which put forth many suggestions for action and change. With the general debate about the drug problem heating up, funding for various types of projects was made available by the government. During the first years of the new century the rise in illegal drug use rates among the young flattened out and gradually declined (Figure 77.3).

There are many in Sweden who believe there are further challenges in the nation's efforts to curtail illegal drug use. However, with unusually low rates of drug use, Sweden compares very favorably to other developed nations. Since 1971 the Swedish Council for Information in Alcohol and other Drugs (CAN) has administered drug use surveys among teenagers during the year they have their 16th birthday. The model used in these surveys was adopted from a European survey conducted in 1995 in 26 countries, the European School Survey Project on Alcohol and other Drugs (ESPAD). The latest ESPAD survey was presented in February 2009 and shows data from 2007.

Figure 77.3. Lifetime use of any illicit drug and use of any illicit drug during last 30 days (data not available, 1983–1985), by gender, 1971–2008. (Data from Hvitfeldt T, Nystrom S. *Skolelevers Droghanor 2008*. Stockholm, Sweden: Swedish Council for Information on Alcohol and other Drugs; 2009.)

Figure 77.4 shows a comparison among self-reported lifetime marijuana and hashish use by 16-year-olds from 35 European countries. The reported drug use of boys can be found in the left-side graphs, while the reported drug use of girls appears in graphs on the right. The average of the reported use of the boys and girls combined can be found as a number to the right of the country name. The differences in self-reported use of cannabis are very large between the European countries with the lowest and the highest prevalence levels. Several comparisons of other countries with Sweden are of interest. There is a striking difference between Sweden and the United Kingdom even though the modern drug epidemic started at about the same time in both countries and even though both are liberal welfare states with high levels of economic development. In another comparison, it is interesting to note the reported drug use between teenagers in Sweden and in the Netherlands. During the 1970s Sweden, after a heated internal debate, began enforcing stricter drug laws. The Netherlands in 1976 decided to go the opposite way by passing the Opium Act, making a distinction between the permissive enforcement of *soft* drug use and a more restrictive enforcement of *hard* drugs. It is helpful to consider the impact of significant change in a country's political structure and the resulting impact on drug policy when viewing these data. For example, a number of these countries endured harsh and repressive experiences of dictatorship. It can be inferred that some of these countries, such as the Czech Republic, Slovak Republic, Spain, and Estonia, having become democratic, include the freedom to use illegal drugs in their

concept of freedom. However, this is not a uniform experience, as other countries, such as Greece, have had a similar historical experience yet the country maintains a restrictive drug policy and experiences low levels of drug use among its teenagers. Portugal, which became a democracy in 1974, has adopted a less stringent policy, with resulting reported teenage use approximately midway between the data reported by teens in Spain and Greece. From this ESPAD scale, it is possible to infer the presence of quite permissive drug policy associated with the increased prevalence levels of illegal drugs.

The authors of the ESPAD survey concluded in their summary that in the 2007 data there are apparent associations between the aggregate use of different substances at the country level. In countries where teenagers drink more, they also tend to use illegal drugs more. A nation's drug policy reflects a cultural set of values, beliefs, and behaviors, and its associated laws result in normative actions on the part of its citizens. People, especially young people, adapt quickly to laws that impact on behavior related to the use of illegal drugs.

One of the common stereotypes in global drug policy debates is that successful welfare states adopt permissive drug policies as part of their commitment to compassion and tolerance of diversity. Sweden, a country noted for its liberal views, stands out as an exception to this stereotype and offers a model for a more restrictive drug policy, not because it is repressive politically but because it promotes the public health and lowers both drug use and the harms caused by drug use (77,78).

Figure 77.4. Lifetime use of marijuana or hashish by gender, 2007. (1) Belgium and Germany: Limited geographical coverage. (2) Denmark, Spain, and the United States: Limited comparability. (Data from Hibell B, Guttormsson U, Ahlstrom A, et al. *The 2007 ESPAD Report: Substance Abuse Among Students in 35 European Countries*. Stockholm, Sweden: Swedish Council for Information on Alcohol and other Drugs; 2009.)

THE CENTRAL DRUG POLICY ISSUES TODAY

During recent years, a short, and still evolving list of highly charged drug policy issues has been prominent in the mass media. One group of these issues has included medical marijuana, needle exchange programs, injection rooms (where addicts can inject government-provided heroin, cocaine, and other drugs), and hemp cultivation. Another group springing from a different view of drug policy has included random student drug testing and more vigorous drugged driving enforcement. Until the past few years the media chatter pitted arguments about the merits of harm reduction versus

abstinence. More recently new support has emerged for the legalization of marijuana or even of all currently illegal drugs—a proposal rarely articulated in public debate even a few years ago. The argument for legalization rests on the belief that most of the costs of illegal drug use are not from the drug use itself but from the efforts to prohibit illegal drug use such as arrests and imprisonment for both the use and sale of illegal drugs. The supporters of legalization advocate making these currently illegal substances available just as tobacco and alcohol are available, regulated, and taxed in a similar manner. Considerations of the health cost of such a measure is absent from this proposal.

Entirely separate from these often heated media debates are a wide range of practical drug policy questions ranging from the coverage of substance use disorders by private and public health insurance—focused on efforts to achieve *parity* for substance abuse with other disorders—to issues of the proper goals of drug treatment programs (pharmacotherapy maintenance vs. abstinence, for example).

Separate from both the sensationalized media and practical policy discussions are innovations that quietly contribute to the solution of important problems. One example can be found in the terrible epidemic of escalating use of prescribed controlled substances especially the opiates, but also the benzodiazepines and the stimulants. There are important, ongoing discussion regarding the policies needed to curb this massive problem and how those proposed efforts impact on the legitimate medical treatment of serious medical disorders including pain, anxiety, and attention deficit-hyperactivity disorder (ADHD)? This is a policy issue that has no political traction and rarely engages the traditional drug policy debate. One of the most promising strategies to reduce prescription drug abuse without inhibiting legitimate medical treatment of diseases is widespread use of abuse-resistant formulations, an innovation of biomanufacturing (78). Another example is a socio-legal innovation that links the criminal justice system to treatment in creative ways that reduce incarceration and improve treatment outcomes (80). These are examples of out-of-the-box innovations that can impact upon the future of drug policy. They are utterly absent from the static, politicized debates about drug policy that preoccupy the media and party politics.

Resuming the consideration of hot topics in today's drug policy debates, what are appropriate goals for drug abuse prevention efforts? By one side the primary goal is seen as reducing the use of the currently illegal drugs in the society. On the other side, this use is regarded as protected by privacy rights and the appropriate goal is reducing the harm produced by drug use, especially heavy use. Prevention efforts advocated by proponents of harm reduction include teaching young people how to use drugs more safely, clean needle giveaway programs for intravenous drug users to limit the spread of HIV-AIDS, with optional treatment opportunities offered as well, and the distribution of Narcan-containing syringes to intravenous opiate users for treatment for themselves and their friends for opiate overdose.

As stated earlier in this chapter, the complex issues of drug policy provoke strong opinions. Almost everyone is an expert on drug policy. Readers no doubt recognize these intense reactions and opinions in themselves and in others of their acquaintance. This all but universal response reflects the importance of the illegal drug problem in the modern world and in particular, the unsettled nature of the response to the problems associated since the dramatic rise in illegal drug use since the 1960s. If the solution were entirely clear there would be no debate. The drug policy will endure for some time to come. However, the questions over time will be shaped and reshaped by changes in values, experience, and lessons learned as policies evolve. The fact that the illegal

drug epidemic has become global insures that there will be a variety of responses from countries all over the world and that diverse experiences will provide useful data to inform and enrich drug policy considerations. This is a subject that invites active engagement with these highly visible policy disputes but at the same time requires respect for the adversarial process. While there are life-and-death issues at stake it is not reasonable to deny the legitimacy of the other side of these issues. Civility can result in greater productivity, understanding, and the possibility of resolution and even agreement on many drug policies.

Perhaps more important in the long run than the settling of these fundamental drug policy disputes is the fact that most drug policy issues never get to the mass media and are not captured by partisan politics. Instead they are worked out by individuals, by programs, and by communities. Here are a few examples of the drug policy issues that are flying below the media radar: What should a substance abuse treatment program do about continuing nonmedical drug use by patients? How often should patients be drug tested and what drugs should they be tested for? What should drug treatment programs do—if anything—about patients continuing to use alcohol and tobacco? With regard to *evidence-based* policies, what is the evidence showing the most effective and humane goals of substance abuse treatment? Even well-conducted studies (and most of the most important policy disputes produce little controlled research), are fraught with caveats and limitations. They are never definitive. The most common outcome of research is the need for more research. Experience and research is likely to be the foundation of future drug policies.

THE FUTURE OF UNITED STATES AND INTERNATIONAL DRUG POLICY

The future will rise from current drug policies. One of the principal goals of future drug policy is for the criminal justice system to work better with the treatment system so that together they can achieve results that neither alone can achieve. While the common way of expressing the fundamental drug policy debate is to ask whether one supports the criminal justice system (and prison) *or* drug treatment, the reality is that nearly half of those people in drug treatment today are there *because* of the criminal justice system. That fact alone leads to the conclusion that one of the challenges to drug policy lies in finding better, more cost-effective ways to link the criminal justice system and treatment.

With respect to the debate about pharmacotherapy versus abstinence-based treatment, it seems clear that most drug abusers, however ambivalently and inconstantly, seek to be drug free. The future rests with long-term outcome studies that show how various approaches to substance abuse and dependence contribute to long-term favorable outcomes which, for most patients, means abstinence from the use of abused drugs. To date most treatment evaluations are short term. The most common findings of treatment research are first, that a large percentage of substance abuse patients prematurely

terminate treatment and second, after-treatment relapses to drug use are common—often quickly after leaving treatment. Of course these findings on outcome studies are far from unique to substance abuse treatment. Noncompliance with treatment, especially behaviorally oriented treatment, is common across the spectrum of medical care. The use of coerced abstinence linked to prolonged treatment for substance abuse is a possible model for other behavior-related health problems (81–86).

Drug abuse prevention will also be a major area of development as new approaches to education and intervention, including random student drug testing and efforts to curb drugged driving, become more prominent. The future will almost certainly explore more actively the environment in which the choice to use or not to use drugs takes place including the role of coercive actions like random student drug testing and active and prolonged monitoring for alcohol and drug use after treatment (81–86).

Most striking will be the worldwide response to the problems of both drug supply and drug use. The drug problem is a human problem that knows no political, economic, demographic, or geographic boundaries. Because the drug problem is global, the solutions to the drug problem must also be global. Any country that fails to contain drug users and drug sellers is a threat to every other nation. No country is or will be without both drug users and drug sellers. Surely in the enduring words of Walt Kelly's beloved cartoon character, Pogo, when it comes to drug problems "We have met the enemy and they are us."

CONCLUSIONS

The experience of health care professionals with individual drug abusers will continue to be the foundation for the evolution of new drug policies. Across the political spectrum there is a rapidly growing conviction that the future of drug policy lies in linking the supply side activities with those on the demand side. Increasingly the global drug prevention policy focus has shifted toward greater emphasis on demand reduction. This shift reflects the knowledge coming from the experience of those who have worked with addicts over long periods of time, new information from brain science, and a growing body of public health research.

In their recent review of United States drug policy, Boyum and Reuter conclude by summarizing their recommendations, "We have offered a series of suggestions for reducing the damage that drug use and drug control inflict upon American society: fewer incarcerations, better and more treatment, elimination of criminal penalties for marijuana possession, and implementation of coerced abstinence for drug-involved offenders are the most prominent. For none of them can we offer strong empirical evidence of substantial effectiveness" (16). This summary strikes a fine balance in drug policy and links it to a thoroughly appropriate humility about the state of the research evidence about what works and what does not when it comes to drug policy in the United States and throughout the world.

Drug problems and the risk for their significant escalation are ubiquitous in the modern world. Drug policies are needed to mitigate that risk to the extent that they are compatible with modern values, and are affordable and effective. There is no silver bullet, no simple correct answer. No policy will end drug problems, although some policies clearly make them worse while others make them better. Rather than being a signal for resignation, this complexity and this ubiquity of risk are challenges to scientists, policy-makers, and those most dedicated to the public interest. There are few human problems more fascinating, complex, rewarding, and challenging than these.

Substance Abuse Policy and Payment

Anita Everett

Throughout US history, there has been significant public policy debate on substance use and abuse. Policies on alcohol and other substances of abuse have included a wide variety of federal, state, and local government agencies. This has included taxation, law enforcement, armed services, highway transportation, prisons, courts, parks and recreation, social services, education, labor safety, health care delivery, disease surveillance, and more recently behavioral health care. Initially public policies related to substance abuse were more centered on containment of supply and appropriate taxation. Priority in policy development has gradually shifted toward limiting the untoward impact of alcohol and other substance abuse on others including family members and coworkers. More recent policy debate has centered on access to treatment and rehabilitation. The growing literature in support of prevention as viable and effective has had recent increasing prominence in public policy. Funding for substance abuse services and drug control programs has come from a variety of sources including private health insurance, as well as federal, state and local government sources. By far, the single biggest payer for treatment and drug control is the US Federal Government.

This chapter is written in two major parts. The first section provides a basic familiarity with public policy development. The second section outlines several federal government entities, particularly the federal entities that have had and continue to have a role in policy development and implementation. The first section will incorporate an example of an actual event and will explore several potential outcomes in policy development and implementation of strategies in response to a substance abuse-related event. Core knowledge regarding a basic definition, formation, and implementation of public policy on substance abuse will also be provided. This section is intended to demonstrate the complex interplay between various groups that influence and develop public substance abuse policy.

The goal of the second section is to highlight the history and role of several prominent government entities that are involved in developing and implementing substance abuse policy. The section includes entities that are responsible for drug control as well as treatment and prevention. This section will emphasize the sometimes competing interests of drug control with prevention and treatment. Throughout both sections, information on relative budgets and changes in budget over time will be included. This is intended to provide a broad perspective as to the relative investment US

citizens have in substance abuse policy development and implementation.

POLICY DEVELOPMENT

Policy and policy development often moves in a nonlinear and in what may appear to be an illogical, reactionary, and disorderly fashion. This is a fundamental reality that it is critical for students of American Substance Abuse Policy to understand. Rational and science-based individuals who are more comfortable in a world where rational solutions are provided to solve problems of the greatest impact, are often frustrated by the process of the politics that invariably become involved with developing and implementing policy in a mature democracy such as the US government. A goal of this chapter is to provide an orientation to public policy development so that students and practitioners in the field of substance abuse are better equipped to work to influence good public policy development. Often in policy development, relative priorities have to be considered and appropriate resources are not applied to the most important problems. Understanding enough about how a process works is necessary in order to be able to effectively impact the process.

In this chapter, we will consider policy to be a collection of principles and ideas that are organized for the purpose of addressing a problem and with the intent that action will be taken to resolve the problem that is consistent with the policy. Steps in a public policy development process generally include a *problem definition*, consideration of *alternative solutions*, *policy development*, and *policy implementation*. In an ideal situation, the problem is a high-impact problem, all alternative solutions are considered and deliberated by experts, the best rational and most just or fair policy is developed and articulated, and logical steps are implemented that will resolve the problem. Problem-resolving steps can include a wide array of activities which often include new laws, financial resources, new staff, shifting of priorities in enforcement, treatment or prevention, new procedures, public awareness campaigns, etc. This four-element process is a foundation of policy development. The following event will serve as an example for discussion of policy development.

On Thursday March 20, 2008, the Modesto Bea ran a story entitled: *Huge amount of alcohol killed teen, coroner says*. In this article, writer Michael Shea reported that the body of 16-year-old Julia Gonzalez was found in a local park. On

autopsy she had a blood alcohol level of 0.52 which is 6.5 times the legal limit in California. Shea reported that at 100 lbs and only 5 feet 2 in. tall, this would likely mean that she had consumed the equivalent of about one pint of 86 proof alcohol in an hour. Julia was reported to have lived with her grandmother and to have run away on two prior occasions. She left her home at 7 PM with friends and her body was found at 5 AM the following morning. At the time of the article, the exact circumstances of her death were unclear and friends who may have been with her were not providing further information regarding where and with whom she had been drinking. Police Detective Brandon Bertram stated that there could have been a crime associated with her death and that “manslaughter in cases like this is difficult to establish because of the difficulty in proving that the victim was forced to drink alcohol.” Chief Deputy District Attorney Dave Harris related that the prosecution of adults who provide alcohol to minors is difficult and is a “nuanced area of the law.” This article was accessed at the Modesto Bea site, at the following link on 1-8-2010 (http://alcoholism.about.com/gi/o.htm?zi=1/XJ&zTi=1&sdn=alcoholism&cdn=health&tm=181&gps=252_1564_990_535&f=10&su=p284.9.336.ip_p736.8.336.ip_&tt=2&bt=0&bts=0&zu=http%3A//www.modbee.com/local/story/244848.html). This incident will be used to illustrate the various potential entities and issues involved with substance abuse policy on treatment, prevention, and enforcement. The four-element process as described above (problem, solutions, policy, and implementation) will be used to explore a variety of potential outcomes from this incident.

Problem Definition

There are numerous ways a single incident like this can be used as a basis for problem formation. On one level this incident could be seen as the isolated and accidental death of one person, that is, a small and isolated incident that is not representative of a social problem or failure of existing policy and practice. On another level this incident could be framed as representing a serious problem of high risk with high consequences in the US teen population that was not able to be brought to justice due to inadequate underage drinking laws, inadequate law enforcement, inadequate park security or police patrolling, and inadequate alcohol and drug prevention and treatment programs in the community and schools, that is, a single incident that represents a problem of tremendous magnitude and social significance.

In addition to the facts, the context and attention an incident or problem receives can shape the relevant priority a problem is given. Contemporary media often serves to highlight or raise the profile of a problem. If this story became the subject of a Cable News Network (CNN) expose on a media outlet such as the Nancy Grace Show, it might draw a great deal of attention and raise public awareness regarding teen death by alcohol intoxication as a broad public problem affecting many communities that requires immediate remedy. Similarly the association with a high-profile individual can serve to expedite public concern about an incident. If Julie Gonzales

were a family member of a Modesto area celebrity resident such as Star Wars producer George Lucas, the incident might become a prominent problem in terms of public interest.

Advocacy groups can be very influential in raising public awareness and opinion as to the severity of a problem. Several different advocacy groups might be interested in this event as an example of a problem that their group works to address. Examples of primary advocacy groups would include: *Students Against Drugs and Alcohol* (SADA, <http://www.sada.org>) and *Students Against Destructive Decisions* (SADD) which was founded as *Students Against Driving Drunk* in 1981. Currently SADD includes over 10,000 chapters throughout the United States (information from website retrieved 1-10-2010, <http://www.sad.org>).

Mothers Against Drunk Driving (MADD, <http://www.madd.org>) is another advocacy organization with a primary interest in underage drinking. MADD has been described by author Malcolm Gladwell (1) in his bestseller, *Tipping Point*, as one of our nation’s most successful advocacy organizations. Gladwell describes MADD as having catalyzed a national tipping point in American society such that it is no longer socially acceptable to drive under the influence of alcohol. This group has been extremely successful since its origin in 1980 in influencing public policy centered on the core problem of driving while under the influence of alcohol. MADD focuses advocacy on three priority areas, drunk driving, support for the victims of drunk driving, and underage drinking. This organization has strongly supported the creation and enforcement of strict penalties for Driving Under the Influence charges. Thus MADD might be instrumental in highlighting this tragic alcohol intoxication death as a representative example of the consequences of underage drinking. Other types of groups that might play a role in publicizing the significance of the problem of underage drinking on a local or national scale might include professional organizations such as the American Academy of Pediatrics (AAP), the California Chapter of the AAP (in their role as advocates for the health and safety of children and adolescents), the National Association of Medical Examiners (advocacy for reduction in preventable deaths), law-enforcement organizations such as the Fraternal Order of Police (FOP), the Parent Teacher Associations (PTA), or other local civic groups.

Solution Deliberation

Once the problem is identified and takes form, a general next step in policy process is the consideration of various solutions that would remedy the problem. Proposed solutions can come from a wide variety of sources and often include scientific expertise as well as consultation with individuals who have had direct experience with the problem. This might include input from a senior level of advisors or cabinet members, community members, opinion editorials, individual experts, or special advisors. A common approach to the generation of a solution in a political arena is to convene a “blue ribbon” panel of experts that deliberate aspects of a problem and

create a report that includes recommendation for resolution of the problem.

Generally a blue ribbon panel has some degree of independence from government and is set up to impartially deliberate the problem and make recommendations for policy. In this case, a possible scenario might have been the mayor, county board of commissioners, county school board, a California state legislator, a governor or other elected official convening such a panel or commission. Blue ribbon panels are comprised of experts as well as stakeholders with vested interest in the problem. Membership of a blue ribbon panel in the situation of underage drinking might include local elected officials, representatives of the PTA, student body, local city council or school board, parents or other prominent community members. Generally a series of presentations and testimony is organized to inform the panel regarding the current status of the problem as well as to provide expert opinion regarding potential solutions to the problem. Thus there might be presentations from the county school system drug and alcohol prevention coordinator so that the current content and status of prevention curriculum could be considered. Existing state laws and local ordinances regarding the provision of alcohol to underage individuals might be reviewed for the panel and the level of evidence required for prosecuting manslaughter or other potential crimes under current laws might be reviewed. Individuals from other states with more aggressive laws or school prevention programs might be consulted to provide their data and experience with similar problems. Researchers might be invited to provide testimony that summarizes current literature regarding effective prevention and law-enforcement programs.

The work of a panel often culminates in a report that includes at a minimum, a listing of recommendations or potential solutions to the problem. Advocacy groups themselves are very often involved with advocating for panels to be set up to focus attention to a specific problem. Advocacy groups often provide testimony and resources to panel members on their particular aspect of the problem. Blue ribbon panels can be a very effective mechanism for assembling a set of possible recommendations or solutions to a problem in the political policy formation process. Panels have the advantage of being independent from an elected government official and thereby have independence in the types of policy and recommendations they make.

Policy Development

The policy itself may be a clearly written document that articulates the problem and solutions that are to be taken to remedy the problem, or it may be much less formal. In this particular case, there may be recommendations that are oriented around drug and alcohol control and there may be recommendations oriented around increased access to treatment and preventive services. An elected official, with a candidacy based on a platform of being tough on crime, might be more likely to support policy that prioritizes law enforcement and includes tightening of any gaps in the laws so that law enforcement is more able

to make arrests and so that prosecutors are more likely to successfully prosecute. In our example situation, a resultant policy might be to assure that youth who appear intoxicated in public can be detained; to create laws so that it becomes a criminal act to facilitate the provision of alcohol or other illicit substance of abuse to minors even if they did not force the minor to use the substance; or to strengthen the enforcement of laws regarding the illegal retail sale of alcohol to underage individuals. On the other hand, an individual or party elected on a broad policy in support of harm reduction and treatment of individuals with substance abuse problems might be much more oriented toward strengthening prevention curriculum in schools, increasing access to adolescent treatment centers, providing hot lines and community escort services for inebriated youth and individuals, and community education of involved adults such as teachers and peers so that excessive and risky drinking and substance abuse behaviors can be identified and addressed early.

Implementation

Implementation and execution are an important component of the policy development process. How a policy is executed, that is how it is codified and enforced is critical to success. Codification is the clear articulation and/or passage of a written procedure, law, act, ordinance, or regulation itself. Enforcement is the actual plan for assurance that the policy is followed as intended. Codification for prevention could include school board policy that mandates prevention classes for all high school freshmen, budget revisions that provide a prevention staff for every high school, etc. Enforcement of mandated prevention could include no passing to 10th grade without prevention classes or budget and staffing audits to assure that schools have complied. Codification of actual laws could come from a review of existing laws and passage of amendments and new laws that make any act that enables an underage person to have access to alcohol or illicit drugs to be able to be arrested and convicted. Enforcement could come from priorities established with local law enforcement to make arrests of adults that are involved with enabling underage access to alcohol or other drugs.

In this section, four steps in the process of the development and implementation of policy have been presented and discussed. These steps are not always linear and orderly, however, these four steps are generally seen with public policy development. Factors that are commonly involved with problem definition, alternative consideration, policy development, and pursuant implementation were presented. The goal of this section is to provide a basic foundation as to how policy is developed and implemented.

FEDERAL POLICY AGENCIES

The historical and policy context of several entities that are involved with substance abuse policy and funding will be presented in this section. One cannot understand contemporary substance abuse policy without a basic understanding as to the

rich historical context of alcohol and substances of abuse in American history. A thorough review of substance abuse history is beyond the scope of this chapter, however, a few prominent highlights of early American history as well as a basic summary of the historical political origin of several substance abuse-related government and advocacy agencies will provide readers with a basic foundation as to the importance of substance abuse policy in American history.

Alcohol has been integrally involved with American history since before government was created. In *The Spirits of America: A Social History of Alcohol*, Eric Burns, writes that General George Washington was a strong believer in the necessity of spirits for his troops. Burns recounts General Washington's distress when shipments of alcohol for his troops were disrupted. In a letter to the president of the Continental Congress, Washington wrote: "The benefits arising from the moderate use of strong liquor have been experienced in all armies and are not to be disrupted" (2). Thus at the very outset of American history, a founding father asserted a policy that alcohol was essential for his soldiers and must be included as a component of the proper provisioning for his troops. The requested alcohol provision was 4 ounces per man per day.

Following the Revolutionary War, many US colonial farms and plantations, including George Washington's Mount Vernon, operated highly profitable distilleries. Alcohol was also included as an essential component of provisions for the Discovery Corps for the Lewis and Clark Expedition. Throughout early American history, distilled spirits in the form of rum have been an important part of the economy as a product for trade with Caribbean farmers for sugar cane and slaves from Africa.

As the young federal government developed, one of the first challenges in sustaining credibility as a viable government was to repay revolutionary war debt. Initially, the federal government had no authority to levy taxes, even to pay for federal government functions such as maintaining an army. A policy for funding federal government functions was developed and one of the first taxes was a tax on imported spirits. A special office was created to collect these taxes and today this office is known as the Bureau of Alcohol, Tobacco, Firearms, and Explosives (ATF).

Many federal agencies that are involved with substance abuse were formed as a part of the implementation step in response to public pressure that resulted in policy development. In the following section, several of these agencies will be reviewed in terms of the historical problem they were designed to solve as well as the current role in substance abuse policy. The Office of National Drug Control Policy (ONDCP) as well as several agencies that have been designed to control the supply of drugs and alcohol and several agencies that have been designed to control the use or demand for drugs and alcohol.

The ONDCP is the national coordinating entity for all federal drug policy. The ONDCP was formed as a component of the Anti-Drug Abuse Act in November of 1988 during the Reagan administration. The Anti-Drug Abuse Act also

created the Drug Free Workplace rules that require workplaces to maintain a drug-free workplace as a condition of receiving federal funding for contracts and/or grants. The phrase "just say no" was coined by first lady, Nancy Reagan, as a component of President Reagan's crusade against drug use in America. The ONDCP was formed to solve the problem of rising drug and cocaine abuse in the early 1980s as well as to align widespread variability in the approach to substance abuse policy within the executive branch of the federal government. With central coordination and alignment of all the federal entities and agencies that are involved with substance abuse there is a much greater likelihood of success in addressing the adverse impact that licit and illicit substance use has on society.

The ONDCP is within the Executive Office of the president and a chief function is to produce the National Drug Control Strategy, which is the chief policy document that is designed to align all federal activities that are related to substance abuse policy, enforcement, research, prevention, and treatment. This strategy outlines a budget as well as guidelines for coordination and cooperation among federal state and local entities. The ONDCP also evaluates and advises the president on international anti-drug policy. The ONDCP tracks and coordinates all federal spending on substance abuse. A detailed review of the functions of the ONDCP can be found on the website: <http://www.whitehousedrugpolicy.gov/about/index.html>.

The two broad policy priority areas that ONDCP considers include drug control and drug demand. Drug demand, that is, demand for drugs by drug abusers, includes policy and activities that address treatment and prevention. Treatment and prevention reduce demand. Policies that relate to the control of drug availability include domestic law enforcement and international counter drug enforcement.

Table 1 from the 2010 ONDCP budget (<http://www.ondc.gov/publications/policy/10budget/index.html>) represents the administrative budget requests for the federal 2010 budget. This provides aggregated information from across cabinets and agencies that enable a broad comparison of the relative federal expenditures on drug demand versus drug control expenditures. This table demonstrates that over the last several years, approximately twice as many federal dollars have been allocated for drug control and law enforcement as opposed to funding for treatment and prevention services.

The federal entities that are included within the substance abuse demand realm include the Departments of Health and Human Services, Interior, Veterans Affairs, Education, and the Small Business Administration. The federal entities that are counted as being within the drug supply control realm include the Departments of Defense, Homeland Security, Justice, State, Transportation, and Treasury. Each of these federal demand and control entities was created to address an aspect of public substance abuse policy. In the following section, several important federal entities will be discussed. Sections will include a discussion of the historical policy problem that the agency was formed to address as well

as provide information about the current budget and active programs.

DRUG CONTROL AGENCIES

The ATF was created as an agency of the Department of Justice in January 2003 under the Homeland Security Act. This agency had previously been within the Treasury Department and was known as the Bureau of Alcohol, Tobacco and Firearms, which was also designated by the same three-letter acronym, ATF. The ATF is the oldest of the federal agencies related to drug control and has origins in federal policy on tax collection. In 1789, congress imposed a national tax on imported spirits in order to help repay debt associated with the Revolutionary War. Accountants were trained to be investigators to function within the Department of Treasury to enforce the collection of taxes on alcohol. Similar federal taxes were enacted on tobacco products and the task of enforcing these taxes was given to a group of special agents within the office of Internal Revenue.

In response to growing public concern that alcohol consumption had grave impact on American families, prohibition was passed as the 18th amendment to the Constitution in 1919 and it resulted in laws that made it illegal to manufacture, sell, or transport alcohol. The Office of Internal Revenue was a major force of the federal attempt to enforce these laws. The term “revenueurs” was coined from this era and describes internal revenue agents from the Treasury Department who were responsible for the investigation of illegal production of alcohol (moonshine) thus resulting in tax evasion. A special unit called the Prohibition Unit was formed from the expertise of the revenueurs which today is part of the historic legacy of the ATF. Prohibition lasted for 14 years until it was repealed in 1933 with the ratification of the 21st amendment. In response to public concern regarding firearms exposure that was present throughout prohibition, the national firearms act was passed in 1934 which added firearms regulatory responsibilities to the ATF precursor. Duties regarding explosives were added to the ATF in the 1970s and the most recent reorganization of ATF moved it from treasury and into the Department of Homeland Security in 1998 (<http://www.atf.gov/about/history/atf-from-1789-1998.html>).

Today the ATF employs about 5000 people and in 2009 had a budget of just over 1 billion dollars. In the Fiscal year 2010 Congressional Budget Submission, the ATF lists its mission as “the U.S. law enforcement agency dedicated to protecting our Nation from the illicit use of firearms and explosives in violent crime and acts of terrorism. ATF protects our communities from violent criminals and criminal organizations by investigating and preventing the illegal use and trafficking of firearms, the illegal use and improper storage of explosives, acts of arson and bombings, and the illegal diversion of alcohol and tobacco products” (ATF congressional Budget Report, accessed on January 20, 2010 at <http://www.justice.gov/jmd/2010justification/pdf/fy10-atf.pdf>). Whereas

this agency has its origins in alcohol and tobacco control, it now currently focuses predominantly on violent crime and gun and explosives control.

The Drug Enforcement Administration or DEA was established by congress in 1973 during the Nixon Administration and was started in response to growing concern about illicit drug use in the United States in the 1960s to 1970s. In a speech in 1971, President Nixon declared drug abuse as “public enemy number one.” Of particular concern at that time was the importation of Mexican cannabis as well as heroin. President Nixon coined the term “War on Drugs,” and strengthened the role of the federal government considerably in the coordination of the control of illicit drugs.

A brief description of the historic lineage of the DEA helps to demonstrate the complexity and far reaching involvement of the federal government in substance abuse policy. In 1968, President Johnson formed the US Bureau of Narcotics and Dangerous Drugs (BNDD) from two agencies: the Bureau of Narcotics in the Treasury Department which was responsible for the control of marijuana and heroin (illicit drugs), with the Bureau of Drug Abuse Control, in the Department of Health, Education, and Welfare, which was responsible for the control of dangerous drugs. The BNDD was then placed under the Department of Justice which is primarily concerned with law enforcement. Five years later in 1973 and during the Nixon Administration, the DEA was developed in order to create a stronger federal agency that could better enforce domestic federal drug laws as well as address the growing sophistication of international drug traffickers primarily from Europe and South America. The DEA was formed from the BNDD, the US Customs Department, the Office of National Narcotics Intelligence, and the Office of Drug Abuse Law Enforcement. At the outset, the DEA had 1470 Special Agents with a budget of 74.9 million dollars. Currently there are over 5000 DEA agents and the annual budget is just over 2 billion dollars. The DEA operates as an agency within the US Department of Justice (<http://www.justice.gov/dea/pubs/history/1970-1975.pdf>).

Today an important function of the DEA is the enforcement of the legal prescribing of narcotics. This function has its origins in the Harrison Narcotic Act. The Harrison Narcotic Act was passed in 1914 and required prescriptions for narcotics and mandated record keeping for physicians and pharmacists who dispense narcotics. The Harrison Narcotic Act was passed to solve the problem of uncontrolled growth in the use of narcotics as well as the use of heroin and cocaine. This act followed US participation in the Shanghai Opium Commission of 1909 which was the first international conference convened to address worldwide the problem of drug abuse, most particularly heroin. With growing concern regarding the abuse and nonmedical use of prescription drugs as reported in the National Survey on Drug Use and Health in 2009, DEA has worked with state government drug control agencies to develop more coordinated policy that enhances the capacity to identify and control prescription drug abuse (3).

The Federal Bureau of Investigation (FBI) has its origins in 1908 during the presidency of Theodore Roosevelt. This agency was created to provide investigative ability to the US Attorney General in the Department of Justice. The FBI does not have a primary mission in the investigation of drug-related crime; however, much of the crime that the FBI investigates involves or is funded by drug-related criminal activity such as terrorism, organized crime, money laundering, and gangs. The FBI works with other local, federal, and international law enforcement to investigate drug crimes. The FBI started 100 years ago with 34 investigators and a budget of several million dollars. Currently there are nearly 30,000 employees and the budget is over 7 billion dollars (<http://www.fbi.gov/homepage.htm>).

The Food and Drug Administration (FDA) is currently within the federal Health and Human Services agencies and is considered to have been founded on June 30, 1906 when the Pure Food and Drugs Act was signed into law by President Theodore Roosevelt. This act restricted interstate commerce in misbranded and adulterated foods, drinks, and drugs. The original bureau responsible for this act was in the Department of Agriculture (<http://www.fda.gov/AboutFDA/WhatWeDo/History/Milestones/ucm128305.htm>). The FDA has a role in regulating the safety of the production of prescription narcotics but does not directly regulate the legal use of addicting medications.

FEDERAL DEMAND DEPARTMENTS AND AGENCIES

The federal departments that operate programs designed to limit the demand for substances of abuse include the Department of Health and Human Services (DHHS), Interior, Veterans Affairs, Education, and the Small Business Administration. In general, programs that are designed to provide treatment are more recent than programs that control supply. The DHHS receives the single largest amount of federal funding for substance abuse of any of the other federal cabinet-level departments. This funding includes funding for treatment that is administered by the Center for Medicare and Medicaid (CMS), funding for treatment and prevention programs that are operated by the Substance Abuse and Mental Health Services Administration (SAMHSA) and the Indian Health Service. The National Institutes of Health (NIH) includes two institutes that address problems related to drugs and alcohol as a primary mission. These are the National Institute on Drug Abuse (NIDA) and the National Institute on Alcohol Abuse and Alcoholism (NIAAA). The Federal Drug Administration (FDA) which is also within DHHS, regulates the safety of licit domestic drugs but does not have a direct role in addressing supply or abuse of addicting medications.

In 1992, the Alcohol and Drug Abuse, Mental Health Administration (ADAMHA) was divided into several research agencies including NIDA, NIAAA, and NIMH. At this time the SAMHSA was created to operate and administer federal substance abuse and mental health programs and services grants. This role is conceptually distinct from research entities

that have some degree of intellectual independence from treatment program administration. SAMHSA is divided into three principal offices: the Center for Mental Health Services (CMHS), the Center for Substance Abuse Treatment (CSAT), and the Center for Substance Abuse Prevention (CSAP).

NIDA and NIAAA are the two primary substance abuse research entities in NIH. These institutes have distinct histories and have been maintained as two entities on the conceptual grounds that alcohol is a legal substance of potential abuse which can be used safely, and other drugs of abuse are illegal. It is likely that this separation has a historical association with prohibition and the subsequent repeal of prohibition in 1933 with the passage of the 21st amendment. Clearly there are inconsistencies in policy that separates alcohol on the grounds that it is a legal substance from other legal and addictive substances such as prescription pain medications and in some states, medical cannabis.

The NIDA budget has more than doubled since its origin in 1992 and in 2008 was just over a billion dollars. The NIAAA budget as well has more than doubled in this period with a budget in 2008 of just under 500 million dollars. This represents tremendous federal investment in research on the underlying causes and treatment of drug use and alcohol abuse. At its core, research is the unbiased discovery of new facts. While research produces new knowledge and information that influences policy and public policy, the scientific knowledge that is produced should be free from bias. In our four-step paradigm of public policy development (problem, identification of potential solutions, policy formation, implementation) NIDA and NIAAA would not be involved in advocacy for a problem rather they would be involved with the provision of scientific information that would help to delineate the problem as well as potential best solutions. Additionally, increased funding for research on a particular problem is often done as an implementation step in response to public policy that is created to solve a societal problem.

A recent example of this would be the problem of rural use of methamphetamine, “crystal meth” in the United States. Methamphetamine has been used in the United States for over a century, however, in the early 1980s methods for easy home manufacturing from common inexpensive household products became widely known. The use of crystal meth has spread primarily from the west to the east coast and may have origins in Japan. The manufacture of crystal meth has increasingly become identified as a significant problem in rural areas. Rural areas are attractive for crystal meth because manufacturing results in large quantities of waste that must be hidden or dispersed and also because the ingredients are inexpensive and readily available. Although there are regional differences in the penetration of the problem, crystal meth use has progressively become defined as a nationally significant problem. As is common in substance abuse policy, the range of potential solutions generally includes both control measures through tighter laws and law enforcement and reducing the demand for the substance through treatment and prevention.

Because crystal meth is a relatively new problem, and not much is known about the relative efficacy of potential

treatments, prevention techniques and/or long-term impact of abuse and/or addiction, NIDA has been involved as a component of a national policy action to reduce the adverse impact of crystal meth on our nation. In this case NIDA was funded by the president and congress to create a series of projects that are designed to provide information on the epidemiology of the problem, best treatment methods, medications and immunizations that may reduce or eliminate craving and abuse as well as to study the impact of high exposure to crystal meth on human bodies and particularly the central nervous system. This research is designed to increase knowledge about the problem so that iterative policy can be developed and implemented that is more able to accurately eliminate the problems associated with crystal meth use. Thus, the federal research institutes are involved with generating science that informs public policy and the budgets of these institutions is impacted by what problems policymakers decide to solve. Research institutes are not generally directly involved in advocacy or in making public policy.

Other entities within the federal government that provide health and substance use information that informs policy development are the US HHS Center for Disease Control (CDC) and the National Highway Traffic Safety Administration (NHTSA). The CDC conducts numerous nationally based disease and health-related surveys that include substance abuse. Two examples of this within the CDC are the Behavioral Risk Factor Surveillance Survey (BRFSS, <http://www.cdc.gov/brfss/about.htm>) which monitors general health behaviors that includes substance abuse, and the National HIV Behavioral Surveillance System (NHBS, <http://www.cdc.gov/hiv/topics/surveillance/index.htm>) which includes statistical information on IV drug abuse and its relationship to trends in HIV/AIDS.

The NHTSA maintains national statistics on highway safety and on motor vehicle accidents and has been a significant source of information for advocacy groups such as the aforementioned MADD which apply pressure to prioritize the problem of driving while under the influence.

The federal government has a large investment in the provision of substance abuse treatment to Americans. The primary agencies that are involved with treatment funding include Medicaid and Medicare. Both of these programs are administered by the Center for Medicare and Medicaid Services (CMS). An additional federal entity that provides funding for treatment includes the federal substance abuse block grant which is administered by CSAT within SAMHSA. Other entities such as the Veterans Administration and the Department of Defense also provide substance abuse treatment for armed services soldiers and employees.

Medicare was formally created in the Johnson administration in 1965. Medicare was enacted after 20 years of pressure in congress and various incremental programs that were designed to solve the problem of health care access for elderly and retired individuals. Elderly individuals were no longer employed and did not have access to employee-based health insurance. They were often living on meager pensions and in poverty. In 1972 Medicare was expanded to include individuals with long-term disability. In 2003, according to the

SAMHSA Behavioral Health Care Expenditures Report, Medicare comprised 5% of total national expenditures on substance abuse treatment (4). The majority of substance abuse-related Medicare expenditures were for inpatient hospital-based detoxification. The benefits that are covered under Medicare are determined by CMS payment policy as well as regulations that are created in response to congressional legislation. A Medicare Evidence Development and Coverage Advisory Committee exists to provide recommendations from experts regarding changes in coverage to include new developments in treatment and to eliminate payment for ineffective treatments.

Medicaid is the second major federal health insurance program that is administered by CMS. Medicaid was enacted just after Medicare and is a significant funder of substance abuse treatment services. Medicaid is a state and federal partnership wherein states provide just under half of the funds. Each state makes determinations regarding the type of substance abuse benefit that its Medicaid program will cover and state programs vary widely regarding coverage of treatment of substance abuse treatment. Medicaid is principally designed to provide health insurance for children and adults in poverty. According to the SAMHSA health care expenditure report, in 2003 Medicaid paid for 18% of all expenditure on substance abuse treatment (4).

Although this chapter focuses primarily on the role of federal government entities that are involved in developing substance abuse policy and in funding control and treatment, state and local government have significant roles in the development of parallel local and regional state policy on substance abuse control and demand. In considering overall sources of funding for substance abuse treatment nationally, state and local government provides 40% of the total US substance abuse treatment expense. In comparison, the national figures for the amount that private insurance pays are only about 10% of all expenditures on substance abuse treatment. This has reduced considerably since 1993, when private insurance paid for 14% of the total substance abuse treatment expenditures (4).

The CSAT within SAMSHA administers the Substance Abuse Block Grant which as of 2003 provides 8% of all monies that are spent on substance abuse treatment (3). This grant is distributed to substance abuse treatment providers through state government recipients.

CONCLUSION

This chapter was written to provide a foundation for understanding the elements in policy development in the area of substance abuse. It is not possible within the confines of a chapter to review the entire history of US substance abuse policy development. Numerous examples were woven into the chapter to demonstrate the basic policy process: problem identification, alternatives consideration, policy development, and implementation. Substance abuse problems are of great social concern and have tremendous capacity to adversely impact individuals, families, communities, and our entire

nation. Policies on substances of abuse have been embedded in US government function throughout the entire history of our nation. A wide variety of government and federal agencies are involved in the provision of drug control enforcement and drug abuse treatment and prevention. In general, the US federal government allocates twice as much funding for drug control activity as it does for activity that would reduce drug demand. The mission of the ONDCP is to coordinate all federal agencies and activities that are related to substance abuse policy. Many other entities are involved with policy implementation. It is essential for stakeholders involved with advocating for substance abuse treatment and prevention to understand the foundations of policy development so that effective solutions can be implemented to reduce the adverse impact of substance abuse on our families and society.

Ihsan M. Salloum

The interface between forensic and addiction psychiatry is rich and spans both clinical and legal arenas within the civil and criminal areas. This chapter is a synoptic overview and is intended to serve as a practical guide to *criminal* forensic practice for the addiction specialist. In this chapter, we will highlight conceptual questions arising from the interaction between the law and addiction medicine and we will provide references to primary legal sources, textbooks, reviews, and commentaries for the interested reader. We will also discuss issues related to the applicability of *DSM-IV-TR* (*Diagnostic and Statistical Manual of Mental Disorders*, 4th ed., text revision) criteria in the courtroom, the relevance of intoxication to intent, and residual effects of substance use following discontinuation of such use.

This chapter is divided into six main sections. In the first section, we summarize the fundamental legal principles and procedures governing expert testimony about the “mental” elements in the criminal law. In the second section, we examine the potential roles for the addiction expert in criminal proceedings. In the third section, we discuss the relevance of the effects of intoxicant substance use on criminal responsibility, considering defenses as well as mitigation based on intoxication, dependence, and withdrawal. (For heuristic purposes, unless otherwise qualified, the term *intoxicant* refers to *substances*, i.e., *drugs*.)

In the remaining sections, we will discuss issues raised by the “addictive processes,” with primary focus on pathologic gambling (fourth section), and we will consider the vexing problem of the credibility of the testimony of intoxicant-involved witnesses (fifth section). In the sixth and final section of this chapter, we will address regulatory and administrative matters related to intoxicant substances, with particular emphasis on the implications of the concept of “impairment” and the regulatory problems of long-term opioid therapy in private practice.

THE ADDICTION MEDICINE SPECIALIST AS A FORENSIC EXPERT

Clinical Experts in the Criminal Law

The addiction specialist’s role as expert in forensic matters has grown significantly over the past decades reflecting the growth of the accredited specialty of addiction psychiatry and addiction medicine and of the maturation of this subspecialty in general. Addiction specialists are being preferentially sought

after by attorneys for consultation and expert testimony about the effects of intoxicant use instead of continuing to resort to general psychiatrists, psychologists, or other mental health professionals. The emergence of a body of “facts” in the specialty of addiction medicine, about which there is little or no difference of opinion in the field, as analyzed by Burglass and Shaffer (1–3), has contributed significantly to this shift. Burglass and Shaffer critically review the state of knowledge in the addictions field, including theory, research, and practice (1–3).

Being Qualified as an Expert

Although there are federal and state standards that govern expert testimony, there is little consistency between and within jurisdictions about the qualifications of expert witnesses. Determining who should be an expert witness for “psychologic” matters has been a difficult task for the courts. Often, decisions regarding who qualifies as an “expert” are made on pragmatic rather than jurisprudential grounds. Some courts have permitted (or precluded) a wide range of individuals, including case workers (4,5), police officers (6–8), and even lay witnesses (9,10), to testify about a variety of psychologic issues (including the question of sanity). Other courts have been unwilling to recognize the expertise of psychiatrists, physicians, psychologists, and others, and have refused to admit their testimony in selected matters. Examples include compulsive gambling (11,12), the effects of drugs on witness credibility (13,14), and satanic ritual murder (15).

With rare exceptions, psychiatrists, physicians who specialize in mental (neurologic and psychologic) disorders, and doctoral-level clinical psychologists are qualified as experts. Although professional associations in psychiatry (16) and psychology (17) have developed guidelines for determining forensic expertise and practice, these criteria have not been adopted as authoritative by the courts. For the most part, courts have been reluctant to admit psychologic evidence tending to favor an accused (18). For a comprehensive review of the determination and utilization of expertise in mental matters in the federal and state jurisdictions, see Ref. 19 (§2:2–11).

Rationale for the Admission of Expert Testimony

The Federal Rule of Evidence 702 provides that “if scientific, technical, or other specialized knowledge will assist the trier of fact [judge or jury] to understand the evidence or to

determine a fact in issue, a witness qualified as an expert by knowledge, skill, experience, training, or education, may testify thereto in the form of an opinion or otherwise” (20). Most states have a rule of evidence that parallels the Federal Rule of Evidence 702, although a few states have adopted different and confusing rules on this point. The states also have tended to follow Federal Rule of Evidence 704, which limits expert testimony to an explanation of the defendant’s diagnosis and the characteristics of the disease or defect. This rule specifically precludes expert opinion on “whether the defendant did or did not have the mental state or condition constituting an element of the crime charged or of a defense thereto” (20). This question (referred to in the law as the “ultimate issue”) is for the jury to decide. The trial judge makes the final decision regarding expertise and the admissibility of expert testimony, despite the prevailing rules of evidence (11,12,21–24).

In practice, if satisfactory evidence of knowledge, skill, experience, or training in the diagnosis and/or active treatment (but not mere research) of intoxicant-involved patients is provided, it is likely that expert qualification in the areas of addiction and the effects of intoxicants will be recognized by the court. Although qualified as an expert by the court, the admissibility of expert testimony into evidence is a separate question to be argued by counsel. Ultimately, all decisions regarding the qualification of experts and the admissibility of their testimony are made at the discretion of the trial judge (25–29).

How the Law Views Expert Testimony

Under prevailing rules of evidence, the testimony of expert witnesses is presented to the court in the form of expert opinion. As such it does not enjoy the same privileged status as “fact” testimony. It is up to the judge or the jury (the trier of fact) to evaluate the credibility, reliability, relevance, and applicability of any expert testimony introduced. Thus, even what is considered accepted medical “fact” is considered only “opinion” when expressed in expert testimony and as such it may be accepted, discounted, or rejected in whole or in part. When testifying, any lapse of awareness of this crucial distinction may result in the expert being perceived as argumentative, defensive, sanctimonious, condescending, or hostile. This always compromises the expert’s credibility and undermines the power of the testimony as evidence, which may prove fatal to the client’s case.

THE ROLE OF THE EXPERT IN ADDICTION MEDICINE

The professional mandate as an expert witness is to assist the court. It is important to remember that the role of the expert witness is not that of an advocate. The expert testimony responsibility is to provide the judge and jury with information that is truthful, intelligible, and clear and to offer the opinions that are unbiased, carefully reasoned, and based on the expert’s understanding of the facts in evidence. The expert witness is more likely to be engaged by the defense than the

by prosecution, as it rarely serves the interest of the prosecution’s case to introduce expert testimony in support of exculpating or mitigating mental defenses. Thus, the following discussion may seem to express a defense bias. The prosecution, on the other hand, may call experts to rebut testimony introduced by defense experts and the expert should be willing to appear for either side.

The Pretrial Phase

The addiction specialist activities in the pretrial phase involve several areas. The addiction specialist can assist the attorney by reviewing the initial discovery materials (e.g., police reports, arrest forms, affidavits of investigating agencies, waivers of rights, medical examiner reports, toxicology screens, statements of witnesses and/or the accused, confessions, the formal complaint, information, or indictment) to identify any immediate or potential issues related to intoxicants. Furthermore, attorneys may seek assistance in managing a difficult, compromised, or dangerous client. It may be necessary to immediately evaluate and refer the client for primary treatment or stabilization so that the client can adequately assist counsel in the preparation of the case. Determination of competency to stand trial is a separate matter, both clinically and legally.

The addiction specialist should make a preliminary assessment of all available background materials of prospective witnesses to identify any possible clinical (i.e., medical, neuropsychiatric, or addiction) issues that require investigation. The addiction specialist can also help the attorney to prepare for depositions by (a) drafting specific questions to be posed, (b) doing content and psycholinguistic analyses of taped or written evidence (e.g., statements or depositions made by the defendant or witnesses), and (c) suggesting strategies and tactics for conducting interviews or depositions. It is often important to interview family members, friends, former teachers, or others who may have particular knowledge or a different perspective of the defendant or witness (30).

The cornerstone of the addiction specialist’s evaluation of the defendant is a comprehensive addiction history. The addiction specialist must aggressively inquire about every aspect of use and experience with intoxicants of all classes and all of the addictive processes. The addiction specialist must take a lifetime neuropsychiatric history, exploring every sign or symptom reported, suggested, implied, or suspected. Also, complete medical (including all responses to prescription and over-the-counter medications), psychosocial, developmental, educational, relational, and vocational histories must be taken. History or indicia of psychologic, sexual, or physical abuse must also be aggressively sought and explored.

The addiction specialist and the attorney work closely together during the pretrial phase with reciprocal responsibilities. The addiction specialist’s responsibility to the attorney is to identify, analyze, develop, and explain facts or issues relating to the use or effects of intoxicants. The attorney’s responsibility to the addiction specialist is to analyze and explain the laws of the jurisdiction that (a) govern the nature and scope of admissible expert testimony, (b) define the

required mental “elements of the offense” for the crime charged, and (c) determine the availability of defenses or mitigation based upon the use and/or effects of intoxicants. This interaction between the disciplines of law and medicine, unfettered by the legal rules of the courtroom, is invariably a stimulating and instructive experience for both the attorney and the addiction specialist. This collaboration will result in the formulation of potential clinical approaches to the defense of the case, and in time, they will develop agreement upon a strategy for the clinical component of the defense and set the general contour of the addiction specialist testimony.

Once the clinical and legal issues are clarified and resolved, the addiction specialist should draft the actual questions that the attorney should ask the addiction specialist on direct examination. At the very least, the addiction specialist must frame the questions that establish his or her expertise and any questions required to elicit the predicate facts and issues to be introduced into evidence as the basis for the addiction specialist testimony and opinions. This is a tedious and time-consuming task; however, it cannot be done by the attorney. Only the expert in addiction medicine can fully appreciate the relevance and implications of the clinical subtleties and distinctions and can identify and illuminate the clinical concepts likely to confuse the judge or jury. And only the addiction specialist can anticipate the pitfalls that loom on the narrow plateau of accommodation between the restrictive rules of legal discourse and the broad latitude required in complex clinical explanations. There is no more frustrating or unsettling experience for an expert than being put or left in a compromised position on the witness stand as a result of having been asked ill-framed questions by an inadequately prepared attorney.

The addiction specialist also can assist the attorney if the other side will be calling an addiction expert by (a) evaluating that expert’s credentials, (b) anticipating the nature of the testimony, (c) analyzing the strengths and weaknesses of both expert positions, and (d) drafting appropriate questions for the attorney to ask in cross-examination.

The Trial Phase

The two most common types of cases in which an addiction specialist will be engaged in are those in which a person either is accused of having committed a crime while drug involved (i.e., while experiencing the acute, subacute, chronic, or residual effects of previous intoxicant use, dependence, or withdrawal), or is on trial as the result of statements made to law enforcement officers or testimony given by witnesses who themselves are or have been drug involved. Typically, the first type of case requires testimony about the nature and effects of intoxicant use on the defendant. Common issues include the impact of specific intoxicants on (a) the physical and mental ability to have committed the crime, (b) the state of mind required for the offense charged, or (c) the formation of the requisite intent. Other questions may involve the special issues of diminished capacity or insanity. The second type of case usually involves testimony about the effects of acute

and/or chronic intoxicant use on cognition and memory, and how such use might affect the credibility of witnesses.

In some jurisdictions, the fact pattern of a specific case and/or the local rules may preclude an expert witness from commenting or offering an opinion on any aspect of the mental state of the defendant. An addiction expert, even in such circumstances, will usually be permitted to “assist the trier of fact” by giving the jury a basic education about the intoxicants involved in the case. Such basic education on intoxicants might include (a) general pharmacology; (b) modes, methods, patterns, and demographics of use; (c) interaction with antecedent or concurrent neuropsychiatric or medical conditions; and (d) specific effects on cognition, emotion, and behavior.

The Postconviction Phase

Usually defenses involving intoxicants do not prevail which may be difficult to accept, even in cases where colleagues in the field would find the clinical evidence supportive of the defense position. Long-standing biases in the criminal law, public opinion, and political factors often have greater influence on the outcome of a case than does the clinical evidence. Although most of the expert clients will be convicted, the expert testimony may result in conviction for a lesser offense, which carries a lesser penalty. It is important to remember that the addiction expert testimony in every case can make a meaningful difference to what eventually happens to the defendant.

The postconviction phase, at sentencing, often offers the opportunity for the addiction expert’s most valuable contribution to a case. During the sentencing phase, the rules governing the nature, content, form, and scope of expert testimony are far more liberal at this phase than at trial and most jurisdictions permit the defense to present evidence (including expert testimony) in support of mitigation during the sentencing process. At sentencing, an expert may be permitted to (a) discuss the defendant’s entire intoxicant history, (b) comment on the influence of intoxicant use on the acts constituting the crime charged, (c) make prescriptive treatment recommendations, or (d) propose an alternative sentencing plan, such as providing for dispositions, for example, supervised release probation, community control (home confinement), or community service. In offering sentencing recommendations to the judge, it is important to be cognizant of the fact that the court has the awesome responsibility of balancing between the needs of the community for protection and justice and those of the defendant for treatment and rehabilitation.

CRIMINAL RESPONSIBILITY AND INTOXICANTS

Although the connection between the use of intoxicants and crime has been universally recognized, the explosive increase in drug-related crime over the past two decades has had only minimal impact on substantive criminal law. The recognition (albeit equivocal) of substance use disorders as “diseases” and

the growth of a professional field and industry around the field has had significant social and professional consequences and instructive (although surprisingly limited) effects on the legal rules.

Recent scientific research illuminating the distinction between mind and brain, mechanisms of cognition, the nature of rationality, the relationship between intention and action, mechanisms of emotional and behavioral control, and the distinctions between reaction, response, compulsion, and decision are of fundamental relevance to the criminal law. Yet, the law remains self-consciously nescient. Its reasoning remains grounded in long discarded models, disproved theories, and culturally dated assumptions about human rationality, intent (knowledge and volition), motivation, and the regulation of behavior (action). Moreover, although well-understood in the addictions field, the specific effects of all classes of intoxicants on these complex processes have been essentially ignored by the law. Legal reasoning about intoxication continues to be informed by eighteenth and nineteenth century understanding of the effects of alcohol on behavior (31).

Conceptual Problems

Definition, Description, and the Problem of DSM-IV-TR

Because the criminal law has a long history of difficulty defining the concepts of “mental disease” and “mental defect,” it is perhaps not surprising that the American Psychiatric Association’s *DSM-IV-TR* (32) has been adopted by the courts as a Rosetta Stone for recognizing a defendant’s alleged “mental” problems as true diseases or defects. As clinicians, we know that *DSM-IV-TR* is not and was never intended to be a textbook of neuropsychiatry or addiction medicine. Despite the very explicit caveat about its limitations stated in the Introduction (32, pp. xxiii–xxiv) and the Cautionary Statement about its validity and application in forensic contexts (32, p. xxxii–xxxiii), expect to see a copy of *DSM-IV-TR* on counsel tables in every criminal case wherein a mental defense is anticipated. Also the addiction experts should expect to be examined and cross-examined about their findings and opinions in the constricting terminology of *DSM-IV-TR*. As one prosecutor remarked, “If it’s listed in *DSM-IV-TR*, then it’s a real mental illness; if it’s not in *DSM-IV-TR*, then it isn’t a real disease and should be given no credence.” To challenge the unwarranted authority this publication has accrued so that the testimony is not bound by its serious limitations, simplifications, and omissions, it must make it clear that neither you (the expert), the psychiatric profession, nor the addiction medicine field recognizes *DSM-IV-TR* as the “authoritative” text. In preparing the testimony, it is vital that to anticipate and analyze all the ways that opposing counsel might use the language of *DSM-IV-TR* to try to make your testimony appear unreliable, inconsistent, or contradictory. Next, you must formulate strategy and tactics for thwarting this predictable assault on your credibility. Finally, you must make your attorney aware of all such potential problems so that the attorney will be prepared to help “rehabilitate” you on redirect

examination. As the DSM-V is being revised; it appears that there will be changes to the current classification of substance use disorders diagnoses; however, these changes will not fundamentally alter current overall concepts expressed in *DSM-IV-TR*(33).

Disease, Disorder, Defect, and Dysfunction

Moving beyond the hurdle of *DSM-IV-TR*, the addiction specialist must be prepared to confront the distinctions between “disease,” “disorder,” and “dysfunction.” The first two terms have long and tortuous histories in the law of every jurisdiction, whereas the concept of cerebral “dysfunction” has virtually none. And yet, it is precisely in terms of cognitive, emotional, and behavioral dysfunction that one can best explain (and even quantify) the effects of acute, subacute, and chronic intoxicant use. Most defendants seeking to avail themselves of an intoxicant-based defense will have grossly normal findings on objective neuropsychiatric diagnostic tests as the electroencephalogram, computed axial tomography scan, or magnetic resonance imaging scan. Even when administered using the latest enhanced techniques, these modalities are of limited value in demonstrating cerebral dysfunction (34–36). Although the newer brain imaging technologies, such as the quantitative electroencephalogram (34), single-photon emission computed tomography (35), and brain electrical activity mapping (36), promise considerable future utility, at present, valid norms for these modalities are still in the earliest stages of development. Because the legal tests applied by the courts for the admissibility of scientific evidence based on “newer” technologies are strict and narrow (21,22). Historically, the courts are slow to recognize the evidentiary validity of emerging scientific technologies, although facilitation of integrating scientific knowledge and evidence-based practice into forensic practices is an active topic of debate (37,38).

Use, Misuse, Abuse, Dependence, Addiction

Terminology in the field of addictive disease remains an unsettled area. Within *DSM-IV-TR*, for example, there is no formal definition or use of the word “addiction.” That term as it is often used is referred to instead as “dependence,” a word less likely to have pejorative connotations within the courtroom. One might argue that substance dependence is a medical disease whereas substance addiction is a social issue. It is crucial to be consistent with the use of terminology, making certain to define the usage of the term at the outset, recognizing that not all use qualifies as abuse. There is no reference to quantity of use within the definitions of abuse or dependence, but that has not stopped the lay public from assuming that any use of heroin constitutes abuse, whereas only high volumes of alcohol intake would amount to abuse. Use of a substance does not establish the presence of a disease, but it does establish the presence of potentially intoxicating effects. Again, be consistent with the use of terminology and the definition of the disease process so that the field remaining unsettled in this area will not cause significant difficulties. Finally, if appropriate, there may be need to educate participants

regarding use of the “substance-induced” category as it applies to alteration of mood or perception, individuals with substance-induced disorders may often be mistakenly presumed to have substance use disorders. The substance-induced category should be used diagnostically, even if the substance to which it refers is not a drug of abuse. If, for example, an antihypertensive has caused depressive symptoms and secondary criminal action, one of the appropriate diagnoses would be a substance-induced mood disorder.

The Elements of the Offense

Definitions of both common law and statutory crimes require the voluntary commission of a bad act or harmful omission (*actus reus*) in conjunction with a bad state of mind (*mens rea*). However, these fundamental concepts have resisted enduring definition. Most older common law crimes have been redefined in modern criminal statutes. Criminal codifications often use adverbial qualifiers such as “knowingly,” “willfully,” or “intentionally” to designate as voluntary an act performed consciously as the result of effort or determination (39).

The Exculpatory Doctrine in Common Law

The early common law made no concession whatsoever because of impaired behavioral control. Justice Story, in an 1828 case involving alcohol intoxication, stressed the merit of “the law allowing not a man to avail himself of the excuse of his own gross vice and misconduct to shield himself from the legal consequences of such crime” (40).

Over time, scientific views of human behavior gradually supplanted moral ones. Concurrently, there was a substantial increase in the consumption of alcohol in all social and economic strata. In response to these societal changes, the common law evolved what came to be known as “the exculpatory doctrine.” This doctrine permitted the presentation of evidence of specified mental conditions (including intoxication) in legal proceedings as a means of mitigating culpability, liability, or responsibility. Such evidence could be introduced in the form of an assertion of a defendant’s insanity or lack of the “specific” intent required as an element of the offense charged. New and more difficult problems arose almost immediately.

The Enduring Problematic Concept of “Intent”

The early cases in which the exculpatory doctrine was applied involved alcohol intoxication. The courts gradually realized that “common sense” suggested that a distinction should be made between a crime committed by an intoxicated as opposed to a sober person. But traditional moral attitudes stigmatizing intoxication as a vice indicated the impropriety of complete exculpation. The criminal rules on “intent” provided an expedient, if inadequate, means of mediation.

These doctrines, which were the foundation for the exculpatory rule, imply that “specific intent” is distinguishable from “general intent.” These also signify that certain crimes require only “general intent,” whereas other offenses require certain “specific” intents. This dubious distinction persists at

law, although neither the courts nor modern cognitive science has yet to formulate a reliable criterion or test for distinguishing “general” from “specific” intent. Today, “specific intent” most often refers to a “special” mental element that must be present in addition to the bad mental state required to accompany the bad act constituting the offense. For an analysis of the evolution and modern status of the legal premise of intent and its application to mental defenses (including intoxication), see Ref. 41 (§§3.5). When impulsive or compulsive behavior is involved, as in intoxicant use, this distinction is even more problematic.

The meaning of “intent” in the criminal law has always been obscure. Traditionally, intent was defined to include elements of both knowledge and volition. In the modern era, a statutory distinction generally is made between the mental states of knowledge and intent. Obviously, certain intoxicants, when used in certain ways by certain persons, affect certain cognitive, emotional, and behavioral functions in certain ways. Defining, distinguishing, and presenting these to the jury in nontechnical, readily intelligible language is the responsibility of the addiction expert. Successful communication of these clinical complexities to the jury by the expert is the cornerstone of a viable intoxicant-based defense.

Despite limited recognition by the courts and society that some degree of exculpation might be warranted in cases where an intoxicant-involved person commits a crime, neither the exculpatory doctrine of the common law nor modern statutory laws dealing with intoxication and related mental defenses has been even moderately satisfactory or equitable. One important reason for this is that both the exculpatory doctrine of the common law and our modern statutory laws were based on very early medical observations and common lay experience with the effects of alcohol. Despite the wealth of scientific knowledge about the specific cognitive, emotional, and behavioral effects of all the intoxicants, the substantive criminal law in this area has evolved very little and still reflects its alcohol-informed heritage.

The implicit public policy in the prevailing law reflects society’s historical vacillation and expedient compromises between the punishment of intoxicant-influenced offenders in complete disregard of their condition (i.e., viewing them as ordinary criminals) and the total exculpation often suggested by the clinical evidence (i.e., viewing them as patients).

Intoxication as a Defense

Today, the effect of intoxication on criminal responsibility is well established but only precariously settled. At law, intoxication can be either (a) involuntary, where the intoxicant is ingested as the result of force or duress (42), deceit or trickery (43), medical advice (44), or lack of awareness of a susceptibility to a recognized atypical reaction to that substance (45), as in pathologic intoxication; or (b) voluntary, where the intoxicant is ingested for effect, as in recreational drug use. Many jurisdictions have recognized involuntary intoxication as a complete defense to criminal behavior in appropriate circumstances. Most jurisdictions, however, adhere to the view

that voluntary intoxication does not excuse a criminal act unless the actor, because of his intoxication, could not form the intent required in the statutory definition of the crime. That is, voluntary intoxication may be raised to negate an element of an offense. Unfortunately, neither the distinctions between voluntary and involuntary intoxication nor those between general and specific intent are clear or consistent. See Ref. 41 for a review of intoxication-based defenses (§4.10).

In cases involving the ingestion of intoxicants, courts have consistently applied the same rules of analysis, mitigation, and exculpation derived from the common law and developed to deal with alcohol intoxication (46). One notable exception was expressed in the dissenting opinion in *State v. Hall* (47), which argued that drug and alcohol intoxication ought to be distinguished, and that “[o]ur intoxication rationale as applied to alcohol simply does not fit the use of modern hallucinatory drugs; and it was never meant to” (47, p. 213). Similarly, most legal commentators have not distinguished intoxication resulting from the ingestion of alcohol and from the other classes of intoxicants (48,49). In 1980, this problem was addressed in a remarkably comprehensive law review article (50). This scholarly commentary (a) examined in detail the specific effects of all of the intoxicants then in general use, (b) reviewed the traditional and prevailing legal reasoning on intoxication and intent, (c) discussed the resultant implications for intoxicant-based defenses against criminal responsibility, and (d) concluded with a recommendation that “. . . either the court or the legislatures must increase their expertise in these areas and respond to these potentially serious flaws in the criminal legal system” (50, p. 1145). Despite having been extensively cited in subsequent cases, its well-reasoned proposals have yet to be implemented. The criminal law continues to fail or refuse to recognize the fundamental differences between the effects of alcohol and those of other intoxicants (most importantly, cocaine) on human cognition, emotion, and behavior (51–53).

The law views alcohol as a neural depressant and disinhibitor that releases (cognitive and moral) inhibitions, thereby setting free ill-defined drives and putative “bad” impulses and traits, which are subsequently expressed in a criminal act. An analogy echoing through many judicial opinions regarding the mechanism of intoxication states: “drinking alcohol is like taking your foot off the brake [of a car].” Although this may not be an entirely ill-informed metaphor, it is surely an inadequate one, for it implicitly maintains that alcohol effects are stable, predictable, and consistent both across and within individuals. When applied to other intoxicants, this analogy is clearly out of touch with currently accepted principles of neuropsychopharmacology and the cognitive sciences. This disparity is most glaring for cocaine intoxication. After introducing the “removing the foot from the brake” analogy for alcohol intoxication for contrast, it is useful to explain to the jury that the effect of ingesting cocaine is better understood as being more like “stepping on the gas.” The outcome may be the same: The metaphoric car moves forward, that is, the person commits a criminal act, but the mechanism is entirely different. It has been suggested that in a sense cocaine

is that drug which supplies intent where otherwise there would have been none. Distinguishing the effects of cocaine (or other intoxicants) from those of alcohol is vital because it problematizes the legal concepts of intent and intoxication. This alone may lead the jury to find “reasonable doubt” about the defendant’s having the required state of mind.

Consider, as an example, the conceptual problem posed for a jury in a case where a polydrug addict with a long history of robbing drugstores to get drugs (not money) now robs a drugstore while grossly intoxicated from high intravenous doses of phencyclidine (PCP), heroin, and cocaine. Eyewitness testimony states that although he looked and acted as if intoxicated, the defendant also appeared to have acted with purpose. His actions clearly demonstrated that he “knew” (at least) the following: (a) to rob a pharmacy (as opposed to, say, a grocery store) to get drugs; (b) which specific (desirably intoxicating) drugs to steal; and (c) how to commit a robbery and get to the controlled substances in the safe. In this scenario, it would be nonetheless possible that the extent and specific effects of the polydrug intoxication had rendered the defendant incapable of forming the specific intent required as an element of the offense of robbery in that jurisdiction. To succeed in negating the elements of the offense of robbery, the defense would have to introduce expert testimony to attempt to explain at least the following: (a) that his “intent” was to get drugs, not specifically to commit the crime of robbery; (b) that his intoxication precluded him from forming the specific intent required for robbery, but (c) that the intoxication did not affect his previously well-learned (“overlearned”) knowledge about intoxicating drugs and about how to rob drugstores. For such expert testimony to be accepted by the jury, it would need to tie together (a) the defendant’s intoxicant history, (b) the specific effects of each intoxicant influencing the defendant at the time of the robbery, (c) his prior experience in robbing drug stores, and (d) the specific facts of the instant case.

Dependence as a Defense

Dependence on an intoxicant or active intoxication, absent more, does not provide a complete defense in any jurisdiction (54,55). The nature, course, and effects of dependence on specific substances on cognition, emotion, or behavior have not been recognized by the law.

Interestingly, opioid intoxication (but not dependence) may be of such extent as to negate the “knowingly” element of criminal intent. But neither opioid intoxication nor dependence has been held to negate the “willfully” element of criminal intent. Intoxication (but not dependence) induced by any substance may be sufficient to render a person incapable of the “deliberation” or “premeditation” required as an element of a specific degree of an offense, as in first-degree murder. In no jurisdiction has dependence on specific intoxicants been differentiated from that of alcohol, thereby warranting special consideration.

Until recently, attempts to use dependence as a defense to criminal responsibility were couched in terms of insanity, by characterizing dependence or addiction as a mental disorder

that rendered the defendant insane and therefore not criminally responsible. For the most part, these attempts have been unsuccessful. In 1984, *United States v. Lyons* held that henceforth no defendant could base any defense of insanity on the claim that he lacked substantial capacity to conform his conduct to the requirements of law, supporting that opinion by citing “the present murky state of medical knowledge” about human volition (56).

A novel defense of “medical necessity” proposed in 1985 by Uelmen and Tennant sought to present addiction not as a mental disorder but, by reason of its involving a putative endorphin deficiency, as a physical condition requiring medical treatment (57). Analogizing the situation of the addict to that of the diabetic, the defense of “medical necessity” sought to conform to the contours of the well-established defenses of duress or necessity. Uelmen and Tennant suggested that “obviously, the legal profession is sleeping through the current revolution in Biochemistry” (57, p. 6). Although inconsistently successful in minor cases involving possession of small quantities of marijuana by persons using that substance to alleviate the symptoms of glaucoma (58), multiple sclerosis (59), or spasticity (60), the defense of “medical necessity” has otherwise been rejected by the courts. Many cases in which this novel defense was rejected relied upon the early case of *United States v. Moore*, which pointed to “the choice that each addict makes at the start as to whether or not he is going to take narcotics and run the risk of becoming addicted to them” (61).

Withdrawal as a Defense

Defenses based upon the argument that the criminal act at issue was the direct or indirect product of withdrawal from an intoxicant have not prevailed, except in the limited and infrequent circumstance where a defendant in withdrawal commits an act while semiconscious or unconscious. An action that, while purposive, is not spontaneous, and therefore is not voluntary, is defined at law as an “automatism” and does not incur criminal responsibility. See Ref. 41 for a discussion of the utilization of automatism in a criminal defense (§4.9).

Intoxicant-Induced Insanity as a Defense

An insanity defense asserts that at the time the accused committed the act for which he is charged, a mental illness precluded him from having the required bad state of mind to be convicted of the act. The insanity defense has been a part of English and American jurisprudence for several hundred years. It reflects a shared belief that only those individuals who have chosen to commit wrongful acts should be punished, and that those without the capacity to appreciate the wrongfulness of their conduct should be absolved. The roots of the insanity defense are ultimately embedded in the Judeo-Christian tradition of linking moral responsibility with punishment and absolution.

The elements of the legal definition of insanity that predominates today were shaped primarily by two famous cases: the 1843 English case of Daniel M’Naghten (62) and the 1982

acquittal of John Hinckley (63), who had shot President Reagan. In both instances, the public outcry over the successful employment of the insanity defense as it existed at those times resulted in a substantial conceptual redefinition and limitation of the availability of the defense. Most notably, the federal 1984 Insanity Defense Reform Act (18) and the Comprehensive Crime Control Act of 1984 (64), which followed in the wake of Hinckley’s successful defense based on a legal test for insanity then in wide use, eliminated many types of mental illness as bases for a defense and reinstated the strict cognitive test of insanity set forth in M’Naghten (62). Temporary insanity caused by voluntary intoxication does not meet the requirements of the 1984 Act, nor does intoxicant dependence, absent more (65). However, where the insanity caused by the chronic use of intoxicants endures beyond any period(s) of intoxication, it may insulate a defendant, provided the resulting insanity otherwise conforms to the requirements of the 1984 Act (19, §§3:13;41, §§4.10(g)). Interestingly, neither intoxication nor dependence has been recognized as a uniquely aggravating factor to an antecedent or concurrent mental condition that by itself would not render a defendant insane as defined in the 1984 Act.

Insanity that arises from either acute or chronic intoxicant use has not been distinguished from insanity produced by other causes. Thus, whether temporary insanity caused by voluntary intoxication will be exculpatory largely depends on the legal test for insanity used in that jurisdiction. Several states have statutorily excluded this defense.

The Concept of Partial Responsibility

Partial responsibility, or diminished capacity, is a difficult and muddled concept in the law, with little coherence or consistency. Many courts appear to reject or not understand it.

Insanity of the legal type is considered a complete defense to criminal acts in most jurisdictions. A mental disorder that constitutes “something less than insanity” is not considered a complete defense to a crime, but is widely thought to lessen the degree of criminal responsibility, at least for crimes where there is a lesser degree of responsibility or severity available (as in murder, which might be reducible from first degree to second or a lesser degree). Today, mitigation, not exculpation, is the most common application of the concept of diminished capacity (19, §§3:16).

Argument asserting diminished capacity can also be made when a defendant claims that a mental illness precluded him or her from having the mental elements required for the crime. That is, because of a mental disorder, the severity of which did not render the defendant insane as provided by the test for insanity employed in that jurisdiction, the defendant nonetheless was unable to have committed the crime as charged because the defendant’s mental disorder prevented the defendant from having the statutorily required elements of the offense charged (e.g., acting with “malice” or “premeditation”). That the effects of specific intoxicants can reach this threshold may be an undisputed clinical “fact”; nonetheless, courts continue to resist its acceptance (66).

Many states disallow any evidence of diminished capacity to be admitted during trial. By public referendum, the California Penal Code eliminated diminished capacity as a defense, but retained its availability as a mitigating factor (67). In *Bethea v. United States*, the court expressed the now widely held view that embracing the concept of diminished responsibility would lead to an unacceptable “sliding scale of sanity in criminal responsibility” (68). Moriarty provides an elegant analysis of the concept and a comparison of the positions taken by the American Bar Association, the federal courts, and the various state courts (19, §§3:19–21).

Intoxicant Use and Effects as Mitigating Factors

Although many states now require judges to adhere to legislatively prescribed sentencing guidelines, in some jurisdictions judges have retained limited discretion to consider a convicted defendant’s complete drug history (including intoxication and dependence) as a mitigating factor. However, it is a general rule that the nature, extent, and effects of the intoxicant history must be introduced into evidence before being eligible for consideration at sentencing. There are marked differences between jurisdictions regarding the type of evidence (expert testimony, corroborating witnesses, etc.) required or admissible to establish the extent and effects of intoxication in support of mitigation.

Under the current Revised Federal Sentencing Guidelines, a federal judge may exercise a downward departure from the legislated guidelines for sentencing based on “diminished capacity” except where it is the result of voluntary intoxication with any substance (69). Nonetheless, in some federal jurisdictions, “addiction” has been accepted as evidence of diminished capacity and therefore as a basis for granting a downward departure at sentencing. This is the exception, however, not the rule.

THE ADDICTIVE PROCESSES

The concept of behaviors involving addictive processes, rather than intoxicating substances, as in “compulsive” or “pathologic” gambling, is of exceptional theoretical importance for the criminal law and the addictions field (70,71). The concept has required a reexamination of many fundamental legal postulates, precedents, and assumptions about criminal responsibility and intentionality. If viewed as addictive disorders (as in “compulsive gambling”) in which no exogenous intoxicating substance is ingested, such processes raise profound questions about the paradigms that inform research, theory, and practice in the addictions field. If viewed as impulse control disorders (as in “pathologic gambling”), these processes raise difficult questions about the causal and temporal relationships between a person’s impulses and the acts issuing therefrom (72). Unfortunately, in recent years, addiction terminology has been used to refer to everything from Internet usage (“Internet addiction”) to dedication to one’s career (“workaholic”), thus lessening its applicability and meaning with respect to physiologic addictive disease. To lessen the potential for difficulties, precise usage of terminology is called for.

Pathologic Gambling

Burglass has reviewed in depth the rationale, process, conceptual problems, and practical implications of introducing dysfunctional gambling behavior in defense or mitigation of criminal responsibility (72). One critical step toward the resolution of the conceptual problems would be for the field to formulate a classification of pathologic gamblers and the situations relevant to their behavior(s) that would be defensible empirically and relevant to the issue of criminal responsibility. For example, pathologic gamblers who commit crimes would be either normal or diseased, and their gambling behavior at the time of the commission of the crime charged would be pathologic in various degrees (72). Unfortunately, no such classification schema has been proposed.

What we find in the fact patterns of cases involving pathologic gambling is not a total or even substantial incapacity to carry out simple (or even complex) acts that can be reasonably attributed to the “disease.” Nor do we find such a compromise of intellectual function as to entirely exclude purposeful conduct. Instead, we observe an apparent blunting of ethical sensitivity sufficient to destroy the understanding, appreciation, or regard for the moral quality of the criminal act, combined with a drastic, often protracted, lapse of inhibition. Rarely do we find a lapse of conscious awareness of the criminal act itself. Because pathologic gambling is a chronic disorder with a recognizable natural history (73,74), these mental elements typically can be identified before, during, and after the crime is committed. In this sense, the problem behavior seen in pathologic gambling is more like a process than like a state. In its effects, it more closely resembles “insanity” of both legally recognized varieties—the inability to distinguish right from wrong or the inability to resist an impulse—than it does any state of intoxication. Before being widely rejected, the “capacity to conform” test for an insanity defense highlighted the problem of defining a “mental disease or defect.” The *Freeman* court held that “an abnormality manifested only by repeated criminal or otherwise anti-social conduct” was not a disease (65, p. 625).

Clinical and Forensic Distinctions

It is recognized clinically that at least some compulsive gamblers who commit crimes are impaired physically and psychologically, and thus may be only partially responsible for their misconduct. In this sense, at law they resemble the inebriate, whose reason has been temporarily compromised; and for them the rules governing intoxication often seem more applicable than do those for insanity. Although they are only very rarely psychotic, and only a few may even be neurotic (73), they are nonetheless considered abnormal by many clinicians (74,75), even though in ways of questionable relevance. Hence, for this subgroup of “impaired” compulsive gamblers, neither complete exculpation nor full responsibility seems appropriate. One might argue that as applied to pathologic gamblers who commit crimes, the legal rules should be applied not in terms of lack of intent, but in terms of lack of

understanding of the ethical quality of the act and/or the ability to control behavior. But the legal rules have not adopted this view. As noted by Strassman, “[t]he link between compulsive gambling and a criminal offense is too tenuous to permit the court to find that the defendant lacks substantial capacity to conform his behavior to the requirements of the law as a result of his compulsive gambling disorder” (76, p. 201).

It must be conceded that many (possibly most) compulsive gamblers accused of crimes are simply persons who gamble to excess, not helpless victims of a “disease” of gambling that drives them to crime; and that such individuals should be accountable for their actions and the consequences thereof.

In practice, rather than raising an insanity defense, counsel for a pathologic gambler is more likely to attack the elements of the offense charged, arguing that the mental disorder of pathologic gambling rendered the defendant incapable of forming the specific intent requisite to the crime. *Wilson v. Commissioner* held that the defendant did not act “willfully” in filing an inaccurate tax return because his mental disorder prevented his forming a specific intent to violate the tax laws (77). For a comprehensive review of mental defenses in federal tax cases, see Ref. 78.

Most judges—unpersuaded by modern scientific knowledge—in exercising their broad discretion in evidentiary matters, hold many persons criminally liable even though they are clearly afflicted with recognized diseases. The general failure of pathologic gambling as a defense in most criminal prosecutions reflects precisely this point of view. Currently, governing case law in most, but not all, jurisdictions is based on *United States v. Shorter* (11).

The Implications of United States v. Shorter

In *Shorter*, Judge Greene clearly considered pathologic gambling to be an addictive disorder. He correctly identified the conceptual problem that arises when the state of mind caused by such disorders exists over a long period, during which time the disordered person commits one or more crimes but otherwise manages to behave in a controlled and rational manner (11). In such cases, the defense faces the daunting task of explaining how selected behaviors can be the substantially involuntary products of the intoxication or disorder, whereas other, relatively contemporaneous, behaviors need not be similarly affected. There is no satisfactory, unitary explanation for this. The elements of each offense must be analyzed in light of the facts of the case and the nature of the addictive process involved.

In *Shorter*, the judge also challenged the qualifications and legitimacy of clinicians specializing in compulsive gambling and refused to admit much of their testimony (11 [1985, p. 257]).

Sexual Addiction

In recent years, the diagnosis of “compulsive sexuality” or “sexual addiction” (79) has been offered as the basis for exculpation or mitigation in cases involving sexual, as well as

less obviously related, offenses. Some few courts have admitted expert testimony about this controversial condition. In no jurisdiction has such a defense prevailed, absent more. A number of courts have admitted a defendant’s alleged “sexual addiction” as a mitigating factor at sentencing. Limited treatment programs (most based on 12-step or other self-help principles) are available in the federal prison system and in that of most states.

Eating Disorders

There have been a few cases involving shoplifting and petty theft from groceries where an eating disorder (bulimia) was advanced as a defense. In none of these cases did the defense exculpate the accused. In two cases, after the defendants were convicted of the crimes charged, the sentencing judge recognized the eating disorder as a legitimate “mental disorder” that constituted a valid mitigating factor. Both defendants were sentenced to community supervision and service and to mandatory professional treatment instead of incarceration.

Compulsive Spending or Shopping

Recently, support groups based on 12-step principles and other self-help models have emerged for persons with the “diseases” of “compulsive spending” and “compulsive shopping.” Advocates in these movements have adopted or endorsed addiction-derived explanations, language, and treatment approaches for these problems. The application of an addiction paradigm to these behaviors is of dubious validity, and neither problem has been widely recognized as an addictive disorder by professionals in the field (80,81).

Criminal defenses based on the “diseases” of compulsive spending or shopping have been rejected by the courts. In a few cases involving petty theft and shoplifting, expert clinical testimony about these excessive behaviors, although admitted, had little mitigatory impact at sentencing. A very thought-provoking feminist analysis of kleptomania and “compulsive shopping” as sexual disorders diagnosed only in women has been advanced by Camhi (82).

THE EFFECTS OF INTOXICANTS ON MEMORY

Expert Testimony About the Memory of Witnesses

Human memory is a complex phenomenon. One would expect the literature on the effects of intoxicants on human cognition, particularly memory, to be extensive—it is not. In cases where the defendant has been accused by persons who are or have been drug involved, an expert must assess the potential impact of their intoxicant use on their credibility as witnesses. The focus must be on the effect of the relevant intoxicant(s) on memory and its constituent cognitive processes (34–36,83–85). Although Federal Rule of Evidence 704(b) prohibits expert testimony on whether or not a defendant had the state of mind required for a particular crime (a decision reserved for the jury), it does not

prohibit expert testimony about mental factors potentially affecting witnesses (20). To be an effective expert in this area, the addiction specialist requires a broad and deep understanding of human memory. Authoritative texts on research and theory about human memory written from both the clinical (86) and legal (19, Chapter 13) perspectives need to be studied closely.

Cocaine-Related Memory Dysfunction in Criminal Proceedings

Although any of the intoxicants can have potentially deleterious effects on selected memory functions, the effects of cocaine raise the most serious and frequent concerns (35,52,85,87,88). A significant number of today's large-scale cocaine trafficking cases are founded principally or solely on the testimony of alleged or self-styled coconspirators, who, more often than not, were themselves using large amounts of cocaine (and usually other intoxicants as well) during the period about which they will testify in great detail as to time, place, person, sequence, and events. In evaluating the credibility of such witnesses, it is critical to look for any possible effects of intoxicant use on their memory functions. It is always important and often productive to look for predicates and indicia of (cocaine-induced) confabulation that may taint their testimony. To establish the possibility that testimony may contain confabulated elements and therefore be subject to "reasonable doubt," it is necessary to assess the circumstances, frequency, extent, and detail of the witness's prior statements, depositions, narratives, or conferences with the authorities. Evidence of high-dose cocaine use, extensive "testimonial schooling" (19, §§13:18), and progressively detailed and inclusive recall provides a sufficient predicate for an addiction medicine expert to consider reasonably and responsibly the possibility that confabulation is present. See Ref. 19 for a discussion of the legal issues, problems, and concerns associated with witness confabulation arising from all causes (§§13:17–19).

The Phenomenon of Confabulation

Confabulation is a neuropsychiatric symptom that is characteristic of diffuse organic brain disease and/or dysfunction. It refers to the unconscious filling in of memory gaps by imagined experiences, fabricated stories, or grossly distorted accounts of recent or remote events. It is absolutely distinct from lying, which implies both motive and awareness of the distortion or untruth. Confabulatory recall is inconsistent; it may change from moment to moment; and it may be induced unwittingly by suggestion. Characteristically, isolated events and information from the past are retained in fragmented form but are at times related without regard for the intervals that separated these or for their proper temporal sequence. Sometimes, in confabulating, a person will telescope events, compressing time, thereby linking as cause and effect events that were widely separated in time and causally unrelated. These memory fragments may be cued, intentionally or unintentionally, during conversation (a) by suggestion, (b) by presentation of selected data about recent or remote events

as if it were unequivocal fact, or (c) by provision of a cogent, internally consistent narrative explanation of some situation or event. The dysfunctional brain, in an attempt to maintain consistency with this apparent "reality," may fill in any memory gaps with associative, derivative, or suggested data.

Confabulation is never a consistent finding in any clinical condition. It is most frequently seen in cases of severe, nutrition-deficient alcoholism, head trauma, cerebral hypoxia, certain heavy metal poisonings, certain infections of the central nervous system (e.g., herpes or HIV encephalitis), or high-dose psychostimulant use.

Cocaine-Induced Confabulation

Confabulation may be seen in two phases of high-dose cocaine use. During the acute intoxication phase, the profound confusion, grandiosity, emotional lability, false sense of mastery, illusions, delusions, and hallucinations occasionally can induce certain users to confabulate "in real time." During the convalescent phase, after a period of abstinence from cocaine, the person gradually recalls fragments of past experience (many of which may have been originally misperceived) in a distorted way. In an attempt to preserve logical consistency, these may be linked with confabulated material. The more often such confabulated material is ratified by the social setting and in particular by authority figures (e.g., physicians, attorneys, or law enforcement officers), the more likely it is to become a fully integrated and unquestioned part of that person's self-history. It even may go on to become the basis for future thoughts, conclusions, and actions.

Although the U.S. Court of Appeals for the Sixth Circuit upheld the disallowance of such testimony in *United States v. Ramirez*, finding that such testimony went to the credibility, not the competence, of a witness (14), the exclusion of such testimony by a qualified addiction expert has been the rare exception, not the rule. A transcript of the direct and cross-examinations of the author about the effects of cocaine on the memory (confabulation) and credibility of a witness in a cocaine conspiracy case can be found in Ref. 19 (Appendix 3E).

REGULATORY AND ADMINISTRATIVE PROCEEDINGS

Members of licensed, regulated, or otherwise supervised professions (e.g., health care professionals, attorneys, airline pilots, interstate truckers) can find their licenses at risk for a number of reasons involving intoxicants. Two, however, are of exceptional importance and are discussed here: (a) allegations of "impairment" consequent to intoxicant use, and (b) for physicians, allegations of the "inappropriate" prescribing of opioids for the long-term management of chronic nonmalignant pain. In cases involving professional impairment, Burglass has identified two fundamental and very serious medical–legal issues: (a) the common presumption that "use equals abuse equals addiction equals impairment" and (b) that only a few regulatory agencies (e.g., the Federal Aviation Administration for pilots and the Department of

Transportation for interstate truck drivers) have normative data defining the cognitive, sensory, or motor skills required of a normal, that is, a “nonimpaired” practitioner (89,90). With the exception of the blood alcohol concentration, which, as a matter of public policy, has been adopted in every state as an objective, affirmative indicium of impairment for the operation of a motorized vehicle, there are no similarly established norms for any other intoxicants, nor for alcohol-mediated impairment in other contexts.

Characteristically, these investigations and prosecutions of professional impairment are undertaken in the name of public health and safety. However, the ill-specified nature of these causes, and the zeal and fervor with which intoxicant regulatory activities are pursued, have led some observers to characterize our present food and drug laws, all medical and scientific justifications aside, as ultimately religious in intent, purpose, and effect, that is, as being, in effect, the dietary and liturgical laws of the modern secular religion of science (2).

Professional Impairment

In the assessment of professional impairment, regulatory policies do not reflect the clinically significant, specific differences between intoxicants in terms of their effects, patterns of use, routes of administration, nature of the dependence and/or withdrawal syndromes (if applicable), or resultant substance-related disabilities. Although there are a few regulatory and legal cases where (limited) consideration was given to these crucial distinctions, such deliberations are clearly the exception, not the rule.

All too often the proverbial deck is stacked against the accused professional, who, upon being accused of even the mere use of an intoxicant, is presumed to be impaired consequent thereto. Contrary to the traditions of Anglo-American jurisprudence, the accused professional then has the effective burden of proving his or her “innocence” in the face of the presumption of guilt. These prosecutions are invariably legitimized and justified as necessary to protect patients or clients, institutions, or professions from the harmful actions of impaired practitioners. But in practice, the hearing panels are often biased, punitive, and easily influenced by professional or institutional interests and politics. Even the isolated or occasional use of an intoxicant is often conflated with impairment, and harsh sanctions are imposed. If the accused admits to any use of intoxicants, impairment is usually presumed. If the accused denies use of intoxicants, the conclusion that accused is in “denial” will likely be drawn and considered as evidence of “addiction” and, consequently, of “impairment.”

Of course, some intoxicant-involved professionals are impaired and in need of treatment until they are able to resume practicing with the skill and safety required in their profession. In recent years, a virtual industry for the diagnosis and treatment of “impaired” professionals has emerged. One can detect therein a disturbing propensity to conceptualize and treat professional “impairment” as if it were itself a distinct disease entity; it is not (89,90). The determination of intoxicant-related impairment in professionals is a very

complex assessment that requires extensive input from independent, unbiased addiction medicine specialists throughout the process. If injustices are to be avoided, specialists in addiction medicine must be willing to become involved in these unpopular and often unsavory cases. They need to offer expert testimony that (a) obligates the regulators (clinically, ethically, and legally) to recognize and consider all relevant intoxicant-specific distinctions and (b) requires the regulators to “prove” their case for impairment by specifying and quantifying the alleged deficiencies or disabilities of cognition, emotion, behavior, or professional skill that define the accused as impaired when measured against the standards of performance, skill, care, and safety required for professional practice in that jurisdiction or context.

As if this entire area was not already sufficiently troubling, Ackerman has identified an ominous trend toward requiring physicians who have been treated for chemical dependency to make informed consent disclosure to all patients (91).

Prescribing Opioids for Pain in Private Practice

Each year the prescribing profiles for controlled substances (class II opioids, in particular) of thousands of physicians are routinely (often automatically) monitored, sampled, or otherwise scanned, and evaluated by state regulatory bodies (92,93). Despite the dubious ethics and questionable purposes/efficacy of such monitoring programs, these practices are increasingly being “justified” by state regulatory bodies in the name of public health and safety, which are (presumptively) privileged over issues of individual privacy and confidentiality. The legal authority for these actions and the regulation of opioid prescribing for pain is provided by health (medical) practice acts legislated at the state level and by federal and state acts governing the use of controlled substances. Hundreds of physicians whose prescribing profiles are deemed “questionable” are then more thoroughly investigated. Such investigations and prosecutions may be initiated by even the brief treatment of a single patient! Of course, there are physicians whose prescribing of opioids is clinically inappropriate and/or unethical. Some in this group simply lack adequate current knowledge about the indications for opioid analgesia and/or the rational choice of appropriate opioid agents. Others are motivated by simple greed or sexual interest. Others are innocently duped, manipulated, or otherwise pressured by cunning and/or demanding patients. Regulatory agencies, in the main, have adequate procedures and appropriate sanctions to deal with these groups of physicians. Review of regulatory programs and new opioid technologies for chronic pain management is presented by Fishbain and colleagues (94). What the majority of the state regulatory agencies lack are provisions and procedures for dealing fairly with physicians whose prescribing of opioids is not inappropriate and/or unethical. Indeed, most of the standards of practice governing opioid use are based on myths, prejudice, and misinformation about opioids, and the unexamined belief that mere exposure to these drugs invariably results in addiction in all patients. The prevailing obsession of regulators

with “police” activities intended to prevent diversion has blinded them to their coequal obligation to ensure adequate access to opioids for patients who require these drugs for legitimate medical purposes (93). Conscientious, compassionate physicians in the latter group face substantial forensic problems: (a) the investigatory process raises serious ethical questions of privacy and confidentiality for both the physician and the patient; and (b) the regulatory hearings not infrequently violate fundamental legal principles of due process. The language of most state medical practice acts is predominantly proscriptive in intent, overly broad and/or vague, and easily subject to misinterpretation (93). It is therefore not surprising that the majority of American physicians tend to be “opiophobic.” As a consequence, many legitimate pain patients are undertreated, mistreated, or not treated at all (95,96).

Although the use of opioids for the treatment of chronic nonmalignant pain remains the subject of sociopolitical controversy, clinical debate, and research (96,97), the validity and utility of the modality have been recognized and conscientious clinical protocols have been developed and implemented (98–101). When such protocols are used by pain specialists based in prestigious academic medical centers or dedicated pain treatment programs, the legitimacy, knowledge, and competence of the prescribing physician(s) are presumed, and regulatory problems rarely arise. The situation in private practice, however, is markedly different. In the latter context, legitimacy, knowledge, and competence are not presumed. The physician in private practice who is charged with the “inappropriate” prescribing of opioids effectively bears the burden of establishing his or her “legitimacy” and proving that the questioned use of opioids was in fact clinically appropriate and/or otherwise in keeping with applicable standards of care and practice. Sadly, state regulators have little difficulty finding addiction medicine experts who do not hesitate to condemn the opioid prescribing practices of knowledgeable and ethical colleagues as “inappropriate” and/or “substandard.”

Each year, dozens of well-informed, well-intentioned physicians are formally charged with violation(s) of a state medical practice act for having “inappropriately” prescribed opioid drugs to patients for chronic nonmalignant pain. They then must defend themselves (and their licenses) in a formal, adversarial hearing process, not unlike a criminal trial. Because such regulatory violations do not in themselves constitute acts of malpractice, medical malpractice insurance rarely provides counsel or funds the costs for the defense of such matters. The accused physician therefore must fund his or her own defense, the cost of which can easily exceed \$100,000.

The two most frequent bases upon which regulators found allegations that a physician’s use of long-term opioid therapy for chronic, nonmalignant pain is inappropriate are that such therapy “creates addicts” and that opioid therapy is contraindicated in any patient with a history of substance abuse. Both assertions are highly controversial, and the underlying assumptions, concerns, and issues of both have been comprehensively examined and challenged by specialists in pain management and addiction medicine (102,103). Although a 1992 review of the literature revealed reported

prevalences of drug abuse, dependence, and addiction in chronic pain patients ranging from 3.2% to 18.9% (104), it has been suggested that the true prevalence of addictive disease in the chronic, nonmalignant pain population is unknown (105). In any event, every chronic pain patient being considered for long-term opioid therapy must undergo a comprehensive, multidimensional evaluation, which must include an analysis of their (a) pain (etiology, history, character), (b) prior experience with all modalities of pain management, including opioids, and (c) prior and current use of all classes of psychoactive drugs, prescribed or otherwise (105,106). The clinician in the pain clinic, private practice, or other settings must make a conscious effort to identify prior or current addictive disease, and must also attempt to identify those patients who are in active recovery (105).

For even the most-knowledgeable, best-intentioned, and best-prepared practitioner accused of opioid prescribing violations, exculpation is by no means assured, and ultimate vindication should never be assumed. However, documentation of the following material in the medical record often has proved to be the pivotal element in the successful defense of such cases:

1. A comprehensive evaluation and assessment of the etiology, history, and character of the patient’s pain.
2. Clinical records or summaries from the specialists or subspecialists who have diagnosed and treated the primary medical or surgical conditions thought to be producing the patient’s pain.
3. An appropriately executed (signed, witnessed, and notarized) document of the patient’s “Informed Consent to Treatment with Opioid Drugs.” Because the law on informed consent varies substantially from state to state and is subject to increasingly frequent review and revision (107), this critical document must be drafted in close consultation with an attorney who is experienced, and absolutely up-to-date in this area of the law. Moreover, the trend in the law of informed consent is in the direction of requiring increased specificity about alternatives and risks, broader comprehensiveness, and clearer evidence of the patient’s practical understanding of both the proposed treatment and the meaning of the signed document of consent.
4. Frequent multidimensional assessment and documentation of the efficacy of opioid therapy, the absence of drug toxicity, and the absence of indicia of “addiction” (including periodic urine toxicology screening). Multidimensional assessment of the frequency and distress illuminates the impact of symptoms and the efficacy of treatment on a patient’s quality of life (108).
5. Annual (or more frequent if indicated) “Letters of Indemnification” from an appropriate surgical or medical specialist stating that the specialist has reexamined the patient found that the underlying medical or surgical condition is still present and/or unchanged, that there have been no treatment innovations or technological breakthroughs from which the patient might be expected to benefit, and that therefore continued management of the patient’s pain is clinically justifiable.

6. If the physician prescribing the opioids is not a credentialed expert or specialist in either pain management or addiction medicine, letters of consultation from a specialist in both of these areas are essential. Moreover, even if the prescribing physician is an expert in one of these two areas, a consultation letter from an expert in the other area is critical. These consultative reports should be updated at intervals appropriate to the patient's underlying diseases and/or reflective of the results of the regular multidimensional assessments described previously. Thus, patients who have exhibited behaviors that might be construed as "drug-seeking behavior" will need to be more frequently assessed by an addiction medicine specialist. Patients whose response to opioid therapy is untoward or inadequate (in terms of enhanced function and comfort) will require more frequent evaluation by a pain specialist.

Despite the application of scrupulous clinical "due diligence" and the maintenance of thorough, ongoing documentation, the use of long-term opioid therapy in patients with chronic nonmalignant pain is still fraught with potential pitfalls. Although articles in law reviews and clinical journals can provide insightful overviews of the policy and law governing the prescribing of opioids for pain (93,109,110), the interpretation and application of those laws by regulatory bodies change substantially from one case to the next. Therefore, for anyone who uses this treatment modality in private practice, knowledge of the current state of the law is absolutely essential!

To date, the attempt to define and control this complex area of medical practice by substituting regulations for clinical judgment has failed—resulting in grievous injustices for many practitioners and patients. The problem is neither "bad regulations" nor "incompetent regulators," and the solution is neither the drafting of more enlightened regulations nor the revision of biased regulatory procedures. The fundamental problem is that regulation is an inappropriate strategy for shaping policy and practice in this area. Clearly, a different approach is needed. The interests and concerns of all parties can be met by the promulgation of practice guidelines—specific, yet broad and flexible. Appropriate guidelines cannot possibly be formulated by bureaucrats, politicians, administrators, third-party payors, or any of the other marginally educated and/or nonclinically trained "watchdogs" of medicine and public health. The task demands comprehensive clinical knowledge and broad patient experience in pain management and addiction medicine. It needs to be an interdisciplinary, collaborative project initiated and directed by medical specialists in the fields of pain management and addictive disease. Fortunately, both fields are currently hard at work developing such guidelines. Input from practitioners (both specialists and generalists), as well as from patients, is being actively solicited and is an indispensable element of the process.

It is early yet to determine whether the availability of buprenorphine for the office-based practitioner will lead to significant legal difficulties. However, given the strict supervision being administered in terms of specialized Drug

Enforcement Agency (DEA) certification, specialized training requirements, and limitations on patient quantity, it is certainly likely to be a closely examined process.

Administrative Proceedings

The effects of intoxicants of different classes have not been differentiated in administrative hearings or other proceedings involving employment eligibility, benefits, restriction, discrimination, supervision, discipline, or termination. In these venues, as in professional regulatory contexts, the prevailing presumption reflects the false and dangerous syllogism that "use equals abuse equals addiction equals impairment" (89). Moreover, routine screening for intoxicant use in the workplace is technically problematic (111) as well as legally and ethically questionable (112). Well-established principles of administrative law procedure are often violated and fundamental legal rights (e.g., due process) often ignored. Despite their being treated like criminal "defendants," the accused in these proceedings are neither guaranteed adequate legal representation nor provided with the funds and resources (e.g., expert witnesses) necessary to present an adequate defense. Data and conclusions from questionably valid screening protocols and dubious testing methods and procedures often go unchallenged. It is vital that an addiction medicine specialist (preferably one with added qualifications as a Medical Review Officer) (a) reviews all of the technical data, (b) examines the accused to assess the nature and extent of any intoxicant-related problems or disabilities that might be relevant to job performance, and (c) provides testimony to the administrative review body to explain the meaning, significance, and implications of the findings. There is no other way to assure fairness for all parties.

Given the cultural prejudices about intoxicant use and the pressures on employers to maintain a "drug-free workplace," an employee who is accused of intoxicant use cannot safely assume that he or she will get a fair hearing or receive an equitable disposition. Addiction medicine specialists must be aware of these prevailing inequities. The need and opportunities for professional involvement in intoxicant-related matters of administrative law are great.

CONCLUSION

Forensic issues involving addiction psychiatry encompass a wide range of problems within a complex clinical and biopsychosocial context. Substance-related problems with forensic implications may range from problems originating from an occasional problematic use to substance use disorders, such as abuse or dependence and a vast array of substances. Areas of forensic psychiatry may involve criminal, civil and administrative, professional and monitoring issues. The forensic arena presents a set of specific definitions, requirements, and criteria that the addiction specialist experts should become familiar with, including the role, expectations, and the court's consideration and view of the latitude of the expert testimony throughout the different phases of the trial. The role of the addiction expert in Forensics has become essential, given the

expanding knowledge in the field of addiction psychiatry and substance use, the secular increase in the prevalence of substance abuse, and the periodic introduction of new trends of patterns and types of substance abuse. The multiplicity of conceptual problems in this field reflects the complexity of the historical and contextual social determinants that shaped these concepts over time. New discoveries in sciences and the interdisciplinary collaboration between the practitioners of law and the doctrines of jurisprudence and medical addiction sciences may ultimately help clarify these conceptual issues, although this may occur at what has been a slow pace. Practicing in the forensic arena presents a wide array of significant challenges for the addiction specialists; some of them, such as heightened adversarial role, are at odd with the predominant “helping” attitudes of the health profession. Other significant challenges include working within the constricting rules of criminal proceedings or facing ethical concerns, opinions, attitudes, and values. On the other hand, addiction experts, adhering to their role, may be instrumental in clarifying the many lingering stigmatizing misconceptions and help bring into focus modern concepts, based on knowledge and objective considerations, which would ultimately enhance the function of justice.

Clinical and Societal Implications of Drug Legalization

Benjamin R. Nordstrom ■ Herbert D. Kleber

INTRODUCTION

The costs of America's struggle with the consequences of drug addiction have been enormous. In 2007, an estimated 19.9 million Americans aged 12 or older (approximately 8% of the population) were current users of illicit drugs. In addition, 6.9 million Americans over the age of 12 were classified as having either abuse of or dependence on illicit substances. This figure has been stable since 2002 (1). Other estimates have held that approximately 3% of the U.S. population will meet criteria for dependence on an illicit substance at some point in their lives (2).

Costs Caused by Addiction

Some of the costs are intrinsic to the physical, psychological, and social consequences of drug addiction. The Office of National Drug Control Policy estimates that the total cost of drug abuse on society in 2002 was \$180.9 billion dollars including the costs of lost productivity, health care costs, and criminal justice costs (3). A study of children placed in foster care showed that 78% of the children came from homes where drug use was a primary reason for placement, and 94% of the mothers of infants in foster care had a history of drug use (4). Heavy and early use of marijuana in adolescence is associated with earlier onset of psychosis. Some drug-related crimes, namely those stemming from "behavioral toxicity" (i.e., disinhibition and poor judgment due to intoxication) are also a direct cost of addiction. Although it is impossible to get an accurate measure of exactly how much crime is caused by behavioral toxicity, it has been found that 27% of victims of violent crime state that their assailant was under the influence of drugs or alcohol at the time of the attack (5,6).

The intangible costs of addictions are well known to any clinician who treats these maladies. Addictions cause incalculable heartache, despair, and strain in the lives of those who have addictions, and in the lives of those who love them. Although it is impossible to monetize these harms, it is important to consider them in any discussion about the consequences of addictions.

Costs Caused by Drug Policy

Other costs are incurred as a consequence of the policies our society has put in place in response to perceived problems associated with drug use. Given that these costs must be

accounted for in government budgets, these costs are much easier to directly measure compared to the sort of estimation of costs seen in the previous section. Nationwide in 2007, approximately 13% of the 14,209,365 total arrests were for drug violations. Only 17.5% of drug-related arrests were for the sale or manufacturing of drugs. The remaining 82.5% of drug-related arrests were for the possession of illicit substances only (7). It has been estimated that of the \$38 billion spent on corrections in 1996, \$30 billion was spent incarcerating drug users or drug offenders (8). As many as 400,000 people are in jails and prisons on drug-related charges (9). Currently 52.2% of the offenders in federal prisons are convicted of drug offenses (10).

One of the consequences of making drugs illegal is that the cost of drugs rises. This makes drug habits more expensive to maintain, which could potentially lead to more crime. Those crimes that are committed to generate revenue with which to acquire drugs are called "acquisitive crimes."

In 2004, 17% of state prisoners and 18% of federal inmates reported having committed their current offense in order to get money to purchase drugs (5,6). During 2002, 68% of offenders in local jails were found to be dependent on or abusing illicit drugs. The same survey revealed that approximately a quarter of convicted property and drug offenders serving time in local jails had committed their crimes to get money with which to purchase drugs. Only 5% of violent offenders in local jails had similarly committed their crimes in order to purchase drugs (11). Although violent drug-related crimes are less common than nonviolent drug-related crimes, they pose a greater cost to society due to the effects that such crimes impose on their victims (12).

Among state prisoners, 30% of property offenders, 26% of drug offenders, and 11% of violent offenders had committed their crimes to obtain money with which to buy drugs. In federal prisons, 25% of drug users (but only 11% of property offenders) reported they had committed their crimes to obtain drug money (13).

Another feature of an illegal market is the absence of any legal manner to adjudicate disputes. Thus, when one feels mistreated in a drug transaction, one can either resign oneself to the situation or retaliate, including using violence. Such crimes that occur from such disputes in drug selling are called "distributive crimes." According to the Uniform Crime Report, approximately 4% of the total 14,831 homicides that occurred

in 2007 were coded as drug related (7). Distributive crime also includes dealers fighting other dealers in fights over turf.

There are intangible harms to our current drug policies as well. When a large number of people perform an act that is technically criminal, it reduces the legitimacy of the criminal code. Further, if arrest and incarceration are so common as to be routine features of life for certain families and communities, the stigma of violating social norms becomes reduced (14) and the bonds between a marginalized group and mainstream society are further weakened. A final intangible harm is the very large amount of suffering caused by long prison sentences, which disrupt families, relationships, and communities. Societal attitudes about drug use/abuse and the appropriate social response tend to go through cycles. Strong punitive responses calling for stiff penalties and prison instead of treatment are often followed by calls for relaxed enforcement, even legalization, and treatment instead of prison. We seem to be heading into that part of the pendulum swing. Occasionally the pendulum stops in the middle with a balanced approach of legal sanctions and treatment and prevention.

DEFINING TERMS

Discussions about drug control policy can be filled with similar-sounding jargon. To help facilitate this chapter, we are using the following definitions:

- *Legalization* means removing laws prohibiting the sale of drugs.
- *Decriminalization* means removing drug-related offenses from the criminal code, while maintaining the illegality of drug use. Speeding and parking violations are examples of behaviors that are illegal without being criminal.
- *Depenalization* means reducing the severity of penalties for drug-related offenses.
- *Harm reduction* means accepting that irrespective of policy remedies, drugs will cause a certain amount of harm to the individual and to society, and that sound public policy should be based on reducing the amount of that harm rather than reducing use.

However, some have argued that harm reduction should be parsed into two forms: micro-harm reduction and macro-harm reduction (15). Micro-harm reduction means reducing the harm per unit dose of drug, while macro-harm reduction means reducing aggregate harm caused by use of the drug. Thus, testing illicitly sold MDMA tablets (Ecstasy) at a dance club to ascertain the safety of their contents would be an example of micro-harm reduction. However, if this led to a greater sense of safety among potential tablet buyers, and more people were thus emboldened to participate in that drug market, this safety check could be inimical to macro-harm reduction. In other words, macro-harm reduction takes into the account the inherent danger in the drug and the prevalence of use. It has been noted that when people who favor legalization speak of harm reduction, they usually mean micro-harm reduction (16).

This chapter is not meant to be a thorough exposition on drug control policy as a whole. We will not take on the broader topic of comprehensive drug policy reform.

The relatively narrow focus of this chapter is on the clinical and societal implications of legalizing drugs.

PHILOSOPHICAL CONSIDERATIONS

It would be impossible to write about the consequences of legalizing drugs without mentioning the philosophical bases from which parties approach this issue. These philosophies basically break down into two broad categories: deontologic and consequentialist.

Deontologic arguments take their name from the Greek *deont*—“it is necessary.” These arguments are based in abstract notions of right and wrong. For the purposes of a discussion about drug legalization, there are two main types of deontologic arguments. The first of these are the moralistic arguments that drug use is fundamentally wrong and should be opposed on this ground. The sociologist Howard Becker writes of how when marijuana use was increasing in the middle part of the 20th century, “moral entrepreneurs” stigmatized the behavior and made a moral case for making marijuana illegal (17). There are also deontologic arguments for legalizing drugs as well. An example of such thought can be seen in the platform of the Libertarian Party, which writes: “Only actions that infringe on the rights of others can be properly termed crimes. We favor the repeal of all laws creating ‘crimes’ without victims, such as the use of drugs for medicinal or recreational purposes.” (18).

Consequentialist philosophies are more concerned with the consequences of, rather than the motives behind, a given policy. A form of consequentialist thought that is widely known is utilitarianism, which postulates that sound policy maximizes the best result for the largest number of people. Consequentialist thought forms the basis of much of our public health law. As this is a textbook for clinicians and not moral philosophers, we will limit our discussion of American drug control policy to consequentialist orientations. Although many people do oppose or support drug legalization for purely ideological reasons, we are not prepared to debate the strengths and weaknesses of these perspectives. Our discussion will only focus on how drug legalization would affect utility for the population as a whole.

THEORETICAL BASIS FOR LEGALIZATION

Consequentialist legalizers believe that, as harmful as addiction may be to individuals, the effect of policies attempting to control drug use lead to unintended consequences that are worse than what is likely to follow were drugs legalized. They note that because there will always be a demand for drugs, there will always be a supply of drugs. They speculate that efforts to reduce or control supply and demand are therefore illogic, create more harm than good, and are doomed to fail anyway. Moreover, a common feature of legalizer ideology is that once the drug trade is legalized it will be able to be taxed

in such a way that sufficient revenue will be generated to offset the costs of the social ills that would follow from a hypothesized increase in the prevalence of addiction (19,20).

THEORETICAL BASIS FOR DRUG PROHIBITION

David Courtwright lists five reasons societies have historically objected to nonmedical drug use: (1) the drugs cause direct harm to the users and others, (2) the drugs cause unjustifiable social costs, (3) religious disapproval, (4) the drug is associated with a deviant or disliked group, and (5) widespread use of the drug endangers the future of the society (21). With respect to Courtwright's fourth point, the role outright racism played in various national moral panics that have been associated with drug control legislation has been noted by other authors as well (22,23). Insofar as racism was endemic to much of public thought in America at the time many of the first drug control laws were promulgated, it is not surprising that racism entered the discourse on drug policy.

Although Courtwright accurately describes the *historical* roots of drug prohibition, the *current* prohibitionist regime can be viewed as an attempt to limit or prevent drug addiction in the population. This can be viewed as a public health prevention effort in addition to a law enforcement endeavor. Empirically, we know that a certain small percentage of people who try any given drug will go on to develop an addiction to that drug. For example, 17% to 22% (snorting vs. smoked) of people who try cocaine will go on to develop a dependence syndrome to it. Similarly, about 23% of people who try heroin will become addicted. Conservatively, 9% to 10% of people who try cannabis will become addicted to it. Approximately 15% of people who try alcohol will become alcoholics, and 32% of people who try cigarettes will become nicotine dependent (24).

In order to limit the prevalence of drug addiction in the population, drug prohibition attempts to make the incidence of drug use as low as possible: the fewer people who try a drug even once, the fewer people who will become addicted. The logic behind this perspective is brought into relief when considering the societal implications of the legal status of alcohol. Even though the risk of getting addicted to alcohol is less than the risk of getting addicted to other drugs, the burden of suffering imposed by alcohol is much higher than that for cocaine, owing to the widespread prevalence of alcohol use and, therefore, dependence.

The decision to use drugs is influenced by a number of factors. First, the drug must be physically available. Second, the drug must be financially available, that is, it cannot be used if its price point is outside of the purchasing power of its intended market. Third, the person must have some curiosity or desire to use the drug. Fourth, there has to be a relative weakness in controls to *not* use the drug. These controls can be formal, such as police observation, or informal, such as an unacceptable social stigma for using the drug, for example, the Mormons' prohibition on alcohol and tobacco use.

As previously noted, legal prohibition attempts to disrupt the supply of drugs, causing the cost of the drug to in-

crease. Also, legal prohibition assigns a criminal and social stigma to drug use. By increasing the cost of the drug in both economic and social terms, legal prohibition attempts to keep the demand for drugs lower than they would be in an unfettered marketplace. Attempting to prevent the initiation of any drug use is an example of primary prevention while the attempt to prevent occasional drug use from progressing into a dependence syndrome is an example of secondary prevention (25).

Legal prohibition also encompasses elements of tertiary prevention as well. Tertiary prevention is concerned with limiting the effects of a disease once it has already taken root (25). Prohibition allows for programs such as drug courts, Drug Treatment as an Alternative to Prison (DTAP), and Treatment Alternatives for Street Crime (TASC). These kinds of program use the authority of the criminal justice system to leverage addicts into drug treatment and, hopefully, abstinence. Also, legal prohibition helps keep informal social controls at maximum strength, which gives leverage to family members, employers, and friends who are attempting to get a substance abuser into treatment.

In short, consequentialist prohibitionists believe that the sum of the harms caused by prohibition are less than the sum of the harms that would be caused were the prevalence of addiction to rise when the controls on it are removed. Legalizers of the consequentialist variety believe the exact opposite. They hold that the current regime is causing so much harm that outright legalization of drugs would cause a net decrease in the burden of suffering in society. As drug legalization does not exist anywhere in contemporary America so its effects can be studied, neither side can assert its position with total certainty. Given the logistical and political constraints, it is unlikely that we will ever see a randomized controlled trial of drug legalization in this country. There are, however, important lessons that can be learned from studying economic models, our own country's past experience with drug policy as well as by paying attention to the experience of other countries.

ECONOMIC MODELS

Demand for a commodity is said to be "elastic" if it decreases as the price increases. Demand is said to be "inelastic" if it does not decrease as price increases (26). Therefore, the demand for novelty T-shirts is likely to be relatively elastic, while the demand for sewage removal is likely to be relatively inelastic. Drug prohibition is partially based on the rationale that increasing the price and risk associated with drug use will discourage consumption (27)—that is, that demand for drugs will be elastic.

There is evidence from laboratory studies of drug self-administration in nontreatment seeking drug users that implies that demand for drugs is relatively elastic. These studies offered subjects the choice between a dose of their drug of choice and money. As the magnitude of the alternative monetary reinforcer and/or the dose of drug decreases, the frequency of the choice to use drugs diminishes (28–33).

Working from data from the National Household Survey of Drug Abuse and the Drug Enforcement Agency's System to Retrieve Information from Drug Evidence (STRIDE)—which collects information on drug price and purity—economists Harry Saffer and Frank Chaloupka created models to investigate the relationship between drug use and price (34). They found that heroin and cocaine both showed elastic demand and that if they were legalized, heroin consumption would double and cocaine consumption would increase by 50%.

Another model was constructed using data from the Monitoring the Future survey of high-school drug use and the STRIDE data set (35). The researchers found that demand for cocaine among high-school students was very sensitive to price. Interestingly, they also found that decriminalizing marijuana did not affect marijuana use, perhaps because enforcement tends to be very lax.

In sum, the economic data show that, as with virtually any commodity, demand for illicit drugs is sensitive to price. While prolegalization advocates are certainly correct that there will always be a demand for illicit drugs, *how much* demand there will be is at least partially dependent on the supply of the drugs in question. Importantly, the economic models imply that this is especially true for youth. There are recent suggestions, for example, that as the price of heroin in New York market has become cheaper, some adolescent abusers of prescription opioids are switching from them to heroin.

HISTORICAL PRECEDENTS

Pre-Harrison Act

It is important to note that all manner of drugs used to be legal in this country. The Harrison Act, passed in 1914, was the first national law that outlawed the unfettered access to drugs such as cocaine, heroin, and morphine. The historian David T. Courtwright has described the pattern by which drugs (including distilled spirits, tobacco, opioids, cocaine, and amphetamine) are first used in medical practice for specific conditions, but once the drug is in the patients' hands, the medical use spreads into using the drug to treat an ever-increasing list of ailments, and soon social experimentation and later addiction follow. Once social use and addiction begin to manifest, agents of social control (e.g., law enforcement and legislators) take notice and begin to take steps to limit the availability of the drug (21). Two recent examples include the long-acting opioid Oxycontin and stimulants such as Ritalin.

At around the turn of the previous century the modal drug addict changed from the largely sympathetic image of a middle-class woman addicted to the opiate in a patent medicine to a frightening specter: cocaine and heroin using young, inner-city men, and racial or ethnic "others" (22,36,37). This shift in the demographics of drug users was partly made possible by advances in organic chemistry which allowed for the ready extraction of powerful alkaloids from

the coca plant and the opium poppy, as well as by the invention of the hypodermic needle (21). Although record keeping from the era is less than adequate, there are data that the legalization regime produced a large number of addicts (22) and that these addicts frequently turned to crime to finance their legal habits (9,23,36). Although there were also economic and diplomatic reasons for the passage of the Harrison Act (22), and although racist and xenophobic hysteria certainly played a part in popularizing antidrug sentiment, it is important to note that it was the significant intrinsic harms associated with drug use that substantially led to prohibition rather than the other way around.

Alcohol Prohibition

In 1920, the 18th Amendment to the United States Constitution banned the "manufacture, sale, or transport of intoxicating liquors within, the importation thereof into, or the exportation thereof from the United States." The status of alcohol under Prohibition is not directly analogous to the status of drugs under the current regime because possession of alcohol for personal consumption was not illegal. However, people who support the legalization of drugs frequently point to the experience with Prohibition as evidence that supply-side efforts to control substance use are inherently ineffective (38).

While it is true that public support for Prohibition waned, and that the 18th Amendment was repealed by the passage of the 21st Amendment in 1934, whether Prohibition "failed" depends on what outcomes are considered in the analysis. Certainly, Prohibition was a massive political failure, but there are data that support the contention that Prohibition had a significant and salutary impact on alcohol-related morbidity and mortality.

At the beginning of the 20th century Americans consumed an average of 2.6 gallons of alcohol per person. Over the next 20 years, the Temperance Movement gained in popularity, and 36 of the 48 states enacted some form of alcohol prohibition at the state level. By 1919, per capita alcohol consumption had dropped to 1.96 gallons per year. In 1934, per capita alcohol use stood at 0.97 gallons per year. From then on, consumption rose to roughly three times as high as that immediately after Prohibition (39).

Deaths from cirrhosis of the liver decreased from their peak in 1907 as the majority of states went dry (40). Cirrhosis deaths fell from 12 per 100,000 in 1916 to 5 per 100,000 in 1920, and then remained at that level throughout Prohibition, only to rise again after Repeal (41). Among men the cirrhosis rate declined even more sharply, from 29.5 per 100,000 to 10.7 per 100,000 in 1929 (42).

The decrease in consumption in alcohol was associated with other positive public health and social consequences as well. Admissions to psychiatric hospitals for alcohol-related psychosis dropped by 60% from 1919 to 1922. Arrests for drunkenness and disorderly conduct dropped 50% between 1916 and 1922, and public welfare agencies reported large declines in the number of alcohol-related family problems (42).

In the public imagination, these health benefits were offset by the increase in violence associated with the black market distribution and sales of alcohol during Prohibition. Movies such as *The Untouchables* and *Public Enemies* paint a vivid picture of gangster-driven “rum running.” However, homicide rates increased faster before Prohibition than during Prohibition, and organized crime was established in cities well before the 18th Amendment was passed (42). It is worth noting again that even today only 4% of homicides are drug related (7).

This pattern of alcohol prohibition leading to significant public health benefits were repeated in 1994 when the residents of Barrow, Alaska voted to ban alcohol possession, sale, and importation. Immediately the town noticed a 70% reduction in crime. In the month before the ban went into effect there were 118 alcohol-related emergency room visits, while in the month after the ban went into effect there were 23 such visits. Despite these salutatory social benefits, the town voted to repeal the ban in 1995. Immediately after the ban was lifted, admissions to the detoxification center resumed and alcohol-related crime began to rise (43).

Neither national Prohibition nor the experience in Barrow was done experimentally, thereby weakening any attempt to ascertain a causal relationship between the public policy changes and public health benefits. That being said, tentative conclusions can be drawn. When societies increase formal and informal social controls around alcohol use, this is associated with less consumption of alcohol and less alcohol-related morbidity and mortality. Another conclusion is that once a substance becomes ingrained as part of a mainstream culture, the majority of substance users who do not use the substance problematically will not tolerate having their own behavior curtailed because of the expense and misery incurred by a minority of problem users.

EXPERIENCES OF OTHER COUNTRIES

Although it is inherently difficult to make comparisons across disparate cultures, there are some lessons that can be learned from observations of what transpires with respect to drug policy in other cultures.

Netherlands

Many people are under the impression that the Netherlands legalized or decriminalized cannabis. In fact, the Netherlands made no changes to any existing laws, but rather since 1976 has opted not to enforce the laws pertaining to cannabis, resulting in what some authors refer to as “*de facto legalization*” (9). Proponents of legalization state that this policy change did not result in increased drug use (19,44,45).

That the prevalence of marijuana use does not increase very much with decriminalization has also been demonstrated in economic models studying those states where marijuana possession has been decriminalized (35). Under the Dutch regime, unlike the American states that decriminalized marijuana possession, however, the coffee shops that

sell marijuana could openly advertise their product. In fact, following this “commercialization” of marijuana, use of the drug did begin to significantly increase (46). Between 1984 and 1992, marijuana use by Dutch adolescents increased 200% (47) while over the same period marijuana use decreased by 66% in their American teenage counterparts. From 1991 to 1993 the Netherlands saw a 30% increase in the number of registered cannabis addicts (48). Between 1990 and 1995, the prevalence of Dutch cannabis users who had smoked cannabis for the previous 5 years increased from 2% to 5%, and that the number of adolescents who ever used cannabis increased from 7% to 17% (49).

In 1996, in response to domestic and international pressure, the Dutch Parliament passed restrictions to cut in half the number of cannabis-selling coffee houses and to reduce the amount of cannabis an individual could buy (50). Although the reduction in the amount of cannabis sold was enacted, the coffee shop proprietors fought the closings in the legal system, and only 10% of these establishments were shuttered (9).

One lesson that can be drawn from the Dutch experience is that advertising and commercialization of drugs, as with any commodity, can affect their consumption. A second lesson is that once a drug market becomes legitimated and can protect its own interests using the institutions and procedures available to all legitimate businesses, it is difficult to curtail or limit that market.

The widespread opening of so-called medical marijuana dispensaries in California and the ease of accessing them has been associated with hundreds of thousands of users, availability of very high-potency marijuana (over 15% THC), advertising by doctors offering the necessary card, and well-financed attempts by the dispensary owners both to legitimize them, and offers to pay taxes (which, again, makes them more legitimate and harder to close). Many flout the referendum that permitted them by making large sums of money while by law they are supposed to be not-for-profit (51). The Los Angeles city council has struggled to contain the number of marijuana dispensaries. Although several hundred are believed to exist, the city council wants to reduce the number of dispensaries to 70. As was seen in the Netherlands, those supporting dispensaries have availed themselves of the court system to protect their interests (52).

As noted above, once national policy and attitudes regarding cannabis changed in the Netherlands, adolescent cannabis consumption increased. It is interesting to note that as more and more U.S. states begin considering making “medical marijuana” available the attitudes and practices of U.S. adolescents seem to be changing in tandem. The 2009 Monitoring the Future study, an annual survey of adolescent drug use and drug-related beliefs, shows that after a decade of decline, the prevalence of adolescent cannabis use has increased over the past 2 years. At the same time, adolescents have begun to regard cannabis with less disapproval and perceive it as less risky than they did in the past (53). As our nation continues to conduct a large-scale, uncontrolled experiment with making cannabis legally available, attention to such trends

will prove critical to the determination of whether the benefits of the policy change are justified by its costs.

United Kingdom

Some in the prolegalization camp speak approvingly of the ability of British doctors to maintain drug addicts on heroin. However, of the estimated 150,000 opioid addicts in Britain, only 17,000 are maintained on methadone and 400 are maintained on heroin (54). It is unclear why, even when available, physicians use heroin so infrequently if this treatment offers an advantage to methadone (55).

This question may be answered by one British study that sought to study the effects of heroin maintenance in an experimental fashion by randomizing subjects to maintenance on oral methadone or injectable heroin (56). Initially 44 participants were randomized to heroin and 52 to oral methadone, but due to attrition and death the analysis included data on only 42 participants receiving heroin and 46 receiving methadone. The study ran for 12 months and the average dose of both heroin and methadone was 60 mg. Those maintained on methadone were significantly more likely to reduce the frequency of injecting drugs illicitly and to cease use of other opioids than those maintained on heroin. There were no benefits to heroin maintenance in terms of crime or health outcomes. Disturbingly, 37% of those in the study admitted to diverting some of their heroin on the black market (55). Thus, in this study, heroin maintenance was, at best, slightly inferior to methadone maintenance. This may well account for part of the reason why British physicians are reluctant to resort to heroin maintenance.

Switzerland

In the third season of the HBO urban crime drama *The Wire*, a Baltimore police commander creates a zone within his district where drug dealing and drug using would be overlooked in an effort to siphon these problems away from residential areas and concentrate them in one small location. In this fictional account, public service agencies rush in to assist the addicted population, but the area, called Hamsterdam, becomes increasingly anarchic—albeit within circumscribed boundaries. Finally, the local news media publicizes what is going on, and Hamsterdam is closed with a massive police sweep, and the viewer is left to consider the mixed results of the social experiment.

In 1987, Zurich, Switzerland actually ran such an uncontrolled experiment. The year prior, heroin had moved into the previously cannabis endemic Platzspitz Park, which quickly earned the moniker “Needle Park.” In response, the city council and police force made it unofficial policy not to enforce any laws regarding individual drug use or drug possession within the park, while vigorously enforcing such laws in the rest of the city and surrounding canton (9).

As in *The Wire*, multiple nonprofit agencies swept in and began offering needle exchange, medical help, resuscitation teams, and mobile kitchens. Users, the majority of whom

came from outside Zurich, poured into the Platzspitz. The number of syringes distributed and the number of resuscitations performed each day increased out of proportion to the increased number of addicts, leading Swiss researchers to conclude that the addicts were injecting ever-larger amounts of heroin (57). Heroin-related deaths began to rise, and Switzerland attained the highest heroin-related mortality rate in Europe and North America (58).

Rather than leading to improved health and decreased crime among addicts, the Platzspitz appears to have caused generally the opposite effect. Although overdoses increased, the adjusted rate of HIV infection began to fall (9), thefts and robberies increased dramatically, and violence was endemic in the Platzspitz (57). Eventually, the citizens of Zurich could not tolerate the anarchic conditions in the midst of their city and the Platzspitz was closed in early 1992 (9). After the closure of the Platzspitz, the open-air heroin market reconstituted itself at an abandoned railway station called Letten. This site was also subsequently closed in 1995, thus ending Switzerland’s experiment with tolerating an open-air drug market. Researchers have found that after closing the zones of tolerance, the number of opiate addicts seeking treatment in methadone maintenance clinics increased (59).

Whether the Platzspitz was a success or failure depends on what endpoints a person considers relevant. Politically, the experiment was a disaster. Crime rates and individual drug use increased and heroin-related deaths rose dramatically. On the other hand, HIV rates did start to fall with the extensive needle exchange program, and rates of drug use in the general population did not increase (9). Ultimately, concentrating a deviant population into one small area may lead to some public health benefits while producing other drawbacks.

After their experience with the Platzspitz the Swiss continued to struggle with finding the best response to heroin use. Initially the Swiss wanted to perform a randomized, controlled trial of heroin maintenance. Inclusion criteria were not stringent: users had to be at least 20 years old, have injected heroin for at least 2 years, and have failed treatment at least twice. The experiment called for assignment into one of three arms: injectable morphine, injectable heroin, and injectable methadone. Only at one site was assignment random. Discomfort associated with injectable morphine led to the abandonment of this arm, and patients did not accept injectable methadone. Thus, the vicissitudes of conducting research caused the study to become an essentially open trial of heroin maintenance. All heroin had to be used on site, thus preventing any leakage onto the black market. The participants could select their desired heroin dose, and average daily dose soared to between 500 and 600 mg a day—roughly 10 times the amount used by an average street user (55).

Without a true control group, the study was limited to a before-and-after study of the heroin recipients. There was no leakage of heroin to the black market and no heroin overdoses occurred. Treatment retention was impressive: 69% remained at 18 months, and half of the drop outs entered into some

other form of drug treatment. Both self-reported criminal activity and rates of arrest decreased and unemployment fell from 44% to 20%, with employment described as permanent rising from 14% to 32%. Cocaine use did not diminish, but there were few new cases of HIV. In addition to being non-randomized and uncontrolled, the study was criticized for using primarily self-report outcomes (60). An analysis of the program showed that the heroin maintenance failed to demonstrate an ability to reduce criminal behavior (61). Because of these limitations, the Swiss data are hard to interpret with confidence.

Canada

Recently, researchers in Montreal, Quebec, and Vancouver, British Columbia performed a much more methodologically rigorous randomized controlled trial of heroin maintenance in opioid-dependent participants (62). In this trial, 111 participants were randomized to 12 months of treatment with oral methadone, 115 were randomized to injected heroin maintenance, and 25 were randomized to injected hydromorphone (Dilaudid). Methadone was dosed once daily (the average dose was 96 mg) and heroin was usually administered twice daily (the average daily dose was 392.3 mg). At 12-month follow-up significantly more participants in the heroin group were retained in treatment compared to the methadone group (87.8% vs. 54.1%, $P < 0.001$).

Other endpoints were measured by reduction in baseline scores of various subscales of the European Addiction Severity Index. The researchers found that more of the heroin maintained participants compared to the methadone maintained participants had at least a 20% reductions in illicit drug use or other illegal activities (67% vs. 48%, $P = 0.004$). This metric seems primarily accounted for by large reductions in days of illicit heroin use in the heroin maintenance group. **A major caveat to accepting this result is the fact that these reductions are based on self-report data only.** The heroin maintenance group also showed statistically significant reduction in subscale scores of psychiatric well-being, employment satisfaction, and social relations.

There were no statistically significant differences between the groups with respect to improvements in subscales for participation in illegal activities (decoupled from illicit drug use), days of cocaine use, medical status, economic status, family relations, or alcohol use. In addition, there were 18 serious adverse events in the methadone group (none were found to be the result of methadone use) while there were 51 adverse events in the heroin group (47% of which were caused by the study drug, including 11 opioid overdoses necessitating the administration of naloxone and hospital transfer, and seven seizures).

The study authors concluded that heroin maintenance is more effective than oral methadone. However, a more jaundiced take on these results would hold that the data showed that, based only on self-report data, when people are offered large amounts of free, legal heroin they will use less costly, illegal heroin. Lastly, the findings supporting improvements in

other domains of functioning are offset by no improvement in other critical domains. Moreover, this is done at the cost of several life-threatening incidents and does not reduce other drug use (e.g., cocaine) or participation in other illicit activity.

The findings of this study raise the question of whether heroin maintenance can be considered a “treatment” at all. Methadone’s once-daily dosing is supposed to allow for people to resume normal functioning, such as finding employment, and this schedule is already considered onerous by many patients (hence its moniker of “liquid handcuffs”). Heroin was given twice a day, at huge doses, and still did not prevent people from overdosing or allowing them to make convincing improvements in their overall psychosocial functioning. As drug policy experts MacCoun and Reuter point out, “Heroin maintenance has a contradiction at its heart. Having chosen to prohibit the drug, society then makes an exception for those who cause sufficient damage, to themselves and society...” If the barrier to getting into heroin maintenance is set too high, requiring individuals to incur severe damages before allowing them access to a supposedly useful solution it “is expensive . . . and inhumane. However, if it sets the barrier low, then access to heroin becomes too easy . . . This raises a fundamental ethical concern. [H]eroin maintenance itself is clearly social policy, not medicine . . . [S]ocial policy should not be dressed up as therapeutic activity.” (9).

Sweden

From 1965 to 1967 Sweden also ran an uncontrolled experiment with maintaining addicts on their drug of choice. Starting around 1950, Sweden experienced an epidemic of amphetamine dependence. In response, the government provided legal, state-financed amphetamines. Between 1965, when the program started, and 1967, when the program ended, the prevalence of amphetamine dependence in Sweden doubled. There are data indicating that some of the spread of amphetamine use was due to young amphetamine-using men proselytizing about the benefits of amphetamines. In addition, there was substantial diversion of drugs from patients to friends and acquaintances. Interestingly, crime among legal users rose, rather than fell, when their drug of choice was made freely available to them (21,63).

Starting in 1972, Swedish policy remained lenient toward individual users, and focused on prosecuting “kingpins.” The police allowed individual possession of up to a week’s worth of drugs at a time, and arrests for drug possession fell. By 1980, legislative priorities changed, and possession of anything more than a single cannabis cigarette was punished. Drug arrests tripled in 3 years, and the government introduced mandatory drug treatment. Afterward, drug use—particularly among young people—fell. By 1998, the percentage of military conscripts using drugs fell by 75% and drug use by ninth graders fell 66%. In 1970, 37% of daily drug users had been under 25; by 1992 this number had fallen to 10% (63).

In Sweden, as in the United States, early policies of permissiveness toward drugs became incrementally more restrictive

as the problems attendant to drug use became clearer, and as attitudes in the electorate changed over time.

China

Contrary to popular belief, the practice of smoking opium was not popular in China prior to the 18th century. It started as a practice of combining a weak opium gum with tobacco, and then smoking the resulting mixture, called *madak* (36). In 1773, in order to correct a trade imbalance, the British East India Company began to import pure opium into China. By the mid-1800s, the practice of opium smoking had progressed to the point that the Imperial government forbade the further import of the substance. When the British refused to comply, the Chinese destroyed 20,000 chests of opium the British had stored off shore.

This set off a series of battles from 1839 to 1842 known as the First Opium War. The British prevailed and forced the Chinese to open five ports to the opium trade and to pay restitution for the opium that had been destroyed. A Second Opium War was fought from 1856 to 1858 and another British victory resulted in the outright legalization of the opium trade in China. The result was that China imported 6 million pounds of opium in 1839, and 15 million pounds by 1879. Although estimates of the rates of opiate addiction vary wildly, China developed one of the highest rates of opiate addiction in the world throughout the 19th century (21,36,64).

Although the data from this period are very limited some broad conclusions can be reached. The Chinese experience with the Opium Wars lends support to the position that when drugs are commoditized in the marketplace they can be as effectively sold as any other good. Second, this historical period again shows the difficulty of making accurate predictions about how increasing the supply and availability of a drug will affect demand for the drug. Third, this is another example of how the financial interests of those dealing in addictive substances will override the interests of the public health. Fourth, as we will see, once a public develops a taste for drugs, getting widespread addiction under control is a difficult business.

By the early 1900s, the Chinese and British agreed to abolish the opium trade, and the Chinese government employed a vigorous poppy eradication campaign and instituted harsh consequences for violations (22). After World War II, the Chinese communists (who, along with their Nationalist rivals, had raised funds via the opium trade) attempted to suppress opium use in their population. This program included roundups, arrests, and executions of drug dealers as well as mass participation in antiopium rallies, and public confessions by ex-addicts (65). In all, relative increases in the 1980s notwithstanding, China had one of the lowest crime rates in the world, and its rate of drug crime was particularly low (66). Although rates of drug use have been rising in China, it was recently found that in six provinces with “high prevalence” drug use, the lifetime prevalence of illicit drug use was only 1.6%, and the 1-year prevalence was 1.17% (67). China’s

main response to drug use has been to increase supply-reduction measures (68).

Afghanistan

After the Vietnam War, much of the world’s poppy cultivation shifted to the Golden Crescent area of Iran, Pakistan, and Afghanistan. Poppy cultivation was particularly widespread in Afghanistan, and by the 1990s, Afghanistan was responsible for growing opium poppies that supplied 70% of the world’s heroin. After the Soviet-client government collapsed, the Taliban took control in Afghanistan. Despite the high prices (relative to other crops) offered for poppy, the Taliban’s harsh style of governance kept poppy cultivation to a minimum. By threatening punishment, punishing transgressors publicly, and close monitoring with tight local accountability, the Taliban reduced poppy cultivation by 99% in the areas they controlled. After the U.S.-led war that deposed the Taliban, poppy cultivation has returned to previous levels despite Western efforts to discourage the practice. Profits from the opium trade are used by the Taliban to fund their war against both the international forces (mainly the United States) and the Afghanistan government (69).

The experiences of China and Afghanistan hold important lessons for proponents of legalization and prohibition alike. In contradiction to the positions held by proponents of legalization, these examples lend evidence to the contention that supply-side interventions can be extremely successful in reducing drug use in a population. An equally important message exists for the advocates of prohibition: supply-side efforts alone can work, but potentially at the expense of civil liberties and a civil society. The amount of government intrusion, scrutiny, and coercion into the lives of citizens necessary to “win” a “war” on drugs may well be inimical to Western and democratic principles.

SUPPLY DISRUPTIONS

Another source of information about how drug supply can affect demand can be found in times when drug supply is temporarily severely reduced. Although these occurrences are not planned, some limited inferences can be made from studying their effects on a quasiexperimental basis (70).

World War II

During World War II, rates of heroin addiction fell dramatically throughout the United States. This was due, in part, to the large-scale disruption in heroin trafficking routes due to the war, and to the increased coastal defenses that prevented smuggling into the country. It is important to note that other factors such as the mobilization of young drug-using-age men into the military and the “aging out” of older addicts also contributed to this decline (21,22,36). Regardless, when considering the inevitability of drug use—pointed out by many who favor a legalization regime (e.g., Ref. 20)—it is important to also consider how the prevalence and

magnitude of use can be sensitive to matters of both supply and demand.

New South Wales Heroin Drought

In January 2001, the heroin supply to the Australian state of New South Wales experienced an abrupt and unexpected disruption. This decrease was likely the result of record low prices of heroin combined with better interdiction. These factors led to low profits and high risk for drug traffickers (71). This “drought” peaked from January to April of 2001, and resulted in a dramatic increase in the difficulty of procuring heroin faced by addicts (72).

The shortage of heroin led to a significant reduction in the amount and frequency of heroin use, number of non-fatal heroin overdoses, heroin-related fatalities and heroin-related hospital visits. There was also a significant reduction in the amount and frequency of heroin use, number of nonfatal heroin overdoses, heroin-related fatalities, and heroin-related hospital visits (73–79). At the same time, there was a reduction in the number of people seeking treatment for opioid dependence (76–78). During the drought the price of heroin rose, while its purity fell. At the same time, there was a transient increase in the number of robberies in New South Wales early in the drought, but rates of theft fell overall (76–78). Although heroin use fell over the drought, the use of other drugs, such as cocaine and methamphetamine, increased (74,75). There was, however, no increase in the number of overdose deaths associated with these other drugs (76–78).

The conclusions that can be drawn from the Australian heroin drought are somewhat limited. The events that precipitated the supply reduction were unique, and the nature of the data gleaned prevents any firm causal inference from being made. However, a sudden, dramatic supply reduction appears to have been associated with reduced heroin use, purity and availability, and with increased price. At the same time, heroin-related injury and deaths fell and crime did not markedly increase. At minimum, were supply shortages to result in increased morbidity and mortality as hypothesized by some prolegalization advocates, such did not turn out to be the case in Australia.

TAXATION

As previously noted, one of the purposes of prohibition is to increase the price of illicit drugs in an attempt to discourage their use. Taxation is one approach that has been extensively used to increase the price of tobacco to decrease its consumption and to generate revenue to offset tobacco-related costs. Increasing the price of tobacco has been shown to decrease its consumption, particularly among lower-income groups and adolescents (80). It has been found that state tobacco taxes significantly decrease tobacco consumption, and that larger tax increases are associated with larger reductions in use (81). Tax increases on tobacco were a component of New York City’s antismoking campaign that resulted in significant reductions in the prevalence of smoking in the city (82).

Interestingly, many proponents of drug legalization say a benefit of legalization would be that revenue could be generated to offset the harm caused by drug use (20). However, these same proponents also identify the black market nature of the drug trade as a source of significant drug-related harm. This puts them in the ideologically precarious position of saying that although meddling with the drug market causes the black market and, thus, harm—they will meddle in the market in such a way as to not produce a black market. History tells us this is probably a naive hope.

Drug markets historically tolerate very little interference before black markets emerge. Prior to the advent of any formal laws regulating cocaine sales, pharmacists attempted to limit dispensing the drug to those with legitimate medical concerns. The market of cocaine addicts did not tolerate even this mild disruption, and a black market emerged well before cocaine was even illegal (23). New York City officials noted that as their strict antitobacco policies went into effect, including the increased excise tax on cigarettes, the number of cigarettes bought outside the city limits to avoid that tax doubled (82). The black market for legal, but taxed, cigarettes in New York has created a violent, even deadly, traffic in bootleg tobacco (83). Canada had a similar experience in the early 1990s when its government raised tobacco taxes (21). Thus, any tax on a legal drug market would have to be set at just the right level: enough to generate sufficient revenue to offset the costs created by drug use, but not so much as to create a black market (9). As the historian, David Courtwright, notes:

“The idea that the black market is the result of something called ‘prohibition’ is the central premise of the liberal view of drug history and the basis of the affiliated proposal called legalization. Licit, taxed sales of drugs...to adults could, theoretically, end the evils attendant to the black market while providing revenue for state-sponsored prevention and treatment programs. The catch, apart from increased addiction due to increased exposure is that retaining taxes (and restrictions like no sales to minors) means retaining, to some degree, the black market. Light taxes and few restrictions would make the black market a minor nuisance, but would increase the amount of compulsive use. Heavy taxes and many restrictions would mean fewer new addicts, but would create incentives for illicit manufacturing, smuggling, diversion and violence.” (21).

Courtwright also identifies a second danger in taxation schemes of psychoactive drugs. He notes that whether governments taxed opium (as in the Dutch East Indies, Indochina, Brunei, Hong Kong, Singapore, or Java), alcohol (as in the United States, the Soviet Union, or post-colonial India), or tobacco, governments were forced to trade off the public health for pecuniary gain. Once the public developed an appetite for the drug in question, and the government developed an appetite for the relatively easy revenue stream, undoing unsound policy is, practically speaking, very difficult (21). A parallel experience can be seen with gambling: states, now well-hooked on lottery revenues, continue to promote their lotteries despite the regressive nature of the revenue they extract and the potential to stimulate problem gambling in the electorate (9).

SUMMARY

In closing, from a public health perspective, our national experience with the two drugs we have legalized, alcohol and nicotine, has been an unmitigated disaster. The interests of the corporations that produce and distribute these substances are defended by talented and well-funded lobbyists exercising the First Amendment right to petition the government for redress of grievances. The ineffectiveness of efforts to limit the marketing of these substances is attested to by noting the abundance of tobacco and alcohol advertising in any magazine, in any store, or at any sporting event.

Due to the widespread availability, low price, and persistent advertising of these products we experience 400,000 excess deaths a year due to tobacco and 100,000 excess deaths a year from alcohol (84). As much money as is spent on the so-called “War on Drugs,” far greater sums are lost due to decreased productivity, increased health care consumption, excess deaths, and criminal justice costs associated with alcohol and tobacco use (85–87). And to what benefit have we incorporated these substances into the mainstream of our society? What quantifiable good have they wrought to offset the harms they have caused? Have they meaningfully and materially enriched and gladdened as many lives as they have destroyed? Ultimately, for alcohol and tobacco, these questions are moot. For good or for ill, these substances have been woven into our social fabric, probably permanently. Alcohol has been a part of the mainstream of our culture for thousands of years—tobacco, for hundreds. Those proverbial bells cannot be un-rung.

However, we do have an opportunity to prevent the ringing of other bells. We do have an opportunity to prevent the more widespread use of, and addiction to, illicit drugs were more people to be exposed to them. We do have an opportunity to prevent the rise of a legalized, legitimized, and organized, Big Cannabis, Big Cocaine, and Big Opium. The data from other places and other times tell us that the inherent good they would bring would not offset the misery that would follow in their wake. History also teaches us that bad policy, when linked to a politically palatable tax source, is hard to undo. Thankfully, the options before us are not limited to the false dichotomy of status quo or legalization. The point of this chapter has not been to dismiss the importance of comprehensive drug policy reform in America, or to imply that the status quo is efficient or even defensible. However, the implications of outright legalization are such that this option is best left off the table.

Pedro Ruiz ■ Eric C. Strain

INTRODUCTION

Since the first edition of this textbook was published in 1981 (1), the field of addiction has grown tremendously. This growth has taken place in all areas of the field, that is, in all dimensions of the biopsychosocial aspects of these disorders. The field of substance abuse has changed a great deal since the early 1960s when a small group of scientists, physicians, and mental health professionals began to focus their interests on the medical and psychosocial consequences of substance abuse. The first edition of this textbook attempted to address all of those medical and societal problems related to the abuse of addictive substances from a clinical and scientific point of view. Specific substances were examined, as well as epidemiologic components, treatment approaches, and prevention models.

The second edition of the textbook was published in 1992 (2). This edition appeared after a decade of extraordinary challenges faced by the addiction field. During this decade, the understanding of substance abuse from a neurobiologic point of view became a necessity. New scientific knowledge evolved rather quickly in this area of the field. This new perspective in the understanding of addictive disorders opened a new window of opportunity for new treatment approaches and possibilities for the exploration of new etiologic factors related to the cause of addictive disorders. During the decade prior to the publishing of this second edition, new perspectives in the areas of prevention, treatment alternatives, and policy planning and implementation became viable. At the time of publication of the first edition of the book, there were only two medications approved for the treatment of substance use disorders in the United States: disulfiram and methadone. By the time the second edition was published, the number of approved medications had doubled, with the addition of oral naltrexone for the treatment of opioid dependence in 1984, and nicotine gum by prescription for the treatment of nicotine dependence also in 1984. These changes illustrate several forces in the field of addictions that would continue in subsequent years—including the entry of pharmaceutical companies into the field of addictions, the gradual shift of addictions treatment into general medical practice, and the tendency to focus upon licit drug use as an area of particular interest in the field of medicine. The idea of the second edition of this book was to provide a comprehensive and detailed description of the thinking and new development in both the basic sciences and clinical practice with respect to addictive conditions.

The third edition of the textbook was published just 5 years after the second edition—in 1997 (3). During the half of a decade that had passed since the publication of the second edition, new scientific advances had greatly impacted the understanding of addictive behaviors and its causes. New knowledge about the impact of substances of abuse on the brain and its behavioral outcomes had become a reality. Cloned receptors in the brain were identified as sites of action for many substances of abuse. Cellular mechanisms of action were also identified for drugs such as cocaine, marijuana, and opiates. Brain circuits were also found to have a role in behavioral manifestations like euphoria, as well as the process of addiction and drug withdrawal. The national emphasis on neurosciences research took place during this half of a decade, and its positive impact on new scientific discoveries vis-à-vis drug addiction was rewarding during this period. Concurrent with this growing awareness of the neuroscientific basis of addiction, the treatment field also was refining its methodologies and demonstrating the efficacy of different approaches—both pharmacologic and nonpharmacologic. Illustrating the growth in the field, six medications were approved in the United States for use in the treatment of substance use disorders during this period: the nicotine patch in 1992; LAAM in 1993; oral naltrexone for alcohol dependence in 1995; nicotine nasal spray in 1996; a nicotine inhaler in 1997; and bupropion for nicotine dependence; a seventh medication—sublingual buprenorphine—was first approved for the treatment of opioid dependence in France, in 1996. Given the limited availability of methadone treatment in that country, it quickly became a valuable treatment for patients who suffered from opioid dependence. In addition, it showed that a medication for an illicit drug use disorder could be a viable product for a pharmaceutical company. Also of note during this period was a major effort to identify cocaine pharmacotherapies (an effort that continues to the present), the growth of neuroimaging as a tool to better understand reward pathways and the differential effects of acute versus chronic drug use, and the efficacy of novel contingency management strategies such as voucher incentives to produce sustained periods of drug abstinence.

The fourth edition of this textbook was published in 2005 (4). This edition was published almost a decade later from the previous one; during this period, new challenges faced the field of addiction and they were fully addressed in this edition. These included issues pertaining to lack of parity between medical illnesses and addictive conditions, and

cost containment via managed care, which has negatively impacted on the clinical care received by patients who suffer from addictive disorders. In addition, new medications such as buprenorphine was approved for use in the United States in 2002 and acamprosate was approved for use in the United States in 2004, but these were marketed in Europe for many years prior to its approval in the United States, offered new hopes in the addiction field; the role of neurosciences vis-à-vis addictive disorders clearly demonstrated its value and relevance in the field of addiction. However, despite the positive advances in the neurosciences, the psychosocial aspects of addictive disorders continued to be very relevant in the addiction field and were thoroughly addressed in that edition.

Obviously, since the first edition of this textbook almost three decades ago, the field of addiction has gained a great deal due to research advances along the lines of the biopsychosocial model, but particularly in the neurosciences area of the field. It is within this context that this fifth edition was produced and, hopefully, has appropriately and thoroughly addressed all major advances that have taken place in the field of addiction since the fourth edition was published almost a decade ago.

CURRENT PERSPECTIVES

A close view and analysis of what is relevant and current at the present time should permit us to elaborate on the most prominent aspects of the future of the addiction field. There are several points that can be highlighted about the current state of addictions, and while these may seem self-evident, it is useful to clearly state them as they have not always been fully acknowledged either in the health professions or by the broader culture.

The first of these is that addictive disorders are medical conditions. That is, the field of medicine is that discipline that addresses this area of science—it has a growing body of experience in the treatment of these disorders, their prevention, and research about these conditions. This is not meant to diminish in any way the expertise that other disciplines bring to our understanding of addictions. Clearly, sociology, economy, criminology, and other disciplines have made and will continue to make important contributions to our understanding of addictive disorders and their impact. However, we believe that medicine is that field of science where work in this area should primarily reside—and, while that may seem clear to the reader, it was not long ago when such a point would be debated. Furthermore, among the disorders in medicine, addictions seem to us to be the most intriguing—in part, because our understanding of them can range from studies of the neuroscience of brain function to cultural aspects of use that encompass broad numbers of populations. Addictions range from epigenetics to epidemiology and from circuits in the brain to cost–benefit analyses of treatments.

The second point regarding the current state of addictions is that addictive disorders are a pressing problem throughout the world, and it is unlikely that addictive disorders will be “cured” anytime soon. The problems of substance use are not

a problem of the contemporary era; as noted in the Old Testament of the Bible:

Who has woe? Who has sorrow? Who has strife? Who has complaints? Who has needless bruises? Who has bloodshot eyes? Those who linger over wine, who go to sample bowls of mixed wine. Do not gaze at wine when it is red, when it sparkles in the cup, when it goes down smoothly! In the end it bites like a snake and poisons like a viper. Your eyes will see strange sights and your mind imagine confusing things. You will be like one sleeping on the high seas, lying on top of the rigging. “They hit me,” you will say, “but I’m not hurt! They beat me, but I don’t feel it! When will I wake up so I can find another drink?” (Proverbs 23: 29–35)

No country is immune from addictions, and while rates of use may fluctuate over time (e.g., due to availability, changes in cultural norms, or economic conditions), substance use disorders persist and in many cases grow as new forms of drugs and delivery systems become available. For students contemplating an area to pursue in their career, understanding these disorders, and helping those who suffer from them holds the promise of intriguing work and satisfying patient care—despite these being conditions that have plagued humans for thousands of years.

We also are optimistic about this field. Advances in understanding all aspects of addictions continue to grow. These advances help in prevention and treatment; in addition, while research in addictions helps our understanding of these disorders, this work also provides insights into the broader topics of motivated behavior—that is, the neuroscientific basis of behavior, as well as the environmental circumstances and determinants of choice and consumption.

Regarding the area of neurosciences, this has been one aspect of the addictions field that has produced substantial and highly relevant scientific advances in the last decade. Mechanisms of memory, reward, and reinforcement have been clarified, and will continue to help drive the field and show the biology of addictions. However, this is not to say that the psychosocial aspects of addictive disorders are no longer important and necessary. On the contrary, nowadays, more than ever before we need to address all aspects of addiction from a psychosocial point of view. In this edition of the book, Section 1 (Foundations), Section 2 (Determinants of Abuse and Dependence), Section 6, Part 2 (Psychosocial and Other Treatments), Section 8 (Models of Prevention), Section 10 (Special Populations), Section 11 (Training and Education), and Section 12 (Policy Issues), all address very comprehensively and thoroughly the psychosocial aspects of the biopsychosocial model.

In addition to growth in our understanding of the neuroscience of addictive disorders, psychiatric genetics is an area full of opportunities for currently assessing the potential relationship between genetic factors and addictive disorders, although the processes underlying mental disorders from a genetic point of view is becoming a very complex one. The genes related to mental conditions appear to be very complex; however, “neural circuits” could be quite promising with

respect to the understanding of mental disorders, including addiction.

Finally, current perspectives on addictions need to acknowledge the growth in our understanding of the treatment of these disorders. While it is now generally accepted, not long ago the statement that treatment for substance abuse is effective was not widely known—and the evidence for such a statement was not readily available. There is now a rich source of controlled clinical trials showing the efficacy of a variety of treatments, well-documented through reviews such as those provided by the Cochrane Database (5–10). These treatments take the form of both pharmacotherapies and nonpharmacologic treatments. As noted earlier in this chapter, there has been a marked increase in the number of approved medications for the treatment of substance use disorders, and this growth has helped health care professionals change their perspective on these conditions, and it has helped a tremendous number of patients. However, growth in treatment has not been limited to medications, and work has demonstrated the efficacy of psychosocial treatments for addictions (11) and that there is a substantial evidence base for particular forms of treatment (12). While there remain important questions about treatment, the field of addictions has provided well-controlled studies showing that interventions can work for these patients, helping in changing a cultural perception that substance abuse was best addressed through nonmedical means such as the criminal justice system.

FUTURE DIRECTIONS

With respect to future directions in the field of addiction, there are many aspects within the area of neurosciences that could be quite relevant to the etiologic understanding and appropriate treatment of addictive disorders.

For instance, preclinical studies indicate that neuroadaptations that take place among adolescents exposed to some substance of abuse like nicotine or cannabinoids are different than those observed during adulthood (13). Obviously, genetics play a major role in addictive conditions; it is estimated that 40% to 60% of the vulnerability to addictive behavior is related to genetic factors (14). For instance, genotypic vulnerability to addiction tends to reflect both variability in the metabolism of the substance of abuse and variability in the sensitivity to the reinforcing effects of the abused substance (15). However, addiction-driven and addiction-resistant phenotypes may also reflect sensitivity to various stressors and alternative reinforces in the individual's environment (16).

Excellent efforts have also been dedicated to study the nature of global versus regional hierarchical brain organization (17). This type of work has also led to the consideration of mental disorders being primarily perturbations in the optimal organization of the brain (18). Certainly, the use of simulation models of the brain from the perspectives of computational neurosciences can be a very promising approach to understand the relationship between brain structures, brain organization, and brain circuits vis-à-vis mental disorders, including addictive conditions. This approach can lead to the potential utilization of brain pacemakers or the

optimization of neural plasticity to improve or cure mental/addictive disorders.

Future possibilities in the field of addiction can also include helping drug addicts to be less dependent or to be able to withdraw from their drug/drugs of dependence, as well as to have access to new medications that can assist them in avoiding relapses (19,20). There is also the possibility that if addiction could be perceived as a chronic, relapsing brain disorder, the moral view of addiction and its punitive social policy consequences can be changed in the near future and, thus, offering the potential for new and more humane policies with respect to the care of addicts. This approach will also eliminate the stigmatization and imprisonment of addicts (21). However, these new approaches can also lead to the justification of heroic treatments and intervention such as ultra-rapid opiate detoxification and/or neurosurgery for heroin dependence (22,23).

From a policy point of view, it is difficult to understand as to why alcohol and tobacco are considered legal drugs while others such as heroin, cocaine, and cannabis are not considered legal (24). Along the lines of policy, it appears that there will be no major changes in the future insofar as international policies toward addiction are concerned (25). Clearly, the neurobiologic research efforts in animals and humans during the last several decades have demonstrated that the most important psychoactive drugs of dependence act on key neurotransmitter systems of our brain and cause related behaviors (26). Twin and adoption studies have also depicted that genetics along with the environment contributes to our vulnerabilities to different types of addiction (26).

Obviously, the applications of neuroscience research on addiction are likely to bring benefits and possible harm as well in the future (26). While so far, neurobiologists have focused on the benefits, it is also important that we focus on the potential harm (26).

From a different point of view, recent research efforts have depicted potential beneficial effects; for instance, it looks that gamma-aminobutyric acid (GABA) transmission and GABA B receptors play a module role in the mechanism of action of different drugs of abuse (27). This discovery has very good future potentials. While there are many unknown aspects concerning the mode of action of abused drugs, a unifying theme for toxicity and addiction was advanced based on electron transfer (ET), reactive oxygen species (ROS), and oxidative stress (OS). This concept applies to nicotine, cocaine, alcohol, phencyclidine, ecstasy, amphetamines, morphine–heroin, tetrahydrocannabinol, and therapeutic drugs such as benzodiazepines, phenytoin, Phenobarbital, aspirin, and acetaminophen (28). This type of new knowledge will certainly help to better understand the neurobiologic mechanisms related to addictive behavior.

CONCLUSION

The field of substance use disorders has shown tremendous growth since the first edition of this textbook was published 30 years ago. Our understanding of the biologic determinants of drug use, and effective prevention and treatment interven-

tions, has steadily improved over time. These accomplishments have helped change cultural attitudes about the nature of addictive disorders, and most importantly, they have brought these disorders into the field of medicine and created a dynamic interest by health care professionals dedicated to helping patients who suffer from these disorders. Despite these accomplishments, much work remains.

In the United States and in many other countries, there is a pressing need to expand services for those who need treatment. Hand-in-hand with such an expansion of treatment is the need to identify ways to encourage people to engage in treatment. There is also a need to identify and promulgate the most effective prevention programs to decrease the number of persons who develop substance abuse problems. For many classes of drugs, there are effective pharmacologic and non-pharmacologic treatments—it is the delivery systems for such treatments that need to be improved.

However, there remains a need to identify pharmacologic treatments for stimulant use disorders (i.e., cocaine and amphetamines). Despite decades of effort and testing, there is still no approved medication to treat these disorders.

There remain other areas that need to be addressed—the optimal treatment of women (including pregnant women), the growing body of older substance users, the seemingly intractable fifth of the population that continues to have nicotine dependence, and the optimal treatment of persons with co-occurring disorders, to name just a few. However, perhaps the most critical need in the future is to identify how the growing neuroscientific and genetic basis of addictions can be translated into clinical practice and improved treatment outcomes. Substance abuse is a clinical disorder. Bringing basic science findings into the clinical setting is an important step. How this will occur remains unclear at this time—it may be related to the study of memory and learning, of behavior and reinforcement, or of pharmacologic manipulation of reward circuits. Regardless of the next step forward, it will be important to remember that there is a patient who seeks our help through the understanding of the unique features of that person's life story.
