Care has been taken to confirm the accuracy of the information presented and to describe generally accepted practices. However, the authors, editors, and publisher are not responsible for errors or omissions or for any consequences from application of the information in this book and make no warranty, expressed or implied, with respect to the currency, completeness, or accuracy of the contents of the publication. Application of the information in a particular situation remains the professional responsibility of the practitioner.

The authors, editors, and publisher have exerted every effort to ensure that drug selection and dosage set forth in this text are in accordance with current recommendations and practice at the time of publication. However, in view of ongoing research, changes in government regulations, and the constant flow of information relating to drug therapy and drug reactions, the reader is urged to check the package insert for each drug for any change in indications and dosage and for added warnings and precautions. This is particularly important when the recommended agent is a new or infrequently employed drug.

Some drugs and medical devices presented in the publication have Food and Drug Administration (FDA) clearance for limited use in restricted research settings. It is the responsibility of the health care provider to ascertain the FDA status of each drug or device planned for use in their clinical practice.

To purchase additional copies of this book, call our customer service department at (800) 638-3030 or fax orders to (301) 223-2320. International customers should call (301) 223-2300.

I wish to dedicate this textbook to Pablo Antonio Holgin,
who at two years of age taught me what love, courage and
resilience were all about.

—PEDRO RUIZ, M.D.

I wish to dedicate this textbook to my family—Grace, Andrew,
Kate and Cori—who have provided me with love and support
through the years and have helped me to keep perspective on
those things that matter most at the end of my day.

—ERIC C. STRAIN, M.D.

We wish to dedicate this textbook to those who suffer from
alcohol and drug use, abuse and dependence; they deserve the
best possible care that our field can offer them.

—PEDRO RUIZ, M.D.

—ERIC C. STRAIN, M.D.

This fifth edition of *Lowinson and Ruiz's Substance Abuse: A Comprehensive Textbook* symbolizes a major effort by the profession to address the devastating effects of alcohol and drug use, abuse, and dependence. Addictive disorders and the conditions associated with drug use clearly have a direct deleterious impact on a person's physical and mental health, but this impact is also felt in numerous other aspects of life—including relationships with family and friends, spiritual life, work and education, the legal system, and the broader communities in which we all live. One goal of this book is to bring together current, state-of-the-art knowledge of what we know about addictions, so that the interested reader has a single resource that can provide answers to questions about all aspects of addictive disorders.

The target audience for this textbook includes medical students, psychiatric residents and residents from other specialties, addiction fellows, physicians in practice, nurses, social workers, and counselors, and other health and mental health practitioners at large. The goal is to provide all health care professionals with a comprehensive textbook on addictive disorders. The content of this book represent the most up-to-date information related to every possible aspect of addiction, that is, the epidemiology, diagnosis, and treatment of all addictive disorders and conditions. All major drug classes are addressed in this textbook, and chapters include information about both our understanding of how a particular drug affects the brain and body and what is known about the most effective approaches to treat the consequences of the abuse of that drug. In addition, this book addresses public policy-related issues, special populations, and other related addictive conditions. Overall, all aspects of addiction are addressed in this edition, including health, mental health, forensic, legal and correctional, judicial, socioeconomic, ethical, and governmental aspects of drug misuse and abuse.

As was the goal and objective of the previous editions, we wanted to provide practitioners and the public at large with the most authoritative and comprehensive resource on the subject of alcohol and drug use and abuse. We believe this textbook continues to be the definitive text for students at large, as well as for mental health professionals, clinicians, and scientists. The previous editions of this book have also served as an important source of information for primary care professionals and professionals at large in the fields of medicine and law, and we hope this objective continues with this edition.

In preparing this edition, we sought authors with the best current and comprehensive expertise in the topic areas covered by this textbook. A large majority of the senior authors of this edition are new additions. In addition to new authors, we also

added new relevant and important topics in this edition. The field of addiction has expanded considerably, and we therefore included these new and relevant topics that needed to be addressed in this edition (e.g., a current perspective on the international epidemiology of drug use; the behavioral aspects of addiction; the use of vaccines as possible treatment agents; contingency management procedures as treatment interventions; new knowledge on medication interactions; and other relevant topics as well). In addition, in recognition that a variety of health care workers currently provide treatment to persons with substance use disorders, new chapters were added for the purpose of specifically addressing professions such as psychology, nursing, social work, and counseling as they participate in the training and treatment of persons with substance use disorders. We hope that these new chapters are useful to the wide variety of health care workers, who devote their professional careers to help persons suffering from addictive disorders and conditions.

Addictive disorders have no geographical boundaries, and thus we hope that this book is of use to persons from all countries of the world. A substantial body of addiction-related research has occurred in the United States, and many large epidemiological studies focusing on addictions have been also conducted in the United States over the last several decades; however, research in addictions is certainly not limited to the United States. In fact, new and effective treatments of addictive disorders occur throughout the world, and there are also a growing number of excellent national and regional epidemiological studies on addictive disorders that are conducted in different regions of the world. We have tried to be mindful of this—while previous editions have tended to focus on the United States, the goal of this new edition (and hopefully in subsequent ones) is to be a valuable resource that reflects the world community—both in authors of chapters and in the content of work presented.

Without question, the addiction field has expanded a great deal since the last edition of this textbook, which was published in 2005. In the United States, the recently approved health care reform might positively affect the delivery of health and mental health care vis-à-vis the population suffering from alcohol and drug abuse in this country. At the same time, the availability of substance abuse treatments in other countries can be hampered by health care financing that fails, at times, to recognize addictions as medical illnesses (or treatments as being effective)—even in systems that provide universal health coverage. The financing of health care—in the United States and in other parts of the world—is an area that continues to evolve, and it will be of great interest to see the balance achieved in the use of health care resources for medical disorders such as substance abuse and dependence.

We are, of course, indebted to the team of distinguished contributors who made this new edition possible; certainly, they have all fully satisfied our expectations. We should also thank Charles Mitchell and Tom Gibbons from Lippincott Williams & Wilkins for their outstanding assistance and support in this

new edition. Finally, we deeply thank the readers of this new edition. We hope to meet all of their expectations.

Pedro Ruiz, MD
Eric C. Strain, MD

Since its first printing in 1981, *Lowinson and Ruiz's Substance Abuse: A Comprehensive Textbook* has served as a primary source of knowledge and practice advice for clinicians treating substance use disorders. The three updates in 1992, 1997, and 2004 chronicle the extraordinary progress in medical understanding about substance abuse and about better means of treating and managing the addiction-related changes in cognition, emotion, desire, and behavior that remain so troubling to affected individuals, their families, and society as a whole. This fifth edition reflects more advances in basic, clinical, epidemiological, and behavioral research, and the volume is being released at a particularly historic and important time. At this writing, there is a historic confluence of scientific discoveries and policy changes that may lead to much greater progress in preventing, treating, and managing substance use problems.

Continuing Substance Use Problems – As was true when each of the four prior editions of this volume were published, our country continues to experience significant and broadly destructive substance use problems. Many of the traditional drug problems continue but with new features. For example, at this writing, a large contingent of U.S. soldiers is again returning from a foreign war and is suffering from dependence upon opioids. But it is pharmaceutical opioids from diverted pain prescriptions, rather than heroin that is the source of this current, lethal epidemic. In fact, opioid overdose deaths are currently the number two cause of accidental death in the United States—second only to automobile accidents.

Other traditional drugs of abuse continue to plague our national health and safety. Specifically, alcohol use remains the major factor contributing to automobile accidents, and binge drinking is largely responsible for most injuries and accidents, especially among adolescents and young adults. Although rates of cigarette and all other forms of nicotine dependence continue to fall among most adolescents, college-attending girls have shown disturbing increases in cigarette use.

Still another indication of our nation's continuing problems with substance use comes from the 2009 report of the National Highway and Traffic Safety Administration. That report indicated that approximately 16% of drivers who were randomly stopped at various locations throughout our nation and voluntarily drug tested (oral swab) were found to be positive for illicit and/or prescribed drugs (11% was marijuana). That this was a voluntary test, and that the oral testing method was only sensitive for drug ingestion within the past 3 to 4 hours, suggests that these already alarming findings may well be a significant under representation of the true prevalence of “drugged driving.”

Changes in U.S. Approach to Substance Use Problems – There have been significant changes in U.S. substance abuse policies expressed within the 2010 National Drug Control Strategy and particularly within the recently enacted healthcare reform legislation. These two new policies bring unprecedented emphasis upon public health-oriented, “demand reduction” efforts including prevention, early intervention, and treatment. The text that follows describes how these new policies set the stage for, and will rely heavily upon the basic information and clinical practice suggestions from this fifth edition of *Lowinson and Ruiz's Substance Abuse: A Comprehensive Textbook*.

The 2010 National Drug Control Strategy – For a long while, it was possible to believe that the U.S. drug problem had been created by a few drug-producing and drug-transit countries, and that significant efforts to disrupt the production, prevent the export, and punish the domestic users of those substances would destroy the market and eliminate U.S. drug problems. This thinking contributed to the decades-long U.S. strategy of waging a “war on drugs.” That strategy did have some positive results on the production and export of several drugs such as cocaine and heroin, but that approach ignored a fundamental part of any market economy—the United States has long been the world's largest market for substances of abuse and that market has continued to expand and differentiate; there is a new or re-emergent drug problem almost every year. As would be expected in any market where foreign suppliers are seen to be meeting, and profiting from internal demand, domestic suppliers within the United States have risen to meet that demand. Indeed, five of the major drug problems now affecting the United States are “Made in the USA” (e.g., tobacco, alcohol, marijuana, methamphetamine, and prescription medications). Moreover, because of several foreign countries' efforts to meet U.S. demand for drugs, the resulting increase in local availability of these drugs appears to have promoted unprecedented levels of local addiction in those countries. Ironically, it is likely that U.S. demand for drugs may be in part responsible for both increased development and export of drugs from foreign countries, as well as significant drug-related health and social problems within those countries. For these reasons, there has been increased interest among countries (particularly in this hemisphere) for technical assistance in developing local drug demand reduction efforts (prevention, intervention, treatment, drug courts, community organization) to deal with the social consequences of illegal drugs. Thus, it will be increasingly important to implement national and international demand reduction efforts—as well as ongoing supply reduction efforts—if we are to reduce the scope and

devastation of drug problems in our country and the rest of the world.

Importantly, and abundantly documented in the present volume, scientific research has now produced potent, practical interventions, therapies, and medications that can play an important role in reducing demand for substances. The United States thus has a unique opportunity to promote demand reduction initiatives at home and to assist key partners in addressing their domestic drug problems. Promoting effective internal and international demand reduction programs will help all partnering countries to control their internal demand for drugs and should thereby help reduce drug production and trafficking around the world.

Healthcare Reform: The American Care Accountability Act – The second change in national policy that will significantly increase emphasis upon substance use demand reduction efforts is the recent passing of healthcare reform through the American Care Accountability Act. This historic legislation will expand and integrate treatments for substance use disorders into mainstream healthcare as never before, as part of an overall effort to improve general healthcare quality, efficiency, and effectiveness. Specialty care providers will of course continue to be necessary—likely more necessary than ever—to treat severe and complicated forms of addiction. But this legislation creates a national requirement for primary care providers to learn and practice screening and brief interventions with emerging cases of “harmful” or “hazardous” substance use, and also to become facile with office-based monitoring, managing, and medicating mild-to-moderate cases of substance “abuse” and “dependence.”

Historical Significance – Like many other illnesses, substance use disorders can be arrayed on a continuum of severity and prevalence. This continuum ranges from “harmful or hazardous use,” which affects more than 50 million adults, through the most serious forms of “abuse or dependence” (i.e., addiction), which affect about 24 million adults. But only “addiction” has been eligible for treatment and then almost exclusively in specialty “addiction treatment programs.” Importantly, very few of these specialty care programs are affiliated with any other part of healthcare. Currently, fewer than 20% of the approximately 13,000 addiction treatment programs are affiliated with a larger healthcare system; less than half of the programs have a part-time physician; only a third have a nurse; even fewer have access to an electronic healthcare record.

Because care for substance use disorders has been divorced from care for all other illnesses, few physicians, nurses, pharmacists, or psychologists have received training or clinical experience in the treatment of substance use disorders. If they do, that experience is typically in an emergency room with the most severely and chronically affected patients in a clinical crisis. It is safe to say that this clinical presentation rarely evokes a strong desire to pursue a career in addiction medicine among young physicians, nurses, pharmacists, or other healthcare professionals.

A second effect of this segregation has been to reduce willingness to enter treatment among affected patients—especially those with less severe or emerging forms of the illness. In fact, only about one tenth of those who meet diagnostic criteria for “addiction” enter treatment each year, and the great majority of these cases are stipulated to attend treatment by an employer, spouse, or particularly some part of the criminal justice system. Because of the severe, multiple, and complex nature of the problems presented in this subgroup of patients, 6- to 12-month outcomes from treatment in these specialty care settings typically show at least 50% have experienced serious relapses.

For these reasons public perception—but also medical perception—of the potential benefit from medical treatments of “substance use disorders” is unnecessarily negative. This type of perception would be—and has been—true for any illness where treatment was available only to the most severely, chronically affected cases, was offered exclusively by provider organizations outside the rest of mainstream healthcare and relied upon methods (e.g., group counseling, therapeutic communities, and court-ordered care) that have rarely been trained or practiced by the rest of healthcare.

Consider, for example, that diseases such as tuberculosis, AIDS, depression, and cancer were also treated almost exclusively in specialty care settings. Because the available treatments were often intrusive, invasive, and had a poor reputation for effectiveness, few patients were interested in early detection. Consequently, these specialty care facilities generally treated the most severely and chronically affected, and these areas of healthcare had trouble in attracting young professionals. In all these cases an important part of improving the quality of care for the full spectrum of those disorders was the creation of care options—“first-line treatments”—for the less severely affected cases that could be practically and effectively applied by primary care providers.

Again, as documented in this volume, scientific research has now produced potent, practical first-line interventions, therapies, and medications that can be used by primary care providers to treat many substance use disorders. These first-line treatments are likely to be important in three ways. First, the availability of these treatments should increase physicians’ willingness to screen and identify emerging cases. Few physicians want to identify conditions they are not able to address. Second, the privacy and convenience of primary care, coupled with the availability of many choices in treatment options, should increase those willing to seek treatment earlier, before the illness and its complications become chronic. Third, first-line treatments that may not work well for the most severely and chronically affected may show effectiveness with those whose condition is identified early. Even those who are not adequately treated with first-line treatments often come to accept the need for a more intensive specialty care while there is still time for the condition to be arrested and managed. In turn, experiences like these should increase the perceived effectiveness of available treatments in the eyes of care providers, insurers, pharmaceutical firms, and the public at large—and could bring new patients, new care providers,

more research, teaching and training in schools, and more investment into treatment quality.

Implications for the Treatment of Substance Use Disorders – As illustrated in this brief discussion there is a clear need for primary care involvement and, in turn, first-line treatments that can be attractive to patients, practically applied by physicians and reimbursed by insurers. Research over the past 10 years has provided effective screening and brief interventions for emerging substance use problems, and a number of FDA-approved medications for the first-line treatment of mild-to-moderate addictions within an office-based setting. Because of these scientific developments and because healthcare reform legislation now demands it, primary care providers will soon begin to learn to recognize and provide appropriate treatments for the full range of “substance use disorders.”

Of course, there are important hurdles that remain. Most practicing primary care physicians, nurses, and pharmacists will have to become educated and trained, as most did not receive adequate education in their schools or residency programs. Existing providers will require support and technical assistance from the relatively small number of primary care providers who are experienced in substance abuse treatment.

Traditional specialty treatment programs will also have to change their practices. Many will find new lines of business from medical referrals. Medically referred patients are likely to have a different constellation of health and social problems than those now referred from the legal system. Those patients and their referring physicians will likely demand new types of services and different types of information exchange; most

primary care physicians will expect regular reports of progress and the assurance of referral back to them for continuing care and management. Thus, traditional specialty care treatment programs will likely have to learn a new language and a new working format and culture—but those who develop these new skills are likely to see a new line of clinical business.

Pharmaceutical firms may have to assist primary and specialty care providers in using addiction treatment medications. Early successful experiences may prompt a market for more and even better medications to assist these providers in managing previously undiagnosed substance use disorders—often in their existing patients. Electronic health record providers will have to work out the complicated issues surrounding the collection and exchange of information on patient alcohol and other drug use in a way that maintains patient privacy but enhances patient safety.

Conclusion – These broad and important implications from the suggested integration of care for “substance use disorders” into primary care set a historic context for the publication of the fifth edition of *Lowinson and Ruiz’s Substance Abuse: A Comprehensive Textbook*. The work presented in this edition is likely to be particularly relevant to the training and basic knowledge needs of both primary and specialty care providers as they face the challenges of integrating treatment for “substance use disorders” into mainstream healthcare in the coming years.

Carlos A. Hernandez-Avila, M.D., Ph.D.
Assistant Professor of Psychiatry
University of Connecticut School of
Medicine
Farmington, Connecticut

Jessica Herrera, M.D.
Post-graduate in Psychiatry
Howard University Hospital
Washington, D.C.

Stephen T. Higgins, Ph.D.
Professor of Psychiatry and Psychology
Vice Chair of Research
University of Vermont
Burlington, Vermont

Kevin P. Hill, M.D., M.H.S.
Instructor in Psychiatry
Harvard Medical School
Psychiatrist-in-Charge, Division of Alcohol
and Drug Abuse
McLean Hospital
Boston, Massachusetts

A. Tom Horvath, Ph.D.
Instructor in Psychology
Alliant International University
San Diego, California
President, Practical Recovery
La Jolla, California
President, SMART Recovery
Mentor, Ohio

Matthew O. Howard, Ph.D.
Frank A. Daniels Distinguished Professor
School of Social Work
University of North Carolina at Chapel Hill
Chapel Hill, North Carolina

Yujiang Jia, M.D., Dr.PH.
Chief Epidemiologist
HIV/AIDS, Hepatitis, STD, and TB
Administration
Department of Health
Washington, D.C.

Per Johansson

Christopher W. Johnson, B.A.
Research Associate in Psychiatry
University of Massachusetts Medical
School
Worcester, Massachusetts

Rolley E. Johnson, Pharm.D.
Adjunct Professor of Psychiatry and
Behavioral Sciences
Johns Hopkins University School of
Medicine
Baltimore, Maryland

Hendrée E. Jones, Ph.D.
Professor of Psychiatry
Johns Hopkins University
Baltimore, Maryland

Laura M. Juliano, Ph.D.
Associate Professor of Psychology
American University
Washington, D.C.

- David Kalman, Ph.D.
Associate Professor of Psychiatry
University of Massachusetts
Worcester, Massachusetts
Health Research Scientist, Research Service
Edith Nourse Rogers Memorial VA Medical
Center
Bedford, Massachusetts
- Karol Kaltenbach, Ph.D.
Clinical Associate Professor of Pediatrics
Jefferson Medical College
Director, Maternal Addiction Treatment,
Education and Research
Thomas Jefferson University
Philadelphia, Pennsylvania
- Timothy W. Kinlock, Ph.D.
Senior Research Scientist
Friends Research Institute
Adjunct Professor of Criminology,
Criminal Justice, and Forensic Studies
University of Baltimore
Baltimore, Maryland
- Berma M. Kinsey, Ph.D.
Assistant Professor of Medicine
Baylor College of Medicine
Houston, Texas
- Herbert D. Kleber, M.D.
Professor of Psychiatry
Columbia University College of Physicians
and Surgeons
Director, Division on Substance Abuse
New York State Psychiatric Institute
Attending
New York Presbyterian Hospital
New York, New York
- Clifford M. Knapp, Ph.D.
Associate Professor of Psychiatry
Boston University School of Medicine
Boston, Massachusetts
- John R. Knight, M.D.
Associate Professor of Pediatrics
Harvard Medical School
Senior Associate
Children's Hospital Boston
Boston, Massachusetts
- Thomas Kosten, M.D.
J.H. Waggoner Professor of Psychiatry
Baylor College of Medicine
Director, SUD-QUERI (Quality Evaluation
Research Initiative)
Michael DeBakey VA Medical Center
Houston, Texas
- Henry R. Kranzler, M.D.
Professor of Psychiatry
University of Connecticut Health Center
Farmington, Connecticut
- Colleen T. LaBelle, R.N., C.A.R.N.
Program Director
Office-Based Opioid Treatment Program
Clinical Addiction Research and Education
Unit (CARE)
Boston University Medical Center
Boston, Massachusetts
- Wendy K. K. Lam
Katie M. Lawson, M.A.
Program Coordinator of Psychiatry and
Behavioral Sciences
Medical University of South Carolina
Charleston, South Carolina
- Robert G. Lawson
William B. Lawson, M.D., Ph.D.,
D.F.A.P.A.
Professor and Chairman of Psychiatry and
Behavioral Sciences
Howard University Hospital
Washington, D.C.
- Joshua D. Lee, M.D., M.Sc.
Assistant Professor of Medicine
New York University School of Medicine
Bellevue Hospital Center
New York, New York
- Jack Levinson, Ph.D.
Assistant Professor of Sociology
City College of New York
New York, New York
- Show W. Lin, M.D.
Associate Clinical Professor of Psychiatry
University of Cincinnati College of
Medicine
Cincinnati, Ohio
- Mercedes Lovrecic
Institute of Public Health of the Republic
of Slovenia
Ljubljana, Slovenia
- (The Honorable) Bertha K. Madras,
B.Sc., Ph.D.
Professor, NEPRC
Harvard Medical School
Southborough, Massachusetts
Research Associate
Massachusetts General Hospital
Boston, Massachusetts
- Jorge L. Maldonado, M.D.
Clinical Assistant Professor of Psychiatry
University of Texas Health Science
Center at San Antonio
St. Luke's Baptist Hospital
Christus Santa Rosa Hospital
San Antonio, Texas
- Kasia Malinowska-Sempruch
Director, Global Drugs Policy Program
Open Society Institute
Warsaw, Poland
- Icro Maremmani, M.D.
Professor of Addiction Medicine
University of Pisa
Chief, Vincent P. Dole Dual Diagnosis Unit
Santa Chiara University Hospital
Pisa, Italy
- G. Alan Marlatt, Ph.D.
Professor of Psychology
University of Washington
Seattle, Washington
- David C. Marsh, M.D., C.C.S.A.M.
Associate Dean, Community Engagement
and Clinical Professor
Northern Ontario School of Medicine
Sudbury, Canada
- Elinore McCance-Katz, M.D., Ph.D.
Professor of Psychiatry
University of California, San Francisco
Director, Addiction Medicine Research
San Francisco General Hospital
San Francisco, California
- Una D. McCann, M.D.
Professor of Psychiatry and Behavioral
Sciences
Director, Anxiety Disorders Program
Johns Hopkins School of Medicine
Baltimore, Maryland
- Jennifer McNeely, M.D., M.S.
Assistant Professor
NYU School of Medicine
Department of Medicine, Division of
General Internal Medicine
New York, New York
- Gerard M. Meenan, M.S.
Laboratory Manager, Clinical and Forensic
Toxicology
Ammon Analytical Laboratory
Linden, New Jersey

- Robert Milin, M.D., F.R.C.P.C.
Associate Professor of Psychiatry
University of Ottawa
Director, Adolescent Day Treatment Unit,
Youth Psychiatry Program
Royal Ottawa Mental Health Centre
Ottawa, Ontario, Canada
- Karen A. Miotto, M.D.
Clinical Professor of Psychiatry and
Behavioral Sciences
David Geffen School of Medicine at UCLA
Director, Addiction Medicine Service
Semel Institute of Neuroscience and
Human Behavior
Los Angeles, California
- Lisa A. Mistler, M.D., M.S.
Assistant Professor of Psychiatry
University of Massachusetts Medical
School
Worcester, Massachusetts
- Rudolf H. Moos, Ph.D.
Professor of Psychiatry and Behavioral
Sciences
Stanford University
Senior Research Career Scientist
Department of Veterans Affairs Health
Care System
Palo Alto, California
- Betty D. Morgan, Ph.D.,
P.M.H.C.N.S., B.C.
Associate Professor of Nursing
University of Massachusetts, Lowell
Lowell, Massachusetts
- David F. Musto, M.A., M.D. (deceased)
Professor of Child Psychiatry
and History of Medicine
Yale University
New Haven, Connecticut
- Ethan Nadelmann, J.D., Ph.D.
Executive Director
Drug Policy Alliance
New York, New York
- Niru S. Nahar, M.D., M.P.H.
Assistant Clinical Professor of Psychiatry
Columbia University
Attending Outpatient Psychiatrist
Harlem Hospital Center
New York, New York
- Robert G. Newman, M.D., M.P.H.
Director, Baron Edmond de Rothschild
Chemical Dependency Institute
Beth Israel Medical Center
Professor, Departments of Epidemiology
and Population Health, and Psychiatry
and Behavioral Sciences
Albert Einstein College of Medicine
New York, New York
- Thomas Anh Nguyen, M.D.
Assistant Professor of Clinical Psychiatry
University of Cincinnati College of
Medicine
Cincinnati, Ohio
- Benjamin R. Nordstrom, M.A., M.D.
Ph.D. Candidate in Criminology
University of Pennsylvania
Medical Director, Addiction Treatment
Services
Penn Presbyterian Medical Center
Philadelphia, Pennsylvania
- William B. O'Brien
President
Daytop Village, Inc.
New York, New York
- Frank M. Orson, M.D.
Associate Professor of Medicine
Baylor College of Medicine
Chief, Allergy/Immunology
Veterans Affairs Medical Center
Houston, Texas

Substance Abuse

A Comprehensive Textbook

**FIFTH
EDITION**

Historical Perspectives

David F. Musto ■ Eric D. Wish

The last three decades of the 19th century saw far-reaching transformations in American life. With immigration from all parts of Europe and from Asia, the population expanded greatly and became heterogeneous in speech, religion, and way of life. Many of the immigrants, unprepared to join the agricultural sector of the economy, crowded into the growing cities, which soon began to exhibit today's familiar urban problems. With the industrial revolution, large enterprises grew and attained a new level of economic power; with the construction of the railroads, vast areas of the West were opened for settlement and exploitation of the timber and mineral resources. In social terms, the geographic dispersal of the population that occurred as many moved west spelled the end of the once close-knit family. In political terms, these changes terminated the hegemony of the Protestant, North European group that had controlled the affairs of the nation through the Civil War.

The variety of social ills that inevitably attended these rapid changes in all aspects of life gave rise to a spirit of reform that ran through American culture from the mid-19th century to 1920. This reformist or "progressive" impulse stemmed largely from the fear of social disorder among the same middle- and upper-class citizens whose political and economic power was increasingly insecure. Rapid transformation seemed to threaten the heart of American life. While most reforms of the Progressive Era (1890 to 1917) were aimed at curing the disorder itself, some movements naturally responded to specific evils that seemed to result from the upheaval (1). Increasingly, crime and immorality were blamed on easily obtained narcotics and alcohol. This goal of moral uplift of the underprivileged was shared by Progressive Era temperance activists, political reformers, and crusaders against the indiscriminate use of psychoactive substances such as opium and cocaine.

THE BACKGROUND OF PROGRESSIVE ERA REFORMS

Alcohol and the Prohibition Movement

Alcohol had been the object of recurrent prohibition crusades in the 19th century, and as the Progressive Era developed, some sociologists began to speculate that alcohol abuse was actually the result, rather than the cause, of poverty. However,

alcohol seemed to exacerbate almost all the evils of a disorderly society. Even if it could not be wholly blamed for economic failure, it certainly did not help. Alcohol lowered efficiency and productivity and, in the eyes of the reformers, increased all the evils of the urban scene: prostitutes worked in and around saloons; alcohol apparently made men more susceptible to the influence of corrupt city bosses; and it broke up families and invited violence. It reduced the chances for freedom, prosperity, and happiness and did not contribute to the virtue and enlightened character of an electorate needed by a democracy.

Furthermore, alcohol worsened the situation of Protestant Christianity. Not only was the saloon associated with Catholic immigrants, but it also seemed to make people incapable of responding to evangelical Protestantism (2). If it made a person unconcerned about something as urgent as salvation, then surely it would make that person oblivious to public concerns. Democratization, therefore, made it even more important that the saloon be abolished. Extending the powers of the landless class, in itself, posed quite a threat to stability; drunken masses would constitute an intolerable danger (3).

With the final temperance movement that led to the adoption in 1919 of the Eighteenth Amendment, the nation moved toward implementation of a prohibition justified on moral, religious, and scientific grounds (4). It is quite likely that by 1919 a majority of Americans believed that liquor prohibition would be a great benefit in reducing poverty, crime, broken families, lost work time, and immorality. Eventually, every state except Rhode Island and Connecticut ratified the amendment.

Narcotics, Cocaine, and Cannabis

By the end of the 19th century, the narcotics problem was also worrying reform-minded legislators, health professionals, and the laity. Opium in its crude form had been imported into North America from the time of the earliest European settlements. Various medicines were made from it. Alcohol extracts of crude opium included laudanum and paregoric, and opium was mixed with other drugs in patent medicines, among the most popular of which was Dover's powder, originating in England in the 18th century. American statistics on opium imports were not kept until the 1840s, but from that

time on, domestic consumption rose rapidly until the mid-1890s, when the annual importation of crude opium leveled off at about a half million pounds (5). After passage of federal laws in 1914 strictly limiting importation of opium, the import statistics became less helpful in estimating national consumption, and smuggling became a greater problem. Yet, statistics for the pre–World War I period provide good evidence that a steady increase of opium use in the United States occurred in the 19th century and that when the 20th century began, there was already a substantial consumption of the drug for medicinal and nonmedicinal purposes. State laws regulating the availability of narcotics were first enacted around the time of the Civil War, and many states attempted to control the drugs by the 1890s.

Several major technologic and chemical advances made the most powerful ingredients in opium available in pure, cheap form. In the first decade of the 19th century, morphine was isolated from opium, and by 1832, American pharmaceutical manufacturers were preparing morphine from imported crude opium. Codeine was isolated in 1832, and this less-addicting substance became a common form of manufactured derivative, particularly after morphine and heroin were severely restricted in the United States after World War I (6,7). Heroin, a trade name of the Bayer Company for diacetylmorphine, was introduced commercially in 1898, with the hope that acetylation of the morphine molecule would reduce its side effects while maintaining its effectiveness in suppressing the cough reflex. A similar hope was entertained the next year for acetylation of salicylic acid, a mild analgesic with undesirable side effects, which was then marketed as Aspirin, the Bayer trademark for sodium acetylsalicylic acid. Heroin, of course, proved to be at least as addictive as morphine and eventually ousted morphine as the drug of choice among American drug habitués (8). The increasing use of heroin in this period is an example of the effectiveness of three innovations adopted by 19th-century industrial enterprises: manufacturing, rapid distribution, and effective marketing techniques.

Coca leaves, in their indigenous growth areas in South America, were known to have stimulant properties and had been used for centuries by natives. Coca's unusual properties were popularized in Europe and America in the mid-19th century, and an alcohol extract of the leaves, which contained some of the active stimulant cocaine, often appeared under the name "wine of coca." In the 1880s, pure cocaine became more easily available because of advances in manufacturing technology, and it was immediately praised, especially in the United States. Its stimulating and euphoric properties were touted for athletes, workers, and students, and bottlers of popular soda drinks, and easily obtained "tonics" added cocaine to obtain a stimulant effect. Medical uses were soon discovered, and worldwide experimentation established cocaine as an anesthetic for the surface of the eye and as a block to pain stimuli when injected near a nerve. The stimulant properties were bothersome side effects of cocaine when used as an anesthetic, but within a few decades, satisfactory substitutes were developed that were considered less habituating, such as pro-

caine in 1905. Cocaine was also convenient for shrinking nasal and sinus membranes, and it became one of the early effective remedies for "hay fever," allergies, and sinusitis. As an over-the-counter remedy for hay fever or "nasal catarrh," in powder form to be sniffed or as a spray, cocaine began to be criticized as misused or carelessly dispensed for mere pleasure or dissipation.

In the period from about 1895 to 1915, cocaine became associated in the popular and medical press with southern blacks' hostility toward whites. Vicious crimes said to have been perpetrated by blacks were commonly attributed to the effects of cocaine. In efforts to pass antinarcotic legislation, this association was repeated by federal officials and spokesmen for the health professions, although direct evidence for such a close and specifically racial association was wanting or even contradictory (9). Eighty years ago, cocaine was considered a typically "Negro" drug, whereas opiates, and specifically heroin, were described as characteristically "white," illustrating the influence of social tensions and racial stereotypes on interpretation of the narcotics problem.

Cannabis, or marihuana, in the form of "reefers" or "joints," seems to have been unfamiliar in the United States until the 20th century, yet there has been a long-standing fear of hashish, a concentrated and powerful form of cannabis. Hashish was known from its use as an esoteric and perilous drug popular in the Middle East and from the description of its bizarre effects by literary figures who experimented with it in the mid-19th century (10).

PROGRESSIVE ERA FOOD AND DRUG REFORMS (1898 TO 1906)

Faced with what they perceived as social breakdown associated with the pernicious effects of drugs and alcohol, reformers turned to the federal government. In the period leading to the Progressive Era, state and local laws were losing credibility as effective measures to control distribution and consumption of both alcohol and psychoactive drugs. The failure was usually ascribed to the patchwork-quilt character of laws below the federal level of government (11). But federal action was limited by the few constitutional bases for laws that would affect abuses. Other than the tariff, the federal government was restricted mostly to regulating interstate commerce and levying taxes. Police and health powers, obviously the most appropriate for combating addiction and illicit drugs, were the province of the states. For example, the United States Public Health Service and its antecedent agencies were limited to dealing with communicable diseases and gathering and disseminating such medical information as vital statistics and public health advice; they could not provide direct delivery of health services except to their legal wards, chiefly the Merchant Marine and American Indians (12). The armed services excepted, federal police agencies included alcohol tax agents, members of the Coast Guard, and customs and immigration officers. Therefore, there was little precedent for federal regulation of dangerous drugs, and no federal policing agency could easily add this burden to its current duties. As a result, the range of activities that were

left to an individual's or company's sense of fair play was remarkably large. In the 19th century, federal law did not require the labeling of drugs on over-the-counter proprietaries. Thus, these patent medicines could contain any amount of, say, morphine without acknowledgment, and could even aver that the potion contained no morphine. The percentage of alcohol in some popular remedies was higher than that in many cocktails today. Claims that a proprietary could cure cancer, tuberculosis, or any other ailment were legally unchallengeable; no tests of efficacy, purity, or standardization were required. In addition, newspapers, the primary source of information for most Americans, were chary of offending their advertisers, and many papers had contracts with proprietary manufacturers that would become invalid with the enactment of any state law requiring disclosure of contents or any modification of advertising claims (13).

Hence, it is not surprising that no federal law requiring content information and some accuracy of claims was enacted until 1906, when public concern reached a pitch sufficient to propel the government to resort to its power over interstate commerce to enact such a measure. The law, the Pure Food and Drug Act, contained some of the earliest federal provisions affecting narcotics; if any over-the-counter remedy in interstate commerce contained an opiate, cannabis, cocaine, or chloral hydrate, the label was required to state its contents and percentage. The effect of this simple measure apparently was to reduce the amount of such drugs in popular remedies and also to hurt their sales, although other proprietaries flourished. The Proprietary Association of America, dismayed at the accusation of being “dopers,” favored strict limitation of dangerous drugs in their products and ostracized manufacturers who continued to put such drugs as cocaine in “asthma cures.”

Although a step had been taken to warn proprietary users of the amount of dangerous drugs in the remedies, still nothing had been done to bring under control another target of reform: “dope doctors” and pharmacists who purveyed opiates and cocaine to anyone who asked for them. The percentage of such deviants in each profession was not large, but they took advantage of the broad authority given to all licensed pharmacists and physicians to use their professional judgment in the delivery of medicines and services, and the dominance of the state in the licensing of the health professions seemed unassailable by the federal government. In addition to purchasing drugs from professional miscreants, one could order them from mail-order houses. How to rectify this promiscuous distribution of narcotics presented another difficult constitutional problem for federal action.

TOWARD PROHIBITION OF NARCOTIC DRUGS (1909–1919)

The Shanghai Commission and the Smoking Opium Act (1909)

Several bills directed at the traffic in narcotics had been introduced into Congress before 1908, but federal legislation was accomplished only after President Theodore Roosevelt

convened the Shanghai Opium Commission in 1909 to aid the Chinese Empire in its desire to stamp out opium addiction, particularly opium smoking (14). The measure, intended more as evidence of America's good faith in convening the commission than as an adequate weapon against American narcotic abuse, was modest and limited. Called The Smoking Opium Exclusion Act, it outlawed importation of opium prepared for smoking (15). Its passage while the Shanghai Commission was in session under the chairmanship of an American, the Right Reverend Charles H. Brent, Episcopal bishop of the Philippine Islands, was designed to show the delegates of other nations that the United States was willing to take steps to aid control of world opium traffic. American delegates reported back to the State Department that the announcement of the act's passage was met with an impressive response from the other 12 nations represented.

The American delegates, however, and indeed the departments most closely associated with narcotic policy planning—State, Treasury, and Agriculture—were aware that the legislation against smoking opium was but the first step in controlling a national problem described as serious and threatening to progress. The nation needed a law that more closely controlled sales of over-the-counter remedies, excessive or careless prescribing of narcotics, and other avenues of easy access to narcotics. The question, of course, was how the federal government could accomplish this by constitutional means. Both the power to regulate interstate commerce and to levy taxes provided some basis for federal narcotics control. The State Department, which coordinated domestic legislation and planning until 1914, eventually opted for the latter, reasoning that by using tax administration, all narcotics could be traced, not just drugs shipped from one state to another.

The first of the administration's proposed bills, drafted in 1909, provided for extremely harsh penalties and was intricately detailed but without exemption for proprietaries that contained very small amounts of the narcotics (16). The effect of such bills would have been to make the handling of narcotic preparations so risky and complicated for retail outlets that the whole narcotic traffic would fall into the hands of physicians. The physicians would be limited only by their good judgment and by restrictions that state legislatures might enact (e.g., record keeping, prohibiting the refilling of narcotic prescriptions, or maintaining addicts) (17).

Such tough proposals met with opposition from the rank and file of the drug trades, proprietary manufacturers, and some members of Congress who feared, among other things, that such a precedent might be extended to alcohol. Before the Webb–Kenyon Act was passed over President Taft's veto in 1913 and upheld by the Supreme Court, it was legal to live in a dry state, purchase liquor from a wet state, and have it delivered via interstate commerce.

The Hague Treaty (1912)

While domestic debate continued among the specific interests affected by the proposed narcotic legislation, the United States continued its campaign to regulate the international traffic in

narcotics. Because the Shanghai Commission was not empowered to draft a treaty (the delegates could only make recommendations), American diplomats sought a second meeting for the preparation of an international treaty. After much persuasion and repeated setbacks, the Netherlands, at America's request, convened the International Opium Conference at The Hague in December 1911. Again, Bishop Brent, head of the American delegation, was chosen to preside, and after weeks of debate and compromise, the delegates signed The Hague Opium Convention in January 1912 (5). The title is somewhat misleading; the treaty also sought to control cocaine. An American and Italian suggestion that cannabis be included was not accepted.

The Hague Treaty emphasized enactment of legislation in each nation to control the production of crude substances, their manufacture into pharmaceutical products, and their distribution within the nation and abroad (18). The United States government believed that its people were extravagant consumers of opiates; federal publications reported that the country was, by far, the largest consumer of opium per capita among Western nations. In the words of the State Department's opium commissioner, Dr. Hamilton Wright, "Uncle Sam is the worst drug fiend in the world," consuming, he claimed, more opium per capita than the fabled opium-using Chinese (19). The thought within the State Department was that if the nations that grew opium and coca enacted strict legislation in the spirit of the treaty, the American problem would be greatly reduced, perhaps would even vanish. The challenge was to persuade other nations to have a "correct" view of narcotic use and to enforce legislation in accord with this view.

Yet the stern international measures envisaged by such reformers as Dr. Wright were not adopted before World War I. The Hague Treaty was not airtight; its vague phrases did not compel the ratifying nations to enact strict laws to reduce narcotic distribution to solely medical purposes. Moreover, American domestic legislation, now promoted as the American implementation of The Hague Treaty, was still hampered by doctrines of states' rights and constitutional interpretation, to say nothing of the competing interests of physicians, pharmacists, and manufacturers of proprietary medicines.

The Harrison Act (1914)

In 1913, the administration of President Woodrow Wilson drafted legislation grounded in its constitutional taxation power. It was hoped that the new measure would, at the very least, bring into the open the vast narcotic traffic so that the states could take appropriate health and police measures or step up enforcement of existing laws. At the most, Wright hoped the Harrison Act, as the legislation was called, would be recognized as the fulfillment of an international obligation in accord with Article VI of the Constitution and thus take precedence over the rights of states. If this were the case, the general phraseology of the Harrison Bill, such as requiring the prescription of narcotics "in good faith," could be interpreted broadly and would allow prosecution of "dope doctors," other malpracticing professionals, and peddlers.

The measure passed the House of Representatives relatively easily but slowed down in the Senate and did not finally pass into law until December 1914. It was to come into effect on March 1, 1915 (20). In its final form, the act allowed proprietary medicines to include small amounts of narcotics, and physicians were not required to keep records of medicines dispensed while they personally attended a patient. Legitimate purveyors of opiate and cocaine preparations were required to register with the Bureau of Internal Revenue and obtain a tax stamp, for which they paid one dollar per year. Detailed record keeping was required for most transactions, and legal possession by a consumer was made dependent on a physician's or dentist's prescription. Individual consumers were forbidden to register (21). But when federal personnel sought to arrest the dope doctors for prescribing, they discovered that many federal district court judges thought the action was an infringement of state police powers. In 1916, a crucial Supreme Court interpretation, known as the first *Jin Fuey Moy* decision, held that it was beyond federal powers to prohibit narcotics possession by anyone to whom the Treasury Department had refused registration, such as a peddler or addict (22).

Not until the height of the war effort—and in the midst of a zealous drive to rid the nation of perceived threats to its integrity and security—was a successful campaign mounted to strengthen the Harrison Act to prevent health professionals from dispensing narcotics to persons whose only problem was addiction itself.

DRUG CONTROL IN A PERIOD OF DIMINISHING USE (1919–1962)

Size and Symbolism of the Addiction Problem

The true size of the drug abuse problem in the early decades of the 20th century (Dr. Wright's hyperbole notwithstanding) was a matter of public debate, much as it is today. Whereas the Public Health Service in rather sober studies published in 1915 and 1924 argued that there were probably never more than a quarter million habitual users of opiates and cocaine in the nation, the Treasury Department assessed the number at slightly more than one million, who were described as moral wretches for the most part (23,24). New York City officials claimed that heroin addicts were responsible for huge numbers of crimes and estimated that in 1924, the remarkable figure of 75% of all crimes were committed by addicts (25). In 1919, the mayor of New York City linked heroin with anarchism and political bombings (26)—and his was not an isolated opinion. There was fear in the nation about several groups that were considered extreme domestic threats: socialists, members of the Industrial Workers of the World, Bolsheviks, and addicts (27). The image of the addict as immoral and criminal, a belief dating back among respectable writers and observers well into the 19th century, made them an obvious target for serious social reformers, as well as for ambitious politicians and bureaucrats. If one accepted that they numbered more than 1 million in a nation of 100 million, stern action and uncompromising control seemed entirely

justified. Nevertheless, this sentiment coexisted with experiments in public-health-based addiction management and medical theories of addiction as a treatable disease. When the results of attempts at treatment proved disappointing, faith in treatment waned, and the punitive model of drug abuse control won, as it were, by default.

Maintenance Clinics (1912 to 1925)

Beginning in 1912 in Jacksonville, Florida, 40 odd clinics were established in various parts of the country to supply addicts with maintenance doses of narcotics in what were designed to be controlled conditions. The clients were usually those too poor or socially marginal to have access to private physicians. A relatively small percentage of the nation's addicts were enrolled in these clinics, particularly if one accepted the extravagant estimate of more than a million addicts for the whole nation. It is likely that the number of addicts registered at any one time in maintenance clinics did not exceed 5,000 (28). The average age of patrons was about 30 years, and they had usually been addicts for at least several years before joining the clinic. Some clinics were operated by police departments (e.g., New Haven) and others by health departments (e.g., Atlanta), and attitudes toward the clinics varied from one city to another. Some were clearly operated under political patronage and for a profit. In a few instances, as in Albany, New York, both cocaine and morphine were dispensed.

An exception to the policy of almost all these clinics, which was to maintain addicts indefinitely on morphine, was the clinic operated in 1919 and 1920 by the New York City Department of Health. Here heroin was used to entice addicts into a detoxification and rehabilitation program. After almost a year of operation, the city ended its experiment. It found that almost all addicts, even if detoxified, returned to heroin after release from 6 weeks of hospital treatment. The Health Department concluded that restriction of availability by the police and federal agents was necessary if addiction was to be effectively diminished. About 7,500 persons registered at the clinic, and almost all received gradually decreasing doses of heroin; 10% were younger than age 19 years (29).

Adoption of a Federal Antimaintenance Policy

Given the inadequacy and variety of state laws, there seemed no way to control physicians and pharmacists—even though the unethical percentage was small—other than by imposition of federal authority. If a physician could exercise judgment as to when and whom to maintain in an opiate habit, it was certain that some physicians would be unscrupulous, thus spreading the habit and reaping a profit. Therefore, in addition to reforms in the medical and pharmaceutical professions, the goal of the federal government was to restrict that breadth of medical judgment by law. The undertaking was hazardous, for such federal encroachment on medicine was unprecedented; the physician would be allowed to maintain

an opiate addict only if approved by a local narcotics agent. These exceptions would be chiefly iatrogenically addicted and middle-class patients. (One should keep in mind that some observers believed that physicians created about half of American opiate addiction.)

In 1918, partly to counteract the *Jin Fuey Moy* decision, the Treasury Department established a Special Committee on Narcotics Traffic. The committee helped persuade Congress to pass strengthening legislation in February 1919 (30). Then, aiding the government effort, the Supreme Court, in two fundamental interpretations of the act, rejected by a vote of five to four the argument that it was legal to maintain an addict by prescription if the addict had no problem except addiction (31). To carry out the strict Supreme Court ruling that addiction maintenance be severely limited in the United States, a Narcotics Division was established in the Treasury Department in December 1919. It was part of the newly formed Prohibition Unit of the Internal Revenue Bureau, which had been created to enforce liquor prohibition. Its first head was Levi G. Nutt, a pharmacist from Ohio who had risen in the ranks of the tax unit. He now oversaw about 150 narcotic agents scattered across the nation.

Addiction Disease and Law Enforcement

One result of antimaintenance law enforcement, which was backed by leading physicians and such reformers as Dr. Alexander Lambert, president of the American Medical Association (AMA) in 1919, was a curious decline in the respectability of a certain medical theory that would have admitted maintenance as a rational therapy response: the immunochemical theory of opiate addiction. This happened because both reformers and government agents feared maintenance and were disgusted by the subterfuges some health professionals used to justify a profitable trade. Their fear and disgust extended to suspicion of any justification for maintenance. Supplying drugs to an addict came to be considered a form of medical malpractice that endangered society by perpetuating criminal and immoral persons in their esoteric pleasures.

In the immunologic reasoning that was popular among some addiction experts prior to 1919, the argument ran that ingestion of, say, morphine stimulated the formation of antibodies, like those produced against smallpox virus, or of antitoxins, like those produced against the toxins of the diphtheria bacterium. Such theories were popular explanations for illnesses in the late 19th and early 20th centuries, and in many cases, saved lives. With regard to addiction, and according to several competent and respected clinicians, the theory held that maintenance doses of an opiate would be required to bring an addict's physiology into balance with the level of antibodies or antitoxins present. If too little opiate were administered, the body would begin to experience withdrawal symptoms as a result of the action of unneutralized antibodies or antitoxins; if too much opiate were administered, the body would experience the physiologic

effects of opiates. According to Dr. Ernest Bishop of New York, the amount of opiate required to balance an individual's physiology could be determined with great precision, and the addict would remain a fully normal person only so long as this exact dose was maintained. However, Dr. Bishop did not rule out cure in some instances by various popular medical regimens (32).

The intimate link between this scientific theory and its implications for public policy made its adherents suspect. Those who practiced medicine in accordance with the theory could be indicted and convicted of violating the laws defining what was legitimate medical practice as interpreted by 1919 Supreme Court decisions. When Dr. A.G. DuMez of the Hygienic Laboratory (now the National Institutes of Health), one of the leading addiction experts of the United States Public Health Service, published his endorsement of some of the immunologic experiments in 1919, he was asked by the AMA's Committee on Addiction to retract his statement, which he did, in part, by qualifying his previous endorsement (33,34). Within 2 years, the question of the cause of addiction was so controversial that the Surgeon General of the Public Health Service wrote to the president of the Louisiana State Board of Health to advise that the phrase "physiological balance" was too controversial to be included in a description of narcotic treatment and the enforcement problem (14).

It was soon demonstrated that immunologic substances could not be found in the blood; the adherents of "addiction disease" caused by a simple and easily detectable immunologic process were evidently in error. Yet the intense political nature of the addiction question and the fear of addicts, whose numbers were very likely overestimated, had an impact on the exchange of scientific information and medical practice. At the level of social planning, maintenance was judged poor public policy, and it was to be eliminated if at all possible. This decision might, indeed, have been the correct one, but the suddenness of implementation and the emotionally charged attitude toward addicts and their maintainers caused policy to collide dramatically with research and medical opinion.

The events of 1919 spelled the eventual end of the clinic experiment and of the concept of addiction as a health problem. Maintenance of nonmedical addicts had become illegal, even if records were carefully kept and a physician examined every patient and tried to keep the drug down to a minimum. By 1925, all the clinics known to the Narcotics Division had been closed.

The rapidity with which opinion on controversial questions like addiction and narcotics can be crystallized is one of the most interesting features of narcotic control in the United States. To resist the closure of maintenance was difficult; the new policy ensued from the anger, scapegoating, fatigue, and frustration of the lawmakers because a simple answer to addiction was still not available. The burden for the next several decades would rest on law enforcement to prevent illegal access to narcotic supplies. The hope for a simple medical cure had been dashed.

Fear of Federal Control on the Part of Health Professions

Court decisions continued to restrict what remained of a physician's right to maintain an addict. Procedures used by agents to get information led to hostility and suspicion, but the reason that enforcement personnel used such methods as informers was that they had repeatedly encountered determined profit-making physicians whose concern for the welfare of their patients and the community was nil. A further disagreement between the federal government and the medical profession arose from a question even more fundamental than maintenance: Did the federal government have the right to interfere with medical practice and exempt certain classes of patients from a doctor's judgment? The medical profession came out of the social agitation associated with World War I with a fear that the federal government would enter into "state medicine" or compulsory health insurance. After 1920, the AMA greatly resisted the various federal measures concerning health, such as the Sheppard-Towner Act for Maternal and Child Care, which was to be financed by matching grants to the states. The medical profession fought such federal intervention with great vigor and generally with success (35).

Yet the Harrison Act remained a thorn in the side of professional medicine. If it was constitutional for government to say who could be maintained or not, a precedent was set for further incursions into medical practice. A similar problem for the AMA was the Willis-Campbell Act of 1921, which limited a physician's prescriptions for alcohol to a fairly modest number and placed other restrictions on the kind and amount of alcohol that could be prescribed. Hence, physicians were disturbed at the Harrison and Willis-Campbell Acts in part not because they wanted to maintain addicts or become saloonkeepers (although at times a few seemed quite willing to do just that), but because they were fearful of where this unprecedented use of federal power in the health fields might lead.

Narcotic Drugs Import and Export Act (1922)

After the outlawing of addiction maintenance, a series of federal statutes in the 1920s sought to fill gaps in the federal control of narcotics. The first, the Narcotic Drugs Import and Export Act of 1922, permitted only crude narcotics to enter the United States; American drug companies would manufacture them into pure substances (36). Any subsequently manufactured foreign narcotic product in the United States, like Swiss morphine or German cocaine, was illegal. Intricate restrictions were placed on American export and transshipment of narcotics because it was feared that a great deal of morphine was arriving in China, via Japan, in this manner or that it was being smuggled back into the United States after export to Canada or Mexico. Finally, the Federal Narcotic Control Board, composed of the secretaries of Treasury, Commerce, and State, was established to authorize legitimate imports and exports.

Restrictions on Heroin (1924)

In the mid-1920s, the United States attempted to obtain international sanctions against the manufacture of heroin, which by then was considered the most dangerous narcotic, particularly for adolescents. Most of the crime in New York City was blamed on heroin, including daring bank robberies, senseless violence, and murders. The danger of heroin was exaggerated by respectable antinarcotic reformers in order to inform the American people of its peril. One excellent example is the educational campaign of Captain Richmond Pearson Hobson, a hero of the Spanish-American War, former congressman, and ardent prohibitionist, who directed his speaking and organizational talents against narcotics shortly after the Eighteenth Amendment's ratification. Captain Hobson was wont to warn women who habitually used any particular face powder to have it checked for heroin, lest they become addicted. He claimed that one dose of heroin was addictive, and that an ounce of heroin could addict 2,000 persons. He blamed a national crime wave on heroin, claiming that it was a stimulant to senseless violence. He desired that a compilation of such warnings be sent into every American home and requested Congress to print 50 million copies of his eight-page brochure, "The Peril of Narcotics" (37). The pamphlet was not printed, but a revised version of his message was printed in the Congressional Record and distributed by sympathetic congressmen (38). Hobson represents a popularizer of heroin dangers who disseminated grossly erroneous information on addiction that tended to alarm the public while providing a convenient explanation for unrelated, serious social problems.

In 1924, partly to encourage other nations to regulate narcotics and partly to assist in the American fight against addiction, Congress prohibited importation of crude opium into the United States for the manufacture of heroin (39). The author of this legislation, Representative Stephen Porter of Pittsburgh, chairman of the House Foreign Affairs Committee, took the leading congressional role in the international negotiations and planning for domestic control of narcotics in the 1920s.

Federal Narcotic Farms (1929)

Porter's second major effort was to provide for two "narcotic farms" where addicts could be treated as sick individuals and detoxified, and where they could perhaps assist investigators in the search for a cure (40). A factor in this legislation was that federal prisons were becoming jammed with Harrison Act violators, most of whom were also addicts. Congress had to build either two new prisons or two treatment centers. Thus came into being the Lexington, Kentucky, and Fort Worth, Texas, narcotic hospitals operated by the United States Public Health Service. This legislation also provided for the Public Health Service Narcotics Division, which evolved into the present National Institute of Mental Health (NIMH) and National Institute on Drug Abuse (NIDA).

The Federal Bureau of Narcotics (1930)

Finally, Representative Porter sought to establish in the Treasury Department an independent narcotics agency. The Narcotics Division had accompanied the Prohibition Unit when the latter was raised to the rank of bureau in 1927, and although still subordinate and headed by an assistant commissioner, it was gradually expanding. In 1930, shortly before his death, Porter shepherded through Congress the act creating the Federal Bureau of Narcotics (FBN) (41). When the Prohibition Bureau moved from the Treasury Department to the Justice Department in the mid-1920s, the Narcotics Division remained behind, but its head, Levi G. Nutt, was not to become the first commissioner of narcotics. Nutt's son and son-in-law were implicated by a federal grand jury in "indiscreet" dealings with the recently slain New York narcotics underworld figure, Arnold Rothstein (42). Nutt was transferred from his post a week after the filing of the grand jury's report, which also touched on his own activities and those of the New York district office. Assistant Prohibition Commissioner Harry J. Anslinger was picked from the international control section of the Prohibition Bureau to take temporary charge of the Narcotics Division.

Anslinger had not been deeply involved with narcotics; his training was in the foreign service and in international negotiations to cut off rum running. To Representative Porter, however, he seemed the ideal candidate. Accustomed to what Porter likely regarded as foreign wiles and ulterior motives in areas of American moral concern, he could ably represent the United States in its struggle, dating back to 1906, to achieve international control of narcotics traffic. The medical aspect of the question seemed secondary, for if smuggling could be ended, the narcotics problem would take care of itself.

Thus began the 32-year tenure of Commissioner Anslinger. Most of the enforcement questions had been settled: maintenance was illegal; the image of the heroin addict was well-publicized by such spokesmen as Captain Hobson; and a national system of agents was established with fairly well-defined styles of enforcement, although there was the eternal integrity problem in the agents' dealings with smugglers. The most profound effect on narcotics enforcement in the immediate future was not new policies but the Depression, which drastically reduced the FBN's budget, led to detailed scrutiny of even its telephone bills by Congress, and probably helped explain the parsimony characteristic of the Anslinger tenure. Even in the 1960s, the Bureau made a fetish of a low budget.

The Marihuana Problem (1930 to 1937)

Commissioner Anslinger's first major issue appeared even as he took office—a quickly burgeoning fear centered in the Southwest about a plant grown and used by Mexicans who had poured into the region as farm laborers in the prosperous 1920s. This drug or plant was known as locoweed, marihuana,

or, more scientifically, cannabis. As the fear of marijuana grew, so did the belief that it stimulated violence and was being slyly sold to American schoolchildren. In the early 1930s, the FBN tried to minimize these fears and suggested that state laws were the appropriate response. The Uniform State Narcotic Drug Act proposed in 1932 included marijuana regulations as an option for state legislation; the Bureau thought it had found the solution. The plant grew in the United States, so the best response would be from local government, not from an agency that had its eyes on the smuggling of drugs from Turkey, France, Bolivia, China, and Siam.

Yet, recalled Anslinger, the Treasury Department decided to make marijuana use a federal offense, more as a gesture to the fearful Southwest than as a comprehensive and probably effective plan for marijuana control. The Department's bill was modeled on the National Firearms Act, which was declared constitutional by the Supreme Court in March 1937. In April, Treasury representatives went before Congress to ask for a similar "transfer tax" and licensing system for marijuana. Congress passed the Marijuana Tax Act of 1937 without dissent, and by October it was in effect (43). Opposition to the act in committee came from an AMA representative, Dr. William C. Woodward, who stated that this was an area of state concern, and that it should not become one more example of federal encroachment on the medical profession.

In the enforcement of the act, the Bureau described marijuana as a fearsome substance, but played down any suggestion that it was a problem out of control. The apparent goal was to make the drug unattractive, but not to create a panic over claims that it was widely disseminated to schoolchildren (10).

Adoption of Mandatory Minimum Sentences (1951 to 1956)

World War II brought narcotic use, particularly opiates, to a low point. Control over the growth of opium poppies had been sought in 1942 by the Opium Poppy Control Act (44). There was other legislation at this time to resolve technical problems, strengthen penalties, and include synthetic narcotics, such as meperidine, under federal regulations (45). At the close of hostilities, however, the FBN anticipated a resumption of illicit world narcotic trade. The Bureau looked back to World War I when, it was claimed, there had been a postwar upsurge. Consequently, when there was a rise in addiction among ghetto youth in Chicago and New York City in the late 1940s, and authorities noted a lower age among those sent to prisons or narcotic hospitals, the Bureau asked Congress for stronger penalties. The variability in judges' sentences and disposition of cases—a short sentence or probation for a trafficker the Bureau might have spent years trying to convict—led to the proposal to take sentencing of certain offenders out of the hands of judges. Also, a mandatory sentence might deter the potential trafficker or even the drug user.

Such legislation was introduced by Representative Hale Boggs and enacted in 1951 (46). In 1956, after Senate hearings

chaired by Senator Price Daniel, the death penalty was allowed at the jury's discretion in some instances of heroin sales (47). This was the peak of punitive legislation against drug addiction in the United States. In a half century, the federal response to dangerous drugs had advanced from requiring accurate labeling of narcotics in over-the-counter remedies (but with no limit on how much could be present) to the possibility of the death penalty or, at least, a mandatory sentence for conveying heroin to a minor (regardless of the quantity of heroin).

Voices were raised against such harsh measures, but they were not very effective in modifying the course of events up to 1956. The American Bar Association (ABA) questioned the wisdom of mandatory minimum sentences, and a joint ABA–AMA committee began to examine the narcotics question with a philosophy far different from that embodied in the Boggs-Daniel acts. Staff of the committee looked at the British experience, in which legal heroin maintenance was available to the several hundred known addicts, and wondered whether some similar system would be suitable for the United States (48). Presidential and congressional confidence in various forms of psychological and chemical treatment flourished and was expressed in such national projects as the Community Mental Health Center program of 1963. Narcotic maintenance programs reappeared, using the synthetic narcotic methadone. The police effort to make narcotic supplies scarce—which seemed so reasonable to progressive medical leadership in 1919—began to seem crude, ineffective, and conducive to gross malfeasance. A turning point in the national approach to narcotics was again at hand.

DRUG CONTROL IN A PERIOD OF RISING USE (1962 TO 1980)

Medical and Psychological Response to Addiction (1962 to 1970)

After Anslinger announced his retirement in 1962—a sign of hope to those wanting to see some form of maintenance or at least less reliance on mandatory prison sentences—President John F. Kennedy called the White House Conference on Narcotics and Drug Abuse (49). Its participants represented the various conflicting points of view; after the conference was over, the President's Advisory Commission on Narcotics and Drug Abuse considered how to carry out the spirit of re-examination and make specific recommendations. The Commission's *Final Report*, published in 1963, marks a definite, if small, shift from the trend to see all "narcotics" as equal in the sight of the law. There was a suggestion that psychological treatment might be useful and that some variations in prison sentencing, such as civil commitment, might prove effective against addiction (50).

In the 1960s, the appearance of psychedelic substances, such as lysergic acid diethylamide (LSD), and the quick rise in marijuana use drew attention to the varieties of drugs available and abusable. Further studies of marijuana suggested that

it was less dangerous than had been assumed in the early 1930s, and the fact that millions of individuals were estimated to have used it in the 1960s also suggested that marijuana was not so very dangerous in moderate use. Other drugs, like amphetamines and barbiturates, became as popular in the streets as they had previously been common in middle-class homes. The number of heroin addicts began to rise, and the nation perceived itself under attack by a “drug culture” linked by many observers to a youth “counterculture.”

Both the legislative and executive branches of the government began to respond to the drug problem in ways that reflected, at the same time, concern about increasing drug use and changing opinions on the nature of drugs and the best ways to prevent abuse. The Drug Abuse Amendments of 1965 created the Bureau of Drug Abuse Control in the Department of Health, Education, and Welfare to address diversion and misuse of barbiturates and amphetamines; and the Narcotic Addict Rehabilitation Act of 1966 approved civil commitment as an alternative to prison for addicted drug offenders (51,52).

The high hopes held for civil commitment of drug addicts were not to be realized. At first such commitment seemed in keeping with advanced notions of psychological and milieu treatment, but it was modified to guarantee that the addict would remain for treatment. Yet the cost and length of treatment, as well as the dismal success rate, brought this apparently more sophisticated form of confinement into question. Civil commitment may also have conflicted with the legal rights of the individual: An addict could be confined for several years, not for a crime but because he or she had a disease. These many difficulties with civil commitment caused a shift from optimism in the Advisory Commission’s report of 1963 to a close questioning of the concept in the report of the President’s Commission on Law Enforcement and the Administration of Justice in 1967 (53).

Reorganization of the Federal Drug Control Bureaucracy

In response to political and social pressures similar to those that had prompted the transfer of the Prohibition Unit from the Treasury Department to the Justice Department in the late 1920s, the FBN was joined with the Bureau of Drug Abuse and Control in 1968 and moved to Justice under the name, Bureau of Narcotics and Dangerous Drugs (BNDD).

When Richard Nixon took office as president in 1969, his advisors saw almost immediately that narcotics control offered an opportunity to make good on Nixon’s campaign promise to reduce crime (54). The first major legislative initiative of the Nixon administration was the Comprehensive Drug Abuse Prevention and Control Act of 1970, which brought together and rationalized all previous drug legislation under the interstate commerce powers of the federal government. The new law also established schedules that differentiated among the various drugs of abuse and formed the basis for a new penalty structure that abandoned mandatory minimum sentences (55).

In the spring of 1971, President Nixon issued an executive order that established the Special Action Office for Drug Abuse Prevention (SAODAP), a White House office that was meant to oversee the prevention and treatment programs of a host of cabinet departments and agencies. SAODAP was given statutory existence through the Drug Abuse Office and Treatment Act of 1972 (56). That same year a special unit in aid of local law enforcement called the Office of Drug Abuse Law Enforcement (ODALE) was also established through executive order, as was the Office of National Narcotics Intelligence (ONNI). The expenditure of the BNDD in fiscal year 1972 was more than \$60 million, a remarkable amount when compared with the FBN expenditures in 1962 of about \$4 million.

In 1973, ODALE and ONNI were combined with BNDD to form the Drug Enforcement Administration. Also in 1973, the NIDA evolved from SAODAP and the Division of Narcotics and Drug Abuse to the NIMH. To date, the Drug Enforcement Agency (DEA) and the NIDA have pursued the law enforcement and drug research components of national drug policy (16).

Methadone Maintenance

Perhaps the most fundamental change in narcotics control of this period was the widespread use of methadone maintenance in control and treatment of narcotic addiction. The technique, begun in the 1960s, was given enthusiastic support by the Nixon administration, in no small measure because of its apparent effectiveness in reducing addict crime. Methadone is a long-acting synthetic narcotic that was developed in Germany during World War II. It is given orally to lessen or even eliminate the desire for heroin. Some of the similarities between the use of and theoretical justification for methadone maintenance now and morphine maintenance in the World War I period are obvious, and both have encountered some of the same practical problems.

Some experts say that methadone may be required by a hard-core addict indefinitely; that is, it does not end narcotic addiction but makes it more socially acceptable or feasible. This policy runs counter to an old theme in American attitudes, namely, that addiction should be stopped, not catered to. As realized a half century ago, however, a maintenance system, if deployed across the nation, is difficult to regulate, and diversion of supplies to nonaddicts can be a problem. One objection to the old maintenance clinics was the enormous profits garnered by some individuals who operated them; the implication was that profits stimulated the distribution of narcotics and the temptation to recruit new customers. Another problem was the failure of neat scientific explanations, such as Dr. Bishop’s theory that a patient in precise opiate maintenance balance is quite normal. This did not work out so conveniently in practice. Maintenance, which was legal, for example, in New York State in 1918 and 1919, eventually led to abuses among health professionals and, in times of national fear, made the thousands of addicts

scapegoats for social problems. Legal maintenance systems can thus become unpalatable or abhorred. They are sensitive to public pressure and political influences, and their existence is precarious, especially when the public believes that addiction itself is the cause of immorality, criminal behavior, and loss of productivity.

Changing Mores, Changing Laws

Gerald R. Ford brought a markedly different political style to the White House in August 1974. The new president wanted to distance himself from Nixon's heated antidrug rhetoric and from his management style that had concentrated power in the White House at the expense of the cabinet departments. To these ends, Ford adamantly resisted congressional attempts to institute an Office of Drug Control Policy in the White House to continue SAODAP-style oversight functions. He did sign amendments to the Drug Abuse Office and Treatment Act of 1972 that mandated establishment of such a body in the Executive Office of the President, but did not seek appropriations to fund it.

In March 1975, in the face of what appeared to be a worsening drug situation, the administration ordered a comprehensive study of the nature and extent of drug use and directions for future remedial policy. The study, known as the *White Paper on Drug Abuse*, was published in September 1975, and set a new tone for drug abuse policy in the years to come. It recognized that the "total elimination of drug abuse is unlikely, but government actions can contain the problem and limit its adverse effects," a view that presaged the "harm reduction" argument of today. It also established antidrug priorities: "All drugs are not equally dangerous, and all drug use is not equally destructive Priority in both supply and demand reduction should be directed toward those drugs which inherently pose a greater risk—heroin, amphetamines (particularly when used intravenously), and mixed barbiturates" (57).

In the end, Ford turned away from the spirit of the *White Paper* and, in an attempt to bolster his chances in the 1976 presidential elections, resorted to the law-and-order approach to narcotics control that still paralleled the sentiments of an ever-narrowing majority of voters. In April 1976, he introduced the Narcotic Sentencing and Seizure Act of 1976, which tried to revive the concept of mandatory minimum sentences for drug-trafficking offenses, and established cabinet committees for drug policy oversight and coordination. Whatever the merits of the bill, Ford was defeated, and the trend toward greater toleration of drug use and less emphasis on control of abuse through law enforcement accelerated.

The election of Jimmy Carter was most welcome to those who supported profound revision of the laws governing possession and use of recreational drugs, particularly marijuana. Carter appointed Dr. Peter Bourne as his special assistant for health issues and decided after some delay to implement the legislation establishing the Office of Drug Abuse Policy with Dr. Bourne as its head. Dr. Bourne set a tone of accommodation to the view that possession of marijuana in small

amounts for personal use ought to be decriminalized as a step toward wiser and more just use of law-enforcement resources. Dr. Bourne was also of the opinion, as he wrote in August 1974, that "Cocaine ... is probably the most benign of illicit drugs currently in widespread use. At least as strong a case could be made for legalizing it as for legalizing marijuana. Short-acting—about 15 minutes—not physically addicting, and acutely pleasurable, cocaine has found increasing favor at all socioeconomic levels in the last year" (58). But the career of Dr. Bourne dramatically illustrates that toleration of recreational drug use would not become characteristic of more than a vocal minority of Americans.

Bourne served the Carter administration from January 1977 until July 1978. During this time, drug policy continued to focus on the international aspects of the heroin problem and on domestic control of barbiturates and amphetamines. The Drug Strategy Council was revitalized and published national strategies for the duration of the administration. Bourne was able to report an apparent reversal of the 1974 and 1975 trends that had indicated a worsening heroin situation: Overdose death rates were declining, as were heroin prices and purity. In early 1977, President Carter decided to advocate decriminalization of marijuana in accordance with a trend that was being acted on by state legislatures throughout the nation. This was startling evidence of the profound change in attitudes toward drug consumption that had taken place since the 1960s. But in July 1978, Dr. Bourne resigned because of allegations that he had written a fraudulent prescription for methaqualone for a member of his staff and that he himself had used cocaine—an accusation that Bourne denied; the Carter administration was suddenly in no position to appear soft on the drug issue. Although not obvious to most observers at the time, the wave of toleration that had been rising since the 1960s had crested, and both public opinion and public policy were about to change course.

THE NEW WAR ON DRUGS (1980 TO THE PRESENT)

Cocaine and Drug Intolerance

As the 1980s opened, cocaine use became more common but seemed to be characteristic of an economic elite who preferred to sniff or inject it. But by the middle of the decade, the method of consuming cocaine was shifting to smoking. Cocaine hydrochloride had to be converted to a base form for successful volatilizing. At first, smokers would use a "free-base kit," a dangerous method involving open flames and ether, often purchased at a drug paraphernalia store or "head shop." Then, about 1985, drug dealers began distributing "crack" to the streets of America's large urban centers. "Crack" was a rocklike base form of cocaine that could be volatilized easily without requiring any preliminary ether treatment. The extraordinary blood levels of cocaine one could achieve by inhaling cocaine fumes from "crack," and its availability in units costing only a few dollars, greatly expanded the cocaine market

among poor and minority populations. Accompanying the “crack epidemic” were turf wars in urban areas as sellers competed for territory. Through the latter part of the decade, the street price drifted lower until eventually, in terms of equivalent value, crack sold for less than cocaine had on New York City streets prior to the Harrison Act of 1914 (59).

The arrival of crack, coupled with the overdose deaths of well-known youthful sports stars, combined with growing political pressure from anxious and angry parents, contributed to a new sense of national crisis over the cocaine problem. From the historian’s perspective, the shift in attitude was rapid, widespread, and profound. The perception of cocaine for many moved from that of a safe, nonaddictive tonic to that of a feared substance linked to ruined careers and families. The stereotypic “coke head”—anxious, fearful, paranoid, hyperactive, and out of touch with others—may be the most fear-producing drug image to the American public. Perhaps the change in attitude is so striking because the initial image of cocaine was so optimistic (60). The fear of cocaine as well as popular and, at times, expert opinion that cocaine use would continue unabated unless legislators took drastic action spurred Congress and President Reagan into dramatic attacks on the drug problem.

In the fall of 1986, shortly before congressional elections, the executive and legislative branches of the federal government competed to enact the most severe laws against drug use. Billions were authorized by the Anti-Drug Abuse Act of 1986, although much less was later appropriated by Congress (61). Many observers, especially those within the treatment community, believed that the actual impact and funding of the law was a discouraging anticlimax to the promises and expectations that had accompanied its passage.

In 1988, as the presidential election approached, the fear of cocaine was reflected in enormous media coverage. Democrats and Republicans were each expressing outrage over drugs and drug use, neither side wanting to appear less determined than its opponent. An emphasis on law enforcement, so characteristic of the decline phase of the earlier wave of drug use, was most clearly demonstrated by the competition between the two major presidential contenders in which the Democratic candidate proposed greatly expanding the number of DEA agents, a stance in favor of law enforcement that eloquently illustrated the great change that had taken place in American attitudes since the Carter–Ford campaign. In 1976, the candidates had vied with one another as to which would be more understanding of casual or recreational use of what were considered to be “soft” drugs.

The 1988 Anti-Drug Abuse Act, like the one passed 2 years earlier, authorized substantial sums for treatment, but about two thirds of funding went to law enforcement (62). Also, the 1988 act targeted the casual user much more prominently, with provisions such as fines for possession of personal amounts of drugs. An indication that the concern over drugs was expanding to include alcohol was the 1988 act’s provision that a year after enactment, every bottle of beverage alcohol manufactured in the United States would have to carry a warning label.

One of the most significant provisions of the 1988 law was its Title I, known as the National Narcotics Leadership Act. Reaching back to the 1972 Drug Abuse Office and Treatment Act and the 1974 amendments to it, this title again established an Office of National Drug Control Policy (ONDCP) in the Executive Office of the President and with it the position of Director of National Drug Control Policy—the so-called “drug czar” (Table 1.1). The legislation also included a requirement that the executive branch provide a comprehensive national strategy with guidelines to measure its success. A series of federal strategies have been published since September 1989, including the latest one, put out by the George W. Bush White House in February 2002.

CONCLUSION

We can now look back on nearly four decades of continuous and widespread exposure to illicit drugs. Those who have lived through this most recent “drug epidemic” can testify to the remarkable change in attitude toward drugs since the 1970s. When we recall Jerry Rubin’s claim in 1970 that “marijuana makes each person God,” Timothy Leary’s recommendation to youth to “turn on, tune in, and drop out,” and a *Time* magazine cover in 1981 attractively exhibiting cocaine in a martini glass, we know that a shift in social norms has taken place. Legislatively, we have moved from softening of antidrug laws in the 1970s to renewing their severity since the late 1980s.

Our society has been through two “experiments in nature” regarding cocaine in the United States: twice (once beginning in the 1880s and again around 1970) a young population with no deeply held antagonism to the drug or even information about it has been exposed to the euphoric effects of cocaine. In each instance, 15 to 20 years passed before the nation started to change its mind on the value and risks of cocaine.

An important difference between the earlier cocaine problem and the present one is that the first anticocaine laws came as public attitudes turned against the drug, while in the current episode, severe anticocaine laws were on the statute books at the very beginning of the new infatuation. The result has been a much longer controversy over control of cocaine and the efficacy of legal restrictions than was the case early in the 20th century.

Debate over legalization of drugs received public prominence during the current wave of drug use, both as drug toleration was quickly rising—in the mid-1970s—and as drug toleration was rapidly falling—in the late 1980s. The dominant argument for legalizing or “decriminalizing” cocaine, marijuana, and opiates in each case reflects the shift in the public’s assumptions about drugs. In the 1970s, the argument was commonly made that the drugs were relatively safe, especially when compared with alcohol or tobacco; in the recent controversy, the argument has seldom been made that a drug like cocaine is safe, but rather that availability of a cheaper product would end turf wars and allow the dollars spent on interdiction to be spent improving conditions in the inner city. Comparison with alcohol and tobacco seems

TABLE 1.1 Drug Czars^a

Name	Birth year	Term	Appointed by	Title	Field/ prior experience	Summary
Dr. Jerome Jaffe	1933	(1971–1973)	Nixon	Director of SAODAP, Special Action Office for Drug Abuse Prevention	Pharmacology/psychiatry	Public health policy model; focus on treating heroin with methadone
Dr. Robert DuPont	1936	(1973–1977)	Nixon, continued under Ford	Director of NIDA, and head of Narcotics Treatment Administration	Psychiatry	Originally treatment/Methadone oriented
Dr. Peter Bourne	1939	(1977–1978)	Carter	Head of Office on Drug Abuse Policy	Physician/psychiatrist /treatment provider	Wanted to decriminalize marijuana possession. Focus on harm reduction. First to have control over both supply and demand
Lee Dogoloff	1939	(1978–1981)	Carter	Head of Office on Drug Abuse Police	Social work	Supported treatment. Came to focus on prevention of teenage marijuana use
Carlton Turner	1940	(1981–1986)	Reagan	Head of Office on Drug Abuse Police	Pharmacology. Director of the University of Mississippi Marijuana Research Program	Strongly supported parents' campaign to prevent adolescent use of marijuana. Less concerned about hard drugs or treatment for them
Dr. D. Ian MacDonald	1931	(1986–1988)	Carter	Deputy Director of Office on Drug Abuse Police	Pediatrician	Supported parents' antimarijuana activities
William Bennett	1943	(1989–1990)	George H.W. Bush	Director of ONDCP, Office of National Drug Control Policy	Secretary of Education	First Cabinet-level drug czar. Bennett, called for an “all-out war on drugs—with more resources for police, more prosecutors, more convictions.” Resigned after 19 months

Robert Martinez	1934	(1991–1993)	George H.W. Bush	Director of ONDCP, Office of National Drug Control Policy	Governor of Florida	Continued Bennett's policies
Lee P. Brown	1937	(1993–1995)	Clinton	Director of ONDCP, Office of National Drug Control Policy	Law enforcement	Initially supported treatment as opposed to war on drugs, but had to change focus to marijuana use, in accordance with White House political stances
General Barry McCaffrey	1942	(1996–2001)	Clinton	Director of ONDCP, Office of National Drug Control Policy	Military	Supported treatment and stopping drug smuggling
John Walters	1952	(2001–1909)	George W. Bush	Director of ONDCP, Office of National Drug Control Policy	Career civil servant	Focused on marijuana, drug war, and stopping drug smuggling
Gil Kerlikowske	1942	(2009–)	Obama	Director of ONDCP, Office of National Drug Control Policy	Law enforcement	Renewed emphasis on treatment and public health as opposed to the war on drugs and incarceration. Drug czar is no longer a cabinet level post

^aThe title “drug czar” does not appear in a statute: it is an informal honorific that has been resisted by some of those listed in the table. President Nixon started the fashion by declaring that Dr. Jaffe was his drug czar.

Sources: Baum, D. *Smoke and Mirrors*. Boston, MA: Little, Brown, 1996; Massing, M. *The Fix*. New York, NY: Simon & Schuster, 1998; Frontline (PBS). *Thirty Years of America's Drug War*, 2000 (<http://www.pbs.org/wgbh/pages/frontline/shows/drugs>).

to have diminished as the public has become increasingly alarmed at these two legal substances.

Crime reduction was a core goal of the Nixon administration's broad campaign against drugs. Interestingly, property crime has fallen since 1980 by about 63%. Violent crime has fallen by 48% in the past 10 years. Curiously, neither side in the drug debate makes much mention of these astounding statistics, which imply that much progress has been made toward the goal of the original impetus for national drug strategies.

The rise of acquired immune deficiency syndrome (AIDS) adds another dimension to drug abuse control; the epidemic is now spreading most rapidly among intravenous drug users, many of whom engage in both needle sharing and unprotected sex. Here the debate about relaxing legal restrictions has centered on the wisdom of distributing sterile syringes and needles, condoms, and methadone without many of the elaborate regulations now controlling this opioid. The full social and medical impact of AIDS lies in the future, but it would not be surprising if the stress of these concerns—as happened in the history of other chronic, often fatal diseases, such as tuberculosis—tended toward restrictive public policies (63).

Change in the perception of alcohol over the past 10 years is another marker of evolving attitudes toward psychoactive substances of all kinds. More people now regard alcohol as a dangerous substance, rather than as a beverage to be used in moderation with meals and on festive occasions. In 1984, the federal government required states to raise the drinking age to 21 years or lose a part of highway taxes; in 1989, as noted, all beverage alcohol had to carry warning labels; the federal government has pressured states to lower the driving under the influence level to 0.08% for those older than age 21 years, and to 0.02% for those younger than age 21 years. In the past, antagonism to alcohol has led, over three or four decades, to extreme restrictions, which, in turn, were followed by a backlash against alcohol's tarnished image. For almost 50 years following repeal of national prohibition in 1933, it was difficult to discuss the problems associated with alcohol consumption without being accused of sympathy with discredited prohibitionists. Now the mood has changed, and the task will be to see whether this time the nation can establish a sustainable alcohol policy that will not be swept aside in frustration and resentment.

Recent legislation bearing on drug abuse control attempts once again to make the consequences of violating drug laws more dire. The Violent Crime Control and Law Enforcement Act of 1994 enhanced penalties for drug trafficking in prisons and drug-free zones, allowed the president to declare a violent crime or drug emergency in a specific area on request of the state or local executive, and amended the National Narcotics Leadership Act of 1988 to strengthen ONDCP (64).

The question for public policy is the degree to which a growing reliance on law enforcement will be balanced by availability of treatment and sustained support for research.

As this chapter goes to press, there are a number of current trends that we would like to mention. First of all, the crack

cocaine epidemic in the United States that began in the 1980s appears to be over, as evidenced by the statistics from national surveys and the D.C. Pretrial Services Administration's arrestee drug testing program. The percentage of arrestees in Washington, D.C. testing positive for cocaine metabolite peaked in 1988 at 64% and in the first 10 months of 2009 is averaging 29%, a level not seen since the mid-1980s at the beginning of the epidemic (65). This is an impressive trend, given that criminals would be expected to be among those least likely to desist from use of the drug. The national household survey statistics also reflect this decline but peaked earlier, with a peak of 17% of 18 to 25 years old reporting use of cocaine in the past year in the 1979 survey, compared with 5.5% in 2008 (66). The reasons behind the end of this Nation's second love affair with cocaine will be debated by historians and politicians for years.

As cocaine use recedes, the misuse of prescription drugs has expanded. In 2008, U.S. youths in grades 7 to 12 indicated that after marijuana, the misuse of inhalants and prescription drugs were tied as the second most prevalent drugs ever tried (67). In 2007, about one fourth of youths ages 12 to 17 who first started using drugs in the past year started with the non-medical use of prescription-type drugs (68). The most commonly misused prescription drugs at all age levels are pain relievers (69). Furthermore, with the growing recognition of and treatment of attention deficit hyperactivity disorder, the misuse of prescription stimulants is being increasingly found among college students (70). The recent approval and expansion of the prescribing of buprenorphine for opiate addiction in the United States is another trend worthy of monitoring over the next decade, given other countries' experience with the abuse of this drug (71).

Finally, we must note the growing approval by states of the use of medical marijuana. As of this writing, 13 states have approved the prescribing of this drug (72). With the steep decline in cigarette use among high school seniors since 1997, the percentage of 12th grade students reporting use of marijuana in the past month in 2009 is virtually identical to the percentage who reported cigarette use (73). It remains to be seen how much marijuana use will grow as the medical use of marijuana becomes more prevalent and visible across the United States.

Charles Winick ■ Jack Levinson

Epidemiology—the population distribution and determinants of the use and problems related to alcohol, tobacco, and other drugs (ATOD)—plays a central role in drug control and health policies in the United States. It permits us to track changes in substance use and abuse through time, and across groups and regions. Epidemiology contributes to the social ecology of substance use, as in its clarification of how the visibility of drug problems—though traditionally associated with neighborhood disadvantage, concentration of minorities, and population density—is not related to levels of drug use (1).

MAJOR SOURCES OF EPIDEMIOLOGICAL DATA

Since 1971, the National Survey on Drug Use and Health (NSDUH) (formerly the National Household Survey on Drug Abuse), sponsored by the Substance Abuse and Mental Health Services Administration (SAMHSA), has been the leading source on incidence and prevalence of ATOD. Since 1999, NSDUH uses an interactive, bilingual, computer-assisted home interview with an annual sample of roughly 67,500 persons 12 and older (2). Between 2002 and 2007, the overall rate of illicit drug use has remained stable.

Beginning in 1975, the University of Michigan has annually conducted Monitoring the Future (MTF), sponsored by the National Institute on Drug Abuse (NIDA). MTF, using self-report questionnaires in schools, is the primary source for survey data on ATOD use by secondary school students. The 2008 MTF sample was about 46,000 students from 386 schools. From 2002 to 2008, annual rates of illicit drug use by 8th, 10th, and 12th graders remained stable or showed modest declines (3).

The National Institute on Alcohol Abuse and Alcoholism (NIAAA) sponsors the National Alcohol Survey (NAS), conducted by the Alcohol Research Group, University of California at Berkeley. NIAAA has also sponsored the longitudinal National Epidemiologic Survey on Alcohol and Related Conditions (NESARC), the largest comorbidity study of alcohol use disorder and treatment utilization among the civilian population, with a sample of roughly 43,000; the first wave of computer-assisted home interviews was conducted in 2001 to 2002 and the second in 2004 to 2005 (4). Among findings from the second wave was that 5.6% of American adults used both alcohol and drugs in the past year and 1.1% had comorbid alcohol and drug use disorders. Past week use of an illicit drug, other drug use, and drug use disorders increased among those with increasing levels of alcohol use and alcohol use disorders (5).

Data on alcohol consumption, along with tobacco and other drug use, are collected by the NSDUH and MTF. The Centers for Disease Control and Prevention (CDC) also provide national data on alcohol and tobacco, via two surveys. First, the Behavioral Risk Factor Surveillance System (BRFSS) is an annual state-based telephone survey of the adult civilian population that began in 1984 and by 1994 had incorporated all 50 states and additional U.S. territories. Second, the Youth Risk Behavior Survey (YRBS), started in 1990, is conducted every 2 years with a sample size of 12,000 to 16,000.

The Drug Abuse Warning Network (DAWN) reports drug-related emergency visits from hospitals in major metropolitan areas and since 1992, has been administered by SAMHSA's Office of Applied Studies (OAS). DAWN tracks all drugs, including over the counter medications and dietary supplements. Fatalities directly or indirectly related to drug use are reported by a sample of coroners and medical examiners. For alcohol alone, drug-related emergency department visits are recorded only for patients under 21. DAWN drug-related visits may result from chronic or unexpected reactions; accidental ingestion or reactions that do not suggest abuse are excluded. The 2006 DAWN national estimates were derived from a sample of 205 hospitals, with 28% of DAWN visits involving pharmaceutical drugs only and 31% illicit drugs only (6). For the most often reported major illicit drugs—cocaine, marijuana, heroin, and stimulants—there were no significant changes from 2004 through 2006.

A key source of regional data is the Community Epidemiology Work Group (CEWG), established in 1976 by NIDA to conduct surveillance in 21 major metropolitan areas, where working groups use survey and qualitative methods to gather data. CEWG epidemiologists meet biannually to assess patterns of use, substance purity, prices, and distribution (7).

SOCIODEMOGRAPHIC FACTORS AND SPECIAL POPULATIONS

Gender Differences

Males' higher use rate than females of most illicit substances increases with age (2). In 2007, among those aged 12 to 17, 10% of males and 9.1% of females were current users of illicit drugs (defined as use in the past month). Among 18 to 25 year olds, 24.1% of males but 15.3% of females reported past month use and for those 26 and older, only 8% of men and 3.8% of women did so. Some 27.1% of men smoked cigarettes

in the past month compared to 21.5% of women, while 56% of men and 46% of women reported binge or heavy alcohol use.

Race and Ethnicity

Rates of illicit drug use in the past month in 2007 for persons aged 12 and older were 4.2% for Asians, 6.6% for Hispanics, 8.2% for whites, 9.5% for blacks, and 12.6% for American and Alaskan Natives (2). Though current use of illicit drugs by black adults roughly equals that of whites, black adolescents have always had substantially lower rates of illicit drug use and cigarette smoking than whites (3). Hispanic adolescents also have lower rates than whites except for some drugs in both the 8th and 12th grades.

The race/ethnicity age crossover effect refers to the consistent finding that despite varying rates of use across racial groups during adolescence and young adulthood, by the mid-thirties such rates are roughly equivalent. Analysis of NSDUH data from 1999 to 2002 suggests that this difference between black and white substance use can be explained by sociodemographic factors, such as patterns of availability and exposure in adulthood (8). When sociodemographic factors are controlled, the crossover effect between whites and blacks disappears and the rates of illegal drug use among black men and heavy drinking among black women are lower than among whites. ATOD use has different meanings and functions for specific subgroups, and risk and protective factors relevant to such use may operate differently across ethnic/racial subgroups (9).

National civilian use rates are inconsistent with those of different racial/ethnic groups in treatment and prison settings. Treatment admissions for marijuana, the most commonly used illicit drug, were 13.5% white and 21.9% black in 2007 (10).

Drug Users and Drug-Related Offenders in the Criminal Justice System

Substance abuse or dependence among individuals involved in the criminal justice system, incarcerated or otherwise, is more than four times that of the general population (11). A large proportion of the incarcerated are presumed to have a substance abuse disorder, with a range from half to more than two-thirds (12, 13). In 2004, 53% of state and 45% of federal inmates met DSM-IV criteria for abuse or dependence (14). Some 32% of state and 26% of federal prisoners in 2004 had used a psychoactive drug at the time they committed their crimes (15).

Some 2.3 million Americans are behind bars; the United States has 5% of the world's population but nearly 25% of its prisoners (16). From 2000 to 2006, persons incarcerated in federal prisons increased by 5% and by another 1.7% from 2006 to 2007 (17). The sharp increase in U.S. prison inmates since the 1980s has resulted from changes in law enforcement and sentencing procedures. Drug offenders accounted for 24.9% of federal prisoners in 1980, 52.2% in 1990, increased

to 60.7% in 1994 and 1995, and declined to 54.1% in 2004 (18). The proportion of drug offenders in federal prisons increased by 4% from 2000 to 2006 and by another 1.7% from 2006 to 2007 (17). In state prisons in 2007, drug offenders represented 19.5% of the total population and 15.4% of white prisoners, compared to 22.5% of black and 21.3% of Hispanic prisoners.

Most correctional facilities offering substance abuse programs are less likely to involve clinical treatment than education and awareness activities, offered in 74% of prisons and 61% of jails, or low-intensity group counseling (for less than 4 hours per week), offered in 55% of prisons and 60% of jails (19). However, less than a quarter of those incarcerated actually have access to these services and few correctional agencies have the means to identify the offender pool needing treatment.

The Life Cycle and Substance Use

The concept of "maturing out" of narcotic addiction directed attention to the relationship between substance use and the life cycle (20). Different subgroups appear to have different rates of loosening and/or maintaining their ties to a substance. Such rates are associated with a range of social and individual variables (21). Current drug use has consistently reached a peak in late adolescence and young adulthood and then declined dramatically. In 2007, current use of any illicit drug was 3.3% for ages 12 or 13, 8.9% for those 14 or 15, 16% for those 16 or 17, and 21.6% for those 18 to 20 (2). For persons aged 21 to 25, rates decline to 18.5% and for those 26 to 34 to 10.9%. Current drug use continues to decline further with age to 4.1% for those 55 to 59, 1.9% for those 60 to 64, and 0.7% for those 65 and older.

Across age groups, the highest rates of past month illicit drug use are associated with heavy alcohol use (defined as 5 or more drinks on the same occasion on each of 5 days in the past 30 days); rates decline for binge alcohol users (defined as 5 or more drinks on the same occasion) who are not heavy users and also for alcohol users who do not binge (2). Concurrent alcohol and illicit drug use declines consistently with age: in 2007, for persons aged 12 to 17, 60.1% of heavy drinkers used illicit drugs, 48.4% of those aged 18 to 25 did so, along with 22.8% of the 26+ age group.

Epidemiological research has recently examined the association between population-based factors and the life cycle of drug use, showing how some common sociodemographic factors have a different impact on the transitions in drug use careers (22). Birth cohort was strongly associated with access and opportunity to try drugs for the first time, as well as to remission from drug use disorders. However, birth cohort was not associated with transition to abuse or dependence. The specific type of drug and individual history of drug use were strongly associated with transition from use to abuse and to dependence. Women abusers were more likely than men to transition to dependence but also more likely to transition to remission.

Employment status is a significant predictor of past month illicit drug use and is related to age. In 2007, for

unemployed persons aged 18 or older, the rate of past month use was 18.3% but 8.4% for those employed full time and 10.1% for those employed part time (2). However, studies since the early 1970s have shown that some occupational environments involve factors that increase the risk of substance misuse (23). Notably, physicians and other medical workers have had historically higher rates and/or different patterns of substance abuse because of the combination of access to and knowledge about drugs, including a sense of invulnerability to potential drug problems, and the unique pressures and role strain related to medical work conditions (24). Research has shown higher rates of nonprescription use of certain drugs among physicians (25), anesthesiology residents (26), nurses (27), pharmacists (28), and hospital employees with access to drugs (29).

Geographic Factors

Local and regional variation can be best explained by factors such as different populations, social class and subcultural differences, proportion of age groups, and climate. In 2007, 8.3% of those aged 12 or older reported past month illicit drug use in large metropolitan areas but only 4.1% did so in rural areas (2). Rates of current cigarette use for those 12 and above in 2007 are lower in large urbanized metropolitan areas (22.7%) than in small metropolitan areas (24.8%), urbanized non-metropolitan areas (28%), and in less urbanized nonmetropolitan areas (29.5%).

In 2007, illicit drug use was 9.3% in the West, 7.9% in the Midwest, 7.8% in the Northeast, and 7.4% in the South (2). Methamphetamine's history of high prevalence in the West stretches back to the 1960s. Between 2002 and 2005, 1.2% in the West reported using it in the past year as opposed to 0.5% in the Midwest and South and 0.1% in the Northeast (30). Not only are there strong regional preferences for types of alcoholic beverages but rates of use also vary: in 2007, for those aged 12 and above, past month alcohol use was lower in the South (46.8%) and West (50.8%) than in the Northeast (56%) and Midwest (54.6%) (2).

COMORBIDITY

Mental Health

Since the 1990s, there has been growing interest in the comorbidity of drug use disorders with each other and with psychiatric syndromes, such as depression, antisocial personality disorder, generalized anxiety disorder, and mood disorders (31). In 2007, among people with drug abuse or dependence aged 18 or older, past month use of alcohol or illicit drugs was 8.8% among those who had a major depressive episode in the past year compared to 2.1% who had not (2). For alcohol alone, past month use was reported by 17% of those who had a major depressive episode in the past year compared with 7% who had not.

Comorbidity research was facilitated in part by the DSM-IV because it categorized co-occurring disorders as primary

(31). Most people with substance abuse disorders do not receive treatment, and treatment disparities exist among those at high risk even though they have disability and co-occurring disorders (31,33). In the preparation of DSM-V, some researchers argue that further refinement of primary co-occurring disorders would improve clinical reliability and encourage longitudinal research (32,33).

HIV and HCV

Since the advent of human immunodeficiency virus (HIV) in the early 1980s, men who have unprotected sex with men (MSM) have accounted for the vast majority of cases; the next largest group consists of injection drug users (IDUs) and their mostly female sexual partners. HIV incidence has declined dramatically from the late 1980s. Although HIV increased slightly among MSM since the 1990s, it continued to decline among IDUs. For the estimated annual incidence of HIV between 2003 and 2006, approximately 56% are MSM, 11% are IDUs, and 3% are both MSM and IDUs (34).

In 2008, all 50 states began reporting new HIV diagnoses to the CDC and relatively new assay technology makes it possible to determine the recency of infection. Since the late 1990s, HIV incidence among IDUs has dropped 80% because of the growth of syringe exchange programs (SEPs), decriminalization and availability of syringes, and education/awareness programs of needle sharing and cleaning (34).

Since the 1990s, there has been concern about the association between noninjection illicit drug and alcohol use and sexual transmission of HIV and other infections among MSM. In particular, the increasing popularity of methamphetamine among certain segments of gay men has been associated with increasing rates of sexually transmitted infection (35). The connection between substance abuse and behaviors that facilitate transmission among those who are already HIV infected remains a growing concern (36).

The vast majority of hepatitis C virus (HCV) cases in the United States are from IDUs. HCV incidence peaked in the mid to late 1990s and then declined substantially from 5.2 cases per 100,000 population in 1995 to 0.5 in 2007 among the age group that historically had the highest rates of infection (25–39 years) (37). The drop in HCV incidence could be attributable to the growth of services, however limited, that provide or enable access to clean syringes and information about cleaning and sharing needles. Still, the prevalence of chronic HCV in 2007 was substantial, with approximately 3.2 million persons infected, largely among those aged 40 to 49, most of whom were likely infected through needle use in the 1970s and 1980s.

SUBSTANCES

Alcohol

Alcohol is the most commonly used psychoactive substance in the United States. NSDUH reported that 60.8% of Americans 26 and older were current alcohol users in 2007 (2).

For those 18 and older in that year, BRFSS reported that 54.8% were current users (38). In the 2007 NSDUH, 31.4% of those over 26 reported binge drinking and 10.1% reported heavy drinking (as defined above) (2). BRFSS, which defines binge drinking by gender (five drinks at a time for men, four for women), in 2007 found that 15.8% of respondents reported an episode of binge drinking in the last month (21.2% of men and 10.1% of women) (38). Even though the BRFSS threshold of heavy drinking (two drinks per day for men and one for women) is lower than the NSDUH, only 6.1% of men and 4% of women reported that they are heavy drinkers.

In the 2007 NSDUH, of the 56.1% of whites who reported past month use, 16.8% reported binge use and 7.8% reported heavy use; of the 39.3% of blacks who were past month users, 15% reported binge drinking and 4.1% heavy drinking (2). American and Alaskan Natives had the highest proportion of binge and heavy use: of the 44.7% who are past month users, 16.6% are binge users and 11.6% are heavy users. Hispanics also have a higher proportion of binge and heavy alcohol use than whites and blacks: of the 42.1% who are past month users, 17.9% reported binge and 5.5% heavy use. Asians have the lowest proportion of all groups: of the 35.2% past month users, only 10% reported an episode of binge and 2.6% heavy use.

According to the BRFSS, between 2001 and 2007, current alcohol use among adults (at least one drink in the past month) appears relatively stable for whites at roughly 59% and for blacks at roughly 43% (38). For both these groups, there was an increase: for whites, from 58.6% (2001) to 60.4% (2002) and 62.1% (2003); and for blacks, from 41.5% (2001) to 45.4% (2002) and 45% (2003). For Hispanics, however, past month use has declined consistently from 52.2% in 2001 to 44.8% in 2007 without increasing in 2002 and 2003. NAS researchers have shown that social disadvantage is associated with psychological distress and problem drinking across racial/ethnic groups (39).

Underage drinking is a continuing concern. Past month alcohol use among those aged 12 to 17 has dropped slightly but significantly from 17.6% in 2002 to 15.9% in 2007 and, consistent with the life cycle, rates of past month use in this group increased with age (2). MTF shows steady but significant declines over the past 10 years in past month alcohol use (28% of 8th, 10th, and 12th graders combined in 2008) and having been drunk in the past month (14.9%) (3). However, trend analysis data from six NASs between 1979 and 2005 suggest that although mean values of drinking measures have declined for those over 26, there has been an increase both in alcohol volume and drinking days among those 18 to 25, indicating the possibility of a sustained increase in future U.S. alcohol consumption (40).

Driving under the influence of alcohol became a major concern in the 1980s, when states increased the legal drinking age to 21. In the past 30 years, there has been a substantial decline in the number of social drinkers arrested for driving under the influence (DUI) (41). DUI rates in the past year reflect, in part, the relationship between drinking behavior and age: 7.8% for the 16- to 17-year-old group, 18.3% for the 18

to 20 group, and 25.8% of 21 to 25 year olds. For the 26- to 29-year-old group, the rate declined to 20.1%. Overall, for Americans 12 and older, past year DUI declined modestly but significantly from 2002 (14.2%) to 2008 (12.7%). Up to 70% of drivers arrested have previous alcohol- or drug-related offenses, and binge/heavy drinkers accounted for most episodes of alcohol-impaired driving (51.3%).

NSDUH annual estimates of Americans with substance abuse or dependence have remained stable between 2002 and 2007 at just above 22 million (2). The vast majority—roughly 15.5 million—abuse or are dependent on alcohol alone; 3.2 million abuse or are dependent on both alcohol and illicit drugs. In an analysis of 2006 and 2007 data, 5.6% of past month alcohol users also used an illicit drug within 2 hours of drinking. Binge drinkers were far more likely to use an illicit drug (13.9%) than nonbinge past month alcohol users (3.8%). Adolescents and young adults who were past month alcohol users were far more likely than older age groups also to have used illicit drugs: 14.2% for the 12 to 17 group and 13.5% for 18 to 25, 7.7% for 26 to 34, 4.3% for 35 to 49, and 1.1% for 50 and over (42). The illicit drug used most frequently in concurrence with alcohol was marijuana (4.8%) followed by cocaine (0.06%) and pain relievers (0.04%). There is no evidence, over time, of a displacement effect between teen alcohol and marijuana use, which have run in parallel (3).

Marihuana

Since the 1970s, marijuana has been by far the most commonly used illicit drug. In 2007, of Americans 12 or older, 40.6% had tried marijuana at least once, 10.1% had used in the past year, and 5.8% or 14.4 million in the past month (2). Some 31 states and the District of Columbia currently have laws that recognize marijuana's medical value. Since 1996, 13 of these states have enacted laws, 9 of which were established by popular ballot, that permit patients to use marijuana despite the conflict with the federal zero-tolerance policy.

The declining stigma of marijuana may have contributed to slight increases in its use during the 1990s. Along with more marijuana-related emergency room visits, there were substantial increases in arrests and treatment admissions. There has been a slight but significant decline in past month use from 11% in 2002 to 10.1% in 2007 (2). Even youths aged 12 to 17, whose rates of past month marijuana use had increased through the 1990s, declined from 8.2% in 2002 to 6.8% in 2005 and had remained stable (43). Despite these declines, analysis of substantial national increases in annual marijuana arrests suggests that low-level marijuana offenders have become a focus of drug enforcement strategy. National arrests for marijuana, which had declined to about 325,000 in 1991, increased to more than 725,000 in 2000 (44) and even as use declined further, the number of arrests continued to increase to about 873,000 in 2007 (45). Few of these arrests were for serious offenses and in 2000 only 6% resulted in a felony conviction. By 2002, marijuana arrests represented 45% of the 1.5 million drug arrests annually (44). Between 1990 and

2000, U.S. marijuana arrests increased two and a half times but in New York City, marijuana possession arrests increased tenfold (46). From 1997 to 2006, in New York City, 335,000 people were arrested and jailed for possessing small amounts of marijuana, 11 times the number in the previous decade. These arrests disproportionately involve young racial/ethnic minority men: between 1997 and 2006, 52% of arrestees were black, 31% Hispanic, and 15% white.

Marijuana was considered the primary drug in the gateway theory of substance abuse, which suggested that teenagers using marijuana were likely to begin using substances such as heroin or cocaine. Some researchers now treat alcohol and tobacco as the initial substances in a normative sequence of drug initiation (47) with marijuana viewed as a terminus rather than a gateway (48).

However, in 2007 only 1.6% of Americans were estimated to have marijuana dependence or abuse, representing a slight but significant decline from 1.8% in 2002 (2). SAMHSA's Treatment Episode Data Set (TEDS) reports that primary treatment admissions for marijuana increased from 11.7% of all admissions in 1996 to 15.8% in 2007 (10,49). Nationally, between 1996 and 2006, the rate of marijuana user admissions increased by 32% from 91 to 120 per 100,000 population aged 12 and over (49). Fifty-seven percent of marijuana admissions resulted from criminal justice referrals (10). Considering the relatively low rate of marijuana dependence/abuse overall and that 63.1% of its treatment admissions are aged 24 and under (49), a sizable number of these referrals could have come to the attention of law enforcement for reasons unrelated to marijuana but attributed to problem use.

Tobacco

Of all substance use, cigarette smoking has the most substantial long-term negative health effects. Rates of current cigarette use have been declining, especially since the late 1990s, with the continued expansion of legal prohibitions, higher taxes, and increasingly negative attitudes toward smokers and smoking (3,50,51). Between 2002 and 2007, past month American cigarette smokers declined from 26% to 24.2% (60.1 million) (2).

Most smokers begin in adolescence and, after a decline through most of the 1980s, current cigarette use among teenagers and young adults began to increase and peaked in the mid-1990s (3,50). Still, the declines in this age group are greater than the overall decline: among 12 to 17 year olds, 9.8% were past month users in 2007, down from 13% in 2002 (2). Between 1996 and 2008, current smoking has declined substantially among 8th graders (67%) and 10th graders (60%) and a cohort effect seems to explain the more modest 44% decline among 12th graders (3).

Heroin and Other Opiates

During the 1990s, heroin of relatively high purity and lower cost became widely available and was accompanied by a rise

in intranasal sniffing and smoking in some areas (52). By the end of the decade, increased "cutting" of heroin began to decrease purity (53) and through the 2000s, fluctuating and generally lower purity has usually been accompanied by increased prices (7). Only 0.1% of Americans 12 and older have reported past month heroin use between 2002 and 2007 (2). Among 12th graders, the annual prevalence of heroin use between 1975 and 1979 fell from 1% to 0.5% and then remained steady until the early 1990s, peaking at 1.5% in 2000 (3). Since then, annual prevalence among 12th graders has declined, fluctuating slightly, to 0.9% in 2007 and 0.7% in 2008.

Since the early 2000s, most parts of the country have reported growing nonprescription use of pharmaceutical opiates such as oxycodone (OxyContin) and hydrocodone (Vicodin). Between 2002 and 2007, previous year illicit use of pharmaceutical pain relievers rose slightly but significantly, from 4.7% to 5% among Americans 12 and older (2). OxyContin has remained steady at 0.5% since 2004. Similarly, past month use of pain relievers in Americans 12 and older has increased slightly from 1.6% in 2002 to 2.1% in 2007 and 2008. In 2007, oxycodone and hydrocodone appeared in the top 10 ranked drugs identified in forensic laboratories in CEWG areas and were the two most frequently identified narcotic analgesics/opiates (7). However, they represented about 1% or less of drugs reported. Among 12th graders, after trending down, the early 1990s saw a rise in annual use of narcotics other than heroin from 3.3% in 1992, peaking at 9.5% in 2004 (3). In contrast to the overall declines in drug use by adolescents since 2004, their prevalence rates of narcotics other than heroin have remained steady at about 9%.

Cocaine

Between 2002 and 2007, the prevalence of past month use of cocaine hydrochloride by Americans 12 and older has remained stable, hovering at 0.9% in 2002, 0.8% in 2004, 1% in 2006, and 0.8% in 2007 (2). Relatively few Americans used crack in the past month: 0.2% in 2002, 0.3% in 2005, and 0.3% in 2007. In 2008, 1.9% of 12th graders reported use of cocaine in the past 30 days, a rate which has been stable since 1991 (3). For crack, 0.9% of 12th graders used in the last 30 days, a rate which has also remained stable since 1991.

Despite low overall rates of use, the majority of drug-related emergency room visits involved cocaine, with blacks and whites accounting for roughly equal numbers (6). Among cocaine abusers, crack remains predominant across 11 CEWG areas in 2008, when between 56% and 95% of cocaine treatment admissions were crack smokers (7).

Club Drugs

Since the 1980s, drugs such as MDMA, GHB, and ketamine have been referred to as club drugs because they have been associated with dance parties and nightclubbing. However, these drugs, especially MDMA or ecstasy, the most commonly used club drug, are also used in different settings for other reasons (54,55). Past month ecstasy use among Americans 12

and older dropped slightly but significantly from 0.3% in 2002 to 0.2% in 2003 through 2007 (2). In 2008, 2.9% of 8th, 10th, and 12th graders had used ecstasy at least once and 0.9% and 1.2% had used GHB and ketamine, respectively (3). Ecstasy use dropped in this group from a peak of 2.4% in 2002 to 1.2% in 2008.

Amphetamine-Like Stimulants

Methamphetamine

In the early 1990s, concern grew about the expectation that methamphetamine would move eastward. By 1996, methamphetamine became a focus of legislation and drug-abuse agencies. Through the late 1990s, both methamphetamine-related emergency room visits and treatment admissions increased, although these numbers began to decline overall. The number of Americans 12 and older who used methamphetamine nonmedically in the past year changed little from 1999 (0.5%) to 2004 (0.6%) (56).

There were relatively low rates of methamphetamine use between 2002 and 2005 by Americans 12 and older, both for annual use (0.7% in 2002 and 0.5% in 2005) and past month use (0.3% in 2002 and 0.2% in 2005) (57). The 18 to 25 group in 2002 used 0.5% in the past month and 0.6% in 2005. Previous month use has remained stable, with 0.2% of those 12 and older using in the past month in 2007 (2).

Concerns about the eastward movement of methamphetamine have not been confirmed. Its regional appeal is confirmed in rates of use (30), treatment admissions, and laboratory forensics (7). In high-use areas, the major routes of administration are smoking or injecting; in contrast, in New York City the primary route of administration is inhalation.

Pharmaceutical Stimulants

The nonmedical use of pharmaceutical stimulant drugs such as amphetamine (Adderall) and methylphenidate (Ritalin) has been a growing concern since the 1990s, especially among youth and college students. As with other teenage drug use, pharmaceutical stimulant use peaked in 1996, when 4.8% of 8th, 10th, and 12th graders combined used in the past 30 days, but their use declined to 3.9% in 2003 and 2.6% in 2008 (3). In contrast to these rates of use, more high schoolers perceive these drugs as easily available. In 2008, 12.8% of 8th graders said the drug was “fairly” or “very” easy to obtain, along with 32% of 10th graders and 47.9% of 12th graders. The higher rate among 12th graders is curious in light of their high rates of disapproval: 87.2% disapprove of using amphetamine once or twice and 94.2% disapprove of its regular use.

Among college students and their age peers, amphetamine use also increased through the 1990s, with college students having lower rates. Even so, in the 1990s and 2000s, rates for college students, their noncollege age peers, and 12th graders were substantially lower than in the 1980s. In the 2000s, use among 12th graders and the noncollege group declined, while annual use among college students increased to 7.2% in 2001

and remained stable at 6.9% in 2007 (58). Monthly prevalence rates among college students reflect a similar pattern, with 3.3% in 2001 and 3.1% in 2007. College students vastly overestimate the levels of nonmedical use of pharmaceutical drug among their peers, as they also do with alcohol and other substances (59).

NSDUH indicates that college students nonmedically using Adderall were more likely to use other drugs (60). Among Adderall users, 8.6% were white, 2.2% were Hispanic, 2.1% were Asian, and 1% were black. There is also difference in rates of use by family income, with the highest use (8.9%) among college students from families earning under \$20,000 per year, followed by students from families with incomes of \$75,000 or more (6%). Only 3% of students from families with incomes between \$20,000 and \$49,000 and 2% from those earning \$50,000 and \$75,000 are users.

DRUG ABUSE AND TREATMENT

In 2007, 22.3 million Americans aged 12 and older were classified with substance dependence or abuse in the past year (based on DSM-IV), a number that has remained stable since 2002 (2). Roughly 15.5 million were dependent on or abusing alcohol only, 3.7 million illicit drugs only, and 3.2 million were dependent on or abused both alcohol and illicit drugs. In 2007, men were twice as likely (3.8%) as women (2.1%) to report past year abuse or dependence. Past year dependence or abuse changes dramatically with age: in 2007, 4.3% of the 12 to 17 group had problems with illicit drugs and 5.4% with alcohol; 7.9% of those 18 to 25 had problems with illicit drugs and 16.8% with alcohol. For those 26 or older, 1.7% had problems with illicit drugs and 6.2% with alcohol. There are racial/ethnic differences among those classified as having substance abuse or dependence: white 9.4%, black 8.5%, Hispanic 8.3%, and Native Americans/Alaskans 13.4% in 2007. The disproportion is greater for those who received treatment: 18.2% of blacks who needed treatment received it in contrast with 9.9% of whites, possibly because relatively more African Americans are involved with public agencies.

In 2007, 7.5 million Americans aged 12 or older needed treatment for an illicit drug problem but only 1.3 million (17.8%) received it at a specialty facility, leaving 6.2 million in need of treatment (2). Of the 19.3 million people who needed treatment for alcohol, only 1.6 million (8.1%) received it, so that 17.7 million people remained without treatment. In 2007, 2.7 million people received treatment for a problem with alcohol or an illicit drug in the past year at a rehabilitation facility. Just less than 2.2 million of the people who received treatment in 2007 did so in self-help groups. These figures changed little between 2002 and 2007. Based on combined 2004 to 2007 NSDUH data, 35.9% of those who tried to get treatment failed because of lack of funds or health coverage.

The proportion of dependence on or abuse of specific drugs has remained stable since 2002, with the exception of a slight but significant decline for marijuana and hashish (1.8% in 2002, 1.9% in 2004, and 1.6% in 2007). Of those persons classified as having substance abuse or dependence, the

largest proportion is for marijuana, with approximately 3.9 million in 2007. Approximately 1.7 million used pain relievers and 1.5 million used cocaine.

From 1996 to 2006, roughly 40% of TEDS treatment admissions were not in the labor force and 30% were unemployed (49). Well over half the admissions during this period were between the ages of 25 and 44, roughly 70% were men, and about 60% of all admissions were white, while blacks comprised 25.7% in 1996 and 21.3% in 2006.

Five substances represented 96% of TEDS admissions in 2007: alcohol (40%); opiates, primarily heroin (19%); marijuana/hashish (16%); cocaine (13%); and stimulants, primarily methamphetamine (8%) (10). Between 1996 and 2006, 40% of admissions were for problems with both alcohol and an illicit drug. Primary admission for treatment of alcohol alone dropped to 40% from 51% in 1996 (49). Although 58.1% of primary heroin admissions were self-referrals, 14.2% came through the criminal justice system; in contrast, for primary marijuana admissions, 56.9% came through the criminal justice system and 14.8% were self-referrals (10).

In 2007, 213,000 Americans were dependent on or abusing heroin (2). From 1996 to 2006, heroin treatment admissions increased 10%, however, the number receiving medication-assisted therapy decreased by 22% (49) and in 2007 only 29.1% received methadone or buprenorphine (10). This is noteworthy, considering not only the growing emphasis on pharmacological treatment for addiction but also, by the mid-2000s, the easing of regulations governing methadone, buprenorphine, and naloxone meant to encourage greater use of these treatments for heroin addiction, especially in physicians' offices.

Since the 1990s there has been a growing body of research on those individuals who change their addictive behaviors without treatment or self-help programs (61,62). Natural recovery (also referred to sometimes as self-change) is the most common form of managing addictive behaviors. Studies suggest the important role of personal and social resources, as well as cultural variation, both in the meaning of drug and alcohol problems and in what constitutes recovery (62,63). Recruiting subjects for studies of natural recovery poses a challenge to epidemiologists who cannot rely on convenience samples (64) but there is a need for more systematic research in this area given that the majority of people with drinking and drug use problems change their behavior without treatment or mutual support programs.

ROLE OF EPIDEMIOLOGICAL INDICATORS

Epidemiology's importance for understanding substance abuse was recognized in the 1970s, with the first systematic national studies on rates of prevalence and incidence of ATOD. By the early 1980s, studies of substances and their users documented the decline in use which began at that time. Since then, new epidemiological approaches and studies have been undertaken. When there are differences between measures, for example, between NSDUH and NESARC, detailed analysis of methodologies illuminates the reasons for the lack of agreement (65). Such triangulation of multiple approaches

is an essential dimension of epidemiology and the role it plays in defining and evaluating goals for programs and policy at all levels of government and in the private sector.

INTRODUCTION

The principal font of information regarding trends of European drug problems is the European Monitoring Centre for Drugs and Drug Addiction (EMCDDA). It provides decision makers and professionals, institutions, and other organizations involved in drug-related interventions with evidence-based information to support the drugs debate and decisions at both political and technical levels. The EMCDDA produces annual reports on the drug situation in Europe, including data about drug trafficking, estimation of consumption, and information about treatment requests and availability (1).

To develop a European overview of drug prevalence, the EMCDDA coordinates a network of National Focal Points (NFPs) set up in the 27 EU Member States, Norway, the European Commission, and the candidate countries. Together, these information collection and exchange points form Reitox, the European Information Network on Drugs and Drug Addiction. Under the responsibility of their respective governments, the NFPs are the national authorities providing drug information to the EMCDDA.

Given the national or regional level of the system of data collection, combining and comparing reported drug prevalence is problematic. Epidemiologic reasoning is conditioned by the heterogeneity of the data regarding the time frame considered, the context of the collection of data, the age range considered, the data collection procedure, the sampling frame and sampling procedure, and the weighting procedure.

In this chapter, we have selected information about treatment demand, which is the best filter to make meaningful comparisons between different use-groups, and describe longitudinal trends. Nevertheless, treatment demand may correspond to a different rate of actual problematic drug use, depending on the availability and accessibility of treatment, the level of information about treatment options in the general population, and not least to the legal consequences of enrolling into treatment. As a result, opiates may be the only substance class for which treatment demand might parallel incidence and prevalence of abuse/addiction cases. On the other hand, the presumption that treatment demands equate to addiction, or indeed any disease at all, is problematic: for example, treatment demand due to drug law offences as an alternative to jail have created an abnormal channel toward therapeutic settings, especially if substance based and not diagnosis based. In fact, although therapeutic parole is reserved to those who display features of pathologic

drug use, some laws draw a direct link between the illicit status of a substance and the possibility of treatment, mistaking therapy for some kind of (re)education or legally oriented behavioral conditioning.

One important restriction applied in EMCDDA reports, to be considered in our reasoning on treatment demand, refers to the case definition, which includes only people entering treatment for drug use. Therefore EMCDDA data do not necessarily include clients in continued treatment from previous years. Moreover, it should be considered that treatment demand data come from each country with varying degrees of national coverage (from 24% to 100% of treatment units covered).

Finally, the EMCDDA definition of “problem drug use” as a key indicator of drug use epidemics is “injecting drug use or long duration/regular use of opioids, cocaine and/or amphetamines.” Such a definition omits noninjectable drug use, at any stage, but does include prescribed opioid use, provided that the opioids are prescribed on a regular basis. Thereby, overall data corresponding to such a definition cannot be easily interpreted.

In our presentation we will refer principally to EMCDDA reports. Other data reported from surveys, prevalence studies, national reports, and observational and experimental studies will be considered for specific subjects.

PATTERN OF SUBSTANCE TREATMENT DEMAND

All Drugs

In Europe, primary heroin use rose from 108,000 in 2002 (63% of all treatment episodes) to 129,000 in 2007 (52%); primary cocaine use rose from 22,000 (13%) to 47,000 (19%); and primary cannabis use from 27,000 (16%) to 50,000 (20%). Stimulants other than cocaine accounted for 15,000 cases of primary problem drug use in 2002 (9%) and 20,000 (8%) in 2007. Among new clients entering treatment, heroin use rose slightly from 36,000 (48%) in 2002 to 38,000 (34%) in 2007, while cocaine increased sharply from 13,000 (17%) to 28,000 (25%) and cannabis from 18,829 (25%) to 34,312 (31%). There was a smaller increase for stimulants other than cocaine, from 8,000 (10%) to 10,000 (9%).

Primary heroin treatment demand increased in number but decreased as a rate of all treatment demand (+20% from 2002 to 2007), due to the absolute and relative rise of

treatment demand for cocaine (+135%), cannabis (+85%), and other stimulants (+33%). The trend is more evident among new clients (+5% for heroin, +115% for cocaine, +82% for cannabis, and +25% for other stimulants). The rise in emerging use, as calculated by the ratio between new client numbers in 2002 and 2007, was twice as much for cocaine than for heroin.

The fact that standardized treatments are available and known for heroin addiction but not generally for cocaine abuse, increases the significance of the rise in problem cocaine use: cocaine abusers may be less likely to enter treatment if no specific treatment perspective is available and may be less likely to make further attempts after the first treatment failure (2).

Alcohol

The EMCDDA report features alcohol as a secondary substance; however, no European data about alcohol treatment episodes are presented. For licit substances such as alcohol, estimates of abuse and addiction epidemiology are problematic. In fact, alcohol use may be regular and heavy but this pattern of use does not necessarily equate with addiction, whereas such a relationship is often presumed with illicit drugs such as heroin.

Increasing alcohol abuse, such as recurrent episodes of heavy drinking, was reported in most countries across the late 1990s, among both men and women. More recently, no uniform course can be observed. By 2006, approximately 5% of male and 2% of female drinkers report negative consequences of habitual drinking on their job or study performance. A significant rate of premature deaths, and disability, are related to alcohol, at least as a contributing risk factor for the cause of death or accident (12% in men and 2% in women). The role of alcohol as a cause of death among young people is relevant: 25% of young men and 10% of young women die of alcohol-related causes. Specifically, 1 out of 3 lethal car accidents, 4 out of 10 killings, and 1 out of 6 suicides are directly related to alcohol use. Further, as many as 17,000 deaths due to neuropsychiatric problems are related to alcohol. Beyond such data, the specific weight and trends of alcoholism remain unclear (3).

Opiates

In most European countries supplying data, between 50% and 80% of all treatment demand (about 387,000 for 24 countries in 2006) is related to opioids as the primary drugs, in the remaining countries the proportion varies between 1% and 40%. Opioids are infrequently reported as a secondary drug (11% to 13%), and are generally less frequent among clients entering their first treatment episode (40%). As a rule, treatment demand related to opioid use has been increasing in recent years. Data from nine countries show that opioids are the most frequent primary drug of abuse among clients who are already in treatment (59%) but account for only 40% of clients entering treatment for the first time in their lives.

Injecting drug use is not as frequent as one may presume: 63% of all opioid users applying for, or currently receiving, treatment reported injecting opioids at the time of treatment entry. Percentages vary between 25% and over 80% across different countries. While some countries, such as Ukraine, report higher percentages such as 97% (4). Among those entering treatment for the first time, the percentage of opioid injectors is generally lower and decreased from 43% to 35% between 2003 and 2006, although there has been a more recent reprise up to 42%.

Generally, the rates of reported injecting opioid use show a decreasing trend over time. In some countries, smoked or snorted opiates are the prominent mode of administration. However, another plausible explanation may be that the availability of opiate addiction treatment has favored a trend toward earlier involvement into treatment, assuming that the transition to injecting drug use is a sign of increasing severity of use. Further, the availability and marketing of newer opioid formulations that are not automatically linked with the risk of addiction, such as smoked opium, may be becoming more popular.

The mean age of patients entering outpatient treatment for primary opiate use is 33 years and has been increasing since 2003. Men outnumber women by 3.5 to one. Among those who develop opioid-related problems and apply for treatment later in life, opioid use is likely to start before the age of 25, and unlikely to start after 25 years. An average time interval of 7 to 9 years stands between first use of opioids and first contact with drug treatment. Men spend a longer time using opioids before entering treatment. However, the mean age of first opioid use is decreasing (one year lower among new clients). A possible reason for this is higher rates of treatment re-entry among previously treated addicts who have been prematurely discharged or dropped out of treatment: thus, the whole population is aging while the average age of new clients is decreasing.

To summarize, mean age at treatment entrance is 32 years, which is usually 7 to 9 years from the very first episode of drug use. Men spend a longer time using opioids before entering treatment. On the whole, new clients tend to be younger, use more frequently, and they may have spent longer snorting or smoking the drugs before starting injecting drug use.

For details consult <http://www.emcdda.europa.eu/situation/analysis> (5).

Cannabis

The rate of treatment requests for a primary cannabis-related drug problem rose to 12% of all clients, and 30% of all new clients, in 2002. Although rates vary across different countries, cannabis appears to be an increasing problem in all European countries for the 1996 to 2002 period. In 2007 primary cannabis-related demands are 20% of all cases and 28% of new cases.

The peculiarity of cannabis-related treatment demand is the high prevalence of compulsory treatment or nonspontaneous treatment requests, such as in the case of treatment

requests to avoid jail or other legal consequences. According to EMCDDA in several countries, cannabis users, regardless of a thorough assessment of their possible addictive state, are referred to hypothetical treatment programs for implicitly supposed problematic cannabis use, thus confusing a legal option with a medical condition of cannabis abuse/dependence. In fact, the majority of presumed abusers, about two thirds, do not use cannabis on a regular basis (less than daily), and in half of those cases consumption is actually infrequent (once a week or less often) (6). In 2007, 24% of clients were classified as occasional users, or had not been using the substance during the last month. As such, the reason for cannabis-related treatment seeking does not always appear related to intensive cannabis use. It may be either that cannabis-related treatment seeking is mostly due to legal problems related to cannabis possession and consumption, or that occasional intoxication or cannabis-related adverse events, rather than addiction, may be the primary reason. Cannabis use generally commenced before the age of 20, while the mean age at treatment request is 24.

Stimulants

In Europe (5), cocaine was the primary drug in 17% of treatment-seeking drug users in 2007, and the secondary drug in 18% of cases. The rate among new clients is higher (22%) and has been increasing in recent years (on the whole, 19% of cases were cocaine related at some level). Spain, in particular, has experienced an increasing rate of primary and secondary cocaine-related treatment demand (over 40% and over 60%, respectively). Most countries report a higher prevalence of primary cocaine problem use among new clients than among all clients, indicating a generally increasing trend in problematic cocaine use. Treatment demand is linked to recent regular consumption in 60% of cases, whereas in other cases clients apply for treatment while not using on a regular basis or during periods of abstinence. Intravenous use is rare (6%) and does not seem to be increasing (being lower among new clients and with respect to previous years, despite the increase in treatment demand).

The rate of cocaine and amphetamine-related problems appear to be inversely related, which may suggest that these two stimulants are seen as equivalent to each other, alternatively dominating each territory's market. Crack cocaine use is limited to some urban areas, and rather uncommon (at any level in 2% of all treatment requests).

Treatment for primary amphetamine use is usually below 5%, although some countries have rates of 25% to 35%, notably Sweden (34%), Finland (Helsinki) 23%. Methamphetamine has become a trend in exceptional cases, up to 59% of treatment demands as a primary drug in 2006. In treatment settings, problematic methamphetamine use is predominantly via injecting. MDMA treatment requests are relatively rare (0.5% down to irrelevant numbers for most countries, a few countries reporting up to 4%). As a rule, MDMA problem users applying for treatment are polydrug abusers, mostly of alcohol, cannabis, or other stimulants. Fifty-two

percent of primary noncocaine stimulant clients are occasional users.

Polydrug Abuse

As many as 57% of clients reported at least one secondary drug (33% one drug, 20% two, 4% three or more) (7). Clients entering treatment for the first time are more likely to be polyabusers, except for first-time heroin treatment clients. The lowest rate of polyabuse is among cannabis clients (43%), while crack-cocaine abusers report the highest (69%). This latter category, however, corresponds to a very small proportion of all clients receiving treatment in most European countries.

The list of secondary drugs reported by polydrug users includes cocaine (32%), alcohol (40%), cannabis (27%), and other stimulants (11%). The involvement of cocaine in polyabuse patterns plausibly increases the weight of this drug in the course and outcome of treatment for primary drug abuse pictures such as heroin (8).

Cannabis polyabuse accounts for most cannabis-related treatment demands (85%), with cannabis predominantly being the secondary substance of abuse. Most featured combinations are with alcohol, cocaine, or both. Primary cocaine users in treatment report 63% of polyabuse, mainly alcohol (42%), cannabis (28%), and heroin (17%).

Opiate clients often engage in polyabuse during the relapsing course of their disease: as such, the likelihood of polyabuse is higher among re-entering clients or those who have been in treatment for some time. A Swedish study reported a history of hospitalization due to alcohol-related problems in 1 out of 3 heroin addicts entering methadone treatment (9). An Irish study reported a 56% rate of alcohol polyabuse among methadone patients (10).

Benzodiazepine use is also frequent, although to a variable extent (11% to 70%). Cocaine polyabuse in methadone maintenance is also common, and seems to mirror the estimated trend of use in the general population. Cocaine polyabusers during methadone treatment are also likely to report alcohol abuse.

POPULATION SUBGROUPS

Gender Differences

Male to female sex ratios show male predominance in all age groups and across all countries (ranging from 1.6 to 9:1). A relatively higher rate of females is found among very young and elderly clients (<15 and >45), which suggests a lowering trend for sex ratios in the future, at least for clients who will stay in long-term treatment or display the usual addictive pattern of recurrent relapse and subsequent re-entering into treatment. The relatively higher proportion of females within the over-45 age group may suggest a gender-specific feature, either the concentration of late-onset drug abuse among women or the higher rate of long-term treatment adherence for females, especially within standard maintenance treatments (i.e., opiate addiction) (11).

TABLE 3.1 Pattern of substance abuse

	Mean age (years)	Started using at (years)	Sex ratio (M/ F)	IDUs	Regular use (daily or several times a week)
Cocaine	33	15–24	5:1	6%	60%
Amphetamine	29	<20	2:1	14% (all)	42%
MDMA	24	<20	n.d.	n.d.	n.d.
Methamphetamines	24–25	<20	(less than 2:1)	41%–82%	n.d.
Cannabis	24	<20	5.5:1	n.d.	76%
Opiates	31–33	<25	3.5:1	63%	60%–70%
Sedatives-hypnotics	n.d.	n.d.	1.4:1	n.d.	n.d.

Data from <http://www.emcdda.europa.eu/>

Table 3.1 presents the sex ratios for the primary reported drug categories. Females may outnumber men just in the case of sedatives-hypnotics, but the number of male sedative-abusers has been increasing as a whole. Some countries report ratios below 1; on average it was 0.9 in 2003 but it rose to 1.4 recently (up to date). Some countries still report ratios below 1, so it may be that in some samples men are fewer (to be noted, the body of data about primary sedative clients is quite small with respect to other drug categories). The mean age of new clients for any drug is similar (about 27) between sexes. Injecting drug use is rather typical of males. Age of onset of drug use is higher for females just in the case of sedatives. The rate of female clients is lower in subgroups of “at least-daily” users for all substances, except for cannabis and sedatives. Female clients are more likely to have been referred by the health system (36% vs. 27%) and less likely to be referred by the criminal justice system (10.6% vs. 22%). It was estimated that the latency period from drug use to treatment is about 2 years shorter for women.

Drug-related deaths have been a predominantly male phenomenon. However, recent data show that the incidence of drug-related deaths have not been decreasing by the same rate in the two sexes (half as much among women). Thereby, factors affecting drug-related deaths do not seem to have the same impact among women as among men. Despite similar rates of infection, the seroconversion of female clients is higher when controlling for the prevalence of intravenous drug use. Given the similar rates of Hepatitis C Virus (HCV) infection, it is plausible that sexual transmission is the basis for such increased risk (5,12).

Younger People, Under 15 Years

In most European countries, fewer than 2% of drug clients are under 15 years of age, although that subpopulation increased between 1999 and 2005, while in 2006 as many as 80% of reported cases came from the United Kingdom. Their

primary drug is almost always cannabis or inhalants, to a lesser extent opiates with other substances being very rare. The male/female sex ratio in younger clients is 2.5:1 versus 4.1:1 among clients over 19 years. Among the younger clients, 78% of under-15 year olds and 67% of 15- to 19-year-old clients are in treatment for primary cannabis use (13). In 2005, 18 drug-related deaths among children under the age of 15 were reported, which represents 0.2% of the total number of drug-related deaths in Europe.

Immigration and Problem Drug Use

Studies about addiction and problem drug use among immigrants are lacking, and no European network aiming at the characterization of immigration-related drug risks has thus far been established. This is surprising, considering migrants are becoming an increasing part of European society. Nevertheless, in the field of drug use and addiction, little attention has been paid to this subject.

Among foreigners immigrating to Italy, mostly in a clandestine way at least when crossing the border, addictive drug use is closely related to immigration. Three out of four of foreigner heroin addicted clients in Rome report starting heroin use after moving to Italy. Successfully settling in Italy is not always protective against the development of addiction: immigrants who have been in Italy for a short time (less than 4 years) report lower rates of injecting and noninjecting drug problems than those who immigrated earlier (4 or more years before). Such a difference is particularly evident for heroin, but has been documented for cocaine too. (14,15).

Data from studies across Europe suggest that the prevalence of migrants with addictive disorders corresponds to, or even exceeds, the general population, yet there are still substantial barriers to accessing facilities that provide help to addicts (16). The literature reports a number of barriers to treatment access, including language difficulties, diffidence, condition of clandestinely, fear of losing residency rights,

culturally different understanding of the causes and treatment of addictive behavior, and a lack of intercultural competence of people working in health and psychosocial care institutions (17). For example, in Hamburg, where migrants represent 33% to 35% of the drug addict population and 16% of the city's total population, only 8% to 10% of people attending drug addiction facilities were migrants (18).

Infectious Disease and Drug Use: The European Experience and the Russian Paradigm

In the epidemiologic study of addictive diseases, infectious needle-borne diseases, especially Human Immunodeficiency Virus (HIV), HCV, and Hepatitis B Virus (HBV) can be regarded as behavioral indicators of drug abuse and treatment outcome. Likewise, prevention strategies and responses to drug-related infectious disease should be founded on a synergy between core addiction treatment and harm reduction, particularly for those initially resistant to treatment.

In several countries, both in and out of the European Community (Middle East, Asia), the increase in the rate of HIV incidence raised the first political concern about the need to limit the impact of injecting drug use upon public health. The control of infectious disease epidemics, together with effective crime control strategies, highlights the relationship between addiction treatment and the more general issue of health and safety for the wider population. The history of opiate addiction treatment in Europe clearly shows the relationship between delivering effective addiction treatment and reducing the rates of infections among injecting drug users. The resistance to the spread of opioid agonist replacement therapy has caused, and is still causing, a paradox of prevention: HIV infection should be considered an exceptional condition for agonist maintenance treatment to be allowed, and not just a priority condition for the access to it. In Germany and Scotland, when methadone was limited exclusively to HIV-positive addicts, cases of drug users who would infect themselves voluntarily in order to access treatment were reported. This paradoxical fact was reported by J. Mordaunt during the "Fourth International Conference on the Reduction of Drug Related Harm" that was held in Rotterdam (March 14 to 18, 1993).

The above situation corresponds to a paradigm where agonist maintenance treatment is not spread evenly throughout Europe. At the beginning of the 1990s, over 90% of AIDS cases among drug users were registered in 3 out of the 12 current European community countries: France, Italy, and Spain, which accounted for less than 50% of the current European community population. Apparently, in 9 out of 11 countries a relationship stood between AIDS prevalence and/or incidence rates among Injecting Drug Users (UDUs) and the percentage of IDUs enrolled in methadone treatment. Countries with a low prevalence and relatively stable incidence were those for which the introduction of methadone treatment dates back to the 1980s or late 1970s. Thus, despite territorial contiguity and membership to a common economic system, the differential impact of HIV infection among high-risk categories such as

IDU was directly related to the availability of treatment in different territories (19,20).

Among countries with a more recent history of opioid addiction epidemics, the Russian Federation shows a higher prevalence and incidence rate of HIV infection among injecting drug users. These data may illustrate the situation of a country facing an epidemic of opioid addiction with no or few specific resources to respond to it, despite nonspecific efforts aiming at detoxification, re-education, or drug-free rehabilitation. The prevalence rate of officially registered cases of drug addiction in Russia leaped from about 60/100,000 in 1997 to 154.8/10,000 in 1999, and 241/100,000 by the end of 2003 (343,000 individuals). The vast majority of cases correspond to opioid addiction (133.1/10,000 in 1999 and 211.6 in 2003, standing at 210.9/10,000 in 2004). The highest prevalence is among young people, with 1025/100,000 in the 18 to 19 age range and a 976.5/100,000 in the 20 to 39 range.

Approximately 87% of drug addicts are primarily engaged with heroin use. The incidence of female cases of drug abuse has risen to 14 times its value across a 15 years period. Injecting drug use accounted for 75% of registered cases of HIV infection registered by June 2004. HIV prevalence demonstrated a 310-fold increase from 1995 to 2003; HIV incidence has risen by a factor of 276. The prevalence of HIV infection among injecting drug users reached 2081/100,000 in 2005.

In one subregion, the seroconversion rate was as high as 41% in a 1-year period in a sample of 426 IDUs, and prevalence of HIV positivity reached 64.5% in another sample. In 2005, this value reached 80% for injecting opiate addicts (21,22).

The majority of HIV infected people in Russia is aged between 20 and 29, and one third are women, mostly within the 15 to 25 age range (25% in the 15 to 20 age group and 50% in the 20 to 30 age group). The incidence of HIV among women has risen 450 times its initial value, and current prevalence among pregnant women is 114.7/100,000. Moreover, 48% of commercial sex workers who are IDUs are also HIV infected. Up to 80% of people with HIV infection are IDUs with variable patterns of use and have had at least occasional experience of sex trading for money. As much as 60% of viral hepatitis B and 90% of hepatitis C are due to injecting drug use.

The role of addictive drug use in the spread of HIV infection becomes "overwhelming" to any nonspecific public health strategy when the availability of evidence-based treatment for opioid addiction is either none or low. The Russian experience demonstrates how the relative neutralization of protective factors (i.e., gender-related protective factors in the case of injecting drug use) may lead to an amplifying effect, as females become more vulnerable to seroconversion. In this background it is difficult to understand why some Russian psychiatrists could openly take sides against the introduction of methadone in Russia (23).

TREATMENT POLICY AND PROCEDURE

In the case of heroin addiction, there are reliable predictors of treatment effectiveness, including the dose of the replacement pharmacotherapy, retention in treatment, and integration with

facilities for concurrent health and social issues. Surprisingly, data about these important predictors of dose and duration of treatment are not reported by EMCDDA. To be more precise, data about duration are incidentally reported in a way that reveals an alarming misconception about gold standards of agonist maintenance. In fact, the distinction between short- and long-term treatment is usually fixed at some months of treatment duration, regardless of dosage regimens. Such a view results in the misclassification as “agonist treatments” of those interventions that do not effectively manage opioid addiction (i.e., detoxification or medium-term tapering). Furthermore, methadone treatment programs that are delivered for a short period of time (e.g., a few months) are grouped together with recognizable methadone maintenance programs, leading to an overestimation of methadone maintenance availability. Moreover, no detail of dosage or regimen is provided, apart from those reported in single subnational studies. Nor is detail provided about the rate of re-entries, dropouts, or accomplishment of therapeutic goals, since no uniform encoding is utilized. In our opinion, it is not appropriate to dilute the results of high-performing services with those of centers where tapering opioid medication dosages is accepted as a therapeutic procedure or 1-month’s program rated as a success. Finally, the EMCDDA makes no discrimination between opioid use, abuse, and addiction, so that it is not possible to determine the adequacy of treatment programs in relation to the actual diagnosis.

Treatment Provision

In general, treatment provision is provided mostly from outpatient settings. Some countries continue to offer no specific treatment approaches for opioid addiction (Hungary, Poland, and Sweden), although agonist treatment is available. It appears that broad-spectrum treatments are increasing in those countries. Further, the provision of agonist treatment does not appear to depend on the duration of the opioid use epidemic: countries with decades of experience such as England and Germany show similar coverage rates with newcomers such as Croatia, Italy, and the Czech Republic. However, the availability of agonist treatment is quite dissimilar among countries with shorter experiences of opioid addiction treatment (e.g., 5% in Slovakia compared with approximately 40% in the Czech Republic).

Surprisingly, in some territories, profiles of drug users entering treatment are changing in a way that suggests improvement in the outreach to problem drug users. In Ukraine, for example, the rate of young people aged up to 20 years enrolled in treatment programs has increased from 16.4% to 21%, with a decrease in the percentage of those between 30 and 40 years of age from 19.3% to 16.4%. Also, the mean duration of opioid use at first-time treatment entry has reduced, from 3.9 to 3.0 years. Thus, the availability of treatment is expected to favor earlier treatment of younger people, with clear improvement in rehabilitation (4).

The involvement of General Practitioners (GPs) in the treatment of heroin addiction is somewhat surprising in some

countries. On one hand, in some countries GPs are the primary treatment provider, representing about 80% in France and 90% in Germany. Such a status should correspond to the capillary spread of specific knowledge about heroin addiction and mental disorders. In the absence of such a situation, the provision of treatment would rather correspond to detoxification or longer-term prescription without specific therapeutic goals (i.e., rehabilitation and relapse prevention at average effective dosages). On the other hand, some countries that are theoretically enabled to provide GP-based methadone treatment fail to do so, or do it exceptionally, as in the case of Italy. Although the feasibility of GP-based methadone maintenance has been documented both in Germany and in Italy, other factors seem to influence such diverging national situations (24,25).

As for harm-reduction campaigns, to date they have been primarily focussed upon the personal and social needs of heroin addicts, with an aim to prevent the consequences of addictive behaviors. An incorrect distinction appears to be employed when comparing harm-reduction interventions to specific treatments for heroin addiction. Nevertheless, some of the specific targets in the treatment of heroin addiction, as well as features of mentally ill subpopulations, may be reasonable targets for harm reduction. Although a tacit dichotomy stands between the two approaches, they may be viewed as different stages in the process of rehabilitation of socially impaired drug addicts, or shared components of large treatment campaigns when waiting lists cannot be avoided.

Convergence upon overlapping targets may be considered when harm-reduction and specific treatment interventions share the same therapeutic components and goals. Opioid agonists, the primary option for the specific treatment of heroin addiction, may also serve as a harm-reduction approach, as long as harm reduction is conceived as a means to act upon the same disease, although at a low-threshold level. From a treatment point of view, what is specifically targeted at treating addiction is also likely to function as an effective form of harm reduction.

The personal and social impact of agonist-mediated harm reduction is particularly important for higher-risk populations, such as mentally ill heroin users, who may demonstrate poorer retention and outcome in standard opioid agonist replacement pharmacotherapies. Harm reduction should be regarded as a lower intensity of treatment delivery for more severely disabled subjects, bridging the gap between the street and the clinical settings by offering less demanding treatment requirements and services but retaining the essence of evidence-based pharmacotherapy. Such low threshold–low intervention methadone programs have been shown to be effective in retaining clients within the treatment system (26). Graduating from a lower threshold harm reduction program to a higher level of intervention should represent the ultimate goal of harm reduction itself. Transition to specific treatment is of particular importance for dually diagnosed addicts who are expected to experience greater relative benefit and who otherwise may be excluded from the opportunity of a positive outcome (27).

The Epidemiologic Black Hole of Heroin Addiction: A Possible Sign of Inadequacy of Treatment Standards or Blindness to Changes in Drug Use Behavior

Opiate addiction is a curable disease, with a standard approach consisting of long-term treatment aimed at the maintenance of rehabilitation through relapse prevention. Agonist treatment is an effective technical instrument for such a purpose. Some information is available about the availability and spread of agonist treatment, but no clear data exist to permit an evaluation that evidence-based treatment standards and principles have been applied.

In 2002, 72,000 “old” clients are recorded in Europe, plus 36,000 new clients. On theoretical grounds, ideally in 2003 some 100,000 clients are expected to be in treatment, and the number of agonist-maintenance clients should increase by the cumulative effect of each year’s new and old clients re-entering treatment. In fact, a stabilizing effect would be expected if older patients who have failed previous treatment attempts were maintained on the gold standard treatment (i.e., agonist maintenance), also providing with the highest retention rates.

Assuming that some 30,000 new clients have applied for primary problem heroin use from 2002 to 2007, and that some 70,000 have been “trying treatment again,” the resulting number of recorded methadone maintenance clients would be presumably higher than the 650,000 reported in 2007 (+150,000 in 6 years). Therefore, out of some cumulative 700,000 theoretical new clients throughout a 6-year period, approximately 550,000 were not recorded after 6 years. Omitting clients lost to treatment due to reasons such as death, emigration, incarceration, or possible switching to other primary substances, the number of “disappeared” clients still remains significant. It can be hypothesized that these clients either dropped out of treatment or were prematurely discharged with no subsequent re-entry in a 6-year period, or were definitely abstinent after a short-/medium-term intervention with no known relapses in a 6-year period. Also, it may be that part of those clients are the same ones re-entering treatment programs each year, or being addressed toward short-term treatment programs every time, regardless of their treatment failure history. Given that no brief intervention is known or reported to be effective in opiate-addiction, the only plausible conclusion is that the majority of opiate addicts, even if treated by agonist drugs, are prematurely discharged or leave treatment in a way that does not favor subsequent re-entry into the same treatment, at least in the following years. The fact that in several countries a 6-month term is referred to as the threshold between short- and long-term treatment is consistent with such a hypothesis.

It is obvious that no increase as such has taken place, which means that longer-term maintenance treatments are not being offered according to best practice principles. Thus, the availability of agonist treatment programs does not necessarily guarantee the effective, evidence-based delivery of treatment. In Italy, for instance, it was documented that 8 treatment programs out of 10 are characterized by methadone dosages below

the minimum effective dose of 60 mg/day, and methadone dose increases did not take place in response to the lack of response in the months following treatment entry (28).

Another study conducted in a university center for the treatment of dual-diagnosis patients investigated new clients’ characteristics across a 10-year period. In this retrospective study, more recent treatment demands came from older patients (33 years on average) with a history of earlier treatment but a lower rate of previous methadone maintenance (regardless of outcome). Thus, earlier intervention had not led those patients to potentially effective treatment options (27%), and patients had continued to be addicted to heroin. The reasons for treatment requests by a University Center demonstrated the relative resistance to treatment re-entry for clients who had previously attempted programs at local addiction treatment units. This phenomenon of missed re-entry after the failure of nonspecific short-term treatments may be a major issue behind the poor outcomes among heroin addicts (29).

Finally, moving from one primary drug of abuse to another remains poorly characterized. An Italian survey in a specialized hospital center for alcohol dependence in a major urban area (Rome) investigated the history of past drug use among new clients. Approximately 15% of clients entering treatment for alcohol abuse or dependence reported a past or present history of heroin use, although heroin was currently a secondary substance. Alcohol consumption started usually before heroin consumption, but reached higher mean and maximum levels with respect to other categories of alcoholics. In those subjects, a history of long-term opioid agonist treatment was quite unlikely, while current mean methadone dosages were lower than the effective average dose of 60 mg/day (30).

Methadone and Buprenorphine Misuse: An Epidemiologic Pitfall Due to Abnormal Treatment Profiles

Some countries report significant rates of primary abuse of opioids other than heroin. Therapeutic opiates are featured, with notably high rates of reported primary abuse in Finland for buprenorphine (51%) and in Denmark for methadone (20.6%). However, it can be difficult to distinguish between addictive use, abuse, and simple generic misuse of prescribed opioids, as indicated in the Danish report.

“Misuse” is an ambiguous term, which does not permit a clear distinction between treatment demands corresponding to addictive use or infrequent supply and handling use of potentially harmful substances. “Street methadone” use is a known phenomenon, but the presence of nontherapeutic methadone use at treatment entry does not necessarily equate to methadone abuse or addiction. The use of illicit long-acting opioids may either correspond to self-medication, with the purpose of withdrawal prevention or sedation, or else to actual misuse and addiction-like behavior (which usually means a change in the route of administration to injection, since a change in the administration route is required to elicit intoxication by oral formulations of methadone and

buprenorphine). It is not clear how many clients have entered treatment due to nontherapeutic use and loss of control upon methadone or buprenorphine, with no history of heroin abuse. Further, the fact that problem drug users may apply for treatment with a goal to leave and detoxify from methadone or buprenorphine does not usually reflect addiction to those compounds, but the request to manage withdrawal discomfort and reverse acquired tolerance.

Curiously, the Danish data show a significant rate of methadone misusers among older clients (<25 years old) rather than younger clients. It is possible that older clients have a greater tendency to self-medicate withdrawal discomfort or have re-entered treatment as they became tolerant to street methadone, and were classified as primary methadone misusers for such a reason. In that case, the improper classification of “street use” as addiction would create the false impression of a rising methadone epidemic. If the following therapeutic response was to detoxify those subjects from methadone instead of offering methadone maintenance at higher dosages, this vicious circle would perpetuate. In fact, the misconception that therapeutic opioids are merely a substitute for heroin has caused many treatment policies to shift from the prevention of relapse to heroin addiction to the short-term tapering of any opiate. In fact, in most countries (Denmark included) national authorities classify maintenance over some months as “long-term” treatment (instead of short-term as it actually is), which mirrors the negative attitudes toward the application of agonist treatment and feeds this misconception. Indeed, the Danish data also show, consistent with other countries, that despite the increasing rate of clients in “long-term” treatment, such a solution is more likely to be adopted for older clients (over 30), which suggests that drug-free approaches or detoxification are still very common, especially among clients in treatment for the first time and younger addicts.

As a consequence, the public (patient and physicians included) often believe that therapeutic opiates create a new dependence. Patients who succeed in reducing their illicit drug use by lower dose methadone, with occasional heroin use, may indeed report methadone as their “primary” drug problem. Paradoxically, their condition at treatment entry (heroin addicted with harm reduction through methadone) would be still rated by many as better than at treatment exit (heroin addicted and methadone-free).

It is important to diagnose addiction to methadone (i.e., psychological and physical dependence) based upon standard objective criteria for addiction (as in Diagnostic and Statistical Manual, Fourth Edition, Text Revision - DSM-IV-TR criteria) rather than relying upon patient self-report or physical dependence criteria alone.

There have been documented cases of the illicit, nontherapeutic use and abuse of Buprenorphine. Buprenorphine misusers are concentrated in France and Finland, countries where buprenorphine treatment was launched earlier than in the rest of Europe, and for many years was the primary agonist treatment option (31).

In Finland, the 2008 National Report reported that 56% of agonist treatment episodes are buprenorphine based (32).

As many as 33% of clients reported buprenorphine as their primary drug of abuse, with a clear trend indicating a decrease in primary heroin use and an increase in primary buprenorphine use (from 7% to 33% and from 20% to 2%, respectively, in the 2000 to 2007 period). Buprenorphine misusers tend to be younger, enter treatment earlier, start injecting sooner and inject more often. In a French survey (32) among low-threshold facilities, 54% of attendees reported using non-prescribed buprenorphine as self-medication, 13% to get “high,” and 34% for both reasons. Older clients tended to use buprenorphine for self-medication of withdrawal discomfort rather than for intoxication.

Given its pharmacological profile as a partial opioid agonist, injecting buprenorphine will produce a “high” (euphoria and intoxication). However, habitual use is somewhat surprising, due to its long half-life and the rapid experience of the ceiling effect on the opioid effects. In a context where long-term maintenance agonist treatment is uncommon, older clients may re-enter treatment reporting injecting buprenorphine use, which may represent an attempt to maintain some direct opioid effects with a reduced reliance upon the use of heroin. Further, it is likely that patients will report polydrug abuse, as pharmacodynamic interactions between buprenorphine and other central nervous system (CNS) depressants (such as benzodiazepines) may increase the likelihood of experiencing sedation, intoxication, and euphoria. Conversely some primary stimulant abusers may use opioids to manage the negative consequences or withdrawal symptoms of the psychostimulants (33).

The introduction of the buprenorphine–naloxone combination product may help to discriminate different patterns of buprenorphine abuse and reduce its nontherapeutic use.

Drug-Related Crime

Data are available regarding drug law offences (EMCCDA). However, the interrelationship of drug use, pathologic drug use (i.e., addictive), and involvement in criminal behavior provides complexity. Specific indicators of drug addiction (as opposed to drug use) are missing from the EMCCDA reports, which makes it difficult to identify addiction-related criminal records from drug law offences and general crime committed by nonaddicted individuals. Further, drug use data from prison populations also fails to discriminate between addicts and recreational users.

The rate of drug users who are in treatment at the time of arrest may provide a marker of treatment effectiveness within a region. According to various reports to Italian Parliament (years 1986 to 2002), the number of addicts in jail increased from about 6,000 in 1986 to about 15,000 in 2002. The rate of addicts in treatment at the time of arrest rose from below 5% in 1986 to over 20% in 1989, congruent with the greater availability of methadone programs throughout the territory. The 2002 trend continues. Thus, the spread of methadone treatment in the wider community has not directly translated into a reduction in criminal behavior, although the increased numbers of clients receiving methadone, and the classification criteria used, may explain

the apparent rise in the number of addicts being incarcerated. The initiation of methadone maintenance in jail is quite unlikely in Italy; however, the rate of continued maintenance among existing clients in jail has been growing to a small extent up to date.

Drug-Related Deaths

The EMCDDA data permit the monitoring of the incidence of drug-related deaths, poisonings, or overdoses in several European countries. Overall, drug-related deaths have been stable since the early 1990s, although a wide variability of incidence exists between different countries. As a general rule, the age of drug-related deaths has been increasing over the years. While in some countries drug-related deaths have remained relatively stable, in others there have been changes over time. In Poland, the mean age of drug-related deaths has increased from around 40 years in the middle of 1990s to over 45 years by 2006. In Bulgaria, the mean age of death was approximately 45 years in the early 1990s and has fallen to 30 by 2007.

Data are difficult to interpret, since different drugs are considered together as one cause of death, and polydrug abuse precludes specific causal linkage. It is commonly thought that drug-related deaths take place after the onset of intensive and heavier use (than usual), during relapses (where tolerance may be lower) or in the period between treatment episodes. The greater availability of treatment programs should theoretically lead to a decrease in death rate and the average age of death.

Data suggest that there has been a decrease in deaths due to acute drug intoxication throughout the 1990s up to 2005. Nevertheless, studies on the profile of either lethal or non-lethal heroin overdoses show unexpected features. In Italy, for instance, almost 70% of overdoses reported in 1997 occurred among people who had gone through some nonspecific form of addiction approach, had been discharged from jail in a drug-free state or had stopped taking naltrexone (i.e., had no tolerance) (34). Such practices endure despite another Italian study (35) clearly showing the protective effect of methadone maintenance treatment against the likelihood of lethal overdose. However, effective daily dosage of methadone is still rare in many treatment services, which may explain the findings that the average age of drug-related deaths rose from about 30 to about 35 in the period from 1996 to 2005, while the rate of drug-related deaths in the over-35 age range rose from about 25% to about 55% in the same period.

Limited case numbers in many countries does not permit firm conclusions to be drawn. Other consequences of drug use, such as infectious diseases and drug-related deaths, seem to be very rare in the youngest drug users, partly because of their short drug career.

FINAL REMARKS AND FUTURE PROSPECTS

We believe that epidemiology should be built upon foundations of clinical medicine. The bedside clinical observation, which includes the classic stages of diagnosis and therapy, is not inconsistent with the epidemiological medical science that

studies the disease: in fact, it just implies a different perspective on the distribution and evolution over time of its determinants in the population.

Epidemiological tradition is not uniform across Europe. There seem to be areas where the epidemiological tradition appears more entrenched than others. A “leopard skin” map (spotted pattern) covers up most of Europe’s territory. In England there is a strong home-grown tradition and at the same time close ties with North America. We could say that metaphorically “The Atlantic Ocean is shorter than the Channel!” In the map of continental Europe, Scandinavian countries and the Netherlands are countries whose academic structures have evolved more quickly, while France’s, Germany’s, and Italy’s academic structures have been growing more slowly. Eastern Europe countries have recently displayed considerable attention and commitment to public health. However, in the long term, this commitment has suffered from a lack of original research and associated infrastructure.

Across Europe, many clinicians remain unfamiliar about the methodology of evaluation of diagnostic interventions; their degree of reliability, efficacy; the safety of therapeutic interventions; and other features of clinical epidemiology. The culture of evaluation is, however, essential to interpret the large body of available research data and to provide evidence-based treatment and best practice. Therefore, we need to promote the transition from clinical epidemiology to etiologic epidemiology and workforce development.

The questions we ask are: (1) “What will be the future of epidemiology?” (2) “Will there be a conflict between the clinician and the epidemiologist?”

We believe that there are positive signs for the continued integration of clinical epidemiology as a key component of public health. The second question really should not exist. Clinicians should be supported to integrate epidemiological research within their clinical practice.

SECTION 2 ■ DETERMINANTS OF ABUSE AND DEPENDENCE

CHAPTER

4

Genetic Factors in the Risk for Substance Use Disorders

Thomas A. Nguyen ■ Jaimee L. Heffner ■ Show W. Lin ■ Robert M. Anthenelli

INTRODUCTION

More than a decade ago, the *New York Times* reported that “scientists (had) link (ed) alcoholism to a specific gene, ... opening the window of hope for the prevention of a deadly disease.” Although the accuracy of the finding on which the headline was based is controversial (1,2), the story remains historically significant.

Sixty years ago there were those who doubted they would ever read such a headline (3). As our understanding of alcoholism (i.e., alcohol dependence) and other substance use disorders has advanced, so, too, have our ideas about their pattern of transmission. The importance of environmental, developmental, and social factors championed by Jellinek and others in the 1940s has had to share the stage with compelling evidence supporting a genetic vulnerability to the disorder. All are important. No one headline tells the whole story, and it is the interaction of genes, environment, and developmental influences that ultimately predict susceptibility to substance use disorders (4,5).

This updated chapter reviews the role of genetic factors in the risk for alcohol, tobacco, cocaine, opioid, and cannabis dependence. Because the preponderance of data is from studies on alcohol and tobacco, these two drugs are emphasized. Reflecting the clinical nature of this text and the authors’ area of expertise, this chapter focuses primarily on human genetic aspects of substance use disorders. Comprehensive reviews of the animal and preclinical literature are available elsewhere (6,7).

GENETIC INFLUENCES IN ALCOHOLISM

Traditionally, the search for genetic influences in any complex disorder begins with studies of families, twins, and adoptees affected with the condition. These investigations can provide preliminary evidence on the probable importance of genetic factors and serve as the foundation for subsequent research. The following sections briefly review the results of more than four decades of family, twin, and adoption studies in alcoholism.

Although these investigations are not unanimous in their results, when taken together, they provide compelling evidence for the importance of genetic influences in this disorder and indicate that 40% to 60% of the phenotypic variance in alcoholism can be attributed to genetic factors (8).

Family, Twin, and Adoption Studies of Alcoholism

Family Studies

For centuries, philosophers, writers, and clergy have commented on the familial nature of alcoholism. Plutarch’s assertion that “drunks beget drunkards” was based on anecdotal observation alone, and it was not until the last few decades that this contention came under careful scientific scrutiny (9).

The basic design for family studies of any complex illness is to compare the risk for developing the disorder in relatives of probands (individuals manifesting the phenotype or trait) with the rate for relatives of control groups or for the general population (10).

Numerous studies have found that rates of alcoholism are substantially higher in relatives of alcoholics than in relatives of nonalcoholics, with children of alcoholics demonstrating a four- to fivefold increased risk for developing the disorder (7,11). Furthermore, Bierut et al. have reported that, relative to controls without alcohol dependence, the siblings of alcohol-dependent probands have elevated rates of the disorder (up to 50% for men and 25% for women) (12). This increased risk appears to be relatively specific to alcoholism, with most family studies showing an increased prevalence of the disorder among relatives of alcoholic probands, without accompanying higher prevalence of other mental disorders, such as schizophrenia or bipolar disorder (13,14).

Although family studies provide preliminary evidence that alcoholism might be inherited, in themselves, they are inconclusive. Familial aggregation might also reflect the shared social and developmental influences of being raised in the same environment by biologic parents. To disentangle these factors, other approaches are required.

Twin Studies

Research with twins evaluates the relative contributions of genetic and environmental factors by comparing the similarity or concordance rates for the condition in pairs of monozygotic (identical) twins with those of dizygotic (fraternal) twins. The twin study design allows researchers to estimate the contribution of genetic and environmental effects to the individual's liability for alcoholism and other substance use disorders. The liability identified in twin research generally has three components: (a) additive genetic effects; (b) common environmental effects shared by twins (e.g., intrauterine environment, parental upbringing); and (c) specific, non-shared environmental experiences (14). Additive genetic influences are shared 100%, on average, between members of monozygotic twin pairs, while dizygotic twin pairs share 50% of their additive genetic influences (15).

Several major twin studies have directly addressed the concordance rates for alcoholism in identical versus fraternal twins. The first of these was conducted in Sweden where Kaij found that the concordance rate for alcoholism in male monozygotic pairs was greater than that for dizygotic twins (approximately 60% vs. 39%) (16). Interestingly, the discrepancy between concordance rates increased in proportion to the severity of alcoholism in these male twin pairs, favoring a genetic diathesis. A Veterans Administration twin register study in the United States revealed similar higher concordance rates for identical male twin pairs (17) as did two other smaller studies (18,19). These findings were further corroborated in a population-based sample of twins in the United States (20). However, not all studies agree (21).

While results among male–male twin pairs had consistently demonstrated that genetic factors were important in the etiology of alcoholism in men, results in women were initially less consistent. Several smaller twin studies found no (19,21) or relatively little (18) genetic influence in females compared to males. However, in a large sample of female same-sex twin pairs in the United States, the concordance for alcoholism was greater in monozygotic than in dizygotic twin pairs (22).

These results were corroborated in a study of Australian twin pairs that found genetic factors play as important a role in determining alcoholism risk in women as in men (23). Thus, the vast majority of twin studies support the notion that alcoholism is genetically influenced and that heritable factors are important in the vulnerability for the disorder in both men and women.

Adoption Studies

Perhaps the most convincing way to separate genetic from environmental effects is to study individuals who were separated soon after birth from their biologic parents and those who were raised by nonrelative adoptive parents (24). This can be done through classical adoption studies or through a half-sibling approach.

There have been several half-sibling and adoption studies evaluating the possibility that alcoholism, at least in part, has genetic determinants. Regarding the half-sibling approach,

Schuckit and colleagues evaluated a group of individuals who had been raised apart from their biologic parents but who had either a biologic or surrogate parent with alcoholism (25). Subjects who had a biologic parent with severe alcohol problems were significantly more likely to have alcoholism themselves than if their surrogate parents were alcoholics.

Comparing the similarities between the offspring behavior and the biologic and adoptive parents' characteristics is the basis of adoption studies. If there are strong associations between the offspring and biologic parents then this is indicative of genetic impact, whereas strong associations between the offspring and the adoptive parents are suggestive of environmental impact (26).

Over the last three decades, several adoption studies in Denmark, Sweden, and the United States have yielded similar results. In Denmark, Goodwin and coworkers found that the sons of alcoholics were about four times more likely to be alcoholic than were sons of nonalcoholics, and that being raised by either nonalcoholic adoptive parents or by biologic parents did not affect this increased risk (27). Furthermore, although the sons of alcoholics were found to be at highest risk for developing alcoholism, they were no more likely to have other psychiatric disorders than were sons of nonalcoholics (24,27). As with some of the twin studies cited above, results for women in the Copenhagen Adoption Study were not significant, but the sample size for women was too small to reach any firm conclusions about potential gender differences in genetic vulnerability. Similar results were found in another large study done in Stockholm, Sweden, where Cloninger and colleagues showed significantly higher rates of alcohol abuse in adopted sons of biologic fathers registered with alcohol problems (28). Data from two smaller-scale adoption studies in Iowa largely confirmed the results of the larger European studies (29,30); however, one of the studies detected genetic influences in female adoptees, as well (31). Only one adoption study has found contrary results (32), and most authors agree that the disparity probably reflects methodologic problems in its design (e.g., small sample size and lack of rigorous diagnostic criteria for alcohol problems in the parents) or differences in the subpopulations studied (9,24,33).

The Search for Genetically Mediated Markers of Alcoholism

The results of family, twin, and adoption studies offer ample support for the heredity of alcohol dependence, thereby justifying a search for what might be inherited to increase the risk for this disorder. However, before such a search can be optimally conducted, it is important to consider several major factors that obscure our ability to identify the genetic factors that predispose individuals to develop alcoholism.

Clinical and Etiologic Heterogeneity

First, when studying complex disorders like alcoholism and other kinds of drug dependence, it is essential to realize that a diagnosis is made at the clinical syndrome level and that it

is likely that many different pathways or etiologies can lead to this combination of symptoms and signs (34,35). As a result of this etiologic heterogeneity and the likelihood that multiple genes are involved for each of the various pathways that may lead to the broad clinical phenotype of alcoholism, consideration of the sample in which the genetic analyses are conducted is of paramount importance.

Comorbidity with Other Psychiatric Disorders

A second, related consideration is that problematic use of alcohol or other drugs may co-occur with other disorders in the same individual. In fact, at least 30% of alcoholic men have evidence of preexisting disorders (36), and this figure soars to 60% to 70% among alcoholic women (37). Alcoholism has been found to co-occur with internalizing disorders (e.g., depression, bipolar disorder) as well as externalizing disorders (e.g., antisocial personality disorder [ASPD], conduct disorder [CD], and attention deficit hyperactivity disorder [ADHD]) (38). Approximately 70% of men with ASPD have secondary alcohol problems during the course of their disorder (36), and during the manic phase of bipolar illness, approximately 50% of patients develop severe ethanol-related difficulties (39). The phenotypic differences between these groups of “alcoholics” are obvious, but genetic influences specific to the development of alcohol dependence become much less clear in the context of psychiatric comorbidity.

Subtypes of Alcoholism

Several overlapping approaches have been used to categorize alcoholics into clinical phenotypes or subgroups based on family history of alcohol dependence, age-at-onset of the disorder, clinical symptoms, and personality traits (24,40–42). Although each of these methods has its strengths and limitations, the validity of any one method over the others has not yet been established (43,44). Reviewed in detail elsewhere (45), the underlying philosophy behind their use is an attempt to better define subtypes of alcoholics who vary in genetic risk for the disorder.

Among the many typologies of alcohol dependence that have been identified, one theory proposed by Cloninger and colleagues gained considerable popularity (28,33,41,46,47). Using a discriminant function analysis of their large sample of Swedish adoptees, this group initially proposed two subtypes of alcoholism (types 1 and 2) that could be distinguished on the basis of the biologic parents’ history of alcohol abuse and the degree to which postnatal environmental factors affected the inheritance of susceptibility to alcoholism (28,46). Type 1, or “milieu-limited,” alcoholism was posited to predominate among female alcoholics and their male relatives, and characterized by loss of control of drinking after the age of 25 years, pronounced environmental reactivity to drinking, minimal associated criminality, and “passive-dependent personality traits” marked by high degrees of harm avoidance, reward dependence, and low levels of novelty seeking as measured by Cloninger’s Tridimensional Personality Questionnaire (TPQ) (41). In contrast, the “male-limited,” or type 2, subgroup was postulated to

have an inheritance pattern less dependent on environmental factors for phenotypic expression and an earlier age of onset, more associated criminal behavior, and a triad of personality traits that run opposite those of the prototypic “milieu-limited” alcoholic (33,41,48). This group later refined their theory to include a *third* class of alcoholism, which they called “antisocial behavior disorder with alcohol abuse” (33,48,49).

Babor and colleagues (42) used an empirical clustering technique and described a subgrouping scheme for alcoholics that included type A and type B alcoholics, named after the Roman gods Apollo and Bacchus. Type A alcoholics are characterized by later age-at-onset, fewer childhood risk factors, less-severe dependence, fewer alcohol-related problems, and less psychopathologic dysfunction. Type B alcoholics typically exhibit an early onset of alcohol-related problems, higher levels of childhood risk factors and familial alcoholism, greater severity of dependence, multiple substance use, a long-term treatment history, greater psychopathologic dysfunction, and greater life stress (42,50). The type A/B dichotomy was replicated in another large sample of alcohol-dependent subjects even after the exclusion of individuals with ASPD and those with an onset of alcohol dependence before age 25 years, further supporting this subtyping method’s potential usefulness (51).

In summary, the search for what is inherited in the predisposition toward alcoholism is challenging because alcoholism is a clinically and etiologically heterogeneous disorder. Moreover, because of the comorbidity between alcoholism and certain other psychiatric disorders, studies that do not adequately control for this increased variability may yield spurious genetic associations. Furthermore, among the broad clinical phenotype of alcoholism, subgroups may exist who differ in the degree of genetic susceptibility.

Intermediate Phenotypes

One way of discovering gene effects in etiologically complex disorders is through restructuring of the complexity into factors that are likely to be less etiologically heterogeneous (52). Prior to the explosion in molecular genetics research (see “Molecular Genetic Studies”), the search for these vulnerability factors for alcoholism focused on identifying endophenotypes or intermediate phenotypes that might be associated with the predisposition toward the disease. These are neurobiologic or neurobehavioral characteristics associated with alcoholism whose manifestation may be more closely linked to gene expression than the broad clinical phenotype of alcoholism itself (53). The focus of many older articles (34,54) and book chapters (55) dedicated to the topic of the genetics of alcoholism, these intermediate phenotypes remain relevant because they may represent some of the end-stage pathophysiologic processes through which genetic factors influence susceptibility to the disease. Because of space limitations, only some of these phenotypic markers are discussed here, and interested readers may seek more detailed reviews of these broad phenotypes elsewhere (53).

Electrophysiologic Markers

Electrophysiologic measurements of brain activity have been demonstrated as potentially promising neurobiologic markers that might be associated with the predisposition toward alcoholism, at least among some subgroups of individuals (56,57). Event-related brain potentials (ERPs) have been used extensively to study information processing in both long-term abstinent alcoholics and unaffected high- and low-risk populations who differ on the presence or absence of a family history of alcoholism, respectively (34). The amplitude of one important component of the ERP, the positive wave observed at 300 to 500 milliseconds after a rare but expected stimulus (P3), has been demonstrated to be significantly decreased in about one third of the sons of alcoholic fathers when compared to controls (56,58). Moreover, this decrease is more dramatic in alcohol-dependent individuals who also have a diagnosis of illicit drug abuse or dependence, especially those with ASPD (59). Although some studies do not agree with these results (60,61), differences probably reflect variations in the studies' designs, including the sample population chosen. Bergleiter and Porjesz have proposed that such ERP anomalies may reflect brain disinhibition and/or hyperexcitability (impulsivity) that is critically involved in the vulnerability toward alcohol dependence (53).

In addition to this elicited brain-wave marker, a second approach has relied on measurements of the power of waveforms on the background cortical electroencephalogram (EEG) (34). Male alcoholics and their sons might demonstrate a decreased amount of slow-wave (e.g., alpha wave) activity at baseline when compared with controls (62,63). Similarly, Ehlers and Schuckit reported that sons of alcoholics differ from lower-risk, matched controls at baseline on the amount of activity in one part of the frequency range of alpha waves (i.e., men with a positive family history of alcoholism had more energy in the fast alpha range than did controls) (64,65).

Low Level of Response to Alcohol

Schuckit et al. and others have documented differences in the response to alcohol between high-risk and control populations. Otherwise healthy groups of 18- to 25-year-old sons of primary alcoholic men were selected as higher risk, or family history positive (FHP), subjects who were then compared with controls comprised of lower-risk, family history negative (FHN) individuals. Each FHP-FHN matched pair was carefully evaluated at baseline and then observed for 3 to 4 hours after consuming placebo or the equivalent of 3 to 5 drinks of beverage alcohol.

After drinking the alcohol, the two family history groups developed similar patterns of blood alcohol concentrations (BACs) over time, making it unlikely that group differences depended on the rate of absorption or metabolism of ethanol (34,66). However, a major consistent difference between FHP and FHN subjects was in the intensity of their subjective feelings of intoxication after imbibing alcohol (66-68). Using an analogue scale and asking subjects to rate the intensity of dif-

ferent aspects of intoxication, FHP men rated themselves as significantly less intoxicated than did their FHN matched controls after drinking ethanol (66-68). This decreased intensity of reaction to alcohol among FHP men was also observed for at least one measure of motor performance; the level of sway in the upper body (69). Furthermore, following the ethanol challenge, FHP men also exhibited less-intense change in the levels of cortisol and prolactin, two hormones shown to be altered after ethanol ingestion (70,71).

Schuckit et al. hypothesized that a decreased intensity of reaction to lower doses of alcohol might make it more difficult for susceptible individuals to discern when they are becoming drunk at low enough blood levels to be able to stop drinking during an evening.

Without this feedback, and especially in the setting of a heavy drinking society, predisposed individuals may be inclined to drink more and thus run an increased risk for subsequent alcohol-related life problems (13). Consequently, viewers blind to the initial family history and the determination of the level of response to alcohol located all 453 subjects an average of 8.2 years after the time of their initial evaluation (72,73). The data revealed that the family groups had been correctly identified, and that the sons of alcoholics had a threefold increased risk for alcohol dependence. The results also demonstrated a strong and significant relationship between a low level of response to alcohol and the future development of alcoholism. A possible explanation for the low response to alcohol is the genetic variation in the serotonin transporter gene and in the gene encoding the subunit alpha-6 of the gamma-aminobutyric acid receptor A, both of which are discussed later in the chapter (74).

Early Onset of Alcohol Use and the Development of Alcohol Dependence

Multiple studies have demonstrated that the early onset of alcohol consumption is associated with increased rates of subsequent alcohol dependence (75,76). Hingson et al. found that the lifetime prevalence of alcohol dependence was 47% among those whose first drink was at 14 years or younger as compared to 9% among those whose first drink was at 21 years or older (75). This finding is comparable between males and females (77). The timing of first alcohol drink is attributable, in part, to both heritable factors and shared environment, although heritable factors appear to exert a greater influence (77).

These studies demonstrate some important attributes regarding genetic influences in alcoholism risk. First, a family history of alcoholism is associated with increased risk for this disorder among people of diverse socioeconomic classes. Second, it is likely that there are multiple roads into the heightened alcohol risk, with, for example, some individuals developing alcoholism in part through very high levels of impulsivity, others having increased risk of alcoholism due to a low level of response to alcohol in the context of a heavy drinking society, and so on (78). Third, it is unlikely that any single gene explains alcoholism risk; but rather, it is multiple genes interacting with the environment.

Molecular Genetic Studies

With the advent of modern molecular genetic techniques blossoming over the past two decades, more recent efforts have attempted to identify genes that influence susceptibility to alcoholism. Although the details of the molecular genetic techniques used to identify such genetic markers are beyond the scope of this chapter, briefly, they involve the meticulous dissection of deoxyribonucleic acid (DNA) into specific nucleotide (i.e., the building blocks of DNA) patterns called markers or microsatellites (for details see references) (57,79,80). Such markers are then analyzed to determine whether there is *linkage* between the marker and the phenotype (i.e., the marker is transmitted along with the disease in families) or whether there is an *association* between the polymorphism and the phenotype (81,82) (i.e., a given marker allele is more common among those individuals with the disease in a population). Indeed, such genetic strategies have been used extensively in the large multicenter effort entitled the Collaborative Study on the Genetics of Alcoholism (COGA) (83).

A number of candidate genes for alcohol dependence have been proposed thus far; interested readers are urged to see other recent reviews of this to appreciate the full breadth of this massive research effort (7,8,84,85). Because genes encoding the alcohol-metabolizing enzymes are the only genes consistently demonstrated to contribute to alcoholism susceptibility, these genes are highlighted.

Alcohol Dehydrogenase and Aldehyde Dehydrogenase

BAC and an individual's subjective response to alcohol represent a complex interaction of pharmacokinetic and pharmacodynamic effects of ethanol in the brain and body. There is a large degree of interindividual variation, as a function of genetic, gender, and ethnic influences, in how one responds to alcohol that involves the drug's absorption, distribution, metabolism, and elimination. Alcohol dehydrogenase (ADH) and aldehyde dehydrogenase (ALDH) are the major enzymes involved in the sequential degradation of ethanol; ADH catabolizes alcohol into acetaldehyde, which ALDH breaks down to acetate and water (86,87). Numerous studies have found that allelic variants of ADH and ALDH genes play an important role in influencing the metabolism of alcohol and that these polymorphisms are associated with the risk for developing alcohol dependence. ALDH is the major enzyme that catabolizes acetaldehyde in the liver and other organs. There are many ALDH gene families distributed on several different chromosomes (88). Family 2 genes (ALDH 2) have been the most well studied genes regarding an association with alcohol dependence. This family of genes encodes mitochondrial enzymes that oxidize acetaldehyde. ALDH 2 has a deficient allelic variant (ALDH 2 \square 2), when compared with the wild type of ALDH 2 (ALDH 2 \square 1). The ALDH 2 \square 2 variant gene is found in approximately 16–35% of Han Chinese, Japanese, Koreans, and Vietnamese (89–93). ALDH 2 \square 2 rarely occurs in other ethnic groups (94). Individuals with the ALDH 2 \square 2 variant typically experience aversive re-

sponses (e.g., facial flushing, tachycardia, headache, hypotension, and a burning sensation in the stomach) to alcohol consumption as a result of the accumulation of acetaldehyde. Several studies demonstrate the protective effect of ALDH 2 \square 2 gene carriers from developing alcohol dependence with homozygosity providing full protection whereas heterozygosity (ALD \square 1/ \square 2) can only afford partial protection against alcoholism (93–97).

The association between polymorphisms in ADH genes (located on chromosome 4) and alcohol dependence is not as robust as for ALDH genes. The variant allele ADH 2 \square 2 (more recently renamed the ADH 1B \square 2 allele) encodes a high-activity enzyme involved in the oxidation of ethanol to acetaldehyde exhibiting no appreciable cardiovascular responses and subjective perceptions following the consumption of alcohol (8,94). ADH 1B \square 2 homozygosity is associated with an eightfold decrease in the risk of alcohol dependence in East Asians (98). Interestingly, it has been found that having the combination of the ADH 2 \square 2 and ALDH 2 \square 2 gene variants is associated with the lowest risk for alcoholism (96,99). Taken together, then, there is compelling evidence that the interaction between a genetically controlled alcohol-metabolizing enzyme system and environmental factors (such as attitudes about drinking and drunkenness) appears to contribute significantly to the lower alcoholism risk among a subgroup of Asians and Ashkenazi Jews (100,101).

Dopaminergic System

The dopaminergic system is involved in the reinforcing effects of drugs of abuse. As alluded to at the beginning of this chapter, the first report of an “alcoholism gene” occurred in 1990, when Blum et al. identified an allele of the gene encoding the D2 dopamine receptor (DRD2) that appeared to be implicated in severe cases of alcoholism (102). The finding had good face validity because the mesolimbic dopamine reward circuit in the brain has been repeatedly demonstrated to play a major role in ethanol's rewarding effects (103,104). The subject of much debate, with studies both finding (1,81,105–111) and not finding (2,112–115) an association with alcoholism, the DRD2 controversy remains relevant because it heralded the advent of modern molecular genetic approaches to this complex genetic disease. Interestingly, there is also some evidence to implicate the DRD2 gene in other substance use disorders, leading some investigators to label it a potential “reward gene” as discussed subsequently in this chapter (107,116).

Ebstein et al. (117) reported an association between a polymorphism of the dopamine D4 receptor (DRD4) and the novelty seeking subscale as measured by Cloninger's TPQ (41). The DRD4 is expressed predominantly in the limbic system. Ebstein and colleagues' finding, along with other confirmatory results (118) published in the same journal issue, provided the first replicated association between a specific genetic polymorphism and a personality trait that has been linked with alcoholism and other substance use disorders (117). Although the subjects in this study were nonalcoholic normal controls, it is intriguing

that a personality trait believed to predict an increased risk for alcoholism might have heritable components. Studies examining the associations among the DRD1 gene polymorphism (affecting the D1 receptor) (119,120) and the dopamine D3 gene (affecting dopamine D3 receptors) (121–123) and alcoholism have yielded inconsistent and generally negative results.

GABAergic System

Gamma-aminobutyric acid (GABA) receptor genes, which encode the GABA_A and GABA_B receptors that bind GABA (the human brain's major inhibitory neurotransmitter), have also been identified as promising candidate genes for alcoholism (8,124,125). *In vitro* studies have found that ethanol potentiates GABAergic neurotransmission (126) and preclinical studies in experimental animals have determined that GABA plays an important role in alcohol's brain depressant behavioral effects (127). Specifically, the cluster of GABA_A receptor genes is found on chromosome 4, and this chromosomal region has been implicated in linkage scans for alcoholism. One variation of this gene is GABRA2, which has been strongly associated with alcohol use disorders (128). Studies in Southwest American Indians have identified GABRA2 as a susceptibility factor for alcoholism (129). These findings have been confirmed in some studies in Caucasian populations, and provocative associations have been described between quantitative trait loci of GABA_A receptor genes and potential intermediate phenotypes such as electroencephalographic markers (130). Furthermore, a study by Enoch et al. identified the gene adjacent to GABRA2, GABRG1, through linkage disequilibrium studies and found that GABRG1 haplotypes and single nucleotide polymorphisms (SNPs) were significantly associated with alcoholism in both Finnish Caucasian men and Plains Indian men and women (131).

Serotonergic System

The serotonergic system has been studied extensively in clinical populations and has been implicated in alcoholism, aggression, impulsivity, and mood disorders (132). Serotonergic dysfunction has also been repeatedly implicated in both preclinical (133,134) and clinical (74,135,136) studies examining the vulnerability for alcoholism. Two main alleles of the serotonin transporter–linked polymorphic region (5-HTTLPR) of the SLC6A4-1 gene have either 14 (short [S]) or 16 (long [L]) copies of a 22 base-pair imperfect repeat. The L allele increases transcriptional activity of the 5-HTT gene, which results in increased production of 5-HTT and more rapid reuptake of serotonin. Conversely, the S allele decreases transcription of the message, the end result of which is a reduction in transporter number and slower serotonin reuptake. It is thought that more rapid reuptake, associated with the L allele, results in lower level of this neurotransmitter and potentially decreased alcohol effects (74). Reviewed in greater detail elsewhere (8), there is controversial support for an association between alcoholism and the L allele of 5-HTTLPR; (74,137–140) however, not all studies agree with

other studies finding that the S allele contributes significantly to risk for alcohol dependence (141–144).

Opioidergic System

The mu-opioid receptor (MOR) OPRM1 plays a central role in the rewarding process of alcohol, opioids, and other substances of abuse such as cocaine and nicotine (145). Ethanol produces some of its rewarding effects through the release of endogenous opioids interacting with the mesocorticolimbic dopaminergic pathways. One of the most widely studied polymorphisms of the OPRM1 gene is the A118G variant in which aspartic acid (Asp40 allele) replaces asparagine (Asn40 allele) at position 40 of the receptor. This single amino acid substitution alters its endogenous ligand's (beta-endorphin's) activity at the receptor, resulting in beta-endorphin binding with threefold greater affinity to variant Asp40 than to the Asn40 MOR (116,146). Some investigators have found an association between the A118G SNP and linkage (147,148); whereas others have not found this association (149–151). Individuals with one copy of the Asp40 allele were found to have a greater response to the effects of alcohol than those who were homozygous for the Asn40 allele (105,152).

Genetic variants in the OPRM1 gene may also influence the response to antirelapse medications used to treat alcohol dependence (153). The therapeutic effects of naltrexone are based on the “endorphin compensation” theory, which suggests that alcohol-dependent subjects have a relative deficiency in endogenous opioids at baseline and possibly following stress, and that alcohol helps restore these levels (116). Naltrexone is a pure opioid receptor antagonist with the greatest affinity for MORs. Among alcohol-dependent patients, naltrexone reduces the occurrence of heavy drinking days (154), increases the time to first relapse (155,156), and reduces the number of drinking days (157) as well as the number of drinks per drinking occasion (158). Using a pharmacogenetic approach, it has been found that alcoholic subjects with the Asp40 allele treated with naltrexone were more likely to have good clinical outcome (87.1%) than those individuals homozygous for the Asn40 allele (54.8%) (159).

In summary, advances in molecular genetics and an explosion of studies in this field within the last decade have added important information to our understanding of the genetic factors associated with the susceptibility to alcoholism. Many potential candidate genes have been identified that might be associated with the risk for the disorder; only a few of these have been highlighted as examples of the findings accumulating from this massive search. What is clear is that many genes likely influence the vulnerability for alcoholism and that different combinations of genes are likely to be more or less salient for each endophenotype associated with the disorder. Certain genes (e.g., the ALDH 2 gene) may provide protection against developing serious alcohol-related problems, while others (e.g., the DRD2 gene) might predispose certain individuals to alcoholism and other substance use disorders that are discussed next.

GENETIC INFLUENCES IN TOBACCO AND OTHER DRUG DEPENDENCE

This section focuses on nicotine dependence because of its high prevalence, associated morbidity and mortality, and common co-occurrence with alcohol and other substance use disorders. There is also significant overlap in the genetic vulnerability to alcohol and nicotine dependence, especially in heavy drinkers and smokers (26); about 50% of the genetic liability to nicotine dependence is shared with alcoholism and 15% of the genetic liability to alcoholism is shared with nicotine dependence (128). Genetic influences on other drugs of abuse (cocaine and other stimulants, opioids, and cannabinoids) are discussed subsequently.

Nicotine/Tobacco Dependence

Cigarette smoking is still the leading preventable cause of death each year in the United States, with more than 440,000 deaths being attributed to tobacco smoking (160). The estimated annual smoking attributable costs in the United States were \$96 billion for direct medical care for adults and \$97 billion for lost productivity (160). Alarming, every day nearly 5000 young people under the age of 18 years try their first cigarette (160). Thus, searching for the genetic and environmental factors that contribute to the initiation and persistence of cigarette smoking is of paramount importance in the prevention and treatment of nicotine dependence. This section reviews the role of genetic factors in the initiation and maintenance of tobacco smoking and organizes this literature into population versus molecular genetics studies.

Family, Twin, and Adoption Studies of Tobacco Dependence

Family Studies

In contrast to the large literature on family studies in the genetics of alcoholism, there are fewer studies examining the familial transmission of tobacco smoking. Initiation of cigarette smoking is strongly associated with parental and sibling smoking, thus, the prevalence of smoking among teenagers is two to four times higher in individuals whose parents or siblings smoke (161). For example, Hughes reported that individuals whose parents smoked during the probands' adolescence were more likely to be smokers (52%) than were individuals whose parents did not smoke during the subjects' adolescence (20%) (161). In the Collaborative Study on the Genetics of Alcoholism (COGA), Bierut et al. found that siblings of habitual smoking probands had a roughly twofold (relative risk = 1.77) elevated risk of becoming smokers when compared with siblings of nonsmoking probands (12). However, as stated previously, family studies have difficulty disentangling genetic from environmental factors because the study subjects involved lived together and shared the same environment. For this reason, more recent studies examining the genetic influences on cigarette smoking have focused on

twin pairs raised in the same or mixed families, and on combined twin and adoption studies, in order to tease out more precisely the relative contributions of genetic and environmental factors that lead to the initiation and perpetuation of tobacco use (162,163).

Twin Studies

Twin studies are a very powerful tool to explore the relative contribution of genetic factors in the etiology of nicotine dependence. Taken together, results of several twin studies indicate there is a significant genetic influence on the development and continuation of habitual cigarette smoking. Carmelli et al. compared male monozygotic and dizygotic twins in the genetic influence on smoking. They found that the concordance rate for smoking was significantly higher in monozygotic twins than among dizygotic twins across all three categorizations (i.e., among never, former, and current smokers) of smokers they examined (164). Interestingly, the data also suggested that genetic factors appear to influence an individual's ability to quit smoking; monozygotic twins were more likely than dizygotic twins to be concordant for quitting smoking (rate ratio = 1.24).

As alluded to earlier, recent studies on the genetics of cigarette smoking not only focus on nicotine dependence itself, but also investigate the related process of initiating tobacco smoking behavior (165–169). Parsing the relative genetic contributions to the various component behaviors that ultimately contribute to tobacco addiction (i.e., initiation, amount smoked, continuation), it appears that approximately 50% of the initiation of smoking behavior is genetically influenced, while persistence of smoking and amount smoked have approximately a 70% genetic contribution (170). Heath et al. retrospectively analyzed 3810 adult Australian twin pairs on age-at-onset of smoking to determine the role of genetic and environmental factors in the onset of smoking (167). For female twins and younger male twins, the onset of smoking was strongly influenced by genetic factors. Kendler et al., studying female twins on smoking initiation and nicotine dependence, suggested that heritable factors played an important etiologic role in both smoking initiation and nicotine dependence (169). However, while the liabilities to smoking initiation and nicotine dependence were highly correlated, they were not identical, suggesting that both independent and common genetic factors may underlie these behaviors.

Even though the twin study design is an important tool in the study of genetic factors in nicotine dependence, studies have found that monozygotic twins cosocialized more, spent more time together, and shared peer groups more closely than dizygotic twins (171,172). Thus, based on these studies, the higher concordance rate of monozygotic twins could be inflated as a consequence of the cosocialization (shared environment), requiring other population genetic techniques be used.

Adoption Studies

Adoption studies provide another approach to disentangle the environmental and genetic contributions to tobacco smoking. An older adoption study found that parental and

child smoking was significantly correlated among biologic pairs, but was not correlated among adoptive parents and adoptees (173). These results were extended in an analysis of the Danish Adoption Register, where it was demonstrated that adoptees' smoking status was strongly associated with their biologic full-siblings' smoking status (174).

Another novel strategy to combine both twin and adoption designs is by examining concordance rates in twins reared together versus those reared apart. Consistent with results from regular twin studies, both male monozygotic twins reared together and reared apart had higher correlations in smoking behavior when compared with their dizygotic twin counterparts. However, the monozygotic twins reared together exhibited greater concordance rates in smoking than monozygotic twins reared apart, providing further evidence that the rearing environment and genetics interact to influence an individual's risk to be a smoker (175).

Gender Differences

An interesting observation from studies of smokers is a potential gender difference in the magnitude of the relative contribution of genetic and environmental effects. Social or cultural constraints might influence the expression of these genetic influences on smoking. This is evident in certain countries such as China and India, as reflected by the lower prevalence of smoking in women as compared to men (176). As far as the ability to stop smoking, there appear to be greater genetic effects on women's ability to quit (68%) than that seen in men (54%) (177).

Molecular Genetic Studies

The evidence to date has been very consistent with respect to the significance of genetic contributions to smoking initiation and tobacco dependence. As was the case for alcoholism, the more daunting task is to determine the genes responsible for nicotine dependence susceptibility. As with other addictive disorders, the inheritance of tobacco smoking is most likely polygenic and multifactorial, involving a complex web of genetic, environmental, and developmental influences. Indeed, the severity of the disorder may reflect on how many different genes are involved.

The search for genetic factors contributing to nicotine dependence susceptibility is focused primarily on genetic variations (polymorphisms) between smokers and nonsmokers. A variety of potential candidate genes are implicated that affect multiple aspects of nicotine metabolism and other components of the mesolimbic brain reward system, including various neurotransmitters, receptors, and transporters, as briefly described in the next four subsections.

Dopaminergic System

Much attention is focused on the mesolimbic dopamine system as playing an important role in mediating the vulnerability for tobacco dependence. There are five categories of dopamine receptor subtypes labeled D1 to D5. Since the first report of an association of the A1 allele of the dopamine D2

receptor (DRD2) gene with alcoholism described previously (178), the DRD2 gene has been intensively studied in other substance use disorders, including nicotine dependence. DRD2 SNPs including the A1 allele have been associated with decreased dopamine binding sites (176). Both past and current cigarette smokers were found to have higher prevalence of the A1 allele of the DRD2 than did nonsmoking controls (179). Moreover, the prevalence of the A1 allele increased progressively from nonsmokers to past smokers to active smokers. Another study found a significantly higher A1 allele frequency (48.7%) of the DRD2 in smokers who made unsuccessful quit attempts, when compared with controls (25.9%) (180). (Interestingly, Spitz et al. suggested that smokers had significantly higher B1 allele frequency of the DRD2 gene than nonsmokers (181).) In addition, subjects with the A1 allele had significant inverse associations between the prevalence of the A1 allele and (a) the age-at-onset of smoking and (b) the number of attempts at quitting smoking. However, other studies have not found any increase in A1 allele frequency when comparing smokers with nonsmokers (182), raising concerns that population stratification in some case control studies might have influenced the results.

How may the A1 allele DRD2 polymorphism influence the risk for developing and maintaining tobacco dependence? As previously mentioned and reported in some studies, the subjects carrying the A1 allele in the DRD2 gene may have significantly reduced D2 receptor density (176,183), as indexed by a lower mean relative glucose metabolic rate on positron emission tomography testing (184). Thus, it has been hypothesized that individuals may use nicotine (and other drugs of abuse) to compensate for a deficiency of their dopaminergic system (185).

As reviewed elsewhere, many other polymorphisms have also been found in genes encoding other dopamine receptors, some of which have been associated with tobacco smoking (186–191).

Lerman et al. compared the dopamine transporter gene (SLC6A3) and the DRD2 genes in a group of smokers and nonsmokers and found that individuals with allele 9 of the SLC6A3 gene (SLC6A3-9) were significantly less likely to be smokers, especially when this polymorphism was found in combination with the A2 allele of the DRD2 genotype (192). Sabol et al. replicated this finding (193). Thus, it has been hypothesized that the presence of the A2 allele of the DRD2 gene may be negatively associated with tobacco smoking or might yield a protective effect against smoking.

Serotonergic System

Several studies have found that nicotine increases central nervous system (CNS) serotonin release and that acute nicotine withdrawal is marked by a relative depletion in central serotonin (194,195). As alluded to previously in the alcoholism section, after serotonin is released into the synaptic cleft from terminals of serotonergic neurons, it is promptly taken back up into the presynaptic neuron via the actions of serotonin transporter (5-HTT). Two functional alleles of the serotonin

transporter-linked polymorphic region (5-HTTLPR) have been identified and labeled the long (L) and short (S) types (196,197). The S-type allele decreases the transcriptional activity of the 5-HTT gene, as compared to the L-type allele, and subsequently decreases the function of the 5-HTT. A strong association between tobacco smoking and the S allele of the 5-HTTLPR has been reported by several investigators (198–200). However, another study failed to confirm this finding (201). Another study found that the short (S/S or S/L) genotype interacted with neuroticism such that neurotic traits were associated with the rate of nicotine intake, nicotine dependence, and smoking motivation in S carriers as compared to those individuals carrying the homozygous long (L/L) genotype (202,203).

Although the relationship between the 5-HTTLPR and cigarette smoking has been studied widely, a recent meta-analysis revealed that this association remains equivocal (204). This same group of investigators found that there was not an effect of 5-HTTLPR genotype on smoking cessation or on nicotine replacement therapy (NRT) response compared with placebo (205). Another study by Trummer et al., supported this finding by showing that neither smoking status nor Fagerström Test for Nicotine Dependence (FTND) score, pack years, number of cigarettes smoked daily, or previous attempts to quit smoking were related to 5-HTTLPR genotype (206). However, a more recent study found that the L/L and the S/L genotypes were significantly higher in smokers than in nonsmokers among Chinese males. Furthermore, this study demonstrated that the number of cigarettes per day and FTND score were significantly higher in smokers with the L/L and S/L genotypes than in smokers with S/S genotype (207). Clearly, these mixed results point to the complexity of these issues and the relatively early stages of this line of inquiry.

To our knowledge, there are no published reports of an association between cigarette smoking and the multiple serotonin-receptor-subtype polymorphisms. However, polymorphic variants in the gene encoding the protein involved with serotonin synthesis are also implicated in tobacco smoking behavior. Tryptophan hydroxylase (TPH) is the enzyme that performs the initial and rate-limiting step in the production of serotonin from tryptophan. Individuals with the A/A genotype of the TPH gene were found to have started smoking earlier than other genotypes, but there was no association of TPH alleles with subjects' current smoking status (208). Interestingly, Sullivan et al. also found that TPH markers were significantly associated with the onset of smoking initiation (209).

Cytochrome P450 Enzyme System

The cytochrome P450 enzyme system plays an important role in the metabolism of drugs and other xenobiotic agents. In vivo, the majority of nicotine is metabolized by CYP2A6 into cotinine (210). CYP2A6 genetic polymorphisms may result in decreased nicotine metabolism, and this reduction in nicotine metabolism may produce favorable outcomes in smokers as reflected in lower amounts of daily cigarette consumption, lower smoking intensity, and improved quit rates. Individuals

who carry the inactive alleles of the CYP2A6 also have a lower risk of becoming smokers because of decreased nicotine metabolism, resulting in lower levels of cotinine in urine (211). Furthermore, individuals carrying these alleles smoke fewer cigarettes if they do smoke (212,213). In those subjects who are homozygous for the CYP2A6 deletion, the systemic levels of nicotine following smoking are about four times higher (214) and the urinary levels of cotinine are approximately 85% higher (215) than smokers who are heterozygous for this deletion. Having one loss-of-function CYP2A6 allele reduces the CYP2A6 activity by 50% and elevates the plasma levels of nicotine by 44% in smokers who are treated with the transdermal patch (210). Conversely, individuals with the CYP2A6 wild-type genotype (faster metabolizers of nicotine) smoke more cigarettes per day and are less likely to successfully quit smoking (186).

CYP2B6 polymorphisms also appear to influence smoking behaviors; smokers of European ancestry who have the CYP2B6*6 genotype have been found to have higher rates of relapse when trying to quit than those with other cytochrome P450 genotypes (216). Thus, as was the case with genes regulating the metabolism of alcohol, CYP2A6 and CYP2B6 are genetically regulated modulators of nicotine metabolism that appear to influence smoking behaviors.

Nicotinic Acetylcholine Receptors

Nicotine is the major addictive ingredient in tobacco smoke (170). Nicotine activates the nicotinic acetylcholine receptors (nAChRs) and stimulates dopamine release in the mesolimbic brain reward system. nAChRs are widely distributed in the CNS and peripheral nervous system. These receptors are excitatory, ligand-gated channels, and are composed of five subunits. Twelve subunit genes have been identified and labeled alpha2 to alpha10 and beta2 to beta4 (213,217,218). The properties of these receptors depend on the various compositions of these subunit combinations.

Genes encoding nAChR subunits have been found adjacent to those genetic loci that are associated with greater susceptibility to nicotine dependence (219). Candidate gene association studies have yielded evidence that several variants of the alpha4 nAChR subunit (CHRNA4) are protective against smoking-related behaviors (220). Feng et al. reported in a study of Chinese men, two SNPs of the CHRNA4 gene that were associated with reduced risk of nicotine dependence (221). Another study found an association between a different SNP in CHRNA4 and heaviness of smoking index (222). Genome-wide association studies (GWAS) have identified a SNP encoding the alpha3 nAChR subunit (CHRNA3) associated with increased smoking quantity (223,224). Using a candidate gene approach, a strong association with nicotine dependence and early subjective response to nicotine was seen with a SNP in CHRNB3 (224). Zeiger et al. found evidence for an association between a SNP in CHRNA6 and early subjective response to nicotine suggesting that the genomic region containing CHRNB3 and CHRNA6 plays an important role in mediating early subjective response to nicotine (225). While the clinical implications of these findings remain unclear,

it is interesting to note that genetic variants of nAChR subunits, especially those involving the alpha7 subunit (226), have been implicated in the cognitive and attentional deficits associated with schizophrenia—one of the serious mental illnesses frequently associated with nicotine dependence.

Other Drugs of Abuse

Before embarking on a brief synopsis of the genetic influences implicated in other categories of drug abuse, some general comments bear mentioning. First, as for nicotine dependence where we focused on genetic factors involved in the initiation of smoking behavior versus those involved in the development of nicotine dependence, a few studies have examined the related process of making the transition from substance use to heavy use to abuse and on to dependence in male–male twin pairs (227,228). In general, these twin studies found that the genetic factors play a significant role in these transitions from drug initiation to dependence. Second, many studies have found that personality variables such as sensation seeking play a salient role in the prediction of both substance abuse and dependence (229–231). Thus, in searching for genes that contribute to the risk of developing substance use disorders, genes affecting personality traits have received consideration.

Cocaine and Other Stimulants

Approximately 5 million Americans have used cocaine and other stimulants within the last 12 months (232,233). Cocaine addiction liability appears to be related to heritable factors (234). Personality traits such as impulsivity and novelty seeking, as well as an individual's response to stress, may contribute to cocaine addiction. Furthermore, vulnerability to cocaine's reinforcing properties is influenced by genetically influenced neurobiologic pathways within the CNS (235).

Kendler et al. estimated that common additive genetic factors account for 50% of the variance in cocaine use. (234). Population genetic studies of cocaine users and addicts found that cocaine use, and especially cocaine abuse and dependence in women, is substantially influenced by genetic factors. One study suggested that twin resemblance for liability to cocaine use was a result of genetic and familial-environmental factors, while twin resemblance for cocaine abuse and dependence was solely a result of genetic factors (236).

Cocaine inhibits the reuptake of dopamine and other monoamines via its blockade effects at monoamine transporters. These mechanisms of action result in an acute accumulation of extracellular dopamine in the synaptic cleft. Although a large preclinical literature exists, there is relatively limited information available about genetic variants affecting dopamine transporter function and cocaine dependence in humans. Regarding dopamine receptor subtypes, Comings et al. reported that the dopamine D3 (DRD3) receptor gene may play a modest role in the susceptibility to cocaine dependence (237), a finding that corroborates results obtained in animals

(238). Allelic variants in the DRD2 gene have also been associated with cocaine dependence (239). However, as was the case for the DRD2 gene and alcoholism, other reports have been unable to replicate this finding (240).

Cocaine and other stimulants also affect serotonin reuptake, prompting some interest in genetic variants in the serotonergic system and their relation to stimulant dependence. To date, these studies have yielded mostly negative results (235). Patkar et al. found that polymorphisms in the serotonin transporter gene were not associated with cocaine dependence among African-American subjects (241,242), and another group reported no association between single-nucleotide polymorphisms in the serotonin B1 receptor gene and cocaine abuse or dependence (243).

Opiates

Opiates, including morphine and codeine, are drugs that originate from opium. Regardless whether they are naturally occurring or synthetic, all opioids are composed of substances with morphine-like activity. There are three types of opioid receptors: mu, kappa, and delta. However, opiates that are misused primarily act as MOR agonists. The MOR is a transmembrane G-protein-coupled receptor consisting of seven subunits that regulates pain responsiveness, stress behaviors, immune activity, and gastrointestinal function (244). As discussed previously, a polymorphism at position 118 (A118G) of the mu receptor gene has been found that changes the receptor's ability to bind opioid ligands, especially endogenous beta-endorphin. The differences in binding of beta-endorphin and activation of the A118G variant receptors *in vitro* has led some investigators to assume that persons carrying this polymorphism might show altered function in the response to pain and stress (244). Szeto et al. found that the 118G allele was associated with opiate addiction in Han Chinese individuals (245). Like the study of Szeto and colleagues, another study found a substantial attributable risk for heroin dependence contributed by the 118G allele (244). However, not all studies have been able to replicate this association (246,247).

Oral opioid analgesics (e.g., oxycodone, hydrocodone, and codeine) are common medications prescribed for pain. The prevalence of oral opioid abuse has increased in the United States from 2002 to 2004, with oxycodone exhibiting the highest increase (248). Some patients become addicted to these oral opioids to the extent that they fulfill the *Diagnostic and Statistical Manual of Mental Disorders, 4th Edition (DSM-IV)* diagnosis of opioid dependence. These oral opioids are metabolized by CYP2D6 to morphine in order to exert their analgesic effects. Individuals with two nonfunctional alleles of CYP2D6 (2D6 \square 3 and 2D6 \square 4) are poor metabolizers of these drugs. These poor metabolizers are less responsive to codeine analgesia and its side effects than individuals with active CYP2D6 who are known as "extensive metabolizers" (244). Intriguingly, Tyndale et al. found no poor metabolizers in a sample of opioid-dependent cases, suggesting that the CYP2D6 defective genotype may provide pharmacogenetic protection against developing opioid dependence (249).

Cannabinoids

Marijuana is the most commonly used illicit drug in the United States, accounting for 75% of all illicit drug use. Family studies have reported that the use, abuse of, and dependence on cannabis seem to aggregate in families (250). Moreover, another study found that among first-degree relatives of probands who abused cannabis, there is a near six-fold increase in the likelihood of cannabis abuse as compared to the relatives of the control group (251). For cannabis use, estimates of heritability range from 0.17 to 0.67. Lynskey et al., studying Australian twins, found that genetic factors were important determinants for the risk of developing cannabis dependence among men, but results among women were less certain (246). However, Kendler and Prescott found that the heavy use of cannabis, as well as cannabis abuse and dependence, were largely attributable to genetic factors, with heritabilities ranging from 62% to 79% in female twins (252).

There is growing evidence that cannabis use may lead to the development of nicotine dependence (253,254). Furthermore, there is a relationship between the use of cannabis and the subsequent use of hard drugs, and this is seen across various populations, sexes, ethnicities, and socioeconomic strata (255). Other studies have suggested that cannabis is a potential gateway drug for harder substances, such as heroin and cocaine (202,256,257). Karkowski et al. observed that the association between cannabis and other illicit drug use may be a consequence of shared genetic factors and common environmental experiences (258).

Recent research suggests that the endogenous cannabinoid (endocannabinoid) system plays an important role in the brain's reward pathways (259). There are at least two cannabinoid receptor subtypes: CB1, primarily located in the CNS, and CB2, located mainly in immune tissues (260). CB1 receptors are the most numerous G-protein-coupled receptors found in the CNS (261). High concentrations of CB1 receptors are located within the dopaminergic mesolimbic system, an area central to the reward process of abused substances, including cannabis. Activation of these CB1 receptors by a CB1 receptor agonist, such as tetrahydrocannabinol, the psychoactive ingredient in cannabis, produces rewarding effects in humans (259). The result of this process is the enhancement of the rewarding properties of food and certain drugs of abuse, including heroin, nicotine, and alcohol (262). However, other investigators have found no effects (263) or a decrease of the CNS reward activity from CB1 synthetic agonists (264). The CB1 receptor antagonist/inverse agonists (e.g., rimonabant and others) diminish the rewarding effects of some drugs of abuse including nicotine (265), opioids (266), and alcohol (267). These consequences of CB1 receptor antagonism appear to be mediated by blocking dopamine accumulation in the nucleus accumbens (266). With regard to food consumption, CB1 receptor antagonism reduces the intake of food, especially sweet food (268). Thus, CB1 blockers have been found to be efficacious in the treatment of obesity (269).

The most important cannabinoid-related candidate genes for substance use disorders are named CNR1 and CNR2, respectively, corresponding to the receptor proteins (i.e., CB1 and CB2) they encode. The CNR1 gene is located on chromosome 6q14–15, and some studies have found evidence for associations among SNPs in CNR1 and vulnerabilities to substance use disorders (270). Specifically, Agrawal et al. found that SNPs in CNR1 were linked with the development of cannabis dependence (85). Recently, other SNPs in CNR1 were found to be associated with alcohol and illicit drug use disorders in Americans of European descent (271). Another study found a relationship between SNPs in CNR1 and nicotine dependence (272). However, other investigators have reported little or no association between substance use disorders and SNPs in CNR1 (273,274).

The gene encoding the CB2 receptor (CNR2) is found on chromosome 1p35.11. Although most of the CB2 receptors are found among leukocytes in the periphery, there is evidence of CB2 receptors located in the CNS (275). Only a few studies have examined the relationship between CNR2 and substance use disorders. In one study, Ishiguro et al., reported SNPs in CNR2 to be linked with alcoholism (276); however, more studies are necessary to confirm this finding.

In summary, genetic factors play an important role in the initiation (in tobacco studies) and persistence of substance dependence. The search for candidate genes that contribute to the risk of developing and maintaining substance use disorders is still in its early stages. The task of identifying such genes is made more arduous because it is likely that variation in substance dependence susceptibility results not only from genotypic differences and environmental influences, but also from their interactions (5). Thus, genetic factors are background sources of variance that can be minimized or exaggerated by environmental factors before the phenotype (substance dependence) can be expressed.

CONCLUSIONS AND IMPLICATIONS

This chapter organizes more than four decades of diverse findings into a format that is understandable and illustrative of the promise of this line of research, while not minimizing the complexity of the issues at hand. The clinical, societal, and research implications of this body of work have already emerged, with results from family, twin, and adoption studies having already shaped programs aimed at preventing the illness by educating children at high risk for alcoholism, tobacco dependence, and other drug use disorders early on, allowing them to modify their drinking and drug use patterns. Individuals already suffering from the disorders are matched to more appropriate therapies using the information obtained from studies of alcoholic subtypes. Pharmacogenetic approaches are offering a powerful new tool to match specific elements of an individual's complex blueprint (e.g., allelic variants in genes encoding various neurotransmitter receptors or transporters) with targeted pharmacotherapies to which that person may optimally respond.

Studies pointing to the importance of gene-environment interactions have demonstrated the need for cooperation among researchers in different disciplines, and they highlight the fact that unitary hypotheses arguing exclusively for any one approach are inadequate in explaining these heterogeneous disorders.

ACKNOWLEDGMENTS

This work was supported, in part, by the National Institute on Alcohol Abuse and Alcoholism (NIAAA) grant award #s R01AA013307 and R01AA013957, NIDA/VA CSP#1022, and by the Department of Veterans Affairs Research Service. Dr. Heffner also receives support from NIDA Award #K23DA026517.

The authors would like to thank Reene Cantwell for her technical assistance.

Neurobiological Factors of Drug Dependence and Addiction

Heath D. Schmidt ■ Fair M. Vassoler ■ R. Christopher Pierce

INTRODUCTION

Drug addiction is a chronically relapsing disorder characterized by compulsive use of one or more drugs of abuse, the inability to control drug intake, and continued drug use despite its associated negative consequences. The complex neurochemical, biochemical, and structural changes in the brain that underlie addiction are steadily coming into focus, and there are many excellent recent review articles addressing these topics (1–6). In this chapter, we focus on the neurobiological factors that mediate the reinforcing effects of five major classes of abused drugs (psychostimulants, opiates, ethanol, cannabinoids, and nicotine). Particular focus is placed on preclinical studies utilizing the drug self-administration paradigm, which is the most homologous model of human drug taking. In self-administration studies, animals are trained to perform an operant response (e.g., pressing a lever) in order to obtain a drug reinforcer. In some instances, critical hypotheses have been addressed only using paradigms such as conditioned place preference, intracranial self-stimulation, drug discrimination, or behavioral hyperactivity. Where appropriate, important findings using these models also are presented. A discussion of the neurobiological factors underlying withdrawal from chronic drug taking is outside the scope of this chapter; however, there are a number of outstanding recent reviews on these phases of drug addiction (see (7–12)).

Although different classes of abused drugs have different mechanisms of action, there are several striking similarities in terms of the brain circuits modified by repeated exposure to these drugs. Thus, the reinforcing effects of all drugs of abuse are due to actions in the limbic system, a circuit of nuclei that is responsible for the influence of motivational, emotional, contextual, and affective information on behavior. Limbic nuclei including the amygdala, hippocampus, and medial prefrontal cortex (mPFC) send major glutamatergic efferent projections to the nucleus accumbens, which is broadly subdivided into limbic and motor subregions known as the shell and core, respectively (13). The nucleus accumbens sends two main GABAergic efferents to the ventral pallidum and ventral tegmental area (VTA), both of which send GABAergic projections to the medial dorsal thalamus. This limbic circuit is closed via glutamatergic projections from the medial dorsal thalamus to the mPFC (14–18). Dopaminergic axons from the VTA innervate the nucleus accumbens, amygdala, hippocampus, mPFC, and ventral pallidum, and changes in dopaminergic transmission in these nuclei play a critical role in

modulating the flow of information through the limbic nuclei comprising this neuronal network (19–22). An overwhelming body of evidence compiled over the last 30 years indicates that increased dopamine neurotransmission contributes significantly to the reinforcing efficacy of psychostimulants, opiates, ethanol, cannabinoids, and nicotine (23,24). The current review is an update of a paper we published in 2006, which focused on the role of dopamine in drug addiction (18). Here, we also have expanded the scope to include information on the role of other neurotransmitter systems in the reinforcing effects of five major classes of abused drugs.

PSYCHOSTIMULANTS

Mechanisms of Action

It is estimated that approximately 3.0 million Americans regularly use a psychostimulant, a class of drugs that includes cocaine and amphetamine-like compounds (25). Psychostimulants produce euphoria, elation, mood elevation, alertness, attention focusing, fatigue reduction, and appetite suppression by interacting with biogenic amine transporters (26). Whereas cocaine inactivates dopamine, norepinephrine, and serotonin transporters, amphetamine and most of its derivatives promote the release of these biogenic amines by reverse transport (26–28). Thus, although the specific mechanisms of action differ, all psychostimulants increase extracellular levels of dopamine, serotonin, and norepinephrine in the nervous system.

Dopamine and Psychostimulant Reinforcement

Although the psychostimulants bind to all of the biogenic amine transporters with high affinity (29), the reinforcing potency of psychostimulants, particularly cocaine, is correlated with their affinity at dopamine but not serotonin or norepinephrine transporters (29,30). Consistent with this finding, selective dopamine reuptake inhibitors are self-administered by rodents and nonhuman primates (30–33). Similarly, in humans there is a positive correlation between dopamine transporter (DAT) occupancy and the desirable subjective effects produced by cocaine (34). Collectively, these data show that increased dopamine transmission plays a critical role in psychostimulant reinforcement.

A substantial body of evidence from animal studies indicates that enhanced dopamine transmission in the nucleus accumbens is important for the initiation and maintenance

of psychostimulant self-administration behavior. Thus, whereas removal of dopaminergic inputs to the nucleus accumbens, but not the neostriatum, substantially reduce self-administration of cocaine or D-amphetamine (35,36), destruction of norepinephrinergic neurons has little impact on cocaine self-administration (37). During cocaine or D-amphetamine self-administration, extracellular levels of dopamine in the striatum and nucleus accumbens of rats and monkeys increase markedly, but rapidly decrease when drug access is removed (38–40). Moreover, there is a close correspondence between falling accumbal dopamine levels between psychostimulant infusions and responding for cocaine or amphetamine. That is, operant responding for psychostimulants appears to be initiated in order to maintain extracellular dopamine above a threshold level (39,41).

Dopamine Receptors and Psychostimulant Reinforcement

The five dopamine receptors were classified as D1-like (D1 and D5) or D2-like (D2, D3, and D4) based on pharmacology and sequence homology (42). D1-like agonists are self-administered by rats (43) (but see also (44)) and monkeys (45,46), whereas D1-like antagonists decrease cocaine reinforcement (see (18,47)). Similarly, D2-like agonists are self-administered by rats (48,49) and monkeys (50,51) and D2-like antagonists reduce the reinforcing effects of cocaine (see (18,47)) and D-amphetamine reinforcement (52,53). Collectively, these results clearly show that both D1-like and D2-like dopamine receptors are critically involved in psychostimulant reinforcement (47,54).

Currently, there are no ligands that effectively distinguish between D1 and D5 receptors, a limitation that has severely interfered with the elucidation of specific roles for D1 or D5 dopamine receptors in psychostimulant reinforcement (see Ref. 55). Despite the absence of appropriate pharmacological tools, the roles of D1 and D5 dopamine receptors in various psychostimulant-mediated behaviors has been assessed using transgenic mice. D1 dopamine receptor-deficient mice were developed in the 1990s and were shown to have a decreased hyperactive behavioral response to cocaine relative to controls (56–58) as well as a lack of behavioral sensitization to cocaine (56,59). It was subsequently shown that these transgenic animals have increased thresholds for intracranial self-stimulation (60). However, cocaine-mediated conditioned place preference was observed in D1 dopamine receptor-deficient mice (61). Self-administration experiments showed that D1 dopamine receptor knockout mice were impervious to the reinforcing effects of cocaine or a D1-like dopamine receptor agonist as well as (somewhat surprisingly) a D2-like dopamine receptor agonist (62). These results indicate that D1 dopamine receptors contribute specifically to cocaine reinforcement and also play a permissive role in the reinforcing effects of dopamine receptor agonists. Although D5 dopamine receptor knockout mice have been created, cocaine self-administration has not yet been assessed in these transgenic animals. The available behavioral data with D5 dopamine receptor knockout mice has thus far

been inconsistent. Some studies have failed to discern a role for D5 receptors in the behavioral effects of psychostimulants. Thus, D5 dopamine receptor knockout mice showed normal behavioral responses to acute and repeated injections of cocaine (56) and the discriminative stimulus properties of cocaine were intact (63). In contrast, other studies have shown that the behavioral hyperactivity induced by cocaine (63) or D1/D5 agonists (64,65) was blunted in D5 dopamine receptor knockout mice. Moreover, D5 dopamine receptor antisense oligodeoxynucleotides (ODNs) administered into the nucleus accumbens disrupted the ability of rats to discriminate cocaine from saline (66), and injections of D5 ODNs into the ventricles actually enhanced the rotations induced by D1-like dopamine receptor agonists in unilateral dopamine-depleted rats (67).

Although there are more options in terms of the availability of relatively selective D2, D3, and D4 ligands, distinctions among the D2-like dopamine receptors in terms of psychostimulant reinforcement remain somewhat unclear. Mice lacking D3 dopamine receptors display increased locomotor activity when challenged with amphetamine or cocaine (68). Although there are no truly selective D3 receptor agonists, the agonists that are most selective for D3 relative to D2 receptors are self-administered (69,70). Consistent with these findings, selective D3 dopamine receptor antagonists or partial agonists attenuated cocaine reinforcement in rats and monkeys (71,72) (but see also (73)). In contrast, although mice lacking D4 dopamine receptors have an enhanced behavioral response to psychostimulants (74–76), a selective D4 dopamine receptor antagonist had no influence on cocaine self-administration in rodents (73). Genetic deletion of D2 dopamine receptors substantially attenuated the behavioral activating effect of cocaine (77). However, D2 receptor knockout mice not only readily self-administered cocaine, but also their rates of consumption of higher doses of cocaine were actually higher than those of wild-type controls (73), which was likely due to compensatory developmental neuroadaptations. Taken together these results indicate that D2 and perhaps D3 dopamine receptors play critical roles in cocaine reinforcement; however, there is little evidence to date supporting a role for D4 dopamine receptors in the reinforcing effects of psychostimulants.

A number of nuclei receiving dopaminergic projections have been shown to be involved in psychostimulant reinforcement. For example, there is evidence suggesting that increased dopamine transmission in the mPFC (78), olfactory tubercle (79), and the amygdala (80–82) contributes to psychostimulant reinforcement. However, the nucleus that has received the greatest attention in terms of psychostimulant reinforcement is the nucleus accumbens and, in particular, the shell subregion of the accumbens. Thus, cocaine and D-amphetamine are self-administered directly into the rat nucleus accumbens including the limbic system-associated shell subregion (79,83–85). This effect is dopamine dependent in that it can be blocked by coinfusion of D1-like or D2-like dopamine receptor antagonists (83,85). Consistent with these findings, intra-accumbal administration of D1-like or D2-like dopamine receptor antagonists attenuates the reinforcing effects of intravenous cocaine (81,82,86).

Cocaine Self-Administration in DAT Knockout Mice

As reviewed above, an overwhelming body of evidence indicates that the action of psychostimulants at DATs plays a key role in psychostimulant reinforcement (30,31). It was very surprising, therefore, when initial reports indicated that mice lacking the DAT were able to self-administer cocaine in the absence of increases in extracellular dopamine in the striatum (87). It was subsequently shown, however, that cocaine increased extracellular dopamine specifically in the nucleus accumbens of these DAT knockout mice (88,89) via compensatory neuroadaptations involving norepinephrine transporters (NETs) (88) and/or serotonin transporters (SERTs) (89) (for reviews see Refs. 90 and 91). More recently, a different line of DAT knockout mice was developed in which cocaine had no influence on extracellular dopamine in the nucleus accumbens (92). Interestingly, cocaine self-administration was dramatically decreased in these DAT knockout mice (93). In addition, mice expressing a cocaine-insensitive DAT failed to self-administer cocaine (94). Thus, although initial results examining cocaine self-administration in mice with genetic deletion of DAT were interpreted as inconsistent with the dopamine hypothesis of the reinforcing effects of cocaine, subsequent behavioral and neurochemical results confirmed that the DAT plays a fundamental role in cocaine reinforcement. Moreover, results from experiments using DAT mutant mice ultimately supported the prevailing notion that increased dopamine transmission in the limbic system generally, and the nucleus accumbens shell in particular, underlies the reinforcing effects of cocaine.

Norepinephrine, Serotonin, and Cocaine Reinforcement

Even though most research on the mechanisms underlying cocaine reinforcement has focused on dopamine systems, there is also evidence that norepinephrine and serotonin contribute to the behavioral effects of cocaine. Although increased norepinephrine transmission may be involved in the discriminative stimulus effects of cocaine (95) as well as the reinstatement of cocaine seeking (96–98) (but see also (99)), norepinephrine does not appear to play a significant role in cocaine reinforcement (100). Thus, selective NET inhibitors are not self-administered and have no effect on cocaine self-administration (101,102), although NET knockout mice actually self-administered cocaine at higher rates than wild-type controls (90).

Although serotonin contributes to the discriminative stimulus properties of cocaine (103), the role of serotonin in cocaine reinforcement remains unclear. Selective SERT inhibitors do not maintain self-administration (104,105) and genetic deletion of SERT had no effect on cocaine self-administration (93). Moreover, direct and indirect serotonin receptor agonists actually attenuate cocaine reinforcement (106,107). However, there is evidence that specific serotonin receptors modulate the reinforcing effects of cocaine. Thus, cocaine reinforcement and cocaine-induced increases in extracellular dopamine in

the nucleus accumbens were enhanced in 5-HT_{2C} knockout mice (108), presumably via effects on dopaminergic neuronal activity in the VTA (109,110). In contrast, administration of 5-HT_{1B} receptor agonists augments cocaine-induced reinforcement (111) as well as cocaine-mediated increases in accumbal dopamine (112). Taken together, the currently available evidence indicates that to the extent that norepinephrine and serotonin influence cocaine reinforcement they do so by modulating mesolimbic dopamine transmission.

Glutamate and Cocaine Reinforcement

Although cocaine does not have a direct effect on glutamatergic neurons, a growing body of evidence indicates that altered glutamate transmission contributes substantially to cocaine-induced neuronal and behavioral plasticity. This is exemplified by the fact that whereas an acute cocaine injection had little or no effect on extracellular accumbal glutamate levels (113,114) (but see also (115)), repeated cocaine administration followed by a cocaine challenge injection increased extracellular glutamate in the core subregion of the nucleus accumbens (114,116,117). Interestingly, repeated exposure to cocaine without subsequent cocaine re-exposure resulted in decreased basal levels of extracellular accumbal glutamate in the nucleus accumbens (114,118). Thus, repeated cocaine administrations reduce basal extracellular glutamate in the nucleus accumbens core but a challenge injection of cocaine increases glutamate release in this structure.

There are several subtypes of glutamate receptors including ionotropic (AMPA [α -amino-3-hydroxy-5-methyl-4-isoxazolepropionate], kainate, and NMDA [N-methyl-D-aspartic acid]) and metabotropic classes. AMPA/kainate and NMDA receptors allow sodium, potassium, and in some cases calcium to pass through the ion channel, while metabotropic glutamate receptors are G-protein-coupled and therefore increase activation of intracellular effectors. AMPA and NMDA receptors are tetrameric and composed of four different subunits: GluR1–4 (119) and NR1–3 (120), respectively. There are three classes of metabotropic glutamate receptors. The group I metabotropic receptors, which include mGluR1 and mGluR5, stimulate phospholipase C and are predominantly postsynaptic (121). Group II includes mGluR2 and mGluR3, while group III encompasses mGluR4, mGluR6, mGluR7, and mGluR8. Both groups II and III are negatively coupled to adenylyl cyclase (AC) and are mainly located presynaptically (121).

A number of studies indicate that repeated exposure to cocaine influences the expression of AMPA and NMDA receptor subunit protein expression. Repeated cocaine injections or cocaine self-administration result in increased GluR1, GluR2/3 (122–125), and phospho-GluR1 (126,127) expression in the nucleus accumbens and also increased NR1 and NR2B in accumbens (122,126) (but see also Ref. 128). Collectively, these studies indicate that following a period of forced abstinence following repeated exposure to cocaine, there is increased expression of AMPA and NMDA receptor subunits in the nucleus accumbens. Recent evidence suggests that the trafficking of AMPA receptors to and from synapses in the nucleus accumbens plays a

critical role in cocaine-induced behavioral and neuronal plasticity. Thus, following repeated administrations of cocaine there is increased surface expression of the GluR1 and GluR2/3 AMPA receptor subunits in the nucleus accumbens (128,129) as well as enhanced accumbal AMPA receptor-mediated synaptic transmission (130). However, these effects were transient and reversed 24 hours following a challenge injection of cocaine (130,131). These results indicate that repeated cocaine exposure produces changes in the expression of AMPA and NMDA subunits as well as bidirectional plasticity of AMPA transmission in the nucleus accumbens (130,131). Although it is not clear to what extent AMPA receptor trafficking contributes to the reinforcing effects of cocaine, emerging evidence indicates that transport of GluR1 and GluR2 subunits in the nucleus accumbens plays an important role in the reinstatement of cocaine seeking (132–134).

Not surprisingly, modulation of AMPA and NMDA receptor-mediated glutamate transmission influences psychostimulant self-administration. Thus, systemic or intra-accumbal administration of an AMPA receptor antagonist decreased cocaine reinforcement (135–137). NMDA receptor antagonists, some of which are reinforcing in their own right (138), disrupt the acquisition of cocaine self-administration (139). Moreover, systemic or intra-accumbal administration of an NMDA receptor antagonist decreases responding for cocaine on an FR schedule (136,140,141) (see also Ref. 142). In terms of metabotropic glutamate receptors, mGluR5 receptor knockout mice do not self-administer cocaine (143). Consistent with this finding, the mGluR5 antagonist, MPEP, decreases self-administration of cocaine and methamphetamine (144–147). A growing literature indicates that stimulation of mGluR2/3 receptors also attenuates cocaine reinforcement (148–150). These findings, collectively, suggest that modulators of ionotropic and metabotropic glutamate receptors may be viable targets for the development of therapeutics for psychostimulant addiction.

OPIATES

Mechanisms of Action

Opiates are analgesic drugs that also have euphorogenic properties that may lead to chronic drug-taking behavior and dependence. Opiates are classified as any natural or synthetic drug with morphine-like actions. Clinical opiate use has escalated over the past 15 years with approximately 9.4 billion dosage units of opiates prescribed annually in the United States of America (151). In terms of illicit drug use, abuse of prescription opiates is second only to marijuana in the United States (25). Moreover, mortality rates related to abuse of prescription opiates continue to rise annually at an alarming rate (152).

Opiates bind to and activate opioid receptors and, thereby, mimic the effects of endogenous opioids (endorphins, enkephalins, dynorphins, and endomorphins) at μ , κ , δ , and/or opioid receptor-like (ORL1) opioid receptors (153,154). Opioid receptors are G-protein-coupled receptors that can form homodimeric as well as heterodimeric protein

complexes with other opioid receptors or nonopioid receptors (i.e., α 2a-adrenoreceptors, β 2-adrenoreceptors, D1-like dopamine receptors, chemokine receptors), respectively (155–157). Heterodimerization of opioid receptors results in altered pharmacology of the individual receptors as well as changes in receptor trafficking and coupling to intracellular signal transduction pathways (153). Stimulation of opioid receptors leads to a variety of physiological and psychological effects, including euphoria, analgesia, sedation, diuresis, miosis, constipation, and/or respiratory depression. Of the opioid receptors, stimulation of μ opioid receptors is mainly responsible for the reinforcing effects of morphine-like opiates, although δ opioid receptors also may contribute to opiate reinforcement (54,154). With regard to localization, μ opioid receptors are widely distributed throughout the central nervous system (CNS), including relatively heavy expression in the VTA and nucleus accumbens (158).

Opiates reduce membrane excitability and subsequently slow cell firing by activating a variety of potassium channels in the plasma membrane of cells in brain regions that send afferents to the VTA (including the nucleus accumbens, ventral pallidum, prefrontal cortex, and amygdala) (159). Furthermore, opiates inhibit voltage-gated calcium channels in presynaptic terminals and thereby modulate neuronal function/networks mainly by inhibiting release of glutamate, gamma aminobutyric acid (GABA), and glycine throughout the CNS (159). Opiates decrease synaptic transmission, in part, by inhibiting AC and, thus, decreasing intracellular levels of cyclic adenosine monophosphate (cAMP) (153). Repeated exposure to opiates results in robust upregulation of AC activity, specifically activity of AC1, AC5, and AC8 isoforms (160). Consistent with these findings, morphine-induced behavioral and physiological changes are modulated in mutant mice lacking AC1, AC5, or AC8 (161).

Dopamine and Opiate Reinforcement

A substantial literature implicates the mesoaccumbens dopamine system in mediating the reinforcing effects of opiates. Opiates exert their effects in the VTA and accumbens through both dopamine-dependent and dopamine-independent mechanisms (36,162,163). Rats will self-administer opioids directly into the VTA (164) or nucleus accumbens (165). Moreover, excitotoxic kainic acid lesions of accumbal cell bodies disrupt opiate self-administration behavior in laboratory animals (166,167). The precise role of the accumbens shell and core subregions in opioid self-administration behavior remains to be determined. However, recent evidence suggests that the core, but not the shell, plays a critical role in the acquisition of heroin self-administration behavior that is under the control of drug-associated stimuli (168). Nucleus accumbens shell dopamine levels are increased in rodents self-administering systemic infusions of opioids (169,170). In contrast, extracellular dopamine levels are not altered within the nucleus accumbens of animals self-administering opioids directly into this nucleus. Thus, pretreatment with the D2/D3 dopamine receptor antagonist, sulpiride, had no effect on

intra-accumbal morphine self-administration (171). Rather, the reinforcing effect of opioids self-administered into the nucleus accumbens appears to result from either direct inhibition of GABAergic accumbal projection neurons (172) or inhibition of excitatory neurotransmitter release from glutamatergic terminals within the accumbens (173).

In contrast to the GABAergic- and glutamatergic-dependent mechanisms underlying the reinforcing effects of opiates in the accumbens, a substantial literature suggests that self-administration of opiates directly into the VTA relies on the activation of the mesoaccumbens dopamine system. Only a very small percentage of dopaminergic neurons in the VTA express μ opioid receptors (174). Therefore, μ opioid receptors most likely influence VTA dopaminergic transmission through an indirect mechanism. Stimulation of μ opioid receptors in the VTA inhibits GABA release, which disinhibits dopaminergic neurons, resulting in increased extracellular dopamine levels in the nucleus accumbens. Consistent with this hypothesis, (i) VTA μ opioid receptors are found primarily on the terminals of inhibitory neurons, many of which synapse onto dopaminergic neurons (174); (ii) opioids do not directly influence the excitability of dopaminergic neurons, but do function to hyperpolarize GABAergic interneurons and thereby disinhibit dopamine neurons (175); (iii) intra-VTA microinjection of μ opioid receptor agonists increases the firing rate of dopaminergic neurons (176,177); (iv) local administration of opiates into the VTA increases dopamine release in the nucleus accumbens (178); and (v) pretreating rodents with a GABAergic receptor agonist prior to microinfusing a μ opioid receptor agonist directly into the VTA impairs intra-VTA μ opioid receptor agonist-induced dopamine release in the nucleus accumbens (179).

The role of dopamine in opiate reinforcement is complex and may depend on prior drug history (180). Recent studies demonstrate that in nondependent, drug-naive subjects, the acute rewarding effects of opiates are produced through dopamine-independent mechanisms that are mediated, in part, by cholinergic input from brain stem nuclei, including the pedunculopontine tegmental nucleus, to the VTA (181, 182). However, in subjects that are experiencing a state of withdrawal from repeated opioid administration, the motivational effects of opioids are mediated, in part, by the mesolimbic dopamine system (183), which suggests that dopamine transmission may underlie opiate craving that is independent from the acute rewarding effects of opiates. The VTA is one nucleus wherein opiates produce their rewarding effects through functionally distinct dopamine-independent (opiate-naive) and dopamine-dependent (opiate-dependent or opiate-withdrawn) signaling mechanisms depending upon prior history of drug use (182). Furthermore, GABA_A receptors in the VTA play a critical role in gating bidirectional reward transmission through these two motivation systems (184). The transition from a dopamine-independent to dopamine-dependent opiate reward state is associated with a physiological switch from inhibitory to excitatory signaling in GABA_A receptors that is facilitated by brain-derived neurotrophic factor (BDNF) in the VTA (185).

Dopamine and Opiate Self-Administration

Preclinical studies using the drug self-administration paradigm suggest that activation of the mesolimbic dopamine system plays an important role in opiate reinforcement. Lesions of dopaminergic inputs to the nucleus accumbens impair the acquisition of heroin self-administration (186) and decrease the reinforcing efficacy of morphine (187). Consistent with these findings, self-administration of morphine directly into the VTA was disrupted by administration of the D2/D3 dopamine receptor antagonist, sulpiride (171). In addition, morphine self-administration behavior was not observed in mutant mice lacking the D2 dopamine receptor (188), which suggests that D2-like dopamine receptors play a critical role in the reinforcing effects of opiates. However, it should be noted that several reports indicate that dopamine receptor antagonists do not consistently alter opiate self-administration behavior (189,190).

The hypothesis that the reinforcing effects of opiates are at least partially due to the disinhibition of dopaminergic neurons in the VTA was also confirmed in experiments using the drug self-administration paradigm. Thus, heroin self-administration behavior is associated with an increase in the firing rate of dopaminergic neurons in the VTA (191) and a corresponding increase in extracellular dopamine levels in the nucleus accumbens (170). Moreover, increases in GABA transmission in the VTA attenuate the reinforcing efficacy of heroin as well as heroin-induced increases in accumbal dopamine (192). Also, rodents will self-administer a GABA_A receptor antagonist directly into the VTA (193,194), an effect that is extinguished by pretreatment with a D2 dopamine receptor antagonist (194). Taken together, these findings suggest that the reinforcing effects of opiates are mediated, in part, by altered GABA transmission in the VTA and subsequent effects on neuronal excitability of dopaminergic neurons in the VTA.

Glutamate, Norepinephrine, Cannabinoids, and Opiate Self-Administration

Turnover of a number of neurotransmitters, including biogenic amine and amino acid neurotransmitters, in limbic nuclei is altered in animals self-administering morphine (195). Blocking ionotropic glutamate receptors in the VTA generally (196) or within the anterior VTA specifically (197) reduces heroin self-administration. Furthermore, noncontingent injections of morphine are associated with decreased expression of the AMPA receptor subunit GluR1 in D1-like dopamine receptor expressing neurons in the accumbens shell and non-D1-containing cells in the accumbens core (198). Taken together, these results suggest that chronic opioid exposure induces plasticity in glutamatergic systems within the VTA and nucleus accumbens. The role of norepinephrine in opiate self-administration is less clear (100), although recent evidence suggests that α 1b-adrenergic receptors play a role in the reinforcing efficacy of morphine (199).

A growing body of evidence indicates that cannabinoids contribute to opiate reinforcement. For example, CB1 cannabinoid receptor antagonist administration attenuates the self-administration of heroin (200–202). Further evidence that

CB1 receptors mediate the reinforcing effects of opiates comes from studies demonstrating that mutant mice lacking CB1 receptors do not acquire morphine self-administration (203,204). Moreover, intra-accumbens administration of a CB1 receptor antagonist attenuates heroin self-administration behavior (205). In contrast, administration of a CB1 receptor agonist enhances the reinforcing efficacy of heroin through a mechanism that involves interactions with μ opioid receptors (206). Taken together, these findings suggest that cannabinoid receptors exert their influence on opiate reinforcement via interactions with the mesoaccumbens dopamine system. Consistent with this hypothesis, CB1 receptor agonists increase the firing rate of dopaminergic neurons in the VTA and subsequently increase extracellular accumbal dopamine levels (207). However, administration of a CB1 receptor antagonist reduced heroin self-administration but did not influence heroin-induced increases in accumbal dopamine (201), which suggests that cannabinoids can modulate opiate self-administration behavior in a dopamine-independent manner.

Opioid Receptor Knockout Mice and Opiate Self-Administration

Mutant mice lacking one of three opioid receptor genes encoding μ , δ , or κ opioid receptors have been generated using homologous recombination technology and have been used to study the cellular and molecular mechanisms underlying the pharmacological effects and behavioral response of opiates (for review see Ref. 208). Constitutive homozygous and heterozygous μ opioid receptor knockout mice display reduced morphine self-administration behavior compared to wild-type controls (209,210), effects that may depend on κ opioid receptor activation in these mice (210). Furthermore, development of somatic withdrawal signs is absent in μ opioid receptor knockout mice (209,211). In addition to mediating the reinforcing effects of opioids, μ opioid receptors have been demonstrated to mediate the reinforcing effects of other drugs of abuse including cannabinoids, ethanol, and nicotine (212). In contrast, morphine withdrawal was attenuated in mutant mice lacking the κ opioid receptor (213), which suggests that the dysphoric effects of opiates are mediated by κ opioid receptors and that these receptors oppose μ opioid receptors in regulating hedonic tone (214). Behavioral phenotypes of δ and κ opioid receptor knockout mice and mutant mice lacking one of three opioid precursor propeptide genes in self-administration paradigms of opiates and other drugs of abuse remain to be fully characterized.

ETHANOL

Mechanisms of Action

Alcohol use and abuse remains a serious public health issue. In 2007, 18.6 million people in the United States over 12 were classified as dependent on alcohol (25). This represents 7.5% of the population, a number that has remained stable since 2002. Ethanol produces numerous neurochemical and phys-

iological effects on both excitatory and inhibitory neurotransmitter systems in the brain, which result in mood elevation, sedative, anxiolytic, and ataxic effects. Ethanol positively modulates GABA_A receptors, inhibits NMDA and kainate glutamate receptors, inhibits N- and P/Q-type calcium channels, has both inhibitory and excitatory effects at nicotinic acetylcholine receptors, enhances the activity of calcium-activated potassium channels, and modulates inwardly rectifying potassium channels (215).

Effects of Ethanol on Mesolimbic Dopamine Transmission

A number of studies suggest that ethanol increases extracellular dopamine levels in the nucleus accumbens (216,217) by increasing the firing rate of dopaminergic neurons in the VTA (218,219) rather than an effect in the nucleus accumbens itself (220,221). There are several potential mechanisms whereby ethanol might influence the firing rate of dopaminergic neurons including effects on potassium channels and GABA_A receptors in the VTA. In terms of potassium channels, ethanol reduces potassium currents in the VTA leading to the attenuation of after-hyperpolarizations following spontaneous action potentials (222,223). In contrast, stimulation of GABA_A receptors on GABAergic interneurons in the VTA by ethanol or a GABA_A receptor agonist disinhibits dopaminergic neuronal activity (179,224) (but see also (225)). However, since GABA_A receptors also are expressed by dopaminergic cells in the VTA (226), GABAergic interneurons must be more sensitive to GABA_A receptor agonists than dopaminergic cells (227).

Dopamine and Ethanol Self-Administration

Much of the research examining the reinforcing effects of ethanol using the self-administration paradigm has focused on differences between ethanol-preferring lines of rodents in comparison to non-ethanol-preferring lines. The behavioral phenotype of ethanol-preferring rats satisfies criteria for an animal model of alcoholism, including freely consuming large quantities of ethanol sufficient to produce intoxicating blood alcohol concentrations, willingness to work to obtain ethanol, self-administration of ethanol for the pharmacological effects as opposed to gustatory or olfactory reinforcement, and development of tolerance to and dependence on ethanol (228). In contrast, other lines of rats require a sucrose-substitution procedure in which rats are initially allowed to drink freely a rewarding sucrose solution and the concentration of sucrose is slowly decreased while simultaneously increasing the concentration of ethanol in order to obtain ethanol self-administration behavior.

There are numerous findings that support the hypothesis that ethanol-induced increases in firing rates of dopaminergic neurons in the VTA and the subsequent increased release of dopamine in the nucleus accumbens may underlie the reinforcing effects of ethanol. For example, ethanol is self-administered directly into the VTA by rats (229), an effect that is blocked by the stimulation of D2-like

dopamine autoreceptors in the VTA (230). In addition, ethanol self-administration behavior is associated with increased extracellular dopamine levels in the nucleus accumbens of rodents (231–233) and rhesus monkeys (234). Moreover, administration of the D2-like dopamine receptor antagonist sulpiride or low doses of the indirect dopamine agonist D-amphetamine increase ethanol self-administration behavior in ethanol-preferring rats (235).

D1-like and D2-like dopamine receptor agonists and antagonists modify ethanol self-administration behavior (236–239) (but see also (238)). Moreover, intra-accumbal microinjection of D1-like (240) or D2-like (240–242) dopamine receptor antagonists reduces ethanol self-administration behavior in rats. Consistent with these findings, genetic deletion of D1 (243) or D2 (244,245) dopamine receptors as well as antisense oligonucleotide-induced decreases in D2 dopamine receptor expression in the nucleus accumbens (246,247) suppressed ethanol self-administration behavior. In contrast, ethanol self-administration behavior was not influenced in constitutive D3 dopamine receptor knockout mice (248,249). Taken together, these results suggest that D1 and D2, but not D3, dopamine receptors in the nucleus accumbens contribute significantly to the reinforcing effects of ethanol. Interestingly, reduced expression of striatal D2 dopamine receptors was observed in alcoholics (250), which may lead to compensatory increases in ethanol intake (250).

GABA, Opiates, Serotonin, Cannabinoids, and Ethanol Self-Administration

The precise role of GABA transmission in the behavioral and physiological effects of ethanol continues to be elucidated. It has been hypothesized that lower doses of ethanol have direct effects on GABA receptor complexes (251). Ethanol appears to be a positive allosteric modulator of the GABA_A receptor in that it potentiates GABA-induced hyperpolarization either through GABA_A receptors or by directly stimulating chloride channel opening (251). GABAergic terminals synapsing on dopaminergic neurons in the VTA have been implicated in the acute rewarding effects of ethanol, and GABA_B receptors appear to play a critical role in this process. Further evidence supporting the role of enhanced GABA transmission in mediating ethanol self-administration behavior comes from animal studies demonstrating that GABA_A receptor antagonists and GABA_B receptor agonists or positive allosteric modulators decrease ethanol self-administration behavior (252–255) (but see also Ref. 256). Moreover, the firing rate of VTA GABAergic neurons increases in animals self-administering intravenous ethanol (257).

The opioid system also mediates ethanol self-administration behavior. The endogenous opioids beta-endorphin and enkephalins, which activate μ and δ opioid receptors, respectively, play a critical role in the reinforcing effects of ethanol (258). In contrast, dynorphin, which activates κ opioid receptors, appears to mediate the dysphoric properties of ethanol (258). Opioid receptor agonists increase ethanol self-administration behavior at low doses and decrease ethanol self-administration at high doses (for review see Ref. 259).

These dose-dependent effects may be due to interspecies variability in the behavioral response to ethanol (260). The selective μ opioid receptor antagonists β -funaltrexamine (261) and CTOP (-Pen-Cys-Tyr- -Trp-Orn-Thr-Pen-Thr-NH₂) (262) decrease ethanol consumption in rodents. Results examining the effects of selective δ opioid receptor antagonist have been less clear. Thus, ICI (174864), a selective δ opioid receptor antagonist, had no effect on ethanol intake (262), but naltrindole was effective in reducing ethanol self-administration behavior (263). The κ opioid receptor antagonist, norbinaltorphimine, did not impair ethanol self-administration behavior, but it attenuated ethanol-induced increases in extracellular levels of dopamine in the nucleus accumbens (264). Buprenorphine, a partial opioid receptor agonist with high affinity for the μ and κ opioid receptors, reduced ethanol intake for 1.5 hours but increased ethanol intake 4 hours post buprenorphine injection (265). Collectively, these data support a role of endogenous opioid systems in ethanol reinforcement. Indeed, the opiate antagonist naltrexone is used in the treatment of alcoholism (266).

The role of serotonin (5-HT) in the reinforcing effects of ethanol has been extensively studied for over 30 years. Serotonergic efferents from the dorsal raphe nucleus to the nucleus accumbens play a critical role in the reinforcing effects of ethanol. Ethanol-preferring rats have lower 5-HT content in the nucleus accumbens and the prefrontal cortex (235, 267). Moreover, administration of 5-HT reuptake inhibitors, fluoxetine and fluvoxamine, markedly decreased ethanol self-administration behavior in ethanol-preferring rats as well as other lines such as Long Evans (268). In addition, administration of the serotonin depletor *p*-chlorophenylalanine increases self-administration behavior (269). However, the role of individual 5-HT receptors in ethanol reinforcement is ambiguous. The vast majority of studies examining the role of 5-HT receptors in the reinforcing effects of ethanol have focused on the 5-HT_{1a}, 5-HT_{1B}, 5-HT₂, and 5-HT₃ receptor subtypes due to a lack of selective pharmacological compounds required to distinguish between other 5-HT receptors (for reviews see (163,228)). Paradoxically, 5-HT receptor agonists and antagonists have both been shown to increase and decrease ethanol self-administration behavior. Thus, direct infusion of a 5-HT receptor agonist into the nucleus accumbens of ethanol-preferring rats enhances ethanol self-administration behavior (270), while systemic and intra-accumbens core injections of the 5-HT_{1A} receptor agonists 8-OH-DPAT and isapirone reduce ethanol intake (271–273). Systemic and intra-accumbens core administration of 5-HT_{1B} receptor agonists also reduces ethanol self-administration behavior (271,273,274). Similarly, administration of a 5-HT₂ receptor agonist or risperidone, which preferentially antagonizes the 5-HT₂ receptor at low doses, reduced ethanol self-administration behavior (273,275). Systemic administration of the specific 5-HT_{2A} receptor agonist amperozide also reduced ethanol self-administration behavior (276). Furthermore, administration of FG 5974, which has 5HT_{1A} receptor agonist and 5HT_{2A} receptor antagonist actions, also reduced ethanol self-administration behavior (277). 5-HT₃ receptor

antagonists decrease ethanol self-administration behavior (278–280) and have synergistic effects when combined with opiates (279), which suggests that 5-HT₃ receptors and opioid receptors activated overlapping mechanisms to produce the reinforcing effects of ethanol. The effects of 5-HT₃ receptor antagonists may be dependent upon temporal-environmental cues associated with the presentation of ethanol (281). However, a different study found that three different 5-HT₃ receptor antagonists were not effective in reducing ethanol self-administration (282), indicating that the role of 5-HT₃ receptors in the rewarding properties of ethanol need to be further examined. Ethanol preference can be induced in rats by administration of the aldehyde dehydrogenase inhibitor cyanamide. In these pharmacologically ethanol-preferring rats, the 5-HT₂ receptor antagonist amperozide significantly reduced ethanol consumption (283,284) but the 5-HT₂ antagonists with no effect on reuptake, trazodone or ritanserin, have no effect on ethanol self-administration behavior (283). In animals self-administering ethanol into the posterior VTA, the 5-HT_{2a} and 5-HT₃, but not the 5-HT_{1B}, receptors have been shown to mediate the reinforcing effects of ethanol administered into this brain region (285).

Finally, a literature has begun to emerge indicating a role for the cannabinoid system in ethanol reinforcement. Administration of the cannabinoid CB₁ receptor agonist CP 55,940 increased breakpoints for the self-administration of beer in rats (286). This effect was reversed with the CB₁ receptor antagonist SR 141716 and the opioid receptor antagonist naloxone (286). The CB₁ receptor antagonist SR 141716A dose-dependently suppressed responding for intravenous infusions of ethanol as well as intra-VTA and intra-accumbens ethanol self-administration (287,288) (but see also (289)). Moreover, ethanol intake is increased following systemic administration of the CB₁ receptor agonist WIN 55,212-2 (288). Blocking the transporter for the endogenous cannabinoid anandamide also reduces ethanol self-administration behavior (290).

Genetically Altered Mice and Ethanol Self-Administration

Constitutive knockout and transgenic mice have been used to further our understanding of the roles of different neurotransmitter systems in the reinforcing effects of ethanol. Mice lacking the $\alpha 1$ subunit of the GABA_A receptor display reduced ethanol self-administration behavior when compared to controls and a significant increase in locomotor activity following administration of ethanol, an effect blocked by administration of either a dopamine or benzodiazepine receptor antagonist (291,292). Intracellular mechanisms responsible for interactions between GABA and dopamine signaling during ethanol self-administration may involve specific kinases as it was recently shown using protein kinase C epsilon null mice that GABA_A receptor regulation of ethanol self-administration was absent (293). Furthermore, mice lacking κ opioid receptors display impaired ethanol self-administration behavior when compared to wild-type littermates (294). Interestingly, these same mice showed decreased saccharin preference and higher quinine pref-

erence, consonant with previous observations of the involvement of opioids in regulating food intake (294). Moreover, beta-endorphin–deficient mice self-administer ethanol more readily than wild-type controls (295,296). Overexpression of 5-HT₃ receptors in the forebrain using a CaMKII-specific promoter decreases ethanol self-administration in mice (297). Genetic deletion of 5-HT_{1B} receptors produces slight preference for ethanol compared to wild-type controls (298). CB₁ receptor knockout mice have a significantly lower baseline ethanol consumption compared with wild-type mice (299). Finally, BDNF (+/–) mice, which display abnormal serotonergic neurotransmission and forebrain innervation, have increased ethanol consumption (300). Taken together, these studies examining the phenotype of genetically altered mice support a role of GABA, opioid, serotonergic, and cannabinoid neurotransmitter systems in the reinforcing effects of ethanol.

CANNABINOIDS

Mechanisms of Action

Marijuana remains one of the most widely abused drugs in the United States of America. Forty-one percent of Americans 12 years and older have used marijuana at least once in their lifetime and 10% of the US population has used marijuana within the past year (25). Marijuana smoke contains numerous chemical compounds, including around 60 different cannabinoids (301). However, there is a general consensus that Δ^9 -tetrahydrocannabinol (Δ^9 -THC) is the primary cannabinoid responsible for the psychoactive effects of marijuana, which include euphoria, enhanced sensory perception, increased appetite, analgesia, disrupted cognitive functioning, anxiety, paranoia and, at higher doses, sedation (301,302). Exogenous cannabinoids appear to mimic the action of endogenous cannabinoids, or endocannabinoids, in the brain by binding to and activating G-protein–coupled cannabinoid receptors. Endocannabinoids constitute a class of compounds that includes anandamide and 2-arachidonoylglycerol (2-AG), which are the best characterized of the endocannabinoids, and 2-arachidonoylglycerol ether, *N*-arachidonoyldopamine, and *O*-arachidonylethanolamine (302). Cannabinoids produce their physiological and psychoactive effects by interacting with cannabinoid receptors, which include CB₁ and CB₂ subtypes. However, since CB₂ receptors are only expressed in the immune system, whereas CB₁ receptors are expressed extensively in the brain (303), CB₁ receptors are responsible for the psychoactive effects of Δ^9 -THC.

Cannabinoid–Dopamine Interactions

Unlike classical neurotransmitters, endocannabinoids are not stored in vesicles but, instead, are synthesized and released in an activity-dependent manner (302). In the CNS, endocannabinoids act as retrograde messengers that are released from a postsynaptic neuron and subsequently inhibit the release of classical neurotransmitters from presynaptic terminals via the stimulation of presynaptic CB₁ receptors (304).

CB1 receptors are abundantly and widely distributed in the brain (301) including the mesoaccumbal system (305) and the nucleus accumbens shell in particular (306).

Although systemic administration of Δ^9 -THC or CB1 receptor agonists increases extracellular accumbal dopamine levels (307,308), particularly in the accumbens shell (308), CB1 receptors are not found on dopaminergic terminals or cell bodies (305,309). It seems likely that, similar to opioids, stimulation of CB1 receptors on GABAergic terminals in the VTA disinhibits dopaminergic neuronal activity, resulting in increased dopamine release in the nucleus accumbens (but see also (310)). Consistent with this hypothesis, administration of a GABA_A receptor antagonist blocked cannabinoid-induced increases in dopaminergic neuronal activity (311–313). Moreover, administration of a cannabinoid receptor agonist decreased GABA_A receptor-mediated inhibitory postsynaptic currents in VTA dopaminergic neurons (314). Taken together, these results suggest that cannabinoids increase dopaminergic neuronal activity by decreasing inhibitory GABAergic tone on these cells.

Dopamine and Cannabinoid Self-Administration

Due to a number of issues, including slow onset of action and a relatively long half-life, reliable self-administration of Δ^9 -THC in animal models has proven to be difficult although not insurmountable (315–317). Nonetheless, much of the behavioral pharmacology of cannabinoid self-administration has focused on self-administration of the CB1 receptor agonist WIN 55,212-2 (318,319). WIN 55,212-2 self-administration increases dopamine release in the nucleus accumbens shell and to a lesser extent in the core (320,321). It also has been shown that the nicotinic $\alpha 7$ acetylcholine receptor antagonist, methyllycaconitine, reduced intravenous self-administration of WIN 55,212-2 and Δ^9 -THC-induced dopamine elevations in the shell subregion of the nucleus accumbens (322), which suggests that nicotinic receptor antagonists may represent a possible therapeutic modality to treat marijuana addiction.

Opioid–Dopamine Interactions and Cannabinoid Self-Administration

A number of studies indicate that there are functional interactions between cannabinoid and opioid systems (323). For example, Δ^9 -THC-induced increases in extracellular dopamine in the nucleus accumbens are attenuated by the systemic or intra-VTA administration of an opiate receptor antagonist (308,324), which suggests that cannabinoids increase dopamine release in the nucleus accumbens by enhancing the firing rate of dopaminergic neurons in the VTA. However, an opioid receptor antagonist had no effects on the increased firing rates of dopaminergic neurons in the VTA produced by Δ^9 -THC (207). Although the precise mechanisms underlying cannabinoid–opioid interactions in the mesoaccumbal dopamine system remain unclear, behavioral studies revealed that an opioid receptor antagonist attenuated self-administration of a CB1 receptor agonist (202,325) or Δ^9 -THC (308,326).

CRF Cannabinoid Interactions

Due to the difficulties maintaining reliable self-administration of cannabinoids, many studies have sought to examine the neurobiological factors underlying addiction to marijuana through noncontingent administration of Δ^9 -THC. Using this experimental design, researchers discovered that Δ^9 -THC, along with other cannabinoids, interacts with the hypothalamic pituitary adrenal (HPA) system. It was shown as early as 1978 that plasma corticosterone levels are increased following noncontingent administration of Δ^9 -THC (see (327)). Acute Δ^9 -THC, anandamide, or HU-210 (a potent CB1 receptor agonist) administration stimulates secretion of adrenocorticotrophic hormone (ACTH) and subsequently corticosterone levels in rats in a dose-dependent manner (328,329). Moreover, these effects can be blocked by administration of the selective cannabinoid receptor antagonist, SR 141716A but not the corticotropin-releasing factor (CRF) receptor antagonist D-Phe CRF, suggesting that the stimulation of the HPA axis and consequent increase in plasma corticosterone levels are mediated by activation of cannabinoid receptors (323,330).

NICOTINE

Mechanisms of Action

The World Health Organization estimates that there were approximately 1.3 billion tobacco smokers worldwide in 2003, and this number is expected to increase to 1.7 billion by 2020 (331). If smoking patterns remain the same, approximately 1 billion people will die from smoking-related diseases in the 21st century (332). Although tobacco smoke contains at least 4000 separate chemical compounds, the principal psychoactive chemical is nicotine, which mediates tobacco's reinforcing effects (333). Stimulation of nicotinic acetylcholine receptors in the CNS is responsible for the diverse psychoactive effects of nicotine including mood elevation, decreased anxiety, increased arousal, improved attentiveness, decreased appetite, muscle relaxation, and cognitive enhancement (333). Twelve nicotinic receptor subunits have been identified in the brain ($\alpha 2$ – $\alpha 10$, $\beta 2$ – $\beta 4$) (334,335). These receptors are heterogenous cation channels that are typically composed of combinations of five α and β subunits; pentameric homomers formed from $\alpha 7$ also have been identified (336).

Nicotine–Dopamine Interactions

In the VTA, nicotinic receptors are found on dopaminergic cell bodies ($\alpha 4\alpha 5\beta 2$, $\alpha 4\alpha 6\alpha 5\beta 2$, $\alpha 7$), glutamatergic terminals ($\alpha 7$) as well as GABAergic cell bodies ($\alpha 4\beta 2\alpha 5$, $\alpha 7$) and terminals ($\alpha 4\beta 2$) (333,337,338). In the nucleus accumbens, nicotinic receptors are localized on presynaptic dopamine terminals ($\alpha 4\beta 2$, $\alpha 4\alpha 5\beta 2$, $\alpha 6\beta 2\beta 3$, $\alpha 4\alpha 6\beta 2\beta 3$) as well as presynaptic GABAergic and glutamatergic terminals ($\alpha 4\beta 2$) (333,339,340). Systemic administration of nicotine increases extracellular dopamine in the nucleus accumbens (341,342),

particularly in the shell subregion (343). Moreover, administration of nicotine into either the VTA (344,345) or the nucleus accumbens (344,346,347) increases extracellular dopamine levels in the nucleus accumbens.

Dopamine release in the nucleus accumbens following the local administration of nicotine into this brain region mainly results from the direct stimulation of $\beta 2$ -containing nicotinic receptors ($\alpha 4\beta 2$ and $\alpha 6\beta 2$) on presynaptic dopamine terminals (333,348,349), although nicotine-induced glutamate release may also contribute to this process (350). In experiments performed in *ex vivo* striatal synaptosome preparations, it was demonstrated that there are four major nicotinic receptors on presynaptic dopamine terminals ($\alpha 4\beta 2$, $\alpha 4\alpha 5\beta 2$, $\alpha 6\beta 2\beta 3$, $\alpha 4\alpha 6\beta 2\beta 3$) that contribute to nicotine-induced dopamine release (338,351,352). In contrast, experiments performed *in vivo* indicate that nicotine-induced dopamine release is attenuated by intra-accumbal administration of nicotine receptor antagonists that target $\alpha 7$ -containing receptors (353).

Nicotine administration also increases phasic burst firing of dopaminergic neurons in the VTA that target the nucleus accumbens shell (354). By increasing the ratio of burst (high-frequency) firing relative to tonic (low-frequency) firing of midbrain dopamine neurons, nicotine effectively increases the signal-to-noise ratio of dopamine afferents in the accumbens shell thereby facilitating dopamine-dependent reinforcement processes that contribute to nicotine addiction. Systemic administration of nicotine increases burst firing of midbrain dopamine neurons (355,356), which results in increased release of dopamine in the nucleus accumbens. This effect is almost completely blocked following administration of a nicotinic receptor antagonist directly into the VTA (345,353). Collectively, these findings indicate that stimulation of nicotinic receptors in the VTA is the primary mechanism underlying nicotine-induced increases in extracellular accumbal dopamine (357), whereas stimulation of nicotinic receptors in the nucleus accumbens appears to modulate the amplitude of this response (353). However, although stimulation of nicotinic receptors on midbrain dopaminergic neurons increases their firing rates, these receptors rapidly desensitize (356). Interestingly, microinjection of a receptor antagonist that targets $\alpha 7$ subunit-containing nicotinic receptors into the VTA decreased dopamine release in the nucleus accumbens induced by nicotine (358). It has been suggested that $\alpha 7$ subunit-containing receptors located on glutamatergic in the VTA desensitize more slowly than other nicotinic receptors, resulting in prolonged glutamate release and stimulation of dopaminergic neuronal activity in the VTA (333,359).

Dopamine and Nicotine Self-Administration

Nicotine is self-administered by a number of species in addition to humans, including primates, dogs, rats, and mice (360). Not surprisingly, nicotinic receptor antagonists attenuate nicotine self-administration (361,362) and blunt nicotine-induced increases in accumbal dopamine levels (363). Interestingly, rodents will self-administer nicotine directly into the posterior VTA and

these effects are blocked by coadministration of a nicotinic receptor antagonist, suggesting that the reinforcing effects of nicotine are mediated by these brain regions (364). Activation of the mesoaccumbal dopamine system appears to contribute significantly to nicotine reinforcement. Thus, the acquisition (365) and maintenance (366) of nicotine self-administration was disrupted following the accumbal dopamine depletion. In addition, D1-like or D2-like dopamine receptor antagonists administered systemically attenuated nicotine self-administration (367) and coadministration of a D2-like dopamine receptor antagonist attenuates intra-VTA self-administration of nicotine (364). Administration of a nicotinic receptor antagonist into the VTA attenuated nicotine self-administration (368), which further indicates that the reinforcing effects of nicotine are due to activation of the mesoaccumbal dopamine system (see Refs. 333, 357, 360, and 369).

GABA and Nicotine Self-Administration

Neurochemical studies suggest that the prolonged stimulation of dopaminergic neuronal activity in the VTA following nicotine exposure is due to decreases in GABAergic and increases in glutamatergic transmission (370). Enhancing GABAergic transmission or stimulating GABA_B receptors has been shown to decrease nicotine self-administration behavior (371,372) as well as nicotine-induced increases in extracellular dopamine levels in the nucleus accumbens (373). Moreover, infusion of GABA_A or GABA_B receptor agonists directly into the VTA reduces nicotine self-administration behavior (374) and suggests that GABAergic mechanisms are involved in mediating the reinforcing efficacy of nicotine (375). GABAergic neurons in the VTA express $\beta 2$ -containing nicotinic receptors (342), and nicotine self-administration as well as nicotine-induced increases in burst firing of VTA dopaminergic neurons and striatal dopamine release were attenuated in mice lacking the $\beta 2$ subunit of the nicotinic receptor (376). Similarly, administration of a high-affinity nicotinic receptor antagonist (including the $\alpha 4\beta 2$ subtype) decreases the reinforcing efficacy of nicotine (377,378). Collectively, these results suggest that nicotine-induced decreases in VTA GABA transmission disinhibit dopaminergic neuronal activity, which in turn promotes the reinforcing effects of nicotine.

Glutamate and Nicotine Self-Administration

Glutamate also has been demonstrated to play a critical role in mediating the reinforcing effects of nicotine (379–381). Systemic administration of NMDA receptor antagonists (382), metabotropic glutamate (mGlu) 5 receptor antagonists (379–381), or presynaptic mGlu(2) and mGlu(3) receptor agonists (383) decreases nicotine self-administration behavior, which suggests that decreasing glutamatergic transmission may reduce the reinforcing effects of nicotine. It has been proposed that the effect of nicotine on glutamate transmission in the VTA is due to interactions with $\alpha 7$ subunit-containing nicotinic receptors (359,384,385). Consistent with this hypoth-

esis, an $\alpha 7$ -selective nicotinic receptor antagonist significantly reduced nicotine self-administration (386). However, in another study, the same $\alpha 7$ -selective nicotinic receptor antagonist had no effect on nicotine self-administration behavior in rats (377). Taken together, these results suggest that glutamate activation and GABA inhibition act concurrently to activate dopamine cells in the VTA following nicotine self-administration. Thus, although it seems likely that both GABA and glutamate play important roles in nicotine reinforcement, the precise interactions among GABA, glutamate, and dopamine in the VTA that combine to support the reinforcing efficacy of nicotine remain to be determined.

Norepinephrine, Opioids, Cannabinoids, and Nicotine Self-Administration

Although these data clearly indicate that interactions among dopamine, GABA, and glutamate transmitter systems play a critical role in the reinforcing efficacy of nicotine, emerging evidence suggests that other neurotransmitter systems are involved as well. In particular, bupropion influences nicotine self-administration behavior by modulating both dopamine and norepinephrine transmission in the CNS (387,388), which suggests a potential role for norepinephrine in nicotine reinforcement. Extracellular norepinephrine levels are increased in the paraventricular nucleus of the hypothalamus (389) and the amygdala (390) of rodents self-administering nicotine, which suggests that nicotine modulates neuroendocrine function and consolidation of amygdala-dependent memories, respectively. Moreover, inhibiting the norepinephrine transporter, which increases extracellular levels of norepinephrine in the brain, attenuates both nicotine and food self-administration behaviors (362,391,392).

Cannabinoids also have been shown to mediate, in part, the reinforcing effects of nicotine. Although CB1 cannabinoid receptor knockout mice self-administer nicotine to a similar extent as their wild-type littermates (203), pharmacological studies indicate that CB1 receptors may contribute to nicotine reinforcement. For example, administration of a CB1 receptor antagonist attenuates nicotine self-administration behavior (393,394) as well as nicotine-induced dopamine release in the nucleus accumbens (393). These findings provided the rationale for clinical studies designed to assess the efficacy of CB1 receptor antagonists as a smoking cessation therapy (395). Systemic administration of nicotine increases opioid levels in the nucleus accumbens (396). While clinical studies have demonstrated that administration of an opioid receptor antagonist attenuates the reinforcing effects of nicotine in human cigarette smokers (397,398), preclinical studies have demonstrated that systemic (367,399,400) or intra-VTA administration (374) of opioid receptor antagonists has no effect on the reinforcing efficacy of nicotine in rodents. However, opioid receptors outside of the dopamine system may play a role in the reinforcing effects of nicotine (401). Thus, the reinforcing efficacy of nicotine may be mediated by both dopamine-dependent and dopamine-independent mechanisms (402).

Nicotine Receptor Knockout Mice and Nicotine Self-Administration

Nicotinic receptors are pentameric protein complexes with different pharmacological and electrophysiological properties depending on their subunit composition. The effects of nicotine on nicotinic receptors in the brain are complex and consist of both activation and desensitization of nicotinic receptors (403). Therefore, nicotine-induced neuroadaptations are likely to be mediated by differential activation and desensitization of nicotinic receptors in neural networks underlying the behavioral response(s) to nicotine. However, identification of precise subunit compositions that comprise functional neuronal nicotinic receptors in vivo is limited due to lack of selective pharmacological compounds that target individual subunits (404). The role of nicotine receptor subunits in nicotine-mediated behaviors has recently been examined using genetically modified mice with null mutations in the genes that encode individual nicotinic receptor subunits. While a number of nicotinic receptor mutant mice have been generated to date (404), the reinforcing effects of nicotine have been studied mainly in constitutive $\beta 2$ knockout mice (376,405). Mutant mice lacking the $\beta 2$ subunit do not self-administer nicotine when compared to wild-type controls, suggesting the $\beta 2$ nicotinic receptor subunit plays a critical role in the reinforcing efficacy of nicotine (376,405). Consistent with these results, constitutive $\beta 2$ knockout mice re-establish nicotine self-administration behavior when the $\beta 2$ subunit is selectively re-expressed in the VTA using viral-mediated gene transfer techniques (406,407). Furthermore, nicotine self-administration increases extracellular dopamine levels in constitutive $\beta 2$ knockout mice re-expressing the $\beta 2$ subunit to similar levels observed in wild-type animals self-administering nicotine (407). Recently, the contribution of different alpha subunit partners of the $\beta 2$ subunit of nicotinic receptors in the reinforcing effects of nicotine was examined by re-expressing $\alpha 4$, $\alpha 6$, or $\alpha 7$ subunits in the VTA of mutant mice in which the corresponding α subunit was knocked out (406). Constitutive $\alpha 4$ or $\alpha 7$ knockout mice do not self-administer nicotine and re-expressing $\alpha 4$ or $\alpha 6$ subunits in the VTA promotes nicotine self-administration in mice lacking these individual subunits (406). In contrast, mutant mice lacking the $\alpha 7$ nicotinic receptor subunit self-administer nicotine in patterns similar to those of wild-type animals which suggests that $\alpha 7$ -containing nicotinic receptors do not mediate the reinforcing efficacy of nicotine (406). Taken together, these results indicate that functional $\alpha 4\beta 2$ and $\alpha 6\beta 2$ -containing nicotinic receptors, but not $\alpha 7$ -containing nicotinic receptors, in the VTA are required for the reinforcing effects of nicotine.

SUMMARY/CONCLUSIONS

As reviewed above, a rapidly expanding literature indicates that changes in the function of diverse neurotransmitter systems independently and in concert underlie the reinforcing

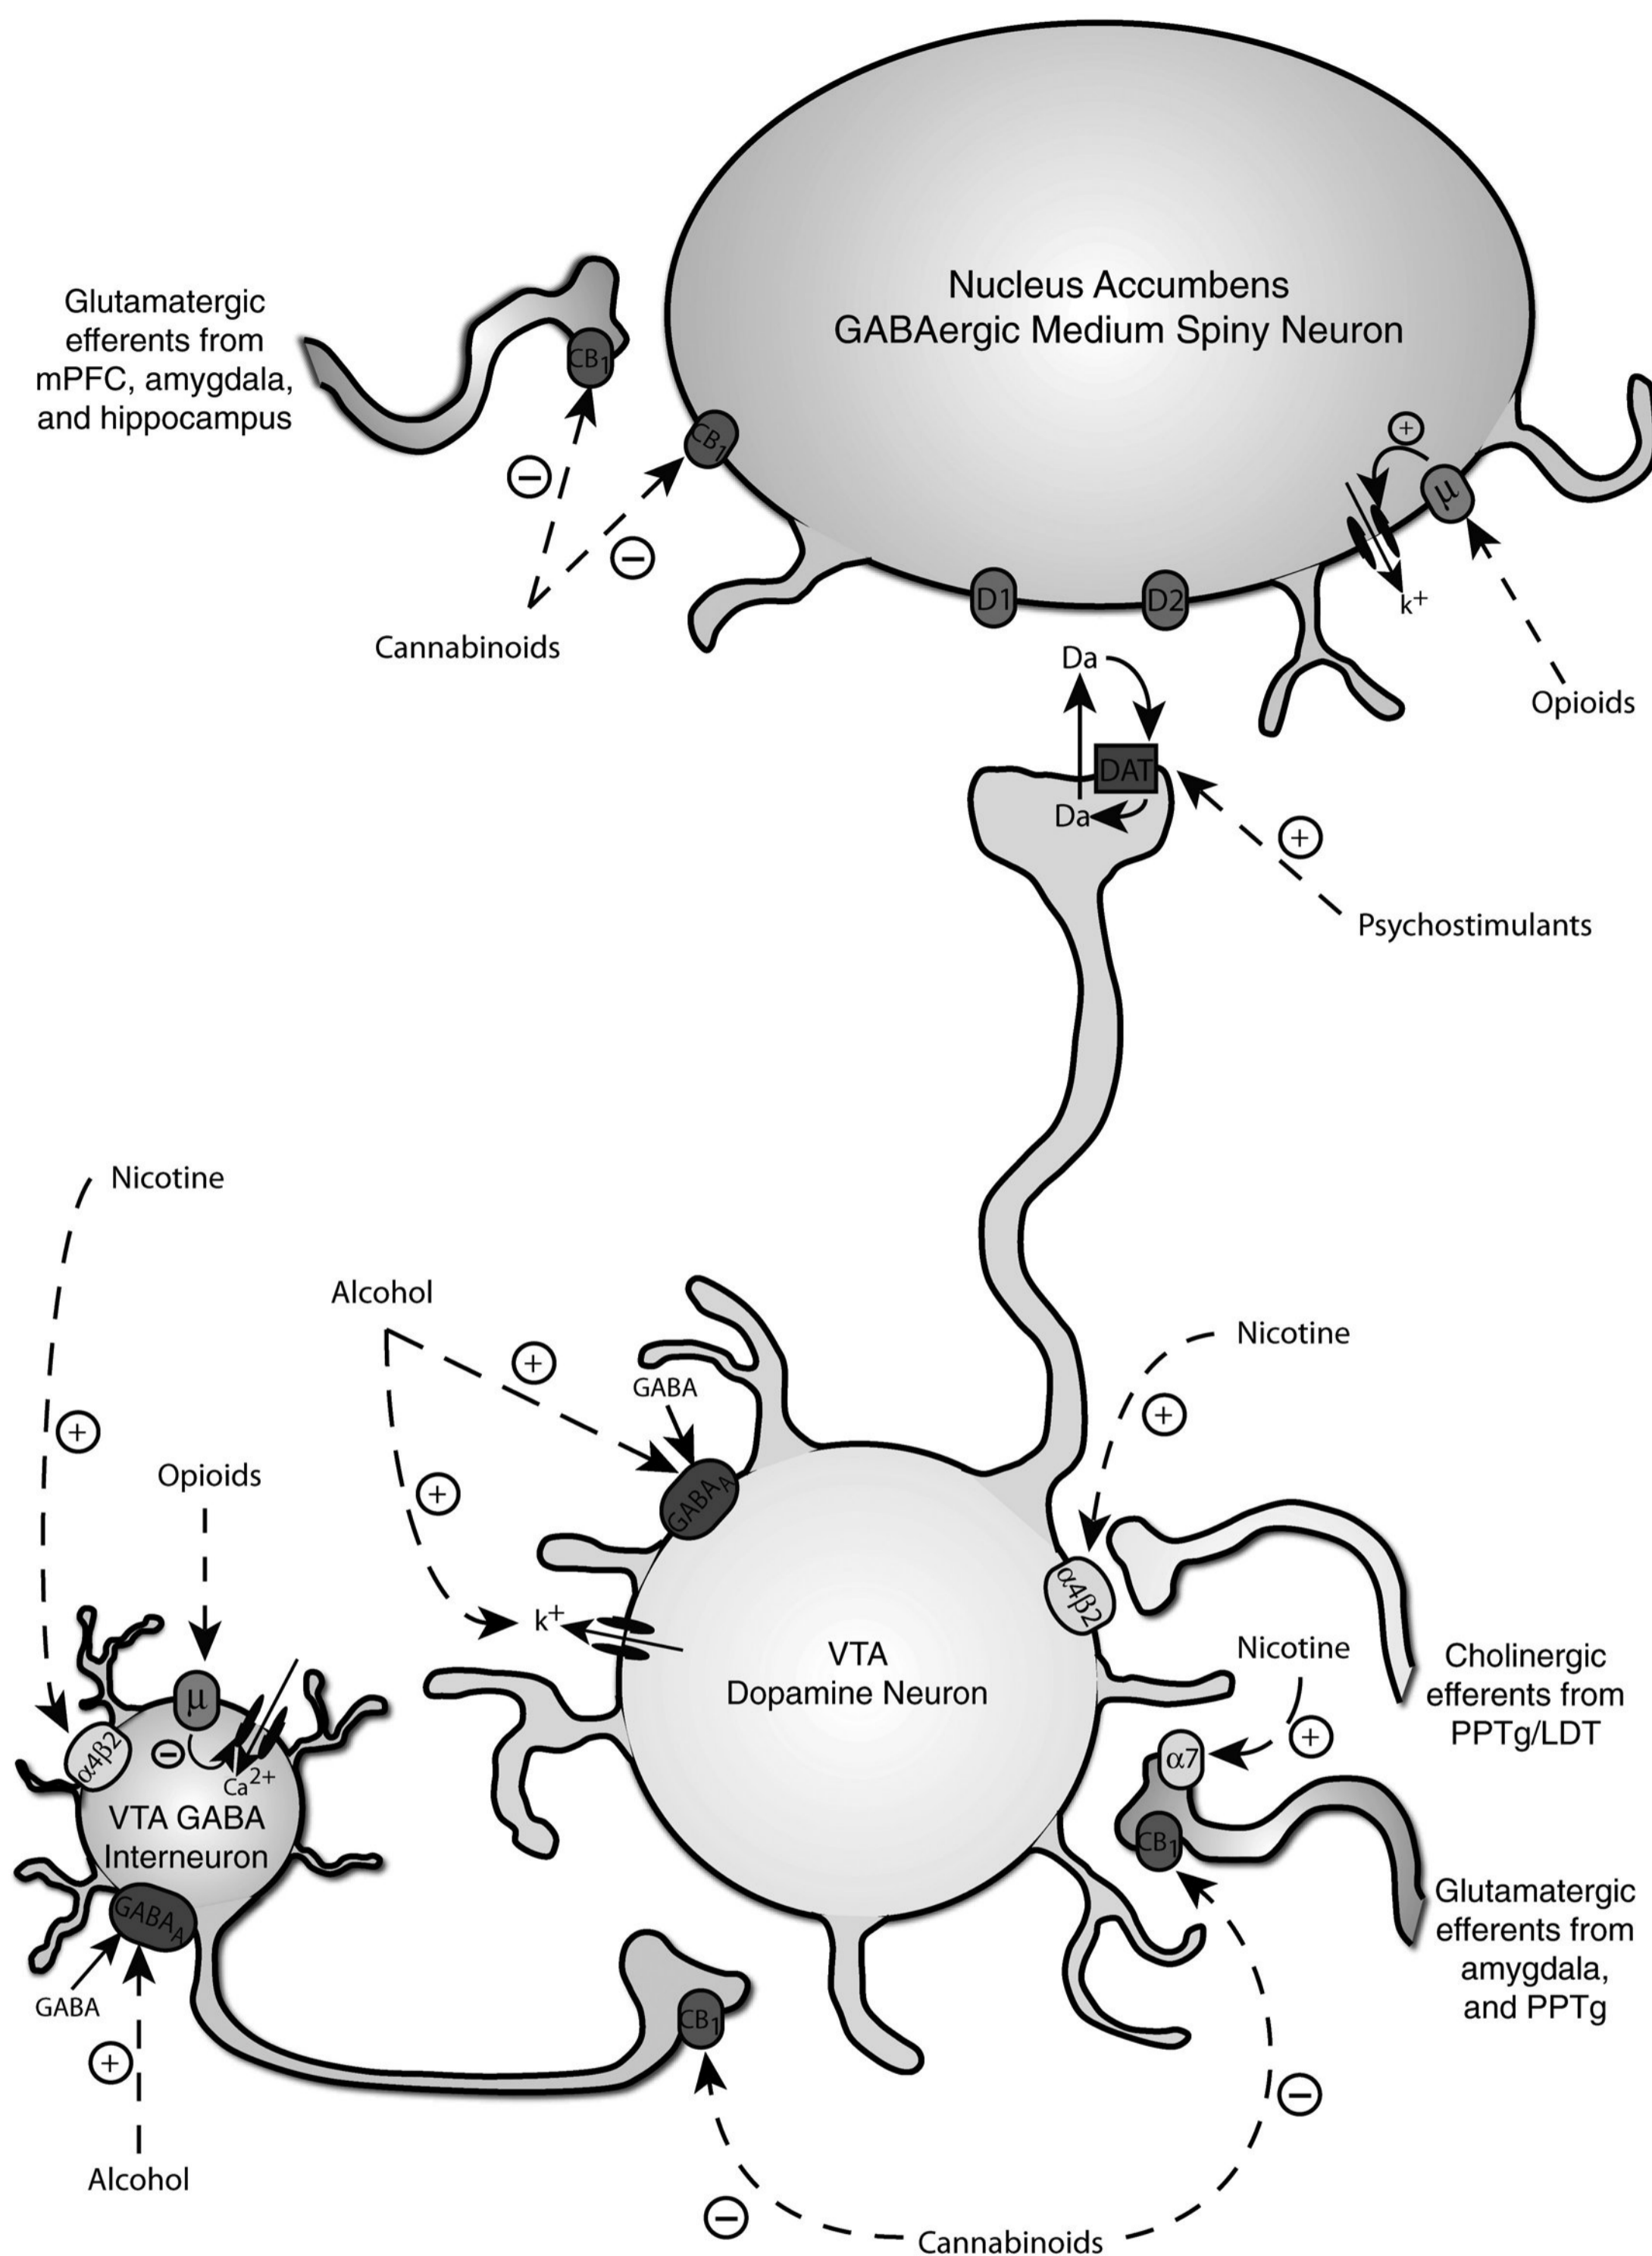

Figure 5.1. Influences of psychostimulants, opioids, cannabinoids, nicotine, and alcohol on the mesoaccumbens dopamine system. See text for details. α₄β₂, α₄β₂ nicotinic receptor subtype; α₇, α₇ nicotinic receptor subtype; CB₁, cannabinoid 1 receptor; D₁, D₁-like dopamine receptor; D₂, D₂-like dopamine receptor; Da, dopamine; DAT, dopamine transporter; μ, μ opioid receptor; VTA, ventral tegmental area.

effects of abused drugs. Although various drugs of abuse influence glutamate, GABA, acetylcholine, opioid, cannabinoid, and other neurotransmitter systems, the mesolimbic dopamine system is the common denominator in terms of the reinforcing effects of psychostimulants, opiates, ethanol,

cannabinoids, and nicotine (see Fig. 5.1). Whereas psychostimulants act directly on dopaminergic neurons by interacting with DATs, the other drugs of abuse increase dopamine release and/or dopaminergic neuronal activity in the mesoaccumbens pathway through interactions with a num-

ber of ionotropic receptors, metabotropic receptors, ion channels, and transporters. Drug self-administration experiments indicate that enhanced dopamine transmission in the nucleus accumbens plays at least a partial role in the reinforcing effects of psychostimulants, opiates, ethanol, cannabinoids, and nicotine, which suggest that the mesoaccumbal dopamine system is the final common pathway underlying the reinforcing effects of the major classes of abused drugs.

Psychological Factors (In Determinants of Abuse and Dependence)

Steven Shoptaw

P psychological and social factors abound in the lives of individuals with substance abuse and dependence. Yet, the interplay of cultural, social and familial, individual predispositions, neurobiology, and genetic factors, though frequent, is apparently not sufficient for reliably determining substance abuse or dependence conditions. While psychological and social factors can contribute to the development and maintenance of substance abuse and dependence across the life span for many individuals, it remains that other individuals often do not develop these disorders, even given similar circumstances and biologies. Indeed, the effect sizes of psychological and social factors in determining substance abuse and dependence are modest (1). Further, once substance use disorders are established, accompanying neural changes and conditioned behaviors ascend in importance, with the roles of psychological and social factors having less impact in maintaining substance abuse or dependence. This chapter reviews the evidence regarding psychological factors and social experiences that contribute to substance abuse and dependence, with particular consideration given to various points across the life span.

SUBSTANCE ABUSE ACROSS THE LIFE SPAN

Estimates from the National Epidemiological Survey on Alcohol and Related Conditions (NESARC) show incidence of drug use disorders is low (2.0%) across the life span, with lifetime prevalence about 10% (2). Two factors, particularly gender and age reliably show differences: males are more likely than females to have drug abuse and dependence. Younger individuals also are more likely to have drug abuse or dependence, with incidence of these disorders peaking in late adolescence and being rare after age 25. Yet for the first time, Americans are not aging out of drug abuse problems, with baby boomers entering retirement with alcohol and drug use problems (2), particularly cannabis abuse.

One of the most potent predictors of substance abuse problems across the life span is a historical or current problem with another drug of abuse. Among youth, this observation took the shape of the “gateway hypothesis,” the observation that use of a licit drug (e.g., alcohol and tobacco) or an illicit drug like marijuana during early adolescence predicted use of other illicit drugs (3). In a very strong prospec-

tive birth cohort study in New Zealand, development of drug abuse or dependence conditions correlated significantly with having parents who used illicit drugs, with male gender, with high needs for novelty seeking and with childhood conduct disorder (4)—associations that were mediated by marijuana use, alcohol use, and affiliation with substance using peers during ages 16 to 25. While strong evidence supporting the gateway hypothesis is provided by findings from the Virginia Twin Registry (5), the registry is comprised exclusively of White twins. For individuals from racial/ethnic groups, the buffering effects of family and culture delay of onset of illicit drug use in adolescents (6). Withdrawal of these buffering effects for youth reaching age of majority, however, contributes to comparable rates of incidence of drug and alcohol abuse. Finally, the logic of predicting substance abuse problems based on prior or current drug use is clearest among those who are already abusers of illicit drugs. Among those who are dependent on cocaine, methamphetamine, or heroin, concomitant use of alcohol, tobacco, and marijuana is highly prevalent (2). It also remains that the vast majority of adolescents who become regular daily users of nicotine and/or alcohol do not go on to become regular daily users of illicit drugs.

PSYCHOLOGICAL FACTORS

Personality

Individuals with substance abuse or dependence often complain they have an “addictive personality.” The concept of the “addictive personality” frequently relates to long-standing and generalizable traits that involve inability to control indulgences with molecules or behaviors. This popular term, though descriptive, has little empirical support. By contrast, research into long-standing psychological and personality “traits” or styles shared by individuals with substance abuse or dependence shows a good deal of support for common characteristics, specifically sensation seeking, delay discounting, and other components of impulsivity (7). Behavioral scientists are likely to understand the factors that co-occur with substance abuse or dependence as constrained and limited. So while the concept of an “addictive personality” can be salient to patients and clinicians, the variance unexplained requires a more careful evaluation of stable intrapersonal styles

that may be involved in determining substance abuse and dependence.

Personality Disorders

In the NESARC, a representative national sample of 43,093 individuals, those who met criteria for *any* personality disorder were 1.8 (95% confidence interval [CI]: 1.3–2.5) and 3.3 (95% CI: 2.0–5.3) times more likely to be comorbid for drug abuse or drug dependence than those who did not meet criteria for a personality disorder, respectively (2). Individuals with antisocial personality disorder, in specific, were two-and-one-half times more likely than those without antisocial personality disorder to also meet criteria for drug abuse and dependence after controlling for demographic characteristics and other psychiatric diagnoses. Antisocial, borderline, and narcissistic personality disorders (Cluster B in the DSM-IV-TR) share a defining feature: impaired capacity of individuals to inhibit impulses, which can facilitate repeated exposures to alcohol and/or illicit drugs sufficient to establish comorbid alcohol and drug use diagnoses (8). Individuals who meet criteria for drug abuse or dependence who are comorbid with personality disorders respond similarly to their peers in treatment who do not have personality disorders along drug use outcomes (9–11). Yet, there remain important ways in which patients living with personality disorders and comorbid substance dependence disorders bring significant disturbances to treatment, including criminal behaviors and overdose that require additional focus during treatment from those who do not have these disorders (12,13).

Bipolar Illness

Individuals with bipolar illness represent an important group who face genetic, neurobiologic, and environmental factors that can contribute to a high prevalence of comorbid substance abuse and dependence disorders (13). Providing evidence suggesting shared genetic pathways that explain the nearly 2.4 times greater risks for tobacco use disorders than the general public (14), three candidate genes have been shown (COMT, SLC6A3, SLC6A4) to interact in predisposing bipolar and tobacco use disorders. Individuals with bipolar illness and comorbid substance abuse and dependence share, at least partially, common neurobiologic pathways that are the biologic bases for expression of these behavioral disorders. Aspects of serious mental illness, such as bipolar disorder, share behavioral features including problems in inhibiting impulses and excessive time spent on sensation seeking. Substance abuse and dependence bring with them significant clinical distress (including independent risks for suicide), which interacts negatively with symptoms of bipolar disorder and can enhance negative individual, familial, and social consequences of either condition alone. Substance use can ameliorate these symptoms and exaggerate expansive experiences related to mania. Further, onset of substance

use disorders and bipolar disorders imparts key information determining the course and severity, particularly of bipolar disease (15). About one third of comorbid individuals report substance abuse disorders preceded onset of their bipolar disorder. Among individuals whose bipolar disorder onset was earlier than or concurrent with onset of substance abuse disorders, a more unstable and severe course of bipolar disorder is noted (15). Continued substance use disorders among individuals with bipolar disorder have no impact on time to resolution of depressive phase, but can contribute to switching directly from depression to mania, hypomania, or mixed states (16). Indeed, substance abuse, particularly stimulant abuse can precipitate a manic episode or perhaps facilitate establishment of a bipolar condition that may have gone unexpressed in the absence of stimulant use (15).

Major Depression

Studies consistently document that depressive disorders co-occur with alcohol and drug abuse and dependence. Individuals with depressive disorders commonly seek out substance use to mediate depressed feelings and thoughts. A recent report noted that individuals in the general population with major depression, dysthymia, generalized anxiety disorder, or panic disorder concurrent with problem drug use are more likely than those who do not have these conditions to initiate and use prescribed opioids (17), presumably to minimize uncomfortable psychological states from those disorders. With repeated administrations, however, substance abuse or dependence conditions can develop and require treatment in their own regard. Compared to those who are not depressed, having a major depressive disorder doubles the odds for meeting criteria for alcohol and drug use disorders (18). Those with concurrent depression and substance abuse disorders are likely to be younger, male, divorced or never married, at greater current suicide risk, have an earlier age of onset of depression, have greater depressive symptomatology, report more previous suicide attempts, have anxiety disorders, and have greater functional impairment than those who are depressed only (19). Negative clinical consequences that result from alcohol and drug abuse or dependence are worsened compared to those with substance problems only, with older individuals showing stronger associations between negative consequences, depression, and substance use (20). The relationship between suicidal behaviors and substance abuse has long been recognized and particularly in individuals with comorbid depression and alcohol use disorders, risks for suicide are extremely high. Up to 7% of individuals with depression and alcohol dependence end their lives by committing suicide (21,22). Suicidal behaviors associated with alcohol dependence are also linked with higher levels of impulsive aggression, drug use, and psychiatric comorbidity, particularly personality and depressive disorders (20–22). As might be expected, depression negatively predicts success in maintaining alcohol abstinence following intensive treatment for alcohol dependence (23). Although clinical reports consistently document

associations between depression and alcohol use disorders, less consistent associations are noted between depression and users of other drugs. Among injecting drug users (IDUs), co-occurring depression is associated with “concurrent” alcohol and drug use (and corresponding negative clinical consequences due to polysubstance use), needle sharing, and substance abuse treatment participation (24). Strong associations between depression and increased substance-related behaviors are not, however, universal across all substances of abuse. The same group failed to find similar substance-related behaviors in a meta-analysis of cocaine abusers with comorbid depression (25).

Thought Disorders

Individuals living with schizophrenia have one of the highest rates of comorbidities with substance use disorders. In a probability sample, 47% of respondents with schizophrenia also met criteria for lifetime diagnoses of substance abuse (13). Clinical researchers have pondered why individuals with thought disorders are prone to substance abuse and dependence and at the same time recognized that heavy use of some substances, particularly hallucinogens and stimulants, can produce experiences similar to schizophrenia in nonpsychotic individuals. As well, one report from Thailand indicates that among 445 methamphetamine-abusing individuals, those who have a first degree relative with schizophrenia were significantly more likely to develop methamphetamine psychosis than users who did not have a relative with schizophrenia (26). More, while there is some indication that dopamine dysregulation may predispose individuals with schizophrenia to abuse drugs (27), it has long been recognized that individuals living with schizophrenia engage in drug abuse behaviors because the substances help them to feel good and provide relief from the dulling effects of their antipsychotic medications and medications to treat side effects. On the other hand, there is scant evidence that even chronic abuse of substances contributes to the development of thought disorders. Among the approximately 1% of adolescents who ultimately develop schizophrenia, there is no indication that their use of marijuana or other substances differs significantly from the vast majority of adolescents who do not develop schizophrenia (28). In their review, individuals with thought disorders who abuse substances face several severe negative consequences including: (1) increased positive symptoms; (2) relapse of psychosis; (3) heightened risk of violence; (4) heightened risk of suicide; (5) increased medical comorbidities; (6) legal complications, including heightened risk of incarceration; and (7) increased propensity to antipsychotic-related side effects. The most important consequence to individuals with schizophrenia and comorbid substance abuse disorders involves disruption of psychiatric medication adherence, which ultimately erodes stability for the individual and increases the potential for negative consequences common to end stage substance abuse disorders such as homelessness and grave disability.

Anxiety Disorders/Posttraumatic Stress Disorder (PTSD)

Anxiety disorders and substance abuse disorders co-occur at substantial rates. Analyses of NESARC data (29) showed that individuals with any mood disorders were substantially more likely than those with any anxiety disorders to also meet criteria for alcohol abuse, alcohol dependence, drug abuse, or drug dependence. Still, compared to individuals who had no anxiety disorders, individuals with any anxiety disorder were 2.6 times (95% CI: 2.2–3.0) and 6.2 times (95% CI: 4.4–8.7) more likely to meet criteria of alcohol dependence and any drug dependence, respectively. Twelve-month prevalence of substance use disorders was highest for any alcohol, any drug, and cannabis use disorders. Individuals with anxiety disorders may abuse alcohol, cannabis, and prescription analgesics or sedatives in order to medicate symptoms of anxiety. The typical anxiety disorder patient with substance abuse or dependence, however, differs in presentation from other types of individuals with comorbid psychological and substance use disorders. Indeed, data from the National Comorbidity Survey-Replication study (30) indicate that presence of an anxiety disorder reduces the association between externalizing problems (such as conduct disorder, oppositional defiant disorder) and substance use disorders, possibly because fear/anxiety interferes with individuals with externalizing problems from engaging in drug-seeking behaviors.

While many Americans have experiences that meet the criterion for trauma, only a minority goes on to develop the full range of PTSD symptoms. Even so, PTSD is prevalent in alcohol and drug abusing populations in treatment. Links between PTSD and substance abuse are well recognized by clinicians and patients. Individuals with PTSD frequently report using substances in order to reduce anxiety and to block re-experiencing the traumatic event. Recent evidence that supports the self-medication rationale comes from a national multisite trial for comorbid PTSD and substance abuse. Participants who experienced reductions in PTSD symptoms correspondingly showed decreases in symptoms of substance abuse (31). By contrast, individuals who responded solely to substance abuse treatment showed no association with their experiences with PTSD symptoms.

Impulsivity

A behaviorally based definition of impulsivity focuses on the likelihood of an individual to rapidly act on an impulse rather than to act based on consideration; the failure to inhibit these impulses can include behaviors that even carry potential for self harm (32). A central psychological characteristic shared by many individuals with substance abuse and dependence involves a significant and principle deficit of inhibiting impulses linked to using substance. Impairments in inhibiting cognitive impulses can generalize beyond substance use to erode overall quality of executive functioning in substance abusers (33). Several examples of

impulsive cognitive style have been noted in individuals with substance abuse or dependence, including delay discounting, that is, discounting the value of rewards that may be more valuable, but more distant, in favor of lower value rewards that are immediately available (34). Using a trait definition, impulsive sensation seeking or behavioral disinhibition traits best predicted substance use in a large sample of 457 young adults at 6-year follow-up evaluations (35). Inhibitory control deficits observed in childhood (36), inhibitory control deficits with onset during adolescence (37), and genetic variation in inhibitory control deficits (38) represent independent contributions to enhanced risks for development of substance abuse or dependence disorders across the lifetime. In specific, impulsivity most likely is a risk factor for development of stimulant abuse (39). One important component of impulsivity that can contribute to establishment of substance abuse disorders is sensation seeking, a behavioral trait that can be conceptualized on a continuum, ranging from excitement-adventure seeking (a vulnerability to boredom) to disinhibition. In her review of the topic, de Wit (7) argued convincingly that impulsive behavior is both a determinant and a consequence of drug use. Individuals who have long-standing (trait) and momentary (state) forms of impulsivity face increased risks for development of substance abuse disorders. At the same time, drug use compromises impulse inhibition and contributes to continued substance use, particularly for those who have made efforts to quit using substances. Neurobiologic studies demonstrate that drug abuse is associated with inhibitory changes not only in the reward circuitry (anterior cingulate), but also in the orbitofrontal cortex, which is a brain region involved in executive functioning (40). Initial voluntary drug use is associated with prefrontal cortical function, executive control, whereas drug dependence represents a neural shift to striatal control involving dorsal striatum dopaminergic innervation. In the absence of impulse controls, a conditioned excitatory cycle of substance-related stimuli and substance availability contributes to attentional biases that favor drug-seeking behavior (41). Dopamine levels can augment conditioned learning (42). Specifically, addictive reinforcing effects of substances are dependent on the amount and the rate of dopamine increases in the striatum (42). Again, in the absence of impulse inhibitions, drug will likely be readministered. Emphasizing that impulsivity can have circular effects on substance use over time and can compound likelihood of establishment of a substance use disorder, evidence from human and animal models is generally consistent in showing feedback loops between impulsive behaviors and substance abuse, periods of abstinence, episodic relapse, and ultimately to treatment (43).

Attention Deficit Hyperactivity Disorder (ADHD)

ADHD is a psychiatric diagnosis of childhood marked by severe behavioral disruptions from pervasive problems in controlling impulses. Children diagnosed with ADHD mature

into adults who vary in the rates of continued problems in impaired inhibitory control. Among adults with substance use disorders, about one in five have ADHD diagnoses (44); between 65% and 89% of all adults who have histories of ADHD diagnoses also are diagnosed with one or more additional psychiatric disorders—most commonly with mood and anxiety disorders, substance use disorders, and personality disorders (45). Individuals diagnosed with ADHD as children who matured into adults with substance abuse disorders carry substantial genetic predisposition for both disorders (46). Interestingly, ADHD among females carries a more serious risk factor for development of substance abuse or dependence than in males. The finding is concerning when considering that a decade separates age of incidence for the two disorders, indicating females may face acute risks for developing substance use disorders as preteens (47). By contrast, while ADHD is not a significant risk factor for substance use disorders when male gender, co-occurring disruptive behavior, and socioeconomic status are controlled (48), the combination of ADHD and conduct disorder is a strong predictor (49). Danish individuals in a large cohort contacted after 40 years and who had conduct disorder and ADHD during childhood were six times more likely to develop severe alcohol dependence than those who did not have the combined disorders during childhood (50). A natural question to parents of children with ADHD is whether treating the disorder with psychostimulants might predispose their child to substance abuse or dependence in adulthood. A meta-analysis of seven studies (51) suggested that treatment had no deleterious effects and may have even extended a protective effect for children who received treatment. As children with ADHD age, treatment with psychostimulants often continues, raising the potential that these individuals may misuse or divert their medications, particularly during college years. Evidence indicates that most students use their medications as prescribed, with only a minority diverting or misusing their medications. Moreover, those who did misuse or divert their medications had co-occurring problems with impulsivity and substance abuse (52).

SOCIAL FACTORS (IN DETERMINANTS OF ABUSE AND DEPENDENCE)

Violence and Aggression

Among individuals with substance abuse and dependence, especially those who have multiple treatment and incarceration experiences, there exists a high prevalence of comorbid violence and aggression. Estimates of the incidence of violence from the NESARC sample ($N = 34,632$) showed significantly higher rates for people living with severe mental illness who are comorbid with substance abuse or dependence than those who have no comorbid conditions. Specifically, severe mental illness alone does not appear sufficient to predict future violence. Variables that correlated with violence included a significant history with violence (past

violence, juvenile detention, physical abuse, parental arrest record), comorbid substance abuse, demographic variables (young age, male gender, low income), and social contexts (recent divorce, unemployment, victimization) (53). As expected, alcohol has a strong and consistent link to violence and aggression, with associations between these variables becoming most apparent as severity of alcohol use disorders increases (54). Links between alcohol and violence are so strong and consistent that some posit that at least for alcohol and violent crime, the links approach causality (55). Rationale for such thinking is based on the observations that among individuals with historical, social, and demographic factors who also have psychiatric comorbidity, chronic and heavy alcohol use diminishes inhibitions or morals against violent or antisocial behaviors, fuels feelings of rage, constrains ability to think of options, and reduces concerns over negative consequences of behaviors—culminating in aggression and criminal behaviors. While alcohol use significantly increases risks for violence and aggression in individuals with predisposing vulnerabilities, combining illicit stimulant use with alcohol, particularly cocaine and methamphetamine, further exaggerates risks for violence. When cocaine and methamphetamine are combined with alcohol use, individuals with predisposing vulnerabilities toward violence are more likely to increase the severity and aggressiveness of their violent acts (56,57). Analyses of combined national data sets (National Household Survey on Drug Abuse, Survey of Inmates in State and Federal Correctional Facilities) showed that risks for committing a homicide were nine times greater when an individual uses methamphetamine and that these risks persist after adjusting for other drug abuse histories and sociodemographic factors (58).

Intimate Partner Violence

Violence and aggression that occurs within the context of a close interpersonal relationship, intimate partner violence (IPV), is a specialized form of violence that is gaining recognition as a social problem and that frequently co-occurs with abuse of alcohol and other drugs. In a large screening trial of women in primary health care settings in Canada, risks for IPV were approximately doubled if the woman or her partner had a drug abuse problem (59). IPV also was significantly more likely to occur among married women and women with a mental health issue. Intimate relationships are the contexts in which adults typically reveal vulnerabilities to their partners, including vulnerabilities for engaging violent behaviors when one or both partners have a predisposition and comorbid substance abuse problem or mental illness. Not all aggression is physical however. Among those predisposed and who engage in heavy drinking episodes, cocaine use, and experience depressive symptoms, psychological aggression is very common (60). The results indicate that there is a small to moderate effect size for the association between alcohol use/abuse and male-to-female partner violence and a small effect size for the association between alcohol use/abuse and

female-to-male partner violence (54). Estimates of the effect size for drug use and drug-related problems in promoting IPV are in the moderate range ($d = .27$). Cocaine use showed medium to large effect sizes in associating with psychological, physical, and sexual aggression ($d = .39$ to $.62$), though marijuana use also correlated significantly with partner aggression. Moderator analyses revealed that relative to other groups, married or cohabiting couples and Black participants showed significantly stronger effect sizes (61). In a descriptive study of home visits by police regarding IPV from Albuquerque, New Mexico, perpetrators were more likely to be male, to have witnessed IPV as a child, and to have used (in descending order) methamphetamine, cocaine, and alcohol during the episode of IPV (62). Though males remain statistically more likely to be the perpetrator, the prevalence of females as perpetrators in IPV is increasing, perhaps due to increased substance use (63).

Childhood Adversity and Family Factors

In retrospective reports, individuals with substance abuse and dependence commonly cite a range of early experiences with childhood adversities, including parental substance abuse, family violence, physical and sexual abuse, and poverty. Childhood adversities are typically studied as single occurrences, yet individuals with substance abuse disorders commonly mention more than one childhood adversity, and among those who do mention more than one adversity, the average number is four (64). Childhood adversities can vary in their relative strength to correlate with health outcomes in adulthood. One large sample of adult women interviewed in primary care settings showed strong associations between childhood sexual abuse and adult psychiatric functioning. Women who reported histories of childhood sexual abuse were significantly more likely to be abusing drugs, to have a history of alcohol abuse and to have significant psychiatric problems, including suicide attempts than their peers without such histories (65). Reflecting the range of associations with symptoms indicating psychiatric problems, women with experiences with childhood sexual abuse also were more likely to have more physical symptoms and higher scores for depression, anxiety, somatization, and lower self-esteem scores than women who had no such experiences. Efforts to refine assessment of associations between multiple childhood adversities, compared to single adversities, with adult psychiatric diagnoses and contextual risk factors (social and familial factors) are now yielding findings. In a large national probability sample, maladaptive family functioning types of childhood adversities, including parental substance abuse, family violence, physical and sexual abuse, predicted the development of and the persistence of substance abuse disorders (66). Moreover, the strength of associations between maladaptive family functioning-type childhood adversities and psychiatric comorbidities were observed throughout the life span, including in elderly respondents. Multivariate analyses of these retrospective data found no support for the

common approach to summing the number of childhood adversities to yield a severity marker, though findings do recognize the potential consequences to psychiatric functioning later in life from early adversities involving maladaptive family functioning. In less quantitative descriptions, childhood adversities combine to make the home a chaotic, unpredictable environment for children. While a significant minority of children who grow up in maladaptive family environments will as adults develop substance abuse or dependence, a majority will avoid associated outcomes as adults.

Life Stress

Adults commonly cope with stressful life events by turning to tobacco, alcohol, or other drugs to reduce psychological discomfort that accompany those stressful life events. Yet it appears relatively uncommon for even severe life stressors to be an independent major contributor to establishing a substance use disorder or worsening an existing one. In the aftermath of the attacks on New York City, PTSD and depressive disorders were detected, particularly for individuals in proximity to the event, but with minimal impact on substance use behaviors (67). As noted, some individuals respond to stressful life events with psychological responses that include experiencing negative emotional states (e.g., depression, overwhelmed) or behavioral disruptions (e.g., destroying property, physical fights). Use of substances in these episodes can both numb negative emotional states corresponding to the life stress and can intensify behavioral disruptions by increasing their destructiveness and threat levels. In adolescents, negative life events are often mediated through “hanging out” with deviant peers and participating in peers’ substance use behaviors, both of which can increase risks for development of substance abuse or dependence. Individuals with comorbid psychological disorders may be constrained in the ways in which they manage stressful life events. In a large, probability survey of community health, mental health, and well-being in Canada, women respondents living with mental disorders reportedly dealt with their stress by talking to others and eating more/less compared to men. By contrast, men with mental disorders were more likely to avoid people and drink alcohol to deal with stress than women (68). At least one example exists of stress exaggerating substance use in an analysis of data from the 2002 National Survey on Drug Use and Health. In that report, adults who reported experiencing serious psychological distress at the time of the survey had greater odds of lifetime, past month, and daily use of cigarettes and other tobacco products than adults without serious psychological distress. As well, those with serious psychological distress were more likely to be nicotine dependent and were less likely to quit or to be former smokers than those without serious psychological distress (69). Findings do not address the question, however, of whether respondents with serious psychological stress were predisposed to heavier use of tobacco products. In perhaps the only prospective test of longitudinal data in adolescents

maturing to young adulthood, youth who experienced stressful life events during adolescence showed increases in both negative emotional states and externalizing symptoms (e.g., behavioral disruptions), though analyses showed that externalizing symptoms alone mediated later effects of stressors on the development of drug dependence in young adulthood (70).

Social Attachment

Development of substance abuse and dependence is less frequent in individuals who have strong social attachments to their families and their culture, including the institutions within the culture. This influence is apparent even among criminals. In an analysis of a large national sample of male arrestees drawn from 24 urban areas, individual social attachments to marriage and to the labor force represented the principal pathway for mediating substance abuse and aggression. Only a minority of the variance in explaining substance abuse and aggression was accounted for by female-headed households and by households receiving welfare support (71), which are factors popularly promoted as explanations of substance abuse and dependence in urban areas. Social attachments also appear to protect against development of substance use disorders among adolescents growing up in families in which the father is an illicit drug user. Among Hispanic adolescents in such families, the father’s level of marijuana and/or methamphetamine use was unrelated to the youths’ bonds with their families. Instead, family bonding was positively influenced by youths’ commitment to their communities and adoption of cultural values and of respect for elders/family (72). Among adolescents, poor family attachment, poor school attachment, involvement with friends who use drugs, and a student’s own use of drugs are predictors in substance use disorders. Moreover, poor family attachments appear to influence youth’s drug use via poor school attachment and involvement with friends who use drugs. By contrast poor school attachment exerts its effect on drug use through involvement with friends who use drugs (73).

SUMMARY

The data presented describe many of the ways in which substance use, abuse, and dependence can be established via factors ranging from use of multiple and other substances to comorbid psychiatric conditions to psychological states to social, cultural, and familial conventions and mores. When available, effect sizes for these factors in establishing substance abuse and dependence generally ranged between weak to moderate sizes. This indicates that across our diverse populations, there are neither psychological factors nor social determinants of drug abuse and dependence that approach causality. To illustrate this heterogeneity, clients seeking treatment commonly cite many and differing reasons that they attribute to their initially becoming involved with their drug(s) of choice. Once abuse and dependence take over, and the neurobiologic and behavioral processes common to

addiction predominate, the ranges of voices of clients begin to harmonize and the principle reason for seeking treatment becomes very simple and universal: “to get my life back.”

Much of human behavior is maintained and modifiable by its consequences through the process of operant conditioning (1). Under this process, some consequences of behavior, called reinforcers, increase the probability that a person will repeat a behavior in the future. Reinforcement is a fundamental process that affects the behavior of a vast range of creatures, from organisms as simple as a sea slug (2) to insects, fish, reptiles, birds, and mammals (3). Sensitivity to reinforcement has clear adaptive value and has probably evolved through natural selection (4). Reinforcement is deeply involved in shaping much of human behavior, from simple activities like walking, turning a doorknob, and riding a bicycle; to complex behaviors like writing, conversing, and composing music (1,5). Early theory (1) and an extensive body of experimental research suggest that the extended pattern of behavior that we call drug addiction, like much of human behavior, is also operant behavior that is maintained by its consequences.

Evidence that the instances of drug addiction we observe in society and treat in our clinics are operant in nature is necessarily indirect. Those instances of addiction develop through some unknown and uncontrolled history of experience and are typically observed by clinicians only after they are well established. Knowing with confidence the factors that produced or currently control a specific instance of addiction may not be possible. However, extensive experimental research conducted over more than four decades provides strong evidence that drug addiction *can* be operant behavior that, like many other human behaviors, is maintained and modifiable by its consequences. This research provides a plausible basis for conceptualizing instances of drug addiction that we see in society as operant behavior. The evidence can be grouped into three broad categories: laboratory models of drug addiction showing drugs are reinforcers that can modify and maintain the behavior of animals and humans; laboratory studies demonstrating the sensitivity of drug use to nondrug consequences; and clinical studies demonstrating the sensitivity of drug addiction to its consequences. This body of laboratory and clinical research has both theoretical and clinical implications. Theoretically, the research provides a framework for understanding drug addiction. Clinically, the research suggests the types of environmental conditions that can lead to the development of drug addiction, and the types and parameters of interventions that could be effective in treating drug addiction. This chapter reviews key experimental research on the operant nature of drug addiction and discusses the theoretical and clinical implications of that research.

Operant conditioning includes four basic elements: an antecedent stimulus, a response, a consequence, and a contingency that specifies the relationship between the other three elements. In a typical laboratory arrangement with a rat as an experimental subject, the antecedent stimulus might be a green light, the response a lever press, and the consequence a food pellet. The contingency might specify that each lever press emitted when the green light is illuminated will produce a food pellet, and that lever presses emitted when the green light is not illuminated will not produce food pellets. If this contingency produces an increase in the frequency of the lever pressing, the food pellets are called reinforcers and the process is called reinforcement. With sufficient exposure to the contingency, lever presses can become common in the presence of the illuminated green light and rare when the green light is not illuminated. If, as a result of the contingency, lever pressing becomes more common when the green light is on than when it is off, then the green light is called a discriminative stimulus. The process whereby discriminative stimuli come to alter the probability of responding is called stimulus discrimination. Certain motivational variables called establishing operations (5) can alter the effectiveness of a reinforcer. In our illustrative example, food deprivation can increase the effectiveness of food pellets to reinforce lever pressing or increase the frequency of lever pressing after reinforcement has occurred; food satiation can have the reverse effects. Research conducted over the past 70 years in the experimental analysis of behavior has revealed in exquisite detail how operant processes shape and maintain behavior, as well as the broad generality of the principles of operant conditioning (5).

LABORATORY MODELS OF DRUG ADDICTION

Early laboratory research in nonhuman subjects provided strong evidence that drug addiction can be viewed as operant behavior maintained by drug reinforcement (6). These studies demonstrated that nonhuman subjects could acquire and maintain behavior that led to the administration of a variety of drugs via a variety of routes of administration. In the typical laboratory arrangement, in the presence of some discriminative stimulus (e.g., a light), a laboratory subject is required to make one or more responses (e.g., lever presses) to receive a single administration (e.g., an intravenous infusion) of a drug. Over the course of an experimental session, the subject has repeated opportunities to respond and receive drug

administrations. The responses required to produce drug administrations are conceptualized as drug seeking and the administration of the drug as drug use.

Laboratory models of drug addiction in nonhumans provide a unique and rich source of information on the nature of drug addiction and the variables that affect it. This research allows investigation of drug use in drug-naive organisms, and the rigorous experimental control of key variables that might influence drug use. This body of research has added to our understanding of drug addiction and to the development of effective behavioral and pharmacologic treatments for drug addiction. One seminal study by Deneau, Yanagita, and Seevers (7) showed that drug-naive monkeys would reliably press a lever that produced infusions of any of a variety of drugs that are commonly abused by humans (morphine, codeine, cocaine, morphine-cocaine, amphetamines, pentobarbital, and ethanol), but that they would not press a lever that produced infusions of saline or drugs that are not abused by humans (nalorphine or chlorpromazine). Animals in this study could press one lever that produced drug infusions or a different lever that did not produce infusions. Drug-naive animals were given continuous access to a drug under this arrangement and were monitored over extended periods of time. Seven of ten monkeys initiated and sustained lever pressing when lever presses produced 2.5 mg/kg infusions of morphine; the remaining three monkeys began morphine-maintained lever pressing after being exposed to periodic (every 4 hours) experimenter-administered infusions of morphine. Monkeys showed progressive increases in the total daily dose administered over several weeks; they maintained regular diurnal patterns of administration, characterized by high intake during the day and low or no intake at night; none of the animals discontinued lever pressing; and the animals maintained good overall health over time. Two of four monkeys initiated and sustained lever pressing when presses produced 0.25 mg/kg infusions of cocaine, and the two who did not initiate lever pressing at that dose initiated pressing when the dose was increased to 1.0 mg/kg. The monkeys showed a rapid increase in cocaine self-administration, although the pattern of self-administration over days was erratic. Remarkably, monkeys continued self-administration of cocaine despite severe toxicity, including biting of their skin and fingers to the point of amputation, and died within 30 days. None of four monkeys initiated self-administration of nalorphine; none of six monkeys initiated self-administration of chlorpromazine and despite “frequent attempts, including the use of raisin inducements,” no animals self-administered physiologic saline. This pioneering work provided an impressive outline of the nature of drug reinforcement in laboratory animals. The study showed that only some drugs are reliably self-administered (e.g., morphine and cocaine are, but nalorphine and chlorpromazine are not); that saline is not self-administered; that the daily and hourly patterns of self-administration differ across drugs; that there are individual differences across monkeys in the propensity to acquire drug self-administration; and that animals will self-administer drugs like cocaine despite severe adverse consequences, up to and including death.

Operant Analyses of Drug Use: Experimental Examinations

Experimental studies in nonhumans and humans have provided thorough analyses of the roles of the basic elements of operant conditioning in drug self-administration. These studies confirm the operant nature of drug addiction and illustrate the critical role of operant conditioning in drug use.

The Reinforcer

A classic review of laboratory research on drug reinforcement showed that animal and human subjects in laboratory settings self-administer the same range of drugs that are commonly abused in society (8). Reviews published since that paper have shown that nonhumans and humans will self-administer most commonly abused drugs, including although not limited to cocaine (9,10), opiates (11), alcohol (12), benzodiazepines (13), nicotine (14), and marijuana (15).

Experimental Demonstrations of Reinforcement A central issue underlying operant laboratory models of drug addiction is whether persistent drug use is operant behavior maintained by drug reinforcement. Do drugs function as reinforcers that maintain drug seeking and drug self-administration? To determine whether reinforcement is responsible for drug self-administration, studies must experimentally manipulate the contingent relation between responding and reinforcer presentation. If responding occurs only when the drug is presented contingent on responding, it provides evidence that drug reinforcement is critical in maintaining responding and that the drug self-administration is operant in nature.

Many studies have provided strong experimental evidence that drug self-administration in laboratory animals is operant in nature. In one recent study (16), rats were studied in a chamber with two holes through which they could poke their noses. One hole was designated as active and the other inactive. Nose pokes through the active hole produced cocaine infusions during some conditions, whereas nose pokes through the inactive hole never produced cocaine infusions. Nose pokes through the inactive hole remained extremely low throughout the experiment. Initially, nose pokes in the active hole produced intravenous infusions of cocaine. Nose pokes in the active hole increased quickly for both doses, but nose pokes in the inactive hole did not increase. When cocaine was replaced with saline, nose pokes in the active hole decreased abruptly and significantly to a level that was comparable to the inactive hole. When cocaine then replaced saline, nose pokes abruptly increased again in the active hole. Finally, when saline again replaced cocaine, nose pokes in the active hole decreased again. This study showed that responding in the study rats increased only when cocaine infusions were presented contingent on nose poking and not when saline infusions were contingent, and that the topography of nose poking (i.e., poking in the active versus the inactive hole) was a product of the cocaine contingency. These data provided

strong evidence that cocaine reinforcement maintained cocaine self-administration in these rats.

A particularly informative way to assess reinforcement is to compare responding when a reinforcer is presented contingent on a response to when the same reinforcer is presented according to the same rate and pattern but independent of responding. This kind of experimental design allows researchers to isolate the role of the behavioral contingency. If responding is maintained at higher rates when a reinforcer is presented contingent on responding than when it is presented independent of responding, it provides firm evidence that the responding is maintained by reinforcement, and is not simply a product of the direct pharmacologic effects of the drug. Numerous studies with nondrug reinforcers have shown that response-contingent presentation of the reinforcer is essential to increase and maintain responding (2,17). A few recent studies have provided clear demonstrations of cocaine (16,18) and morphine (16) reinforcement in rats using noncontingent control conditions. In one of those studies (18), 20 rats were randomly assigned to master and yoked groups. Reinforcement contingencies were arranged for “master” rats in which nose pokes through one (the active hole) of two holes in the chamber produced a cocaine infusion. The number of nose pokes through the active hole required for each cocaine infusion was increased from one to five. Each master rat was paired with a “yoked” rat that received cocaine infusions that were identical in pattern and amount to the infusions received by the master rat; the only difference was the cocaine infusions experienced by a yoked rat occurred independently of whether the yoked rat poked its nose through either of the two holes in the chamber. After several sessions, cocaine was replaced with saline. Figure 7.1 shows the rate of nose poking in active and inactive holes by the master and yoked rats. The figure shows that during the cocaine reinforcement period, nose pokes in the active hole by master rats increased dramatically to a level that was significantly higher than their rate of nose pokes in the inactive hole. Furthermore, when saline replaced cocaine, nose poking in the active hole decreased to a near-zero level. In marked contrast, yoked rats never showed an increase in nose poking in either the active or the inactive holes. This study showed that *contingent* cocaine infusions could reinforce nose poking: nose poking only increased in rats when cocaine infusions were presented contingent on responding, only in the active hole on which reinforcement was contingent, and not when cocaine was presented independent of responding or when cocaine was replaced by saline.

Studies in humans using some of the same control conditions have demonstrated reinforcement by a number of drugs of abuse (8,10,13–15). These studies have used a variety of controls to demonstrate reinforcement, including placebo control conditions and reinforcement of selected response topographies (e.g., left vs. right response choices).

Parameters of the Reinforcement Contingency As with nondrug reinforcers (19), key parameters of the reinforcer and its delivery can modulate drug reinforcement. Immediacy and magnitude of reinforcement are two factors that seem

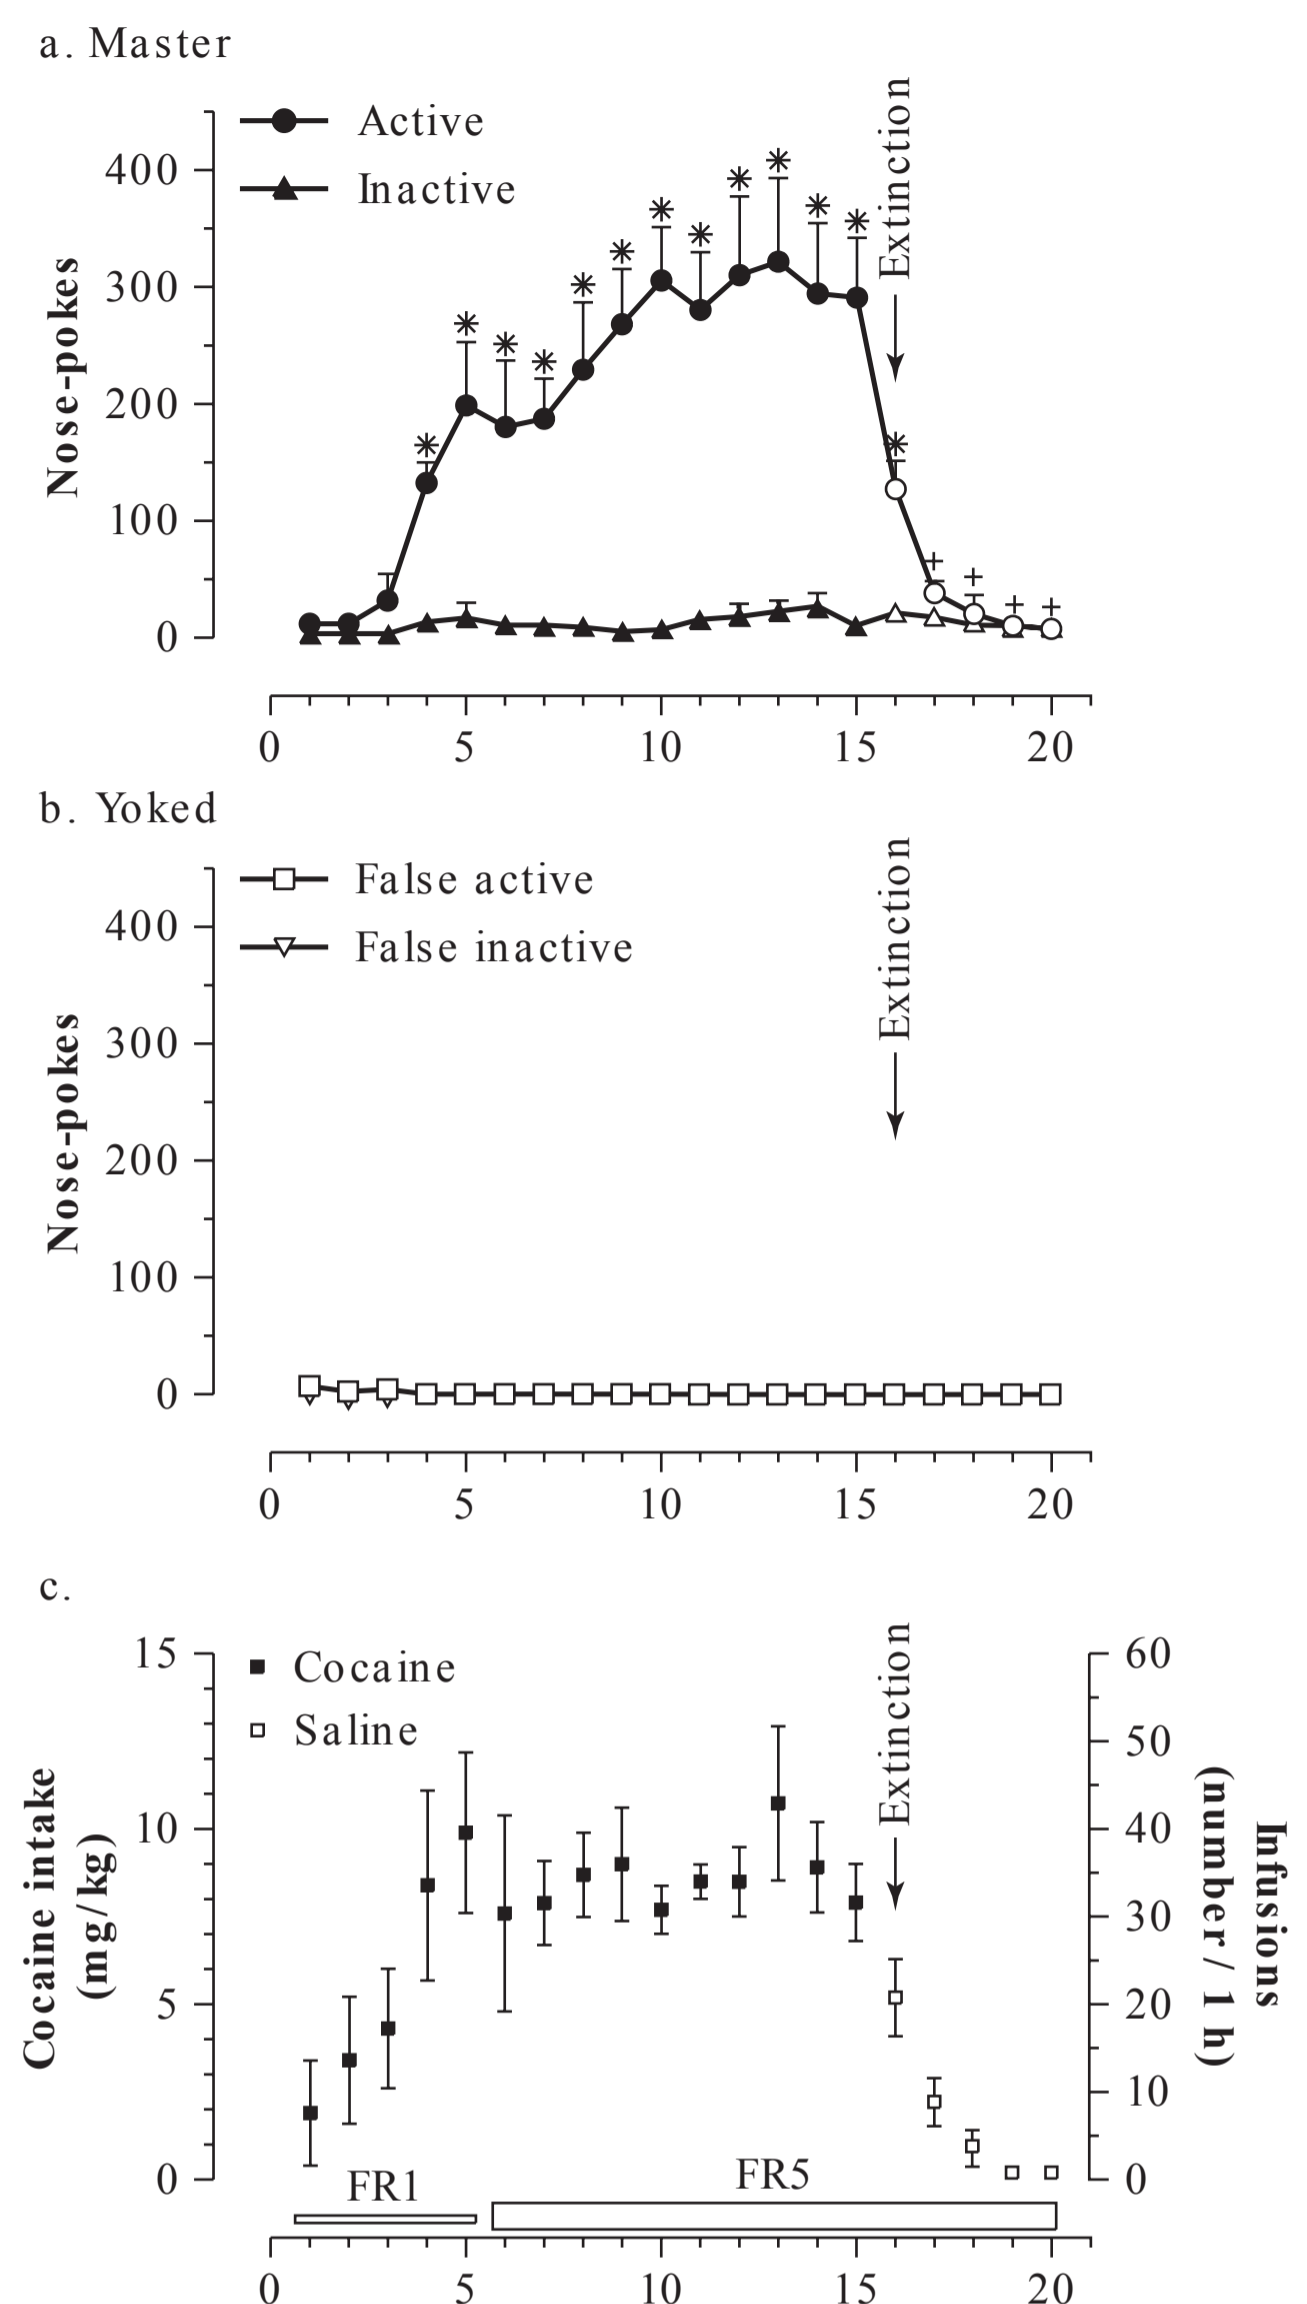

Figure 7.1. A: Cumulative responses (nose pokes) during cocaine self-administration and extinction (master rats). Results are expressed as mean \pm SEM of cumulative nose pokes in the active and inactive holes of $n = 6$ master rats (1st–20th day). Asterisk denotes $p < 0.05$ versus inactive nose pokes, a plus sign denotes $p < 0.05$ versus the corresponding active nose pokes on the 15th day of cocaine SA session. ANOVA followed by Tukey post hoc test. B: Cumulative responses (nose pokes) during passive cocaine and saline administration in rats yoked to the self-administering ones. Results are expressed as mean \pm SEM of cumulative nose pokes in the false active and inactive holes of $n = 6$ yoked rats (1st–20th day). C: Daily cocaine intake and number of infusions during cocaine self- and yoked administration and during extinction. Intake of cocaine, expressed as milligrams per kilogram of cocaine, during each 1-h daily 1st–15th sessions (left Y-axis filled squares). Data are also expressed as number of infusions of cocaine (filled squares) during the corresponding day session (filled squares) or saline (open squares) during the extinction phase (16th–20th days, right Y-axis). (Reproduced from Lecca D, Cacciapaglia F, Valentini V, et al. Differential neurochemical and behavioral adaptation to cocaine after response contingent and noncontingent exposure in the rat. *Psychopharmacology (Berl)*. 2007;191(3):653–667, with permission.)

particularly important. Increasing the delay between response and reinforcer typically diminishes reinforcement effects. One study compared the cocaine reinforcement effects produced when cocaine doses were administered to rhesus monkeys over varying durations (20). That study showed that the amount of responding maintained by cocaine reinforcement increased as the infusion duration decreased, suggesting the faster onset of drug effects increased drug reinforcement.

Assessing the effects of reinforcement magnitude can be complicated. In drug reinforcement, the magnitude of reinforcement can be increased by increasing the dose of the drug. Very high doses of some drugs can have aversive effects, or can lead to satiation, or performance impairment, all of which can affect measures of drug reinforcement (see the section “Regulation of Drug Intake”). However, assessments that mitigate those effects typically show that higher drug doses are more effective reinforcers than lower doses. For example, when subjects are given a choice between two doses of a reinforcing drug, they typically choose the higher over the lower dose (21). Higher doses also can sustain higher amounts of responding when the response requirement for reinforcement is increased (see the section “Drug-Seeking Response”) (22).

The Discriminative Stimulus

In the lives of drug users, certain environmental events seem to serve as triggers that prompt drug seeking and drug use. In one study of methadone patients (23), over 80% of the participants said that having the drug present, being offered the drug, and having money available were likely to lead to drug use. These stimuli or events probably acquired their “triggering” function in large part through operant conditioning. These stimuli are all present when drug seeking and drug taking occurs, and they are typically less common or absent when drug taking does not occur. The availability of money, for example, frequently sets the occasion for a chain of drug seeking behaviors that leads to drug use and drug reinforcement. Thus, the money in the example may come to serve as a discriminative stimulus, whose presence increases the probability of drug seeking and drug taking. In the prototypic laboratory study, the role of discriminative stimuli in drug seeking and drug taking is modeled using arrangements in which two (or more) stimuli are presented in alternating periods. When one of the stimuli is present, drug-seeking responses (e.g., lever pressing) produce drug administrations (e.g., infusions; reinforcement), but when the other stimulus is present responses do not produce drug administrations (i.e., extinction). As with reinforcement by nondrug reinforcers (5), laboratory studies have shown that discriminative stimuli can dramatically influence drug seeking and drug taking.

Discriminative Stimuli and Drug Self-Administration The power of discriminative stimuli to influence drug seeking and drug taking was dramatically illustrated in a study in which rats’ lever presses were reinforced with intravenous cocaine infusions when a tone or a light was on, but not when the tone and light were off (i.e., differential reinforcement) (24). Tests were then conducted in which the light and tone

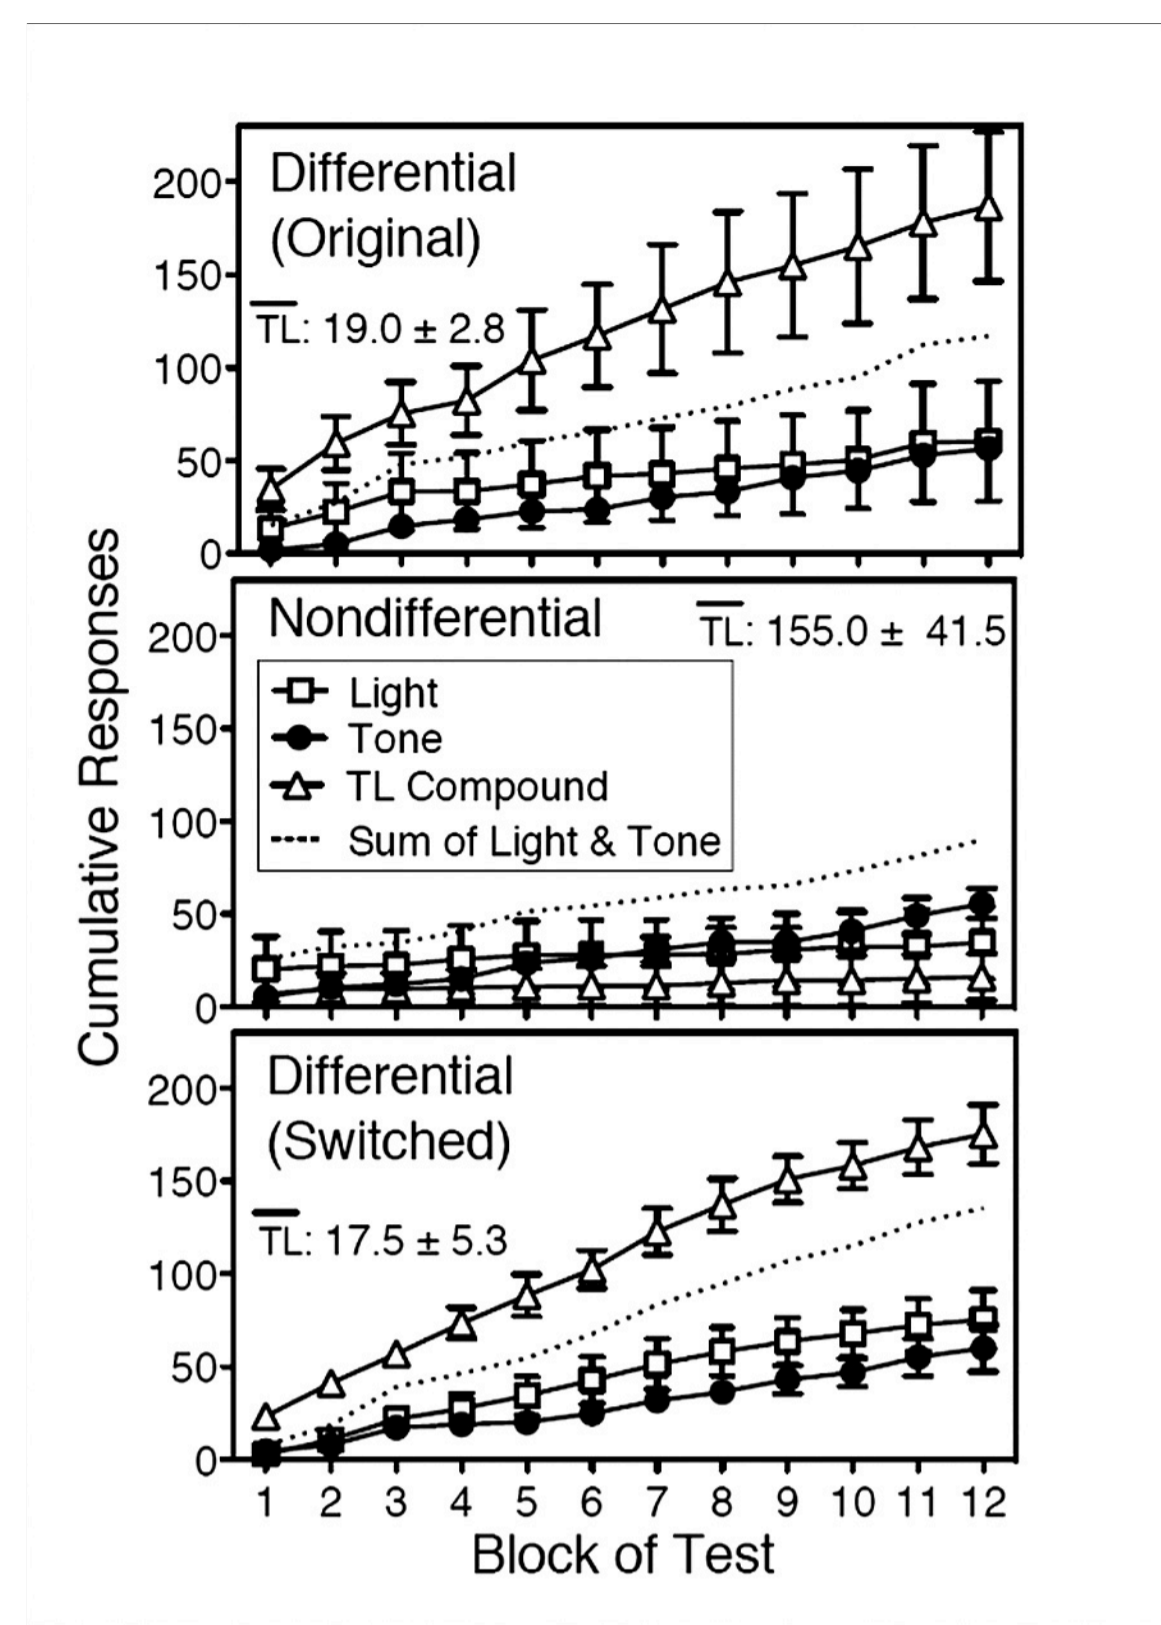

Figure 7.2. Results of stimulus-compounding tests performed in extinction for the rats originally given differential training (Differential group; *upper panel*) and for rats in the nondifferential group after nondifferential training (*center panel*) and after being switched to the differential schedule (*lower panel*). Data presented as mean cumulative number of responses (\pm SEM) by blocks in tone, light, and the tone-light (TL) compound. Dotted lines represent the sum of the tone (T) and light (L) curves. Mean (\pm SEM) number of responses in the absence of tone and light (TL) over the entire test is indicated numerically for each condition. During each block, tone, light, and tone-plus-light were each presented for 1 minute, and the (TL) was presented for a total of 3 minutes. (Reproduced from Panlilio LV, Weiss SJ, Schindler CW. Cocaine self-administration increased by compounding discriminative stimuli. *Psychopharmacology (Berl)*. 1996;125(3): 202–208, with permission.)

were each presented alone and together. In tests in which cocaine infusions were not provided, the rats showed a threefold increase in the rate of lever pressing when the tone and light were presented together above the rate when either of those stimuli was presented alone (see Fig. 7.2, top panel; differential reinforcement). In subsequent tests in which cocaine infusions were provided contingent on lever pressing, the rats showed a twofold increase in the amount of cocaine intake when the tone and light were presented together compared to when either of those stimuli was presented alone (data not shown). Importantly, compounding the two stimuli did not increase lever pressing in rats who had undergone training in which the tone and light were presented at random times, unrelated to the availability of cocaine reinforcement (nondifferential reinforcement,

middle panel). When those rats were subsequently exposed to a differential reinforcement condition similar to the rats in the original group, combining the tone and light had the similar effect of dramatically increasing the rate of lever pressing above the rates observed when each stimulus was presented alone (Fig. 7.2; bottom panel, differential reinforcement). Similar effects of compounding discriminative stimuli can increase heroin-maintained responding and heroin intake, as well as food-maintained responding and food intake. These studies provide clear evidence of the remarkable influence that discriminative stimuli can exert over drug seeking and drug taking.

An Operant Account of Reinstatement For over 30 years, researchers have investigated a laboratory model of relapse called the reinstatement model (25). Under this model, subjects experience self-administration sessions in which a drug-seeking response (e.g., lever pressing) produces drug administrations. After drug seeking and drug self-administration are established under this arrangement, the drug-seeking response is extinguished, typically by replacing the drug with saline or vehicle. In subsequent test sessions, noncontingent administrations of the drug (or of stimuli that were associated with the drug) produce increases in responding above the level of responding when the drug is not presented and above the level of responding when saline or vehicle is administered. In general, reinstatement of responding increases as a function of the dose of the drug tested, the similarity of the test drug to original training drug, and whether the drug is presented alone or in combination with stimuli that were associated with drug administration in the original training sessions (25).

From an operant perspective, a drug that has a reinforcing function (as a consequence) can also acquire a discriminative function (as an antecedent). In drug self-administration sessions, as in other studies of operant reinforcement, the reinforcer is presented contingent on responding on given trials, but it also precedes responding on subsequent trials. Through this arrangement, reinforcers can acquire discriminative functions for subsequent responding. Similar to the studies of drug reinstatement described above, several studies have shown that noncontingent presentation of nondrug reinforcers could reinstate extinguished responding in rats (26,27), pigeons (26), college students (26), developmentally delayed individuals (28), and baboons (29). These studies showed that the reinstated responding occurs uniquely in response to the presentation of the reinforcer, and did not occur when selected other novel stimuli are presented. One study explicitly established the reinforcers as discriminative stimuli (27). In that study, rats were exposed to sessions in which periods of availability of standard food pellets and sucrose pellets alternated. When standard food pellets were available, only left lever presses produced reinforcement, whereas when sucrose pellets were available, only right lever presses produced reinforcement. By the 35th session, the rats shifted their responses throughout the session in concert with the shifting

availability of the different kinds of pellets. When food pellets were provided, the rats made more left-lever presses; when sucrose pellets were available, the rats made more right-lever presses. The results obtained in this study showed that the type of pellet acquired discriminative stimulus and reinforcing functions, and provided experimental evidence that a stimulus can simultaneously serve as a reinforcer and a discriminative stimulus.

Drug-Seeking Response

In general, drug self-administration varies as a function of the effort or price required to procure the drug. In laboratory studies with nonhuman subjects and sometimes with human subjects, this phenomenon is investigated by modulating the number of responses required for each drug administration. While the precise relationship between consumption and response requirement can differ as a function of a variety of conditions, extensive laboratory research in nonhuman and human subjects confirms that consumption of a particular reinforcer generally decreases as the number of responses required for reinforcement increases (22).

If the number of responses required for reinforcement is increased progressively, nonhuman and human subjects will typically reach a response requirement where they stop responding to drug. The point at which a particular subject stops responding is called a breaking point and has been used widely as a measure of the strength of a reinforcer. In a seminal study (30), rats could press a lever to receive sweetened condensed milk, but the number of responses required for each reinforcer increased progressively within the session. When the concentration of the sweetened condensed milk was varied in a random order across days for two rats, breaking points for both subjects increased as the concentration increased. Furthermore, when the total amount of food consumed each day for two other rats was decreased to reduce their body weight, the breaking points increased as their body weights decreased. Analyses of breaking points have been used extensively to study variables that modulate drug reinforcement (31,32).

In general, as the number of responses required for a given dose of a drug increases, intake of that drug decreases (22). Frequently, as the number of drug-seeking responses required for each drug administration increases, overall responding increases in a way that produces a relatively small decrease in the overall intake of the drug. However, at some point, progressive increases in the response requirements will produce more dramatic decreases in response rate and overall drug intake (22).

Establishing Operations

Certain motivational variables called establishing operations can affect the reinforcing effectiveness of a stimulus (5). The effects of deprivation and satiation in increasing and decreasing, respectively, reinforcement-maintained behavior have been recognized for many years and have been demonstrated for behaviors maintained by a variety of reinforcers, from food

reinforcement in rats (30) to social reinforcement in children (33). As with nondrug reinforcers, drug reinforcement can be modulated by a variety of establishing operations.

Early studies of drug reinforcement in nonhuman subjects showed that chronic administration of opioids can produce physical dependence and can serve as a robust establishing operation that modulates the reinforcing effects of opioid drugs (6,11,34). While it quickly became clear that drugs can serve as reinforcers in individuals who are not physically dependent, research conducted over the past 40 years shows that self-administration of opioid drugs like heroin can be increased in opioid-dependent subjects after a period of forced abstinence or after the administration of an opioid antagonist. Provision of opioid agonists prior to self-administrations can also decrease opioid reinforcement (35). Several studies in humans have shown that the behavioral requirements following drug administration can modulate the reinforcing effects of a drug (13). In one study, for example, reinforcement by the sedative triazolam was increased when participants were required to lie down and rest following drug administration, whereas amphetamine reinforcement was increased when participants had to perform a vigilance task following drug administration.

Regulation of Drug Intake As illustrated in the study by Deneau and colleagues described above (7), when laboratory animals are given unrestricted and continuous access to drugs, patterns of drug use emerge that appear specific to the drug and frequently lead to severe toxic consequences up to and including death. However, many laboratory studies impose constraints on drug consumption by, for example, restricting the duration of study sessions or the number of drug administrations allowed. In these laboratory studies, animals and human subjects frequently show patterns of drug use that have been reasonably described as regulated. Under those conditions, animals tend to respond in ways that maintain a relatively constant overall amount of drug over time (21). Increases in the dose of the drug, for example, increases the pausing between responses and thereby increases the duration of the interval between self-administered doses. Lynch and Carroll (21) suggested that regulation of drug intake is controlled by aversive effects of high drug intake that subjects might avoid or escape; direct effects of high drug intake that might directly diminish response rates; and a satiation that occurs with high drug intake and that produces an establishing condition which might diminish the momentary reinforcing value of the drug, similar to the effects of satiation with food or other reinforcers.

Modulation of Drug Reinforcement by Nondrug Consequences

Drug use occurs in complex environments. Drug users engage in many behaviors, of which drug use is only one. These behaviors have varied consequences; and drug reinforcement is only one of those consequences. An extensive body of

laboratory research in nonhuman and human subjects has shown that drug self-administration can be modulated by nondrug consequences when those consequences are arranged directly on the drug self-administration behaviors, and when those consequences are arranged contingent on other behaviors.

Punishment

Behaviors can have both positive and potentially unpleasant consequences. Sweet and bitter tastes in foods might function to increase or decrease, respectively, the eating of different foods. The discussion above has focused on reinforcers, the consequences of behavior that increase the future probability of those behaviors. Here we focus on consequences that decrease the future probability of behaviors. When an event is presented contingent on a behavior and that contingency decreases the future probability of that behavior, the event is called a punisher and the process is called punishment. Research on punishment has shown that events like electric shock can have profound and very orderly effects on operant behavior (5).

In an early study, Grove and Schuster (36) examined the effects of punishment on cocaine self-administration in rhesus monkeys. That study showed that cocaine self-administration was decreased when brief electric shocks were administered along with cocaine administrations contingent on lever pressing. Furthermore, the study showed clearly that the rate of shocked responses decreased as the shock intensity increased.

Relatively little research has been done to evaluate the effects of punishment on human drug taking; however, some classic studies were conducted by Bigelow, Griffiths, and Liebson in the 1970s that demonstrated that alcohol use is sensitive to punishment (37). In one of those studies, 10 “chronic alcoholics” were invited to participate while residing on a residential research unit. Participants were allowed to drink between 12 and 24 drinks (the maximum number differed for different participants). Using a within-subject reversal design, the study evaluated the effects of contingent isolation on alcohol drinking. After an initial baseline period, participants were exposed to a Contingent Isolation condition in which they were required to go to an isolation booth for 10 to 15 minutes immediately after receiving a drink; six of the participants were exposed to a second baseline condition. The study demonstrated clear and substantial decreases in alcohol drinking during the Contingent Isolation condition. Although there was variation in the amount of suppression, on average participants decreased drinking by 50% of the baseline period; drinking was almost completely suppressed in two participants; and only one participant showed no decrease.

Reinforcement of Alternative Behaviors

Organisms engage in a range of behaviors that are maintained by different reinforcers. Drug users, for example, may engage in behaviors to obtain and use drugs; but they also eat, sleep, talk, work, and play, all under the control of different reinforcers. Organisms continually make choices between

reinforcers and distribute their behavior accordingly. A large body of research conducted in laboratory studies suggests that nondrug reinforcement for behaviors that are alternatives to drug use can decrease drug use.

Extensive research, primarily conducted in nonhuman subjects, has shown that organisms distribute their behaviors among available alternatives in ways that increase, and possibly maximize, their overall rate of reinforcement. Research conducted over the past 40 years has generally confirmed a principle proposed by Richard Herrnstein (19) called the matching law that explains how reinforcement rates for different behaviors affect choice. Highly controlled laboratory studies in which subjects have multiple response options have shown that, in general, the relative rate of responding for any response option is equal to the relative rate of reinforcement obtained for that option. Importantly, this relationship is very precise and quantitatively predictable and has been observed in diverse species, including in humans.

The matching law is relevant to understanding and treating drug addiction, because it suggests that drug use could be decreased by arranging nondrug reinforcers for behaviors that would be alternatives to drug seeking and drug use. Indeed, one study showed that when rhesus monkeys were given opportunities to respond for food or cocaine, the matching law provided a good description of how the monkeys distributed their responding across those two options (38).

In matching studies, subjects are generally free to engage in either of two (or more) responses in the same time interval, they can alternate responses continually over time, and obtaining reinforcement for one response option does not preclude obtaining reinforcement for the other option. Many related studies have been conducted in which subjects are given mutually exclusive choices between drug and nondrug reinforcers. In these studies, on repeated trials, the subject can choose to take the drug or the nondrug alternative; taking one option precludes taking the other. This research has shown that drug taking can be decreased dramatically by offering nondrug alternative reinforcers (39). In this paradigm, alternative reinforcers have been shown to decrease use of most commonly abused drugs, including alcohol, cigarettes, cocaine, opiates, benzodiazepines, and in diverse species including rats, monkeys, and humans. Importantly, drug use decreases as the magnitude of the alternative reinforcer increases (35,40).

Validity of the Laboratory Model of Drug Addiction

Are demonstrations of drug self-administration in laboratory animals and humans qualitatively similar to clinical instances of drug addiction? We probably cannot answer this question definitively, but data collected in selected studies provides some evidence of the validity of the laboratory models of drug addiction. First and probably most persuasively, several early studies showed that laboratory animals will self-administer some drugs persistently, despite serious adverse consequences. As noted above, Deneau and colleagues (7) showed that monkeys continued self-administration of cocaine despite severe

toxicity, including biting of their skin and fingers to the point of amputation and death within 30 days.

More recently, researchers studying nonhuman models of addiction (41–43) have developed intriguing models that attempt to apply the clinical criteria for addiction to classify their subjects as addicted or not, including the adaptation of formal clinical criteria for drug dependence. Under one model (41), rats are given repeated opportunities over many sessions to self-administer cocaine under a simple schedule in which nose pokes through a hole in a chamber wall produce infusions of cocaine. Within each session, periods of cocaine availability are signaled by the illumination of a blue key light and alternate with periods in which nose pokes do not produce cocaine infusions; periods of nonavailability are signaled by darkening of the key light and the illumination of the chamber. To assess whether individual rats meet criteria for addiction, three tests were administered. The first test assessed whether the rat “has difficulty stopping drug use or limiting drug intake.” Under this test, the experimenters measured the rats drug seeking (i.e., nose pokes) during the signaled periods within sessions when cocaine is not available. The second test assessed whether the rat had “an extremely high motivation to take the drug, with activities focused on procurement and consumption.” Under this test, cocaine was available to subjects under a progressive ratio schedule in which the number of responses (nose pokes) required for each cocaine infusion increased progressively across the session; the measure of “addiction” was the breakpoint, or the maximum number of responses that the rat made before responding stopped. The third test assessed the extent to which cocaine use is “continued despite its harmful consequences.” To assess this, the experimenters measured the rat’s persistence of cocaine-reinforced responding when responses (nose pokes) were also punished with electric shocks. This arrangement yielded a variety of intriguing observations on the nature of drug self-administration in laboratory animals. Perhaps most interestingly, this research has shown that there is considerable variability in the amount and persistence of drug self-administration both across and within rats. In one study (41), rats were categorized based on the amount of cocaine-seeking responses emitted on the three tests of “addiction”; rats in the 66th to the 99th percentile of each test were considered to be positive for that cocaine addiction criterion. Almost half the rats (41.4%) were not positive for any of the criteria and only a minority (17%) was positive for all three criteria.

Interestingly, the presence or absence of the more extreme and persistent patterns of cocaine self-administration can also vary within individual rats, and appears to be related to a number of parameters of the drug self-administration sessions, such as the duration of cocaine self-administration sessions (42), the number of drug self-administrations sessions, and the duration of the cocaine injections (43). These individual differences in cocaine self-administration provide interesting parallels to human drug use and addiction.

The various models of addiction described in this research demonstrated that some individuals show more persistent

drug use than others, and that certain environmental conditions can lead to more persistent or higher levels of drug use. These are important and interesting observations. However, it is important to note that drug use of “addicted” individuals still appears to be operant behavior that is maintained by drug reinforcement and is sensitive to nondrug consequences (41). Furthermore, in these studies, the designation of “addicted” or “compulsive” seems to convert characteristics that vary on a continuum to dichotomous groupings. While some individuals may be more sensitive to drug reinforcement than others, either due to unspecified biologic differences or due to different environmental histories, even the behavior of the most “addicted” or “compulsive” rats appears sensitive to its consequences and operant in nature.

OPERANT MODULATION OF DRUG USE IN CLINICAL POPULATIONS

Laboratory research shows that drug self-administration can be viewed as operant behavior that is maintained by drug reinforcement and modifiable by the same range of environmental events that affect other operant behavior; however, the relevance of the laboratory research to understanding human drug addiction is not certain. Importantly, clinical research on the effects of environmental interventions provides additional support that drug addiction is operant behavior and sensitive to its consequences. Two types of environmental interventions are particularly informative: (1) interventions that increase the price of a drug and (2) abstinence reinforcement interventions that provide nondrug reinforcement contingent on drug abstinence.

Population level analyses of the effects on price on cigarette smoking have shown that increases in prices can decrease cigarette smoking, particularly among low-income populations and adolescents (44). These data are consistent with studies of drug reinforcement described above that show that an increase in the number of responses required for drug reinforcement, and a laboratory analog of price, can decrease drug self-administration.

For about 40 years, researchers have studied the effectiveness of interventions that arrange for the direct reinforcement of drug abstinence (45). Under these procedures, patients receive a desirable consequence contingent on providing biologic evidence of drug abstinence (e.g., drug-free urine samples). These procedures have proven to be among the most effective behavioral or psychosocial treatments for drug addiction (46). In addition to demonstrating the clinical utility of the operant approach, these studies also show that persistent drug use is sensitive to its consequences and operant in nature.

Some of the clearest data come from research on voucher-based abstinence reinforcement. In 1991, Higgins and colleagues developed a voucher-based reinforcement intervention. In this intervention, patients received monetary vouchers exchangeable for goods and services for providing cocaine-negative urine samples (47). A recent meta-analysis showed that voucher-based abstinence reinforcement has effectively promoted abstinence

from cocaine, opiates, opiates and cocaine, polydrug use, marijuana, and cigarette smoking (47).

A number of the studies reviewed in that meta-analysis compared the effects of voucher-based abstinence reinforcement to control conditions in which participants were randomly assigned to receive vouchers on a noncontingent basis, independent of their urinalysis results. In those studies, the two groups differed only in whether or not vouchers were presented contingent on drug-free urines. This kind of comparison allows for the determination of whether the presentation of vouchers *contingent* on drug-free urine samples is critical in producing the abstinence outcomes. Like the noncontingent control conditions described above in the studies of drug reinforcement, the noncontingent control conditions arranged in clinical research studies allow us to determine whether operant reinforcement is the mechanism responsible for the increase in abstinence. The meta-analysis showed that the outcomes of studies that used noncontingent control conditions were similar to the outcomes of studies that used no-voucher control conditions; and in both groups of studies, the voucher-based abstinence reinforcement produced medium effect sizes.

The first voucher study to use a noncontingent control condition evaluated the effectiveness of a voucher-based abstinence reinforcement intervention in promoting cocaine abstinence in injection drug users who were enrolled in methadone treatment in Baltimore City (48). In that study, participants were randomly assigned to an abstinence reinforcement intervention in which they could earn up to \$1155 in vouchers for providing cocaine-free urine samples (Abstinence Reinforcement Group) or to a noncontingent control group (Control Group). Figure 7.3 shows that 47% of the

Figure 7.3. Longest duration of sustained cocaine abstinence achieved during the 12-week voucher condition. Each point represents data for an individual patient and the lines represent group means. The 19 Abstinence Reinforcement patients are displayed in the left column (circles) and the 18 control patients in the right (squares). Open symbols represent patients who dropped out of the study early. (Reproduced from Silverman K, Higgins ST, Brooner RK, et al. Sustained cocaine abstinence in methadone maintenance patients through voucher-based reinforcement therapy. *Arch Gen Psychiatry*. 1996;53(5):409–415, with permission.)

participants in the Abstinence Reinforcement Group achieved over 7 weeks of sustained cocaine abstinence, whereas only 6% of the Control Group achieved more than 2 weeks of abstinence. This study provided a vivid demonstration of the effectiveness of the voucher-based abstinence reinforcement intervention, and also showed that the contingency between voucher presentation and cocaine urinalysis was critical in producing the abstinence outcomes. These results provide additional evidence that the drug use of many drug users that we see in our clinics is sensitive to its consequences and operant in nature.

Not all individuals achieve sustained abstinence when exposed to an abstinence reinforcement intervention. As would be expected based on the research on operant conditioning described above, responsiveness to abstinence reinforcement interventions can be modulated by manipulating key parameters of operant conditioning. The meta-analysis on voucher-based reinforcement described above, for example, showed that a decreased delay to voucher reinforcement and increased voucher magnitude were associated with better effectiveness of the voucher intervention. These data provide further support for the operant nature of the persistent drug use in clinical populations.

Despite our best efforts, in virtually all (if not all) studies of abstinence reinforcement, some individuals do not achieve abstinence. Is the drug use of those nonresponsive individuals truly “out of control” and not sensitive to consequences? Silverman and colleagues conducted a study that partially addressed this issue (49). In that study, injection drug users who used cocaine persistently during methadone treatment were exposed to a voucher-based abstinence reinforcement intervention in which they could earn \$1,155 in vouchers for providing cocaine-free urine samples over a 12-week period. Patients who failed to achieve sustained cocaine abstinence ($n = 22$) were then enrolled in a study to determine whether these nonresponsive individuals would initiate sustained cocaine abstinence if the magnitude of voucher reinforcement were increased. Using a within-subject crossover design, all participants were exposed to zero-, low-, and high-magnitude voucher intervention conditions in counterbalanced order. Each voucher condition lasted 9 weeks and was separated by a 4-week washout period. Participants could earn up to \$0, \$382, and \$3,480 in vouchers for providing cocaine-free urine samples in the zero-, low-, and high-magnitude voucher conditions, respectively. Figure 7.4 shows that 45% of these previously nonresponsive individuals (10 of 22) achieved long periods of sustained abstinence when exposed to the high-magnitude voucher intervention in which they could earn up to \$3,480 in vouchers over 9 weeks. This study suggests that the proportion of individuals whose cocaine use appears unresponsive to its consequences can be dwindled down by systematically manipulating familiar parameters of operant conditioning. We do not know whether further manipulations could promote abstinence in the remaining group of unresponsive individuals, but the data reviewed in this chapter provide a strong basis to expect that the persistent cocaine use of even the most refractory individuals would prove malleable given the right parameters.

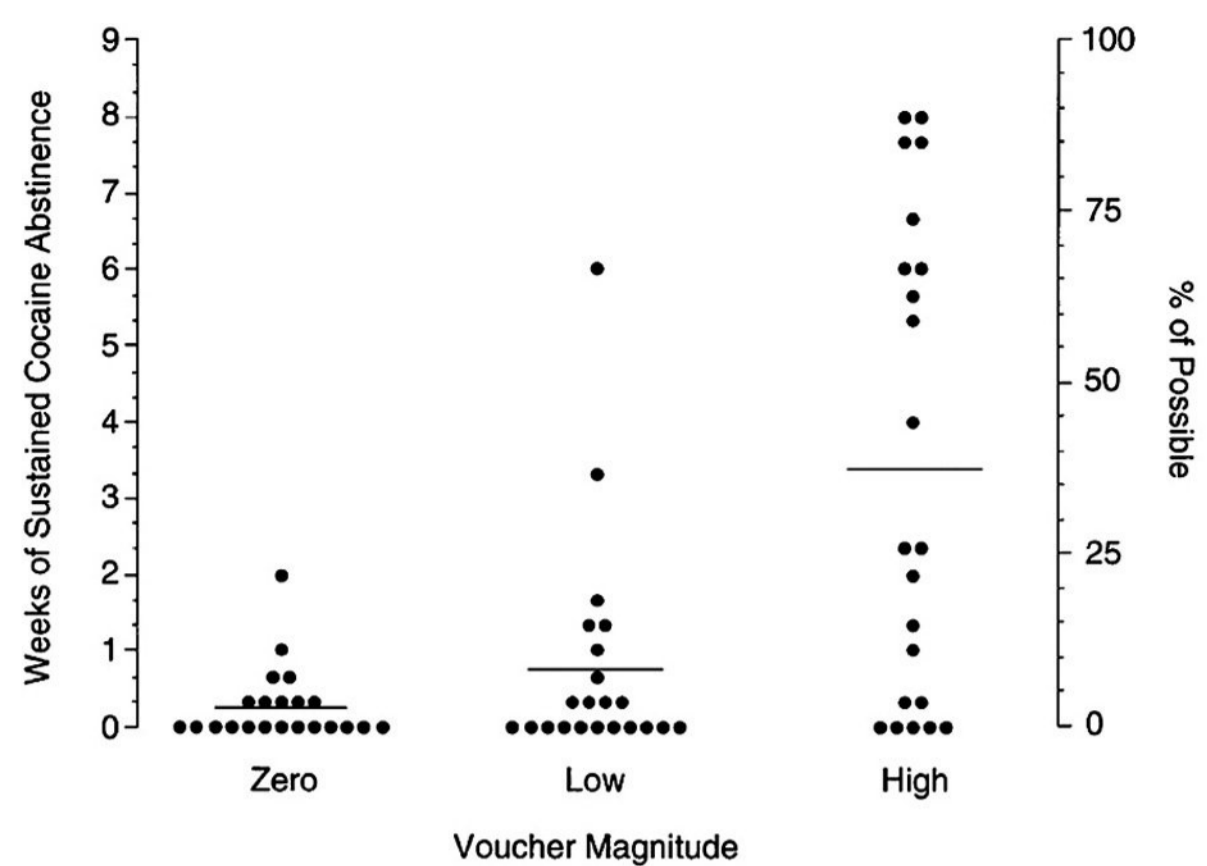

Figure 7.4. Longest duration of sustained cocaine abstinence achieved by a group of methadone maintenance patients who had failed to initiate sustained cocaine abstinence when exposed to a standard voucher intervention in which they could have earned up to \$1,155 in vouchers for providing cocaine-negative urine samples. Each of these individuals was exposed to a zero (*left column*), low (*middle column*), and high (*right column*) magnitude voucher conditions, in counterbalanced order. Each *point* represents data for an individual patient ($n = 22$) and the *lines* represent condition means. Each patient was exposed to each of the three voucher conditions in counterbalanced order. The maximum possible duration of sustained abstinence was 9 weeks for each condition. (Reproduced from Silverman K, Chutuape MA, Bigelow GE, et al. Voucher-based reinforcement of cocaine abstinence in treatment-resistant methadone patients: effects of reinforcement magnitude. *Psychopharmacology (Berl)*. 1999; 146(2):128–138, with permission.)

CONCLUSIONS

The laboratory and clinical research that we have reviewed provides strong evidence that drug addiction *can* be operant behavior that is maintained and modifiable by its consequences. The laboratory research on nonhuman and human drug self-administration has provided an impressive model of drug addiction as operant behavior that is (1) maintained by drug reinforcement; (2) under the strong antecedent control of discriminative stimuli that acquire their influence through conditioning histories; (3) sensitive to the effort or price required to procure the drug; (4) modulated by a variety of establishing operations that alter the reinforcing value of drugs; and (5) profoundly modified by nondrug consequences, either through the direct punishment of drug seeking or drug use or through the reinforcement of behaviors that are alternatives to drug use. Drug self-administration in the laboratory bears important resemblances to the persistent drug use that we see in clinical populations and suggests that laboratory studies of drug reinforcement provide a valid model of drug addiction. The validity of the operant model of drug addiction is probably most impressively established in the applications of these principles to the treatment of drug addiction in clinical populations, particularly in the large number of studies that have demonstrated that persistent

drug use, including drug use in some of the most refractory patients, can be decreased by the direct reinforcement of drug abstinence.

In offering this analysis, we do not intend to suggest that the principles of operant conditioning are the only factors that influence drug addiction. To say that drug addiction can be viewed as operant behavior that is maintained and modifiable by its consequences does not ignore the importance of biologic or genetic factors in understanding addiction. As emphasized in this chapter, the basic process of reinforcement that underlies addiction is a fundamental principle of behavior that is common across a vast range of organisms from the simple sea slug to humans. If nothing else, the commonality of the basic process of reinforcement across biologic species suggests that reinforcement itself is a fundamental biologic process. Furthermore, as we have described in this chapter, sensitivity to drug reinforcement is also common across a wide range of organisms, a fact that provides further evidence of the genetic basis of drug reinforcement itself. Like all genetically determined characteristics, organisms can vary in their susceptibility to drug reinforcement because of their genetic makeup.

To recognize that drug addiction is ultimately controlled by observable environmental events (reinforcers, discriminative stimuli, response requirements, contingencies, and establishing operations) does not deny the existence of private events (50). Private events can serve as discriminative stimuli, responses, and even reinforcers in a conceptual analysis. However, private events like craving or pleasure that are frequently considered internal causes of addiction have yet to be objectively measured (i.e., by two independent observers) or manipulated, and thus must remain outside of our present analysis. Importantly, the existence of private events does not diminish the value of the experimental manipulation of environmental events that have been shown to modulate drug use in laboratory models and in clinical settings. The facts related to the role of private events (or other intervening variables) in drug addiction, whatever they may be, do not alter the functional relations between behavior and environment reviewed here.

Drug addiction is frequently described as behavior that is “out of control.” Yet, the operant analysis described in this chapter suggests that much of what we describe as drug addiction is orderly behavior under clear environmental control. Far from being out of control, persistent drug use in laboratory subjects and in clinical populations can be systematically modulated by manipulating key features of the operant arrangement. The operant analysis has much to contribute to our understanding of drug addiction at the conceptual level and to the treatment of this troubling clinical problem.

Sociocultural Factors and Their Implications

Nady el-Guebaly ■ Pedro Ruiz

Mankind's relationship with substances served socially desired functions. Drugs were used as medicine, in the performance of rituals and religious functions and as recreation. Not surprisingly, sociocultural factors have played a major role in moderating or modulating the use of these substances. Sociocultural factors affect individuals either through small group effects or through the larger social environment. Each of these factors may have both risk and protective properties. They are part of the etiology as well as prevention and treatment of substance abuse. Increasingly, over the last decade the focus of research has moved from the investigation of a list of sociocultural factors in isolation to a study of their relative relevance and interdependence as well as their links with genetic influences. This chapter highlights the promises of these fields of inquiry. The following are current definitions of the concepts of society and culture, including race and ethnicity as an extension of culture.

Society refers to a group of persons regarded as forming a single community of related, interdependent individuals. Social factors are the variables affecting their dealings with one another.

Culture is the set of meanings, behavioral norms, values, every day practices, and beliefs used by members of a particular group in society as a way of conceptualizing their views of the world and during their interactions with their environment. In this context, culture includes language, nonverbal expressions, social relationships, style of expressions of emotions, conditions, and/or philosophies.

Ethnicity refers to a subjective sense of belonging to a given group of persons who are held to have a common origin and share a matrix of cultural beliefs and practices. In this context, ethnicity becomes a component of one's sense of identity; it, thus, needs to be regarded as an important source of clinical and social manifestations with respect to the person's self-image and intrapsychic life.

Race is a concept under which human beings historically chose to group themselves, based primarily on their common physiognomy; in this context, physical, biologic, and genetic connotations can also be attached to this concept (1).

SOCIAL GROUPS AND THE MICROENVIRONMENT

Small group effects may protect or facilitate an individual's drug use through one or several of the following social communities.

The Family Unit and Parenting

Family interactions may serve as protective or risk factors for drug use. Youth's first drug-related discussions and/or modeling of use occurs through the parental and older siblings' perceptions and behaviors. Examples of predictive factors for drug use include conflict-ridden versus warm family interactions, quality and quantity of family time a child experiences as well as parental monitoring of child's activities (2). Earlier general statements about family interactions are now challenged by further contextual analyses in recent research.

Parenting styles have been a focus of evaluation both as protective factors including degree of parental warmth as well as limit setting. In general, substance abusers have been described as dysfunctional parents. Addicted women's parenting has been, in prior research, characterized by a range of across the board parenting deficits including neglect, physical and emotional abuse, excessive control and punishment, inconsistent discipline, and lack of emotional involvement. This indictment uniquely attributed to the mother's drug abuse needs to be investigated against other contextual factors such as low socioeconomic status (SES) and the mother's perceptions of the children's maladaptive behavior. A study compared 120 mothers (i.e., methadone enrollees) with a child under 16 years of age demographically matched with mothers attending a primary care facility serving comparable lower SES women. While the link between maternal addiction and a lack of parental involvement was confirmed, the link between low SES and a parental style leading to a child's restricted autonomy could be an adaptive response to living in environments where children's exposure to violence, crime, drug addiction, and health hazards is more. Cohabitation with partners and having fewer children may also lead to more protective and enmeshed parenting style. This study demonstrates the importance of studying the impact of drug use against other contextual factors, such as poverty, transience, vocational instability, trauma exposure, and children's maladjustment, as well as the need to differentiate parenting effectiveness across different parenting domains (3).

Another related challenge has been the study of partner support or coping in response to the addiction (4). Initial notions about family members pathologized their reactions to disordered drinking or attributed blame for the drinking on spouses of alcoholics. Significant others are now recognized to engage in coping behaviors with substance abusers along with experiencing significant mental and physical strain

resulting from their specific types of caretaking and attempts to stabilize the dyadic or family environment. Such specific behaviors have ranged from enabling, potentially reinforcing continued use of alcohol or other drugs to the more ambiguous construct of codependency with themes of caretaking, pleasing others, and association with a person who has alcohol or drug problems. The coping behaviors of wives of alcoholics have been described as a trial-and-error progression from attempts at logical persuasion, nagging, threats to leave to more “behind the scenes” manipulative approaches, many futile (5). In general, studies using control groups and psychologically oriented measures with adult children of alcoholics have not supported the codependency construct (6).

The Peer Group

Friends and peer affiliation can inhibit or promote drug use behaviors. Group members are influenced to act consistently to gain or maintain acceptance of other group members. Affiliation with deviant peer groups increase the likelihood that one will experiment with drugs as group members offer drugs to each other and role model drug use. Parental influence dominates until early adolescence, by then, peer groups act as informational source for how to behave. Parents may still exert more of an indirect influence on behavior through friendship selection (2).

The Schools

The school environment may be conducive to drug experimentation or may promote delay in exposure to drugs. Large community surveys concur that for men and women of all ages, an increased risk for alcohol use and illicit drug disorders is associated with dropping out of high school or leaving college early. Schools have been the stage of a number of educational initiatives aiming at informing children as to why drug use is bad for them. Strategies based on inducing fear or providing information, that is, if youths are frightened about the negative effects of drugs, or just know the facts, they would not want to experiment with them, have been found to be largely ineffective. An alternate assumption is a value-based model aimed at producing more global attitudinal changes including enhanced self-esteem without addressing drug use specifically; the evidence of its effectiveness is scant (7).

The Workplace

Employment, or working for pay, is also related to the prevalence of substance use. Unemployment is associated with higher risk for alcoholism and so are “blue collar” occupations and lower SES. This association may be a cause or result of substance use. Stressful work circumstances have been associated with high levels of alcohol intake. In a longitudinal study of 1010 teenagers in St. Paul, Minnesota, long hours of after school work (over 20 hrs/week) increased levels of drinking. This was possibly mediated through work-

derived independence from parents and an early transition to an adult role (8). The prevention of problem drinking in the workplace can be achieved by effective controls of the work environment (9). In safety-sensitive situations, a program of urine monitoring of illegal substances can ensure the safe handling of vehicles and machines.

The Social Networks and Support Availability

Assistance provided by social support networks may include companionship (i.e., sharing time or life experiences), conformity (i.e., pressure to engage in a certain behavior), and information (i.e., contextual knowledge). It may also provide support such as attention to basic needs. Social support may be either provided by family, friends, and other acquaintances or through community agencies (10). Within these networks, role models as sports coaches and youths’ support groups may act as teachers of the time and place and quantity and methods of drug use.

Social networks influence an individual’s choices about those with whom they have contact or interact with. These interactions can determine behavior either through constraints to inhibit action or influences promoting action. A youth may likely be a member of a variety of networks at school, home, and other public organizations such as religious institutions and sports and recreational activities. An individual’s connections may be different in different contexts and the outcome as to one’s drug use may be derived from a balance of influences.

Group Identification and Deviancy

Further to the development of social networks, people also tend to identify or place themselves and others into labeled groups, which may promote or inhibit drug use behavior. Adolescence is a period when youth begins to make independent choices about life. Unsure about the life decisions they should make, an adolescent will search for a place to belong among peers they identify with and conform to their norms (11). Differential socialization may lead to group norms that serve to rationalize problem behavior or deviant subcultures. These norms include the development of beliefs, intentions, expectations, perceptions, and modeling of social behaviors. Time spent with deviant peers, their positive reactions for rule-breaking behavior, and the resulting attention earned are all components of deviancy training that may lead to exposure followed by increase in drug use (12).

LARGER SOCIAL STRUCTURES AND THE MACRO ENVIRONMENT

The larger physical and sociocultural environment will also protect from or facilitate drug use. The size, density, and configuration of a geographical area or its climate are all determinants in the availability of drugs and so is the common culture modulating individual behaviors.

Neighborhood Disorganization

A lack of centralized authority or an unstable one may result in a lack of behavioral monitoring.

Chaotic areas may be more heavily exposed to social disobedience. Access to more prosocial activities (i.e., community centers or movie theaters) is typically limited. Abandoned, dilapidated buildings and enclosed public spaces may result in greater incidence of drug exposures as one of the local gang activities (13).

Adverse Socioeconomic Conditions

The association between these adverse conditions and drug abuse is complex and can be a two-way process, that is, low status, leading to drug abuse or drug abuse resulting in a downward socioeconomic drift. Low socioeconomic conditions, often in densely populated areas, are often twinned with sparse community remedial resources or may increase the exposure to drug-related criminal activity. Disadvantaged conditions reduce the impact of the family or social fabrics resulting in self-medication with drugs. Other confounding factors may include the association with poor mental health status (14). Conversely, individuals of higher SES may be able to financially afford large quantities of drugs resulting in significant physical damage prior to a descent in social status.

In a large population survey ($n = 23,564$) carried out in Quebec, Canada, and that included smoking behavior, SES was defined as household incomes above or below Can\$40,000 per year, employment status, and level of education. Smokers, as expected, reported health as poor or fair more frequently than nonsmokers, in addition this difference was significantly greater among those with low incomes and no employment (15).

Environmental Availability

Individual drug use is influenced by the local ease of distribution, access, and acquisition of drugs. Areas of drug production (i.e., cannabis or opium fields), manufacturing (i.e., cocaine or heroin creation), and distribution routes tend to equally be regions at high risk for abuse. In South America, cocaine-type drugs dominate while the majority of treatment admissions in Southeast Asia are for opioid use. In Washington DC, using geographic information systems (GIS), Mason et al. computed the linear distances between the homes of adolescent substance users and the reported “risky” (i.e., alcohol outlets) and “safe” places (i.e., boys and girls clubs). The homes of substance users were three times closer to “risky” places than “safe” places (14).

Cultural Influences

Culturally shaped life habits or rituals, normative structures, and expectations as well as beliefs about drug use and its effects all may affect drug use initiation and maintenance. The

regular use of wine as food with meals in France or Italy is an example of a normed “life habit” while the use of peyote by few Native American Church groups is an example of “ritualized” belief (16).

Cross-culturally, a defining characteristic of the transition from drug use to abuse appears to be the ability to carry or not to carry a culturally specific role (17). These roles may vary by gender or ethnicity. Sex-role expectations within one’s environment and differential stigma associated with use may affect drug prevalence or self-disclosure. There may be a world expectation that females do not misuse drugs and that their misuse is more stigmatizing than for males. Female drug abusers may fear seeking treatment because of reprisal such as the loss of custody of their children. Indeed, part of the stigma against female drug use may derive from the potential harm coming to the child including the risk of fetal alcohol syndrome and low birth weight from maternal cigarette smoking (18). Females are also more likely to be victims of traumatic life events such as various forms of childhood physical or sexual abuse (19).

Ethnicity also plays a role as a predictor or protective factor for drug use. In the United States, Asian groups have reported lower rates of alcohol abuse and dependence than other ethnic groups. A possible explanation has been the presence of an alcohol aldehyde deficiency resulting in a “flushing response” after consuming alcohol (20). However, Native Americans, many of whom with a flushing response but in a socially disadvantaged position, have relatively worse alcohol and drug problems than other ethnic groups. Ethnic pride may also be a strong direct protective factor among disadvantaged groups (21).

The impact of ethnicity interacts with demographics such as gender and age, as well as type of drug or SES. Methodologic challenges encountered in a review of the examination of ethnicity in 18 US-based treatment outcome studies of adolescent substance abusers involved (22):

- a general tendency to report ethnicity as defined by funding agencies such as the National Institutes of Health (i.e., American Indian/Alaska Native, Asian/Pacific Islander, Black/African American and Hispanic). These groupings do not acknowledge the heterogeneity that exists within each of these ethnic minority groups (23).
- the referral sources used to recruit study participants and particularly referrals from juvenile justice agencies, and courts could influence the reported prevalence of the predominant substances abused per ethnic group. For example, Caucasian youths report higher use of methamphetamines but are less likely to be mandated for treatment compared to African American and Hispanic/Latino youths predominantly using marijuana.
- aside from the “culture neutral” urinalysis, the validity and appropriateness of outcome measures and the caveats on the interpretation of cultural findings were not addressed. Translation of an instrument into another language does not equate with cultural appropriateness.

- based on the groups' heterogeneity involved, even family-oriented therapies compatible with the cultural values and beliefs of interdependence in some ethnic minority groups resulted in mixed findings.
- a qualitative investigation of the degree to which it was important for the person to address culture-related factors, but that investigation was lacking to tailor an individualized intervention.

Failing to address the above challenges may result in overly simplistic conclusions of limited clinical utility.

Acculturation

Acculturation has been defined as the processes whereby immigrants change their behavior and attitudes toward those of the host society. The degree to which newly exposed individuals adopt a culture may inhibit or promote drug use depending on the culture they are from and the norms of the new culture. There is still no agreement on the best way to operationalize this construct. There are at least 15 popular scales assessing acculturation among Latinos alone where particular attention has been paid to the relationship between acculturation and drinking outcomes (24). A review of 24 studies disaggregating genders and using appropriate outcomes resulted in some consistent findings among the women in particular. Higher acculturation was strongly related to a higher probability of drinking, greater consumption, and problems. Such effects were not attributable to demographic confounds. By contrast the results for Latino men were more ambiguous. There was a probability that higher acculturation was related to higher odds of drinking but not to other drinking outcomes. Rising income and SES generally seemed to be a strong candidate for explaining the relationship between higher acculturation and higher odds of drinking. The particular effect on women seemed to be more related to the more favorable drinking norms of the host culture compared to the relative discouragement from drinking in the culture of origin.

The stressors of acculturation resulting from the migration process have been pointed out, among Hispanic Americans, to lead to a range of adaptation in the context of the host culture (i.e., "integration," "assimilation," "rejection," or "marginalization"). These adaptive modalities influence the abuse of substances as well as the rate of alcoholism (25). Additionally, the first 5 years of the migration process constitute the most vulnerable ones for migrants, not only with respect to the abuse of substances including alcohol, but for suicide as well (26).

Another body of studies have investigated the relationship between drinking patterns and ethnic identity and enculturation among Native Americans. Such studies have provided inconsistent results concerning the associations between loss of ethnic identity and greater alcohol use perhaps as a result of measurement limitations (27). Earlier work also suggested that biculturalism (i.e., having positive attitudes toward and involvement in both cultures) is most adaptive generally and protective against alcohol-related problems.

In studying the complex role of acculturation, it is also important to recognize that family dynamics, socioeconomic factors up to poverty levels, ethnocultural characteristics, and the role of religion, among others, have their direct and/or indirect influences in the frequency, amount, and types of drugs used and/or abused among the different ethnic groups who reside in the United States (28,29).

Media and Worldwide Electronic Information

Increasingly, the sociocultural influence of the media affects the initiation and experimentation to drug use. Media advertisement can affect an individual's preferences and behavioral options toward drug use. The glamorized portraying of rock stars' struggle with drug dependence encourage youths seeking a "cool" subculture to accept them as their role models. In a study of seventh graders in Southern California ($N = 2998$), increased exposure to televised alcohol advertisements was found to be associated with increased consumption in the eighth grade (30). Mass media disseminates quickly large amounts of information to worldwide audiences. Indeed, a concern from cultural traditionalists worldwide is the media-promoted potential dominance of Western culture on a range of local host cultures with more limited media marketing potential.

Movies glamorize various drug-related behaviors, and over the years their stars have promoted cigarette smoking and alcohol use. Smoking in movies rarely depicts negative health outcomes and smokers in movies appear to be in very good shape (31). The World Wide Web is a trove of wide ranging information about drugs. The impact of the Internet or various demographic groups remains to be systematically investigated.

MANAGEMENT IMPLICATIONS AND THEIR CHALLENGES

The sociocultural variables, just reviewed, have significant implications in every aspect of the management of the spectrum of the substance use disorders.

Diagnoses and Sociocultural Variation

Sociocultural variations may affect the meaningfulness of the diagnostic categories in the substance use disorders (32). A comparative analysis by the WHO of the Alcohol Use Disorder and Associated Disabilities Interview Schedule—Alcohol/Drug-Revised (AUDADIS-ADR) found substantial variations across sites of administration in test–retest reliability. Sydney, Australia, showed the highest reliability on seven of nine current alcohol dependence items, the results from Jember, Romania, were close to those of Sydney while responders from Bangalore, India, had "difficulty understanding the constructs underlying the questions" (33). In the context of categorical diagnoses and criteria, cross-culturally many different thresholds may be applied. Where regular drinking is normalized, thresholds for what is problematized are set much higher than in cultures where use of substances is particularly suspect.

Social stigmatization is also built in the terms “abuse” or “dependence.” A part of the diagnostic decision-making process depends on the threshold whereby family, friends, or a societal representative notices a behavior and decides that it should be brought to a professional’s attention. Regarding withdrawal from alcohol, those in the “wet” wine cultures may be inclined to set relatively low thresholds and no clear distinction from hangovers. In the WHO study, graver signs were assigned in cultures where drinking was viewed as more problematic.

While the diagnostic category of dependence has fared better, both “harmful use” (the ICD category) and “abuse” (the DSM category) have not performed well in test-retest studies. Deciding on a failure in work role cannot be culture-free. Half of the diagnosis of “abuse” in the United States follows a drinking an impaired offence, a behavior that may not be equivalent to a psychiatric disorder (34).

The Need for an Individualized Sociocultural Formulation

The multiaxial assessment process in the *Diagnostic and Statistical Manual of Mental Disorders* (35) recognizes in its Axis IV the need to assess an individual’s psychosocial and environmental problems that may affect the diagnosis, treatment, and prognosis. These include problems with the primary support group, social environment, and educational, occupational, housing, economic, and legal problems as well as problems with access to health care services.

The cultural dimension, by contrast, is addressed only as an appendix to supplement the multiaxial diagnostic assessment. This may unwittingly reduce the clinical perception of the importance of identifying the person’s cultural identity involvement with both culture of origin and host culture as well as his or her parents’ ethnicity. In a cultural formulation, the meaning and perceived severity of the symptoms, the perception of social stressors, or supports in relation to cultural norms needs also to be identified. While rare culture-bound syndromes have been identified, there are common clinical presentations where culture plays a significant part including:

- norm conflict between the person’s behavior and his or her cultural standard
- normative or socially prescribed substance use involving religious rites or meal-related practices
- cultural change achieved through migration or exposure to new norms

Perceptions of similarities and differences between the clinician and patient’s cultures of relevance to the therapy should conclude the formulation (36).

Social Preventive Strategies

Could people be “inoculated” against the social pressures precipitating drug trial and experimentation through social coalition building? There are many examples of evidence-based interventions targeting social units.

The Family: Prevention programs include early childhood education, social support for parents and skills acquisition in parent–child communication, crisis management, and resource networking. Examples of evidence-based programs include Strengthening Families, three 14-week courses on parenting training, children’s skills training, and family life skills training (37). Another such program is Family Matters, involving four booklets, delivered to the home and follow-up telephone calls by health educators (38).

The School: Drug education programming relies on a number of mediating agents of change. These include a mix of beliefs and skills (39). Mediating beliefs include the perceived prevalence of drug use and its acceptability among peers, the consequences of use, and the potential incongruence with other future aspirations. Mediating skills include the ability to resist pressure, goal setting, and prosocial alternatives as well as stress management, self-esteem, and social skills.

In public schools, optimal cultural communication occurs when the intervention program includes cultural elements from each of the ethnic groups in the school (multicultural curriculum) rather than targeting an individual’s ethnic group. A message of inclusion, rather than exclusion, followed by actions and practices that embrace diversity has been shown to be optimal for a school (40). Cultural grounding must convey inclusiveness, not exclusiveness. School-based assistance programs can also provide nonthreatening early interventions for students at risk.

The Use of Media

High-profile media campaigns “against drugs” abound, many of dubious effectiveness. Mass media campaigns targeted at youths that appear to exert the strongest effect on drug misuse depict dramatic true consequences, appeal to sensation-seeking youths through fast-paced and exciting material, take an activism stance including correction of normative misperceptions, and offer greater autonomy from nondrug lifestyles (41).

Prevention Efforts on a Global Scale

Historically, the only strategic focus of international conventions was supply reduction of illegal drugs through interdiction by authorities, crop burning, drug seizures, and so on. The results of this strategy have been limited. The globalization of trade efforts for legal drugs, that is, tobacco and alcohol, in addition to illegal drugs has necessitated the draft of international “conventions” for both seeking to coordinate a global preventative effort. A recent intervention has been the WHO Framework Convention on Tobacco Control signed by some 168 countries and encouraging an array of preventative interventions including the enactment of bans on tobacco advertising and the use of deceptive terms such as “light” and “mild” cigarettes, the placement of principally displayed health warnings on packaging, the protection from second-hand exposure to

smoke in the workplace, public transport, and indoor public places, increase of tobacco taxes, and the combat of smuggling (42).

Social Treatment Strategies

Could a treatment modality targeting the social environment reduce the demand for substances? A number of socially based therapeutic interventions have been developed.

Family Therapy: The use of a family's strength and resources can help drug users minimize the negative impact of their behavior on themselves as well as their families. A safe environment is provided for the family members to express their feelings and concerns and in the process improve communication with each other.

Group Therapy: In contrast to the family, the group is composed exclusively of drug abusers providing support and corrective feedback to each other guided by a trained leader. Both approaches are cornerstones of many treatment programs (43).

Network Therapy: In this multimodal approach, specific family friends and friends are enlisted with the help of the therapist to provide ongoing support to the abuser and promote attitudinal change aiming at the prompt achievement of abstinence, relapse prevention, and a drug-free lifestyle (44).

Therapeutic Community: The community serves as the primary therapist often in a residence. In addition to a primary counselor, each resident has the responsibility to be therapist and teacher to the rest of this community. Peers often lead peer group meetings. Individuals are provided with increased responsibility and privileges as they pass through structured phases of treatment (45).

Sober Living Homes: A safe environment is provided for those who have completed residential treatment or inpatient care, or for those who need a structured living environment to maintain sobriety. Residents are expected to work or attend school or treatment sessions outside the home.

Twelve-Step Program: A worldwide network based on small group support and a basic philosophy is the cornerstone of the recovery of many considered outsiders in their community. The fellowship is established through autonomous groups, ensuring members' anonymity and a sense of belonging to anyone who wants to stop drinking or using. A blueprint for recovery is laid through the 12 steps (46).

Employee Assistance Programs (EAPs): The combined prevalence of drug-induced absenteeism and risk of mistakes and injuries has led the organized workplace to develop programs aiming at motivating employees to improve their performance rather than risk losing their jobs as well as saving corporate losses. Typical programmatic components include educational and counseling services, supervisory training, drug testing and other screening services, and eventually referral to services (47).

Prison Settings: Programs in prisons have gradually expanded to provide the gamut of prevention and treatment

services as well as provision for after care. Recently, a formal diversion program from incarceration to community-based treatment through Drug Courts has gained increased recognition for its cost-effectiveness (48).

Treatment and Cultural Competence

Cultural competence consists of the capacity to make accurate assessments (devoid of stereotypes or misconceptions) and to conduct potent interventions in addressing the complex real-world issues that affect the addictive behaviors of racial/ethnic minority clients struggling to recover from substance abuse and dependence. A clinician's awareness of his or her own cultural values and biases is important. Examples of culturally relevant thematic issues in substance abuse treatment have included the following:

- For African Americans, the stressors of racial discrimination and related life challenges. Similarly gender-role obligations may pose significant burdens and barriers for African American women (50).
- For Hispanics/Latinos, issues include linguistic barriers and acculturation conflicts as well as issues of ethnic identity development, family conflicts, and family obligations. In a recent study, Spanish-Speaking Latinos/Hispanics residing in the United States were more socioeconomically stable and thus exposed to less stress than those Latinos/Hispanics who did not speak Spanish fluently. Likewise, their rates of incarceration as well as the prevalence of substance use disorders were lower among Spanish-Speaking Latinos/Hispanics than among non-English-speaking Latinos/Hispanics or Caucasian populations (51).
- For American Indians, issues include feelings of alienation and staff insensitivity, requirement of disclosure of personal feelings conflicting with traditional Indian ways (52).
- For Asian Americans, issues include culturally incongruent need to admit to antisocial behaviors or prompt to self-disclosure creating shame or "loss of face" (53).

A taxonomy of the ways programs can be made culturally sensitive has been proposed by Kreuter et al. (54), which is as follows:

- *Peripheral Strategies:* Packaging the program to reflect the intended cultural gap through appropriate colors, images, fonts, and pictures.
- *Evidential Strategies:* Enhancing the perceived relevance of a health issue for a group by presenting evidence as to how it impacts that group.
- *Linguistic Strategies:* Making the program more accessible by using the intended audience dominant or native tongue.
- *Constituent-involving Strategies:* Involving lay community members in the program's planning and decision making.
- *Sociocultural Strategies:* Discussion of the health issue in the broader context of the audience's sociocultural values and characteristics.

CONCLUDING REMARKS

1. The study of sociocultural factors in isolation may lead to simplistic stereotypes. As each factor may have both risk and protective properties, the study of their differential relevance and interdependence is important.
2. Sociocultural factors may be of particular relevance in understanding the relative risk of initiation of substance use and in the early phases of drug experimentation while the genetic and neurophysiologic influences may become more relevant in the progression to the substance-dependence stage.
3. The Acculturation Process plays a role in determining the increases in the use and abuse of substances among migrants who arrive to the United States; particularly in their first 5 years of arrival. The acquisition of language competence in the host country may act as a protective factor to substance abuse.
4. The gene–environment or nature–nurture dichotomy perception is increasingly a phase in history. The study of outcome variables for prevention and treatment activities aiming to disentangle the respective roles of the individual and that of the environment eventually unravels their effect on each other. Genetic factors significantly influence the probability that an individual will be exposed to environmental risk factors such as the occurrence of stressful life events, low levels of social support, and poor parenting. Genetic factors may also render individuals more or less vulnerable to the pathogenic effects of environmental risk factors (55). Conversely, adverse environments may lead to genetic risks. Future research will further consider how the environment gets “under the skin.”
5. Statistical innovation methods such as twin studies, growth curve trajectories, and/or mediation analysis may contribute further to the understanding of the interaction between biologic and environmental causal pathways. Unreliability of measurements remains a real problem (55).
6. A comprehensive assessment requires an individualized contextual sociocultural formulation. There is huge variation in the individual response to all types of physical and psychological hazards demonstrating the interaction of individual risk and resilience.
7. Evidence-based prevention and treatment interventions targeting social and cultural units are available. Demonstrating the efficacy and effectiveness of these approaches remains however a complex endeavor.

Clinical Assessment

LaVerne Hanes Stevens ■ Michael L Dennis

A good clinical assessment is one of the fundamental elements of effective treatment planning for substance use disorders. An assessment that effectively synthesizes the patient's self-report with information from additional sources and sound clinical judgment on a wide array of patient issues will do more than provide a diagnosis; it will accurately identify the patient's needs across a broad spectrum of related life domains, consider how those needs may affect the delivery of treatment, ensure that they are the basis for the ongoing process of counselor–patient collaboration on treatment planning, and monitor the patient's progress (1).

Expert panels (2) suggest that the best assessment is a comprehensive process sensitive to a broad range of life areas and that collects information necessary for treatment planning and evaluating the patient's progress. However, for decades the field of substance use disorder treatment has been characterized by multiple service sectors (e.g., medical, legal) with disjointed and often competing approaches to treating clinical disorders. Each sector has its own model and has historically operated in a vacuum, with one-way passive referrals that tend to focus on different aspects of the patient's history (1). This has frequently resulted in an inefficient clinical process that leads to patient frustration and inefficient use of increasingly scarce treatment dollars.

In this chapter, we will discuss assessment principles for identifying multiple patient needs, synthesizing them into a cohesive picture, translating them into treatment planning, and facilitating communication between multiple service providers to address those needs. While these principles are based on our clinical interpretation training for the Global Appraisal of Individual Needs (GAIN) (3,4), they can be readily applied to any clinical assessment.

CORE PRINCIPLES

Sources of Information

The clinical assessment process is like a three-legged stool that requires three components, or “legs,” to generate a solidly supported treatment plan:

- **Clinical judgment.** Before any patient's information is gathered, the clinician's knowledge is the primary factor in the assessment process. The patient's interview then informs the treatment professional's clinical judgment and treatment recommendations.
- **Patient's self-report.** The patient's self-report information is gathered in the interview itself. This is essential for successful clinical planning and treatment engagement because without patient input, treatment plans are likely to be generic, may omit important individualized treatment issues, and may include services that are unnecessary or counterproductive for the patient's progress. When treatment goals are mutually determined and targeted at real needs, they are more likely to enhance the patient's motivation.
- **Collateral reports.** The assessment should also incorporate information from the patient's family, prior treatment records, and other systems of care. This information can be significant because patients may not always recognize or be willing to share all of the salient issues in their lives. It can also be beneficial to know how others perceive the patient's problems and to note whether the patient has had trouble with other interventions.

GOALS OF A CLINICAL NEEDS ASSESSMENT

Besides providing a diagnosis for the treatment of substance use disorders, it is essential to utilize a comprehensive needs assessment process that (a) provides a report that is sharable and usable by professionals in multiple service sectors; (b) covers a broad range of life areas; (c) promotes early identification and response to co-occurring disorders and environmental or situational risk factors; (d) identifies strengths, supports, personal resources, and interpersonal resources; (e) identifies the patient's involvement with other systems; (f) identifies and addresses possible barriers to treatment; (g) provides a baseline for monitoring change in problems; (h) supports evidence-based practice (EBP); (i) has good validity and reliability; and (j) can be administered and interpreted with cultural sensitivity. Each of these is examined below.

Provide a Report That Is Sharable and Usable by Professionals in Multiple Service Sectors

Often, assessment processes are inefficient and consumer unfriendly because they ask the same questions, or slight variations, multiple times: over the phone, at intake, and again with the patient's primary counselor, social worker, nurse, and psychiatrist! Furthermore, because multiple episodes of treatment are actually the norm (5), this process can be repeated with every admission to treatment, further frustrating the patient (6). Thus, an efficient needs assessment must be sharable with professionals and with others outside the direct treatment system who may need access to the information. If the assessment report is highly transferable, it will eliminate the need for repeated assessments as the patient moves through the provider system and will allow more systematic tracking of services provided in response to the identified need.

Cover a Broad Range of Life Areas

Over 80% of the people presenting for substance abuse treatment have three or more major diagnoses or clinical conditions, and half have five or more (7–13). Thus, a good assessment process should cover multiple domains, including substance use, physical health, health risk behaviors, mental health, victimization and other sources of psychosocial stress, recovery environment, legal issues, and vocational concerns, as well as social and spiritual support systems and personal strengths. Because multiple admissions to treatment are also common, it is very important that the assessment includes questions about past treatment and service utilization. These kinds of questions can help inform level-of-care placement decisions and can also provide an important validity check on areas that may be underreported or misrepresented.

Promote Early Identification and Response to Co-occurring Disorders and Environmental or Situational Risk Factors

A competent, experienced clinician can often get to the main problem quickly with an unstructured assessment, but in doing so they also routinely miss co-occurring problems that contribute to the core problem or lead to treatment dropout if not addressed. These may include relatively common problems such as internalizing and externalizing disorders, victimization, suicidal thoughts, self-mutilation, and even problems that the patients may not recognize as posing serious threats to themselves and others, such as tobacco use or high-risk sexual activity. These kinds of issues are overlooked more often than most clinicians realize. Research suggests that 60% to 80% of people entering treatment for substance use disorders have one or more co-occurring psychiatric disorders, yet only 16% of adults and 28% of adolescents have a co-occurring disorder actually documented in their intake assessments (14,15). In a review of a hundred cases where a patient's self-report identified such major clinical problems while the staff evaluation did not, supervisors agreed that the clinical problems were present but

were missed by the staff in all but one case (16). Thus, using a comprehensive needs assessment to screen for a wide range of clinical problems is essential for improving the total reliability of practice and for identifying, documenting, and addressing co-occurring disorders, abuse, victimization, and other problems that the patient might not otherwise disclose at intake.

Identify Strengths, Psycho–Social–Spiritual Supports, Personal Resources, and Interpersonal Resources

Frequently the patient's problems become the focal point of the assessment and subsequent interventions. A good assessment, however, will also assess for positive aspects of the patient's life. These positive resources can be beneficial for several reasons, two of which are described below.

First, in the case of substance use disorders, the patient's strengths and resources can easily be overlooked or disregarded by the patient. A high score on a strength-based measure indicates the presence of factors that can be further developed to assist the patient in achieving recovery goals. Strength-based questions in an assessment can help identify the patient's personal reasons for quitting, the patient's perceived self-efficacy for avoiding relapse in various high-risk situations, spiritual or faith-beliefs and support systems, recognition of the presenting problems, motivation, perceived personal strengths, social supports, and much more. The result is that the assessment process can help boost patients' morale and give them a sense of mastery over their problems. Those assets can then provide hope and promote resiliency for attaining recovery goals.

Second, when the assessment identifies the patient's strengths, those strengths can be the basis for therapeutic interventions that help the patient replace drug-related activities with more prosocial activities. Recovery typically involves significant changes and losses. The loss of the patient's relationship with the substance itself is compounded by the loss of drug-associated activities and friends. Because substance use impacts all life domains, especially as the disorder becomes more severe, it can also result in the loss of employment and educational opportunities, relationships, housing, a car or driving privileges, health, and numerous other things that will be grieved by the patient. If the patient has been institutionalized, the substance use disorder has even resulted in a loss of personal freedom. Yet by using the assessment to also identify strengths and supportive resources, the clinician can help the patient see opportunities for gaining new ground.

Identify Involvement in Other Systems and How That May Impact Treatment

Each system of care in which the patient is involved may have its own set of competing demands that have to be managed. For instance, an adult patient may not be able to spend 90 days in residential treatment without losing their job, or an adolescent patient (for whom schooling is important developmentally) may not be able to receive traditional schooling while in treatment. The role of the individual in

a family system (e.g., primary caregiver, babysitter) may also be a critical issue that has to be managed to minimize conflicts and treatment dropouts. Involvement with the justice or welfare systems can be particularly complicated because they often operate on longer timelines than does a single treatment episode (e.g., a patient may have made considerable progress in treatment but still be sentenced based on a prior event). It is also important to coordinate care if someone is already being treated for co-occurring mental or physical conditions. Substance use treatment must support compliance with the requirements of these other systems, and providers and decision makers in these systems must be apprised of treatment progress. Additionally, understanding and ensuring that patients are complying with the expectations of these systems may help with treatment, if these requirements involve goals in which the patient is willing to invest.

Identify and Address Possible Barriers to Treatment

If an assessment identifies the patient's treatment needs without addressing the potential barriers to accessing needed services, the assessment is incomplete. Barriers may be physical or material, such as funding, transportation, and childcare. Or they can be psychological, such as motivation, fear of losing relationships, or fear of change. Thus, the treatment staff must have an assessment process that is comprehensive enough to help both the clinician and the patient recognize potential roadblocks to treatment.

Provide a Baseline for Monitoring Change in Problems

If patient's progress is to be measured, the needs assessment must provide a baseline for monitoring change. When a treatment provider has an empirical method for assessing the severity of a patient's problems at intake, that provider can use similar questions at selected intervals to determine the degree of progressive or regressive change in those problems. This ability to monitor and quantify the patient's progress allows for both individual and program-level outcome measurement.

Support Evidence-Based Practice

Treatment providers are increasingly facing demands from payers, policymakers, and the public at large to use EBPs that can (a) reliably produce practical and cost-effective interventions, therapies, and medications to reduce substance use and its negative consequences among those who are abusing or dependent, (b) reduce the likelihood of relapse for those who are recovering, and (c) reduce risks for initiating drug use among those not yet using. The move toward EBP involves:

- Introducing reliable and valid assessments that can be used at the individual level to immediately guide clinical judgments about diagnosis, problem severity, treatment planning, level-of-care placement, and the patient's responsiveness to treatment.
- Introducing explicit intervention protocols targeted at specific problems, subgroups, and outcomes. These protocols should have explicit quality assurance procedures to encourage protocol adherence at the individual level and implementation at the program level.
- Having the ability to pool the data to evaluate performance and outcomes for both the same program over time and relative to other interventions.

A good assessment should feed directly into the treatment plan and help a clinician match individuals to evidence-based approaches targeted to their needs. In practice, many critical needs (such as child maltreatment or suicide ideation) go unaddressed, and it is common for a program to routinely assign *all* patients to certain core services regardless of need. This results in wasted resources that could be redirected toward other gaps in services.

Additionally, a good assessment should help support the actual implementation of an EBP. One of the most common methods is to restate the information from the assessment using a personal feedback report as part of a formal process of motivational interviewing (17). Such interventions work best when relevant information from the assessment is formally passed on to the clinician in a format designed to support the specific intervention. Yet, in practice, this rarely happens because most interventions and assessments are developed separately.

It is also important to have an assessment that can be a part of the infrastructure to support program planning at a higher level. By pooling data, programs can identify the most common needs of their patients, determine where they do or do not have evidence-based programs to address them, and assess which practices work best with a given patient or particular subgroups.

Has Good Validity and Reliability

Highly standardized measures have historically been recognized as more reliable, while clinical interviews (which are often relatively unstructured) have historically been deemed more valid (4). The most useful needs assessment will integrate the best of both processes to produce results that are statistically reliable *and* clinically valid. Reliable data means that if we ask the patient the same question twice, we will get the same answer twice. Valid data is truthful, accurate, and precisely captures and describes the phenomena that we intend to measure. Neither reliability nor validity is sufficient by itself. Patients in an interview can reliably give an invalid answer because they misunderstand the question. Conversely, a clinical insight by one interviewer might lead to further clarification of a patient's response, thereby increasing its validity, but this same response may not be replicated when the same question is asked by a different interviewer.

Research has typically achieved reliability by using classical test theory or a "stimulus–response" model. The interviewer asked the question exactly as printed (stimulus),

and whatever the patient answered was recorded (response). This administration style leads to the most reliable answers and typically includes instruments like a standardized intelligence test. A major advantage of this approach is the ability to produce norms and to evaluate how they compare for different subgroups (e.g., by gender, race) or over time (e.g., by age). The problem with this approach is that it does not take into account whether the patient misunderstood the item, had a question about the item, or gave an answer that did not make sense relative to other answers or information known to the interviewer. This becomes particularly problematic when we move from questions about facts to questions about symptoms, behaviors, and perceptions.

Clinical interviews, on the other hand, typically contain a series of topic areas to cover and a list of general questions. The clinical data-gathering session follows the patient's lead more like a journalist or investigator might. Follow-up questions are based on information provided by the patient, and the interviewer probes areas needing further explanation. Clinicians have found this informal clinical interview to be appealing because of its ability to immediately build patient-counselor rapport and the speed with which it often gets to a core problem. Two downsides of this approach are that the lack of structure invites room for error in the hands of less experienced staff members (common in our field), and even experienced clinicians routinely miss important co-occurring problems. It is also difficult to pool or generate norms from this kind of interview.

A *semi structured assessment* is a cross between a traditionally structured assessment and a clinical interview. It attempts to balance the reliability of a standardized assessment against the validity of a clinical interview. With a semi structured assessment like the GAIN (3), the focus is on standardization of understanding over strict standardization of administration. The goal is for patients to understand the items as the assessment intends so that they can give valid answers while allowing the interviewer to deviate from the administration guidelines if those guidelines prevent the participant from understanding an item. Rapport is still maintained by using skip-outs that mimic the process of moving on if there is not a problem or probing when there is evidence of a possible problem. The advantage of this approach is that being able to deviate from general administration guidelines results in greater validity while preserving reliability and the ability to pool data. The major disadvantage of this approach is that it requires investment in training, greater clinical experience by the interviewer (vs. a structured interview), and quality assurance to implement it well.

Administer and Interpret with Cultural Sensitivity

The importance of cultural competence in assessments cannot be overemphasized. This applies to both the interview and the interpretive phases of the process. Any assessment is only as culturally sensitive as the person who administers and

interprets the assessment. Whether the interview is structured, semi structured, or unstructured, the assessor must be aware of their own potential biases related to race, ethnicity, socioeconomics, gender, religion, sexual orientation, age, disability, and other factors.

Those who administer assessments must take responsibility for their own cultural competence in asking and clarifying questions in ways that are relevant, understandable, sensitive, and unbiased. Additionally, treatment providers have an ethical obligation to undertake due diligence in recognizing and safeguarding against individual, institutional, and systemic biases in order to avoid creating a disservice or disparity. Simply stated, questions need to be framed in a reasonable cultural framework, examples should be culturally relevant, clarifications must be culturally clear to the patient, interpretation needs to be culturally contextualized, and nothing should be culturally offensive.

HALLMARKS OF A GOOD CLINICAL ASSESSMENT

Informs the Treatment Plan

Ideally, the assessment summary should flow directly into treatment planning. In practice, however, most assessments focus primarily on diagnosis and do not always take the necessary steps to facilitate treatment planning, either in general or with specific EBPs. While diagnosis is important, it should not be the only goal of the assessment. When the assessment merely categorizes the patient with a diagnostic label, then the value and intent of the assessment are lost. Additionally, if the patient believes that they were merely labeled, they may be less likely to comply with treatment recommendations. On the other hand, if the patient is assured that the assessment will be used to identify their needs, to understand and prioritize their problems, and to develop a plan for accessing appropriate services, then the patient may be more likely to provide more accurate information and to make a greater commitment to treatment goals. Throughout the assessment and debriefing, the assessor should make it clear to the patient that they are listening and understand the patient's individual situations and desires. This is an essential step in being an effective agent for change and in supporting positive treatment outcomes.

It is essential to use the assessment information to start an informal treatment plan during the very first session, even before developing a formal treatment plan. Some patients may require admission into detoxification services before they can complete the assessment or before they can enter primary treatment. Others may require immediate help with suicidal thoughts or safety issues. The clinician should be sure to assess and immediately address any other barriers to returning to treatment, such as transportation difficulties, childcare, work schedules, or lack of insurance. Even if the patient does not have major barriers, it is important for the clinician to make sure that the patient has an explicit plan for coming back for the next session. Finally, it

is often desirable to provide some level of intervention or make sure that the patient has access to some kind of drug-free environment or support system, such as a sponsor or friend in recovery, to reduce the risk associated with relapse between treatment sessions. All of these areas are informal steps that provide a link to the formal treatment plan. Clearly communicating that the needs assessment will be used for treatment planning and reinforcing this perspective during the assessment will typically result in obtaining more valid information from the patient.

Cross-checks for Inconsistencies in the Patient's Self-reported Information

With any needs assessment, the clinician must know how to use the full body of self-reported and collateral information to check for the possibility of inaccurate or misreported information that might affect the report's validity. Patients may overreport or underreport information in order to achieve a desired outcome (e.g., exaggerating substance use in order to enter treatment and lessen legal consequences of their use, or understating substance use to keep a job). In other cases, the patient may have an asymptomatic self-report because of the effective use of medication, treatment, or environmental controls such as institutionalization. It is incumbent on the clinician to compare the patient's self-reported problems and severity against the report of consequences and service utilization to verify the validity of the clinical information. Where available, current self-report information should be compared to prior self-reports to check for discrepancies. Biological tests such as breath, saliva, hair, and urine tests provide another means of verifying the patient's report. Additionally, prior treatment records and input from family members, employers, teachers, social workers, doctors, and probation or parole officers can often provide valuable insight into the patient's report. Ideally, such additional information should be revealed early in the process to avoid a “gotcha” moment that makes the patient feel like they have been tricked.

Help Facilitate Patient Recall and Give the Patient “Voice”

A good needs assessment should also help address a common patient complaint: that they did not remember, know how, or even have an opportunity to articulate one or more of their problems. The assessment process must be designed to help patients define and communicate problems and desires that they might not otherwise have been able to discuss. This is very different from approaches that focus more on categorizing people based on diagnostic boxes or meeting paperwork or funding requirements. Additionally, the assessment should assist the patient in identifying the effects of substance use on their current life problems and the effects of continued harmful use or abuse.

USING THE ASSESSMENT FOR SEVERITY-BASED PROBLEM PRIORITIZATION

Assessing Recency, Breadth, and Prevalence of Clinical Problems

A thorough clinical needs assessment should show the treatment provider the severity level of the reported problems based on three concrete factors: the problem's recency, the breadth of symptoms and services, and the current rate of prevalence. This is useful for both diagnosis and placement.

Recency looks at timing, specifically the most recent occurrence of a problem. It reflects whether a clinical problem is occurring presently, occurred in the past, or has never occurred. Things that happened in the past week, past month, or past 90 days will typically play a greater role in current treatment than those that happened 3 to 12 months ago or 1 or more years ago. For any current problems, the clinician should include an appropriate treatment recommendation and a referral for further evaluation, or other ancillary services.

Breadth looks at the severity of a current problem and is measured by the extent and diversity of the presenting symptoms or the service utilization history. Characteristically, a more diverse symptom presentation and more service utilization are associated with higher severity. For clinical problems, the focus will generally be on the past year (or since the last interview when conducting follow-up assessments). For service utilization, the focus will be on the lifetime service history.

Current prevalence looks at the frequency of a current problem or service utilization and is measured by how often something has happened in the past 90 days or some other recent period. As a rule, things that happen more frequently are going to be more important than those that happened only once or twice. Even if something is common, it is also useful to understand the extent to which it interferes with responsibilities or functioning at home, work or school, or socially. Typically, things that interfere more frequently with functioning or responsibilities are more important than those that do not.

Using Scale Scores in Assessments as Measures of Problem Severity

Combining multiple questions into an index or scale, with clearly defined cut points for marking severity and clinical decisions, also helps generate more reliable, valid, and useful information. Clinicians often do this intuitively: recognizing that while one symptom or problem might be a red flag, greater priority needs to be given to areas where there is a pattern of recent problems, multiple symptoms, high prevalence, or impaired functioning.

The GAIN is an example of a clinical assessment that is widely used (over 1,200 agencies in 49 states, half the provinces of Canada, and several other countries) and known for its effective use of scales and indices (described further below). The GAIN is based on a measurement model that combines classical scales and summative indices. Classical scales are those where the items represent symptoms of a larger

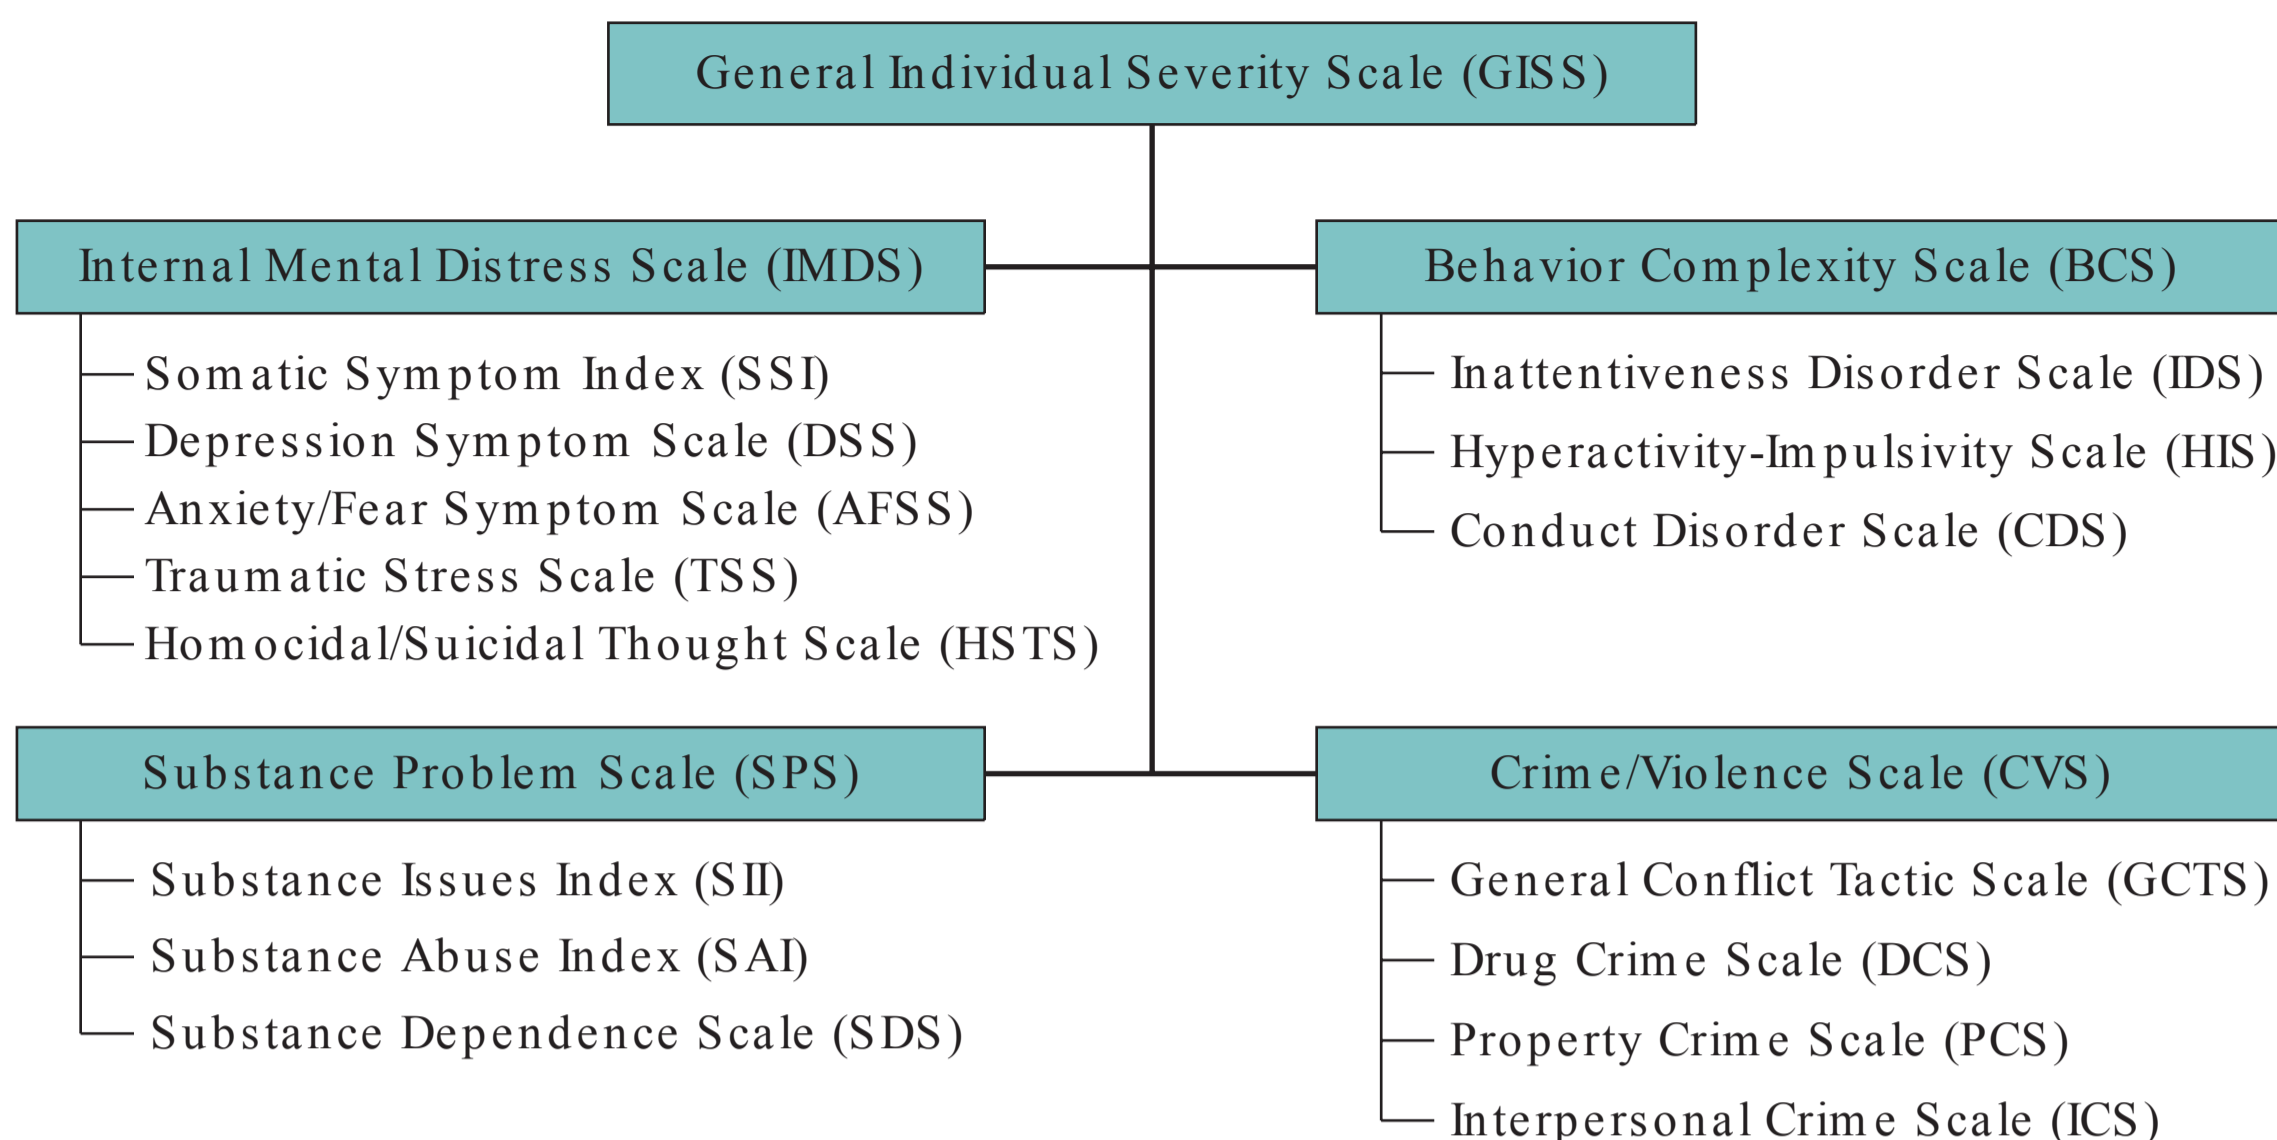

Figure 9.1. Structure of GAIN clinical scales.

underlying disorder, syndrome, or latent construct, such as dependence, depression, or violence. Indices (also known as formative or summative measures) are counts of problems that may not have the same cause but still add up to predict outcomes of interest (18). Examples of index measurements include sources of stress, sources of pressure to be in treatment, or a count of the patient's clinical diagnoses or problems. The GAIN arranges several of these scales and indices into a hierarchical system (see example in Fig. 9.1) that gives clinicians and researchers information about overall severity (the total symptom count). It also has scales representing the main dimensions of variation (substance use, internal distress, external behavior problems, crime/violence) and clinically oriented subscales within each, for problems like dependence, depression, anxiety, attention-deficit/hyperactivity disorder (ADHD), and conduct disorder. These in turn are made up of face-valid individual items that address salient issues like suicidal thoughts (19). Another notable advantage of using scales and indices is that many individual questions have slightly different meanings for key subgroups (e.g., by gender, race, age, sexual orientation, geography), but these differences average out when you look at the pattern across multiple items (20). This helps reduce bias and ensure cultural sensitivity when doing the assessment. It should be noted that many of these properties are not unique to the GAIN; there are actually compendiums of other scales, indices, and multiple domain assessment batteries available (see http://www.athealth.com/practitioner/ceduc/health_tip31k.html; <http://pubs.niaaa.nih.gov/publications/Assesing%20Alcohol/index.htm>).

Treatment History and Problem History as an Indicator of Severity

The needs assessment should help treatment providers look not only at the presence of a particular problem but also at the patient's treatment history and the severity of the re-

ported problems. Table 9.1 shows the possible combinations of problem and treatment history and the typical next clinical step. In assessing placement and treatment needs, the clinician will need to consider both problem severity and treatment. The horizontal axis in Table 9.1 represents whether the patient has a current high-severity or low-severity problem, a past history of problems, or no problem. The vertical axis represents current treatment, a history of past treatment, or no treatment history. The type of service or treatment becomes more intense from the left side of the chart to the right. Consider, for instance, a current problem. In the absence of any prior treatment history for a problem of low to moderate severity, the clinician would be more likely to recommend a less invasive treatment (e.g., buprenorphine vs. methadone, outpatient vs. residential). Reporting the same severity of problems while already in treatment, in contrast, may indicate the need to increase the intensity, level of care, or range of services.

The response to treatment (whether positive, neutral, or negative) can be one of the most clinically significant pieces of information in deciding what to do next. Past treatment requires consideration of the recency of the problem, the extent to which the patient complied with treatment recommendations, the speed with which the problem returned (if it dissipated), and the willingness of the patient to try again. The last point is important because while 60% of all people reporting substance use disorders eventually achieve sustained recovery (no use, abuse, or dependence for at least a year), most require multiple episodes of treatment before reaching at least a year of sobriety (5). Past problems and past treatment suggest the need for relapse prevention and monitoring for change. Past problems with current treatment suggest the potential readiness to step down or be discharged. If a patient reports treatment for a problem they do not endorse, it suggests that they may be mis-

TABLE 9.1 Problem Severity and Intervention History Grid

Problem recency					
Service/intervention history		None	Past	Current (past 90-day period)	
				Low/moderate severity	High severity
	None	1. No problem	2. Past problem <i>Consider monitoring and relapse prevention.</i>	3. Low/moderate problems; not in treatment <i>Consider initial or low invasive treatment.</i>	4. Severe problems; not in treatment <i>Consider a more intensive treatment or intervention strategies.</i>
		Past	0. Not logical <i>Check for misunderstanding of problem/treatment or lying and recode.</i>	5. No current problems; currently in treatment <i>Review for step down or discharge.</i>	6. Low/moderate problems; currently in treatment <i>Review need to continue or step up.</i>
Current (Past 90 days)					

understanding or misreporting their symptoms or treatment history and the problem generally should be reviewed and reclassified.

Clinicians can do this kind of evaluation for the overall need for substance abuse treatment as well as for related life domains such as withdrawal problems and detoxification services history, physical health, emotional and behavioral health, readiness for change and motivational interventions, relapse potential and relapse prevention interventions, and recovery environment factors. In each case, there is a continuum of problem severity and treatment history.

WRITING THE FINAL REPORT

After the interview, most agencies and funders require a written report summarizing the assessment. The following is the format we generate from the GAIN and generally suggest.

Presenting Concerns and Identifying Information

Include basic demographics such as age, race, gender, and marital status; number of children; physical appearance and disabilities; source and reason for referral; vocational status; and custody arrangements; and current living situation.

Evaluation Procedure and Validity Concerns

Describe the type of administration, for example, orally administered by staff; the environmental context of the assessment; the patient's behaviors during the meeting; and any other sources of information consulted as a part of evaluation, such as urine test results, records, referral letters, family

assessments, and probation reports. This also includes comments on possible areas of underreporting, overreporting, and symptom suppression or other factors that may have influenced the validity of the participant's responses, such as other people within hearing range of the interview.

Diagnosis

Document the patient's diagnoses from the *Diagnostic and Statistical Manual of Mental Disorders* (21) or the *International Classification of Disease* (22) using the multiaxial system that includes Clinical Disorders/Focal Conditions (Axis I), Personality Disorders/Mental Retardation (Axis II), General Medical Conditions (Axis III), Psychosocial and Environmental Problems (Axis IV), and Ratings of Functioning (Axis V). The latter generally includes the Global Assessment of Functioning (GAF) during the past year and past 90 days. It may also include ratings of Global Assessment of Relational Functioning (GARF) and Social and Occupational Functioning Assessment Scale (SOFAS).

Summary of Substance Use and Treatment History

Summarize the patient's lifetime history of substance use and treatment, including age of first use, preferred substance, and other substances used; abuse and dependency diagnoses and the specific symptoms reported; recency, frequency, and peak amount of use; date and amount of last use (required by some insurance organizations); other drugs used even if diagnostic criteria are not met; and substances identified through biometric testing (e.g., urine, saliva, or hair) or collateral reports. Also include the patient's history of substance abuse treatment, including a detailed treatment history with programs, levels of care, and intake and discharge dates.

Treatment Planning

The American Society of Addiction Medicine's (ASAM) Patient Placement Criteria (PPC) outlines six treatment planning dimensions that should be considered when assessing a patient for admission, continued stay, or discharge from any level of care (23). Those treatment planning dimensions are:

1. acute alcohol or drug intoxication or withdrawal potential;
2. biomedical conditions and complications;
3. emotional, behavioral, or cognitive conditions and complications;
4. readiness to change;
5. relapse, continued use, and continued problem potential; and
6. recovery environment.

For each of these dimensions or other areas of assessment, there should be a summary of the problems, treatment history, and treatment planning recommendations. The recommendations are the most important part of the report and should address three areas.

First, the report should acknowledge specific requests for help or services from the patient. By beginning with the patient's requests, rather than the clinician's list of recommendations, the treatment plan reinforces the therapeutic alliance and shows respect for the patient's understanding of their own problems. It validates the patient and the therapeutic relationship by showing that the treatment provider has listened to them and is not minimizing the issues that the patient wants to address. This is an important step toward garnering patient buy-in of other clinical recommendations.

Second, other recommendations in the needs assessment will be represented by Table 9.1 cell placements. These "cell-specific" treatment planning options are generated based on treatment history and problem recency and severity. For example, if a patient is currently experiencing low to moderate mental health problems but is not currently receiving services for those problems, their mental health service needs would fall into cell 3. The treatment recommendations might include statements such as:

- Discussing current emotional, behavioral, or cognitive problems to review the need for services, barriers to accessing them, and accommodations needed to participate in treatment.
- Discussing how the emotional, behavioral, or cognitive problems and other problems (school, work, custody) may be related.
- Referral to specific services or specific skill-building related to emotional, behavioral, or cognitive conditions required to participate in treatment: [list].
- Help identify triggers or areas that agitate mental health or behavioral problems.

As another example, if a patient reports high-severity problems with continued use and relapse but has never been in

substance abuse treatment or relapse prevention programs, the clinician would generate cell 4 treatment planning recommendations. The text might read as follows:

- Discussing situations that pose a risk of relapse, for example, who are the people, places, and things that put the patient at high risk? How can such situations be avoided? What refusal skills does the patient have or need to develop? What will be the plan for handling emergency risk situations?
- Discussing the patient's willingness to participate in a 12-step or other recovery program.
- Developing and discussing options for building or enhancing a nonusing social support network; engaging in substance-free recreational activities; building situational confidence; strengthening refusal skills; and coping with relapse.

The third type of recommendation statements reflect service needs that are not specific to any level of treatment history, that are generally expected by funding or monitoring entities, or that are so significant that they take precedence in treatment prioritization. These recommendations are based on the patient's responses to key items that generally carry an ethical, legal, or clinical responsibility. They include responses to safety issues such as suicidal ideations, homelessness, or current abuse, or responses that suggest the need for intensive case management or coordination of care with other systems.

Summary of Recommendations

This section should include a program or level-of-care placement recommendation based on the patient's needs and where the recommended services can be accessed in the available treatment system. Where ideal placement or services are not immediately available, this should be noted explicitly and interim recommendations should be given. This section should also summarize any barriers to returning to treatment, existing treatment or systems involvement, and things that need to happen before the next session.

Signatures

Most agencies and funders require multiple signatures on the summary report. Typically this includes the signatures of anyone who must read and approve the report. Most commonly these include the patient, clinician, clinical supervisor, and medical doctor.

ADOPTING A PROGRESSIVE APPROACH TO ASSESSMENT

There are numerous benefits of using a progressive approach to assessment instead of a one-size-fits-all approach. In a general population setting, it is useful to administer a 5-minute screener like the GAIN Short Screener (19) to first decide whether an assessment is warranted. In a targeted population,

it is useful to use a 20- to 30-minute assessment like the GAIN-Quick (24) for screening, brief interventions, and referral to treatment for more severe cases. When patients present for more formal substance abuse treatment, they generally have multiple problems and benefit from a more extensive (60- to 120-minute) assessment like the full GAIN-Initial (3). Although each of these assessments has successively more information and opportunities for use, the principles outlined in this chapter generally apply to each of them and to the dozens of available alternatives to the GAIN.

CONCLUSION

In this chapter, we have conveyed several overarching messages. First, there is a need to shift our focus from finding the fastest way to provide patient information to one staff person at one point in time to instead, finding the most efficient and least frustrating way for information to be collected and shared with multiple staff and programs over time. Second, clinical assessment rests on good clinical judgment as well as reliable and valid information from both patients and collateral sources. Third, great clinical assessment is all about how the information is used to guide clinical decision making related to diagnosis, treatment planning, and placement at the individual level and pooling of the data to guide program planning. As these principles are incorporated into practice, the field of addiction treatment advances.

ACKNOWLEDGMENTS AND CONTACT INFORMATION

Diagnosis and Classification: *DSM-IV-TR* and *ICD-10*

George E. Woody ■ John Cacciola

The *Diagnostic and Statistical Manual of Mental Disorders*, 4th ed. (*DSM-IV*) (1) is the diagnostic classification system developed by the American Psychiatric Association. Although the *DSM-IV* was updated and published as the *DSM-IV-TR* (*Text Revision*), the disorders and diagnostic criteria have not changed as of this writing (2) though changes are being considered for *DSM-V*, which is tentatively scheduled for publication in 2013. The *International Classification of Disease, Tenth Revision* (*ICD-10*) (3) is the system used by the World Health Organization and has also remained unchanged though it may be modified after *DSM-V* is published. The substance use disorders sections of previous iterations of each classification system differed significantly from each other, though many of the concepts they contained were similar. As a result, considerable efforts were made to make these two systems as similar as possible and these efforts were mostly successful. *ICD-10* actually has two versions: the clinical and the research. The clinical version is the manual that is used in clinical practice and is the main focus of this chapter, although the research version of *ICD-10* is mentioned briefly in the discussion of course modifiers for dependence.

This chapter compares the sections of *ICD-10* and *DSM-IV-TR* that deal with substance-related disorders and discusses proposed changes in *DSM-IV-TR* that are being considered for *DSM-V*. Many details are only mentioned or described in very general terms so as to present an easily readable and memorable comparison of the two systems.

OVERVIEW

Psychiatric disorders attributable to abusable substances are of two general types: (a) disorders related to the pattern and/or consequences of substance use itself (i.e., dependence, abuse [in *DSM-IV-TR*], and harmful use [in *ICD-10*]) and (b) disorders produced by the pharmacologic effects of the substances themselves (i.e., intoxication, withdrawal, and substance-induced mental disorders).

The edition preceding *DSM-IV-TR*, the *Diagnostic and Statistical Manual of Mental Disorders*, 3rd ed., revised (*DSM-III-R*), organized these two general types of disorders into two areas, whereas *ICD-10* placed them in one section. In *DSM-III-R*, the substance-induced disorders were found in a section titled “Psychoactive Substance-Induced Organic Mental Disorders,” whereas dependence and abuse were found in the “Psychoactive Substance Use Disorders” section. A major

accomplishment of *DSM-IV* was to place all of these disorders into one section, “Substance-Related Disorders,” consisting of two parts: “Substance Use Disorders,” which includes dependence and abuse, and “Substance-Induced Disorders,” which includes intoxication, withdrawal, and substance-induced mental disorders. This major change in the organization of *DSM-IV*, and retained in the *DSM-IV-TR*, has made their overall organization much more similar to that of *ICD-10*. Nevertheless, there still exist substance-induced disorders that are not shared by the two classification systems, and criteria-level differences still exist between disorders that are shared by the two systems.

In each classification system, abusable substances or their general drug class are listed and criteria are provided so that any of the disorders attributable to that substance can be identified and numbered. For example, “Alcohol Withdrawal” in the *DSM-IV-TR* is described and diagnostic criteria are summarized and coded as 291.8; “Amphetamine-Induced Mood Disorder” is identified and coded as 292.84; “Cocaine Dependence” is described and coded as 304.20; and so on. In general, the descriptive text for each of the diagnostic categories in *DSM-IV-TR* is more detailed than that found in *ICD-10*.

Differences remain, however, the most prominent of which is found in the use of the terms “abuse” in *DSM-IV-TR* and “harmful use” in *ICD-10*. Most importantly, each classification system is founded on the Edwards and Gross definition of the dependence syndrome (4,5), a concept that was originally developed from work with individuals having problems with alcohol but later expanded to all abusable substances.

DEPENDENCE, ABUSE, AND HARMFUL USE

Dependence

DSM-IV-TR has seven criteria items for dependence and *ICD-10* has six. In each classification system, three items are necessary to make a diagnosis of dependence. Specific items are ordered differently in each system; however, as Table 10.1 illustrates, their similarities are readily apparent when they are compared.

In *DSM-IV-TR*, dependence is specified as being either with or without physiologic features. Dependence with physiologic features is present if there is evidence of tolerance or withdrawal (i.e., criterion items 1 or 2 are present). Dependence without physiologic features is present if three or more items

TABLE 10.1 Comparison of *DSM-IV* and *ICD-10* criteria items for dependence

<i>DSM-IV</i>	<i>ICD-10</i>
Three or more of:	same
1) tolerance	iv) same
2) withdrawal	iii) same
3) the substance is often taken in larger amounts or over a longer period than was intended	ii) difficulties in controlling substance-taking behavior in terms of its onset, termination, or levels of use
4) any unsuccessful effort or a persistent desire to cut down or control substance use	no corresponding <i>ICD</i> category
5) a great deal of time is spent in activities necessary to obtain substance or recover from its effects	v) increased amounts of time necessary to obtain or take the substance or recover from its effects. Note: (v) item has two parts; this phrase represents one part
6) important social, occupational, or recreational activities given up or reduced because of substance use	v) progressive neglect of the alternative pleasures or interests. Note: (v) item has two parts; this phrase represents one part
7) continued substance use despite knowledge of having had a persistent or recurrent physical or psychological problems that are likely to be caused or exacerbated by the substance	vi) persisting with substance use despite evidence of overtly harmful problem consequences
no corresponding <i>DSM</i> category	i) a strong desire or sense of compulsion to take the substance

are present but none of these are items 1 or 2. There is no comparable subtyping of dependence in *ICD-10*.

Abuse and Harmful Use

Although the current *ICD* and the *DSM* definitions of dependence are very similar, the two systems differ sharply on the concepts of abuse and harmful use. In *DSM-IV-TR*, abuse is defined in social terms, that is, problematic use in the absence of compulsive use, tolerance, and withdrawal. *ICD* has been reluctant to accept criteria items that are defined in terms of social impairment. However, *ICD* does recognize a nondependent type of substance use disorder. In *ICD-10*, this disorder is called “Harmful Use” and involves substance use that results in actual physical or mental damage.

This difference between *DSM* and *ICD* in the acceptability of social criteria for defining a disorder is primarily because *ICD* must be applicable to a wide range of cultures. Social mores differ so markedly between countries that it is difficult to develop socially defined criteria that can be applied across cultures. For example, any use of alcohol in a Moslem country

can lead to major adverse social consequences, whereas Western societies have integrated alcohol use into their social fabric. The *ICD-10* category of harmful use is one that can be applied cross-culturally, and is the closest that *ICD* comes to the *DSM* concept of abuse. However, harmful use is really a different construct because it is limited to use that causes actual physical or mental damage. Harmful use is in many ways a more restrictive category than abuse, and some persons having a *DSM-IV-TR* abuse diagnosis do not meet criteria for harmful use. Table 10.2 is a summary comparison of Abuse and Harmful Use.

In addition to pointing out the major differences between *DSM-IV-TR* and *ICD-10* in this area, Table 10.2 also reflects a major change made to the definition of abuse. Unlike *DSM-III-R* and other earlier iterations of the *DSM*, *DSM-IV-TR* separates the criteria items for abuse from those for dependence. This change was done by attempting to identify only items that signify problematic or hazardous use as abuse and by leaving only items signifying compulsive use, tolerance, or withdrawal as dependence.

Four *DSM-IV* criteria items were developed for abuse. One (hazardous use) had been part of earlier definitions.

TABLE 10.2 A comparison of abuse and harmful use

<i>DSM-IV</i>	<i>ICD-10</i>
Abuse	Harmful use
One or more of the following occurring over the same 12-month period:	Clear evidence that the substance use was responsible for (or substantially contributed to) physical or psychological harm, including impaired judgment or dysfunctional behavior.
1) recurrent substance use resulting in a failure to fulfill major role obligations at work, school, or home	
2) recurrent substance use in situations in which it is physically hazardous	
3) recurrent substance-related legal problems	
4) continued substance use despite having persistent or recurrent social or interpersonal problems caused or exacerbated by the effects of the substance	
Never met criteria for dependence	

Another (use resulting in failure to fulfill role obligations) was moved from a *DSM-III-R* dependence criterion item to abuse. The third and fourth items (recurrent substance-related legal problems; continued use despite having recurrent social or interpersonal problems) were split from one *DSM-III-R* dependence item and moved to abuse. Portions of that original item (recurrent substance-related medical or psychiatric problems) remained in a *DSM-IV* dependence item. Because diagnostic criteria did not change from *DSM-IV* to *DSM-IV-TR*, the operationalization of abuse is the same for both.

DSM-IV-TR DEPENDENCE COURSE MODIFIERS

Both *DSM-IV-TR* and *ICD-10* include course modifiers for dependence. *DSM-IV* expanded the limited number of course modifiers that were present in *DSM-III-R*, again resulting in greater consistency between *DSM-IV-TR* and *CD-10*. The course modifiers for both classification systems apply only to dependence and not to abuse or harmful use.

DSM-IV-TR organizes its course modifiers in terms of stage of remission, agonist therapy, or being in a controlled environment.

Remission

A person is not classified as being in remission until that person has been free of all criteria items for dependence and all of the “A” items for abuse (to be described later in Table 10.2) for at least 1 month. The first 12 months following cessation of problems with the substance is a period of particularly high

risk for relapse; thus, it is given the special designation of “Early Remission.” There are two categories:

- *Early Full Remission*: No criteria for dependence, and none of the “A” criteria for abuse, have been met for the last 1 to 12 months.
- *Early Partial Remission*: Full criteria for dependence or abuse have not been met for the last 1 to 12 months; however, one or two dependence, or one or more of the “A” abuse criteria, have been met, intermittently or continuously, during this period of Early Remission.

When 12 months of Early Remission have passed without relapse to dependence, the person is in “Sustained Remission.” There are two categories in this case:

- *Sustained Full Remission*: None of the criterion items for dependence and none of the criterion items for abuse have been present in the last 12 months.
- *Sustained Partial Remission*: Full criteria for dependence have not been met for a period of 12 months or longer. However, one or two dependence, or one or more of the “A” criteria for abuse, have been met, either continuously or intermittently, during this period of Sustained Remission.

On Agonist Therapy

For the course modifier “on agonist therapy,” the person is on prescribed, supervised agonist medication related to the substance, and the criteria for dependence or abuse (other than tolerance or withdrawal) have not been met for the

agonist medication in the last month. This category also applies to persons being treated for dependence using an agonist/antagonist with prominent agonist properties, such as buprenorphine.

In a Controlled Environment

Another course modifier is that the person is “in a controlled environment.” In this case, no criteria for dependence or abuse are met but the person has been in an environment for 1 month or longer where controlled substances are highly restricted. Examples are closely supervised and substance-free jails, therapeutic communities, or locked hospital units. Occasionally, persons will be on agonist therapy while also in a controlled environment. In such cases, both course modifiers (on agonist therapy and in a controlled environment) apply.

Just as the remission categories require a transitional month without satisfying any criteria for dependence or abuse, the 1-month period after cessation of agonist therapy or release from a controlled environment is a corresponding transition period. Thus, persons in this 1-month period are still considered dependent. They will move into an Early Remission category after being free of all criteria for dependence and of the “A” abuse criteria for 1 month.

ICD-10 DEPENDENCE COURSE MODIFIERS

The course modifiers for *ICD* are similar but not identical and are as follows:

- Currently abstinent
- Currently abstinent, but in a protected environment (e.g., hospital, therapeutic community, prison)
- Currently on a clinically supervised maintenance or replacement regime (controlled dependence) (e.g., with methadone, nicotine gum, or nicotine patch)
- Currently abstinent, but receiving treatment with aversive or blocking drugs (e.g., naltrexone [Narcan] or disulfiram [Antabuse])
- Currently using the substance (active dependence)
- Continuous use
- Episodic use (dipsomania)

After publication of the *ICD-10* clinical criteria, the *ICD-10* research criteria were published. The section on course modifiers in the research criteria were made even more similar to those of *DSM-IV-TR* by adding three subcategories to “Currently abstinent,” namely, “Early Remission,” “Partial Remission,” and “Full Remission.” Also, two subcategories were added to “Currently using the substance,” “Without physical features” and “With physical features.” The phrase, “The course of the dependence may be further specified, if desired, as follows:” was added before the terms “Continuous use” and “Episodic use [dipsomania].” These changes to the *ICD-10* research criteria set the stage for even more integration between *DSM-V* and the next iteration of the *ICD*.

SUBSTANCE-INDUCED DISORDERS

As described above, intoxication, withdrawal, and the wide range of substance-induced mental disorders are included in a single section in both *DSM-IV-TR* and *ICD-10*. *DSM-IV-TR* provides a brief description of the clinical manifestations of intoxication and withdrawal for each substance; exceptions are those few substances that do not have an identified withdrawal syndrome, such as lysergic acid diethylamide (LSD). *ICD-10* provides less detail about each substance but provides general criteria that allow for classification of intoxication or withdrawal according to specific substances.

DSM-IV-TR also provides considerable detail for the substance-induced mental disorders. Table 10.3 identifies and summarizes the wide range of mental disorders that can be produced by substances.

Each of the mental disorders that are listed in Table 10.3 are referenced and coded in the text accompanying that specific substance. They are also cross-referenced with the section of *DSM-IV-TR* that deals with that type of disorder. For example, psychotic disorders attributable to alcohol intoxication or withdrawal are mentioned and coded in the text dealing with alcohol, and the reader is directed to the psychotic disorders section of *DSM-IV-TR* for a more complete description of these disorders. *ICD-10* provides a more general format that allows for classification of substance-induced mental disorders, but provides much less substance-specific detail than *DSM-IV-TR*.

COMPARISONS OF DIFFERENCES IN SPECIFIC DIAGNOSTIC CATEGORIES

There are a few other important categories that are found in one system but not the other. For instance, *DSM-IV-TR* has three categories that are not specified in *ICD-10*: “Polysubstance Dependence,” “Other (or Unknown) Substance-Related Disorders,” and “Phencyclidine (or Phencyclidine-Like)-Related Disorders.” These categories would likely be classified under the *ICD-10* heading of “Disorders Resulting from Multiple Drug Use and Use of Other Psychoactive Substances.”

A number of substances have limited diagnostic possibilities in *DSM-IV-TR* but have a wider range of *ICD-10* diagnostic labels. For instance, caffeine is included in the stimulant section of *ICD-10* and thus is open to a wide range of subcategories. In contrast, “Caffeine Intoxication,” “Caffeine-Induced Anxiety Disorder,” and “Caffeine-Induced Sleep Disorder” are the only categories available for this substance in *DSM-IV*. Similarly, *DSM-IV-TR* has only two categories involving nicotine: dependence and withdrawal. *ICD-10* has the same wide range of diagnostic categories for nicotine that is available for all other substances.

ICD-10 has a section (listed as a subsection of “Behavioural Syndromes Associated with Physiological Disturbances and Physical Factors”) that is separate from the psychoactive substance use section and that is used for classifying abuse of non-dependence-producing substances. This includes problematic use of antidepressants, laxatives, steroids, and

TABLE 10.3 Diagnoses associated with class of substances

Alcohol	X	X	X	X	I	WP	P	I/W	I/W	I/W	I	I/W		
Amphetamines	X	X	X	X	I			I	I/W	I	I	I/W

Other	X	X	X	X	I	W	P	P	I/W	I/W	I/W	I	I/W	

^aAlso “Hallucinogens Persisting Disorder (Flashbacks).”

Note: X, I, W, I/W, and P indicate that the category is recognized in *DSM-IV*. In addition, I indicates that the specifier “With Onset During Intoxication” may be noted for the category (except for “Intoxication Delirium”); W indicates that the specifier “With Onset During Withdrawal” may be noted for the category (except for “Withdrawal Delirium”); and I/W indicates that either “With Onset During Intoxication” or “With Onset During Withdrawal” may be noted for the category. P indicates that the disorder is persisting. Reproduced from Frances A, Pincus HA, First MB, eds. *Diagnostic and Statistical Manual of Mental Disorders*. 4th ed. Washington, DC: American Psychiatric Association Press; 1994:177, with permission.

hormones. A comparable section in *DSM-IV-TR* is found under “Other (or Unknown) Substance-Related Disorders.”

CHANGES CURRENTLY UNDER CONSIDERATION FOR *DSM-V*

Several changes are under consideration for *DSM-V* though no final decisions have been made. Among the changes that appear most likely to occur are substituting “addiction” for “dependence,” merging some or all of the abuse criteria with those for dependence (i.e., the new category of “addiction”) so there is one disorder with varying levels of severity (6), and adding a category for marijuana withdrawal (7).

Changes that are being discussed but with less certainty are adding a category for compulsive behaviors such as gambling, and listing in the Appendix other potential nonsubstance addictions such as Internet use, eating, shopping, and sex (6); adding a category for disorders first diagnosed in infancy, childhood, or adolescence that would include conduct disorder and problematic substance use, since they often occur together and there are data showing that they share common genetic factors; adding age of onset and number of substances used to determine severity of the disorder; being more specific about terms such as “recurrent” or “continued” use in the definitions so as to improve the precision of assessments that are used to make diagnoses (8); and modifying the remission criteria so a patient can be diagnosed as in remission from opioid dependence while on medication-assisted

therapy (medication to be specified). All disorders will have a dimensional component, at least for severity, and comorbidity of substance use disorder with other mental disorders will be listed though the format for such a listing has not been determined as of this writing (6).

SUMMARY

Many of the major differences between the *DSM* and *ICD* classification systems were eliminated or considerably reduced by the development of the *DSM-IV-TR* and *ICD-10*. The most prominent remaining difference is in the concepts underlying abuse and harmful use but this difference may lessen in *DSM-V*. Less-prominent differences are found in the less-detailed descriptions of the various clinical syndromes in *ICD-10* as compared to *DSM-IV-TR*, and in *ICD-10*'s ability to attach the entire range of substance-related diagnoses to any drug class, whereas *DSM-IV-TR* provides more limits on the number of diagnostic possibilities. Generally, *ICD-10* has more categories available for each substance than *DSM-IV-TR*, but some of these categories are rarely used because their existence is unclear. An example is hallucinogen withdrawal—a possible category in *ICD-10* that is not present in *DSM-IV-TR* and probably rarely used in *ICD-10* due to uncertainty about its existence.

Overall, there are many more similarities than differences between *DSM-IV-TR* and *ICD-10*, especially when one focuses on the specific categories described (with the exception of

abuse and harmful use, also likely to change in *DSM-V*), and on the similarities in the ways dependence and its course modifiers are defined. It is hoped that future work will succeed in creating even more consistency between these two classification systems. A review of the two systems by Rounsaville discusses other barriers to reconciling *ICD* and *DSM* in the future (9). He concludes, as suggested by this review, that reconciliation may be most difficult for the abuse/harmful use disparity, perhaps less so for the substance-induced disorders, and most readily achieved for dependence.

Diagnostic Laboratory: Screening for Drug Abuse

Karl G. Verebey ■ Gerard Meenan

Alcohol and drug abuse are two major health care problems in America. This has prompted advancement in laboratory methods diagnosing substance abuse in psychiatric patients and suspected drug abusers. Physicians are more knowledgeable today than in the past about the nature of drug abuse, yet uncertainty remains over the use of the “diagnostic laboratory.” The confusion surrounding drug-abuse testing is a result of many variable technicalities. Each drug is unique, and detectability depends on the drug’s chemical properties, size of the dose, frequency of use, the biologic specimen tested, differences in individual drug metabolism, sample collection time in relation to use, and sensitivity of the analytic method (1,2). All these variables make each test request unique, and there are no general rules for all drugs and all situations.

This chapter reviews drug-abuse testing from several perspectives. A brief history is followed by a section on the reasons for testing. In addition, sections on the available methodologies, testing strategies, and data interpretation are included.

HISTORY OF DRUG TESTING

The modern drug-abuse testing laboratory is a relatively recent development. Initially, drug testing was exclusively part of the pathology services in which overdose or fatal toxicity cases were investigated for the causative agents. Very large sample volumes were processed with crude, nonspecific methodology. As drugs of abuse became a major social problem, overdose cases also became more common. Hospital laboratories were called upon to perform emergency toxicology procedures to identify drug classes or specific drugs.

Another branch of testing developed when patients in drug-abuse treatment programs needed follow-up to objectively monitor whether or not the substitute drug (generally methadone) was taken. Also, testing for drugs of abuse checked if abstinence was maintained. Such testing that aided rehabilitation was performed mostly in hospitals or clinical laboratories.

The volume of drug-abuse testing has increased as a consequence of widespread employee testing by the federal government, the military, and the private industry. This has influenced the development of specific urine drug testing laboratories.

Forensic drug testing is the newest to appear on the scene, forced upon the clinical laboratories by the legal profession. The results of a drug test were used for more than clinical purposes. The results could have punitive consequences. Positive results

were sometimes questioned or flatly denied, and lawyers started to scrutinize every step of the testing process from collection to reporting of results. Forensic accountability was then required to protect the “due process rights” of clients. After losing court cases, clinical laboratories that performed legally sensitive testing began to reorganize. “Chain of custody” procedures were designed, and quality control and quality assurance procedures were implemented to promote reliability and reproducibility of test results. Drug-testing procedures and instrumentation became more sophisticated, more sensitive, and more specific. As a result, extremely small quantities of drugs can be determined reliably at the nanogram and picogram range, and gas chromatography-mass spectrometry (GC-MS) and gas chromatography-tandem mass spectrometry (GC-MS-MS) provide assurance of specific drug identification (2,3). More recently LC-MS and LC-MS-MS became favored because in many cases no extraction was needed, simplifying analysis.

RATIONALE FOR TESTING

Drug abuse is characterized by impulsive drug-seeking behavior with occasional interruption and later almost certain relapses. A common feature of many drug abusers is denial. Abusers lie to themselves and the forbidding outside world to protect their continued, obsessive use of drugs and/or alcohol. For this reason, physicians are seldom given voluntarily the diagnostically important information about addictive habits.

The type of drug and the abuse pattern are important parts of the medical history. The attending physician cannot properly design treatment when kept in the dark about the patient’s addiction. Symptoms of physical and/or psychiatric illness may be simulated by the presence or absence of certain drugs. The dichotomy of symptoms associated with the presence or absence of a drug is best illustrated by the opioid class of drugs (4). While under the influence of an opioid drug such as heroin, the addict experiences euphoric, anxiolytic sedation; mental clouding; sweating; and constipation. Opioid withdrawal signs and symptoms are characterized by pupillary mydriasis, agitation, anxiety, panic, muscle aches, gooseflesh, rhinorrhea, salivation, and diarrhea. Thus, the two different sets of symptoms belong to the abuse of the same drug, observed at times when opioid drugs are present and at times when opioid drugs are absent.

In predisposed individuals, drugs can trigger behavior similar or identical to psychosis. For example, phencyclidine (PCP), lysergic acid diethylamide (LSD), amphetamines, or

cocaine can cause toxic psychosis that is indistinguishable from paranoid schizophrenia. These drugs can produce model psychosis in anyone given an adequate dose. Drug-induced psychosis has a different prognosis and must be treated differently from psychosis related to endogenous organic, anatomic, or neurochemical disorders (5).

Treatment of drug abusers in therapy would be extremely handicapped if testing were not used. Comprehensive drug testing is important for making precise follow-up evaluations and selecting appropriate treatment (6). Thus, the first good reason for laboratory drug testing is to provide objective identification of drug abusers and identify the substance abused.

Testing is also important after drug abusers are identified. Treatment strategies are intimately connected to frequent urinalyses to monitor recovering addicts. Negative results support the success of treatment, while positive results alert the physician to relapses. An exception is methadone treatment, where a positive result proves that the substitute drug is taken as prescribed. Objective testing, therefore, is a necessary component of modern substance abuse treatment (6).

Drug-abuse testing may also be forensic in nature. Parole officers monitor ex-drug abusers after release from incarceration. A positive drug test may signal to law enforcement the parolee's involvement with drugs and may invalidate the parole.

Often health care professionals such as doctors, dentists, and nurses are afflicted with drug-abuse problems. Once involvement with drugs is exposed, professional medical licenses are in danger of suspension. Rehabilitation of addicted health care professionals is linked to drug testing as a condition of probation. But testing must meet forensic standards because of possible legal challenges.

Professional athletes sometimes abuse drugs. Both national and international sport associations prohibit the use of performance-enhancing drugs (7). Staying drug free is a prerequisite for athletes to be allowed to compete. Forensic laboratory testing for drugs of abuse and performance-enhancing drugs is the objective technique used to enforce these rules.

Finally, workplace and public safety may be endangered by impaired or intoxicated employees. Bankers and stockbro-

kers who handle investors' money must not be influenced by psychoactive drugs, especially drugs that cause delusions and impulsive risk-taking behavior such as cocaine and amphetamine. Similarly, drug-abusing professionals in other fields may endanger the public. Drug and alcohol abuse has been identified among airline pilots, bus drivers, railroad engineers, and police officers. In all these professions, drug-abuse testing is helpful to the drug abuser and in protecting the general public. The abuser gets early treatment and a chance for early rehabilitation. The public is saved from potential drug-related accidents and associated damages.

A decrease in drug abuse as a result of drug testing has been demonstrated clearly in the military. Prior to the institution of mandated random testing in 1981, 48% of armed forces personnel used illegal drugs. Three years after testing began, fewer than 5% were using drugs (8). Although critics often attack testing as ineffective, drug abuse clearly decreases where effective drug testing exists. Testing is a deterrent because most people do not take chances if they know that when their drug use is identified it can result in the loss of their job.

ABUSED DRUGS TESTED

Epidemiologic studies expose the types of drugs used, new trends, and frequency of drug abuse by different populations in specific geographic regions and countries. Such information is used to help identify drug abusers in critical areas. The testing of five drugs, selected by the Department of Health and Human Services/Substance Abuse and Mental Health Services Administration (DHHS/SAMHSA), is required for accreditation by their National Laboratory Certification Program (NLCP) (Table 11.1). Panel I testing includes amphetamines, cannabinoids, cocaine, opioids, and PCP (usually referred to as the SAMHSA-5). Panel II represents other commonly abused drugs, such as barbiturates, benzodiazepines, methadone, oxycodone, methylenedioxymethamphetamine (MDMA), methylenedioxyamphetamine (MDA), and ethanol. Interestingly, some powerful hallucinogens are seldom tested routinely. LSD, psilocybin, and ketamine are listed in Panel III with club drugs and other designer drugs. Some of these drugs are psychoactive

TABLE 11.1 Panel groups of abused drugs: tests performed by laboratories

I: Required^a	II: Commonly performed	III: Not commonly performed
Amphetamines	Barbiturates	LSD
Cannabinoids	Benzodiazepines	Fentanyl
Cocaine	Methadone	Psilocybin
Opioids	Oxycodone	Ketamine
Phencyclidine	MDMA	GHB
	MDA	Designer drugs
	Ethanol	

^aTesting required for certification by the DHHS/SAMHSA National Laboratory Certification Program.

in very low doses. Therefore, when they are diluted in total body water, concentration is low and detection is difficult, unless large doses are taken or samples are collected shortly after drug use.

“Designer drugs” often are structurally similar to the commonly abused drugs. While they are new and structurally different, they are already regulated when sold and used. Nevertheless, “street chemists” are synthesizing new and often dangerous drugs. They will operate as long as abusers will try new drugs, and their illegal trade remains profitable. Alpha-methylfentanyl is an example of an illicit analog of fentanyl. The laboratory’s role is to develop new and sensitive methods for the detection of new designer drugs in the biofluids of users.

CLUB DRUGS OF ABUSE

Gamma-hydroxybutyrate (GHB) is a central nervous system depressant. It is an endogenous substance in human and mammalian tissues at very low concentrations and thought to be a neuromodulator. It has clinical use in the treatment of cataplexy. Some of the pharmacologic effects are drowsiness, euphoria, dizziness, vomiting, respiratory depression, and death. Use of this drug as a recreational or club drug has resulted in GHB intoxication and death (9). Detection of GHB is accomplished with analysis of urine by GC-MS.

Another drug used in clubs and date rapes is flunitrazepam (Rohypnol), a member of the benzodiazepine family of drugs. Only available in Europe, it is abused in the United States as a club drug. At low doses it causes relaxation and sleepiness, and at larger doses, anesthesia. Similar to other benzodiazepines, detection is performed by screening with an immunoassay and confirmation with GC-MS or high performance liquid chromatography (HPLC) (10).

Recently, ketamine (Ketalar) or Special K has appeared in clubs. It is chemically related to PCP or angel dust (10). Both of these drugs were used as rapidly acting dissociative anesthetics. However, in some individuals, ketamine and PCP produce exit psychosis with paranoid ideation. For this reason ketamine is currently not used in humans; it is used in veterinary medicine. Abuse of ketamine results in a diverse set of reactions depending on individual predispositions: numbness, loss of coordination, sense of invulnerability and muscle rigidity in some individuals, aggressive/violent behavior, slurred speech, blank stare, and an exaggerated sense of strength in others. Immunoassays were developed for ketamine screening. Positive results are confirmed by GC-MS, GC-MS-MS, or LC-MS-MS (10).

TESTS AVAILABLE

A number of different laboratory methods are available for drug screening. When the drug-abuse habit of a patient is unknown, the physician usually requests a “comprehensive drug screen.” Different laboratories have different definitions of the term “comprehensive,” omitting some important but less used drugs. The physician should be familiar with laboratory menus to ensure effective use of the drug-testing laboratory.

Urine samples are most commonly sent for a “routine drug screen.” But oral fluid (saliva) testing is becoming more popular because of the ease of observed collection (11). Psychiatrists and other physicians assume that a comprehensive drug test detects all abused drugs. Thin-layer chromatography (TLC), mostly used in the past, is not sensitive enough to detect drugs such as marijuana, PCP, LSD, psilocybin, mescaline, and fentanyl, among others. Thus, a negative drug screen may mean one or more of the following: the test menu doesn’t contain the drug(s) of interest, the test cutoff is too high, and there is no evidence of high dose or recent abuse of drugs commonly detected by the screening method used. Low-level abuse of drugs is not likely to be detected; therefore, “false negatives” are a possible result. More sensitive enzyme immunoassays (EIA) have replaced TLC as an initial screening procedure. EIA, enzyme-linked immunosorbent assay (ELISA), fluorescent polarization immunoassay (FPIA), and radioimmunoassay (RIA) are routinely used for initial drug screening in serum, urine, oral fluid, sweat, and hair.

If, for example, a physician suspects marijuana abuse, he/she must specifically request that a marijuana screen be performed by an immunoassay at the lowest cutoff. Screening for an unknown drug can be performed by capillary gas-liquid chromatography (GLC). In a single GLC analysis, more than 25 drugs can be identified (Fig. 11.1). This system is advantageous when there is no clue to the identity of the

Figure 11.1. Gas-liquid chromatographic (GLC) tracing showing separation of a drug mixture. The abscissa is time in minutes; the ordinate is detector response. The different drugs are number coded on the tracing. The drugs are 1, amphetamine; 2, methamphetamine; 3, meperidine; 4, phencyclidine (PCP); 5, methadone; 6, amitriptyline; 7, imipramine; 8, cocaine; 9, desipramine; 10, pentazocine; 11, codeine; and 12, oxycodone. (Reprinted with permission from Alltech Associates, Inc., Deerfield, IL.)

abused or toxic substance. However, GLC, LC-MS, and GC-MS are all time-consuming, labor-intensive, and usually expensive procedures. LC-MS is similar to GC-MS in principle; however, sample preparation is easier. *LC-MS* is preferable for the water-soluble drugs that are difficult to extract. The EIA and ELISA tests are significantly less expensive and more practical for screening. Also, EIA procedures are easily adaptable for high-volume automated screening of drugs. In fact, most good laboratories offer a 5- or 10-drug panel, with or without alcohol, performed by EIA.

ANALYTIC METHODOLOGIES

Alcohol

Alcohol abuse is a legal version of drug abuse in the United States and most parts of the world. The addictive chemical substance in all alcoholic beverages is ethanol or ethyl alcohol. Ethanol is present in beer (3.2% to 4.5%), wine (7.11% to 14%), and distilled beverages (40% to 75%) (12). Using an average of 0.02 g% blood alcohol increase per drink, a 170-pound subject must ingest about four drinks of either 12 oz beer, 4 oz wine, or 1.5 oz whiskey in 1 hour to reach the ethanol level of 0.08 g/100 mL blood, or 80 mg/100 mL blood. The per se illegal limit to operate an automobile in most states is 0.08 g%.

Ethanol is one of the few drugs for which blood levels correlate relatively well to levels of intoxication or impairment, although large individual variations do exist due to tolerance and genetic variations. Ethanol is analyzed by means of enzymatic assays or GLC methods (13). The most specific quantitative method for blood alcohol determination is GLC or “head space” analysis by GLC. Volatile substances such as ethanol are driven out of aqueous biofluids into the “head space” or air space above the liquid layer in the heated and sealed vials. After adding an internal standard (n-propanol) and incubating at 37°C, air samples are taken from the test tubes by a special airtight syringe and injected into the gas chromatograph for separation and quantitation. This quantitative method separates ethanol from other alcohols and other volatile substances (13).

If ethanol analysis is performed on breath by means of a breathalyzer, or on blood or urine by one of the chemical or enzymatic assays, the results are reliable for general use. Some states allow breathalyzer results in driving while intoxicated (DWI) cases and driving accidents to determine legal impairment (13). In forensic cases, results should be confirmed with a blood specimen using a GLC analysis. Alcoholism is hidden by denial. Therefore, ethanol measurement must be requested in addition to a drug screen because alcohol testing is not performed routinely by most laboratories. For clinical purposes, urine alcohol levels can be converted to blood levels by a factor of 1.3 urine-to-blood ratio. In other words, the urine levels are usually 30% higher than blood levels. However, there is a great variation in the ratios shown in numerous studies. Breath alcohol analysis is widely used by law

enforcement officers due to its practicality and quick noninvasive characteristic.

Alcohol Biomarkers

Alcohol biomarkers have been described as useful, objective indicators of outcome measures of pharmacologic or behavioral interventions for alcohol abuse, screening tests for people with alcohol problems, and a means of confirming abstinence in people prohibited from drinking (14). Alcohol biomarkers are either indirect or direct. Indirect biomarkers include blood chemistry analytes that demonstrate the harmful effects of alcohol. Examples of indirect biomarkers include gamma-glutamyltransferase (GGT), alanine aminotransferase (ALT), aspartate aminotransferase (AST), and carbohydrate-deficient transferrin (CDT). Direct alcohol biomarkers are metabolites of alcohol. Examples of direct biomarkers include ethyl glucuronide (EtG) and ethyl sulfate (EtS) (14).

Ethyl Glucuronide

EtG is a biomarker for recent alcohol use or exposure. Laboratory testing is performed on urine specimens, and EtG is detected for a significantly longer time after ingestion than alcohol (15). Testing for EtG includes EIA, HPLC, GC-MS, and LC-MS-MS. EIA offers a fast, inexpensive screen that can be performed on analyzers found in most clinical laboratories. EIA helps rule out alcohol consumption. All nonnegative EIA screens should be confirmed by an alternate methodology such as LC-MS-MS, which provides sensitive and highly specific results for EtG. The significant cost of an LC-MS-MS instrument and the need for a highly skilled instrument operator make EtG confirmation testing available at more specialized laboratories. LC-MS-MS can provide detection levels much lower than that of EIA. However, alcohol is ubiquitous in society; it is present in a number of commercial and household goods. Definitive data about a reliable cutoff to differentiate between alcohol abuse and accidental exposure is still under investigation.

Information in the scientific literature has reported that EtG levels greater than 500 ng/mL are extremely unlikely to be caused by accidental exposure to alcohol (15–17). Scientific studies have been made of different types of accidental exposures. One study (16) of hand sanitizer use (i.e., 20 washes per day with 60% ethanol containing handwash for 5 days) has been reported. Nine subjects' first morning urine samples, the most concentrated of the day, demonstrated levels between less than 10 and 114 ng/mL. Similarly, another study (17) of mouthwash use (i.e., three times daily with mouthwash containing 12% alcohol) demonstrated the following after 5 days. The first morning urine specimens were tested and all showed levels of less than 120 ng/mL. The risk of accidental exposure exists and must be considered in the evaluation of any patient.

An additional caution in the interpretation of a positive EtG result is the presence of glucose in a patient's urine. A study of postcollection synthesis of EtG by bacteria suggests

the following: The risk of glucose in the urine of a diabetic patient is high. Microbial fermentation of the glucose to produce ethanol is likely. Bacterial contamination of the urine because of a urinary tract infection can occur. When these three factors are present, the likelihood of a positive EtG result is at least one in three (18).

Similar to the interpretation of other laboratory tests, a positive EtG result should be used as a sign—in this case a sign of possible alcoholic beverage consumption. Upon receipt of a positive EtG result, the health care professional needs to make further evaluation of the patient.

Enzyme Immunoassays and Enzyme-Linked Immunosorbent Assays

Figure 11.2 depicts the principle of immunoassays in drug detection. Antibodies are used to seek out specific drugs in biofluids. In samples containing one or more drugs, competition exists for available antibody-binding sites. The presence or absence of specific drugs is determined by the percent binding.

The specificity and sensitivity of the antibodies to a given drug differ depending on the particular drug assay and the assay manufacturer. Immunoassay can be very specific; however, compounds structurally similar to the drug of interest (i.e., metabolites or structural congeners) often cross-react. Interaction of the antibody with a drug plus its metabolites increases the sensitivity of the assay.

EIA, ELISA, and FPIA are commonly used for drug-abuse screening because no complicated extraction is required and

the system lends itself to easy automation. EIA with specific antibodies is sensitive for most drugs and detects low drug and metabolite concentrations in biofluids (19).

ELISA offers greater sensitivity than some other screening assays (11). The sensitivity and specificity of the ELISA provide valuable utility to the clinician. A variety of biologic samples are applicable to ELISA such as urine, serum/plasma/blood, and oral fluid (saliva). Depending on the concentration of drug expected in the specimen, sample size can be adjusted accordingly. ELISA is available for manual, semiautomated, and fully automated platforms. Analysis time varies between 1 and 2 hours. ELISA cutoff levels and limits of detection (LODs) for oral fluid samples are very low: amphetamines 50 and 1 ng/mL, barbiturates 20 and 1 ng/mL, benzodiazepines 5 and 2 ng/mL, cocaine 20 and 1 ng/mL, methadone 5 and 1 ng/mL, opiates 40 and 0.25 ng/mL, PCP 10 and 0.5 ng/mL, THC 4 and 0.1 ng/mL, respectively. Also sample volumes for ELISA are as low as 10 μ L per analysis (20).

As seen in the preceding paragraph, allowing for analysis of low levels of drug abuse, the LOD is in the very low nanogram range (11).

Comparative studies in the scientific literature support oral fluid as an excellent alternative to urine and blood for the identification of drug abuse. Because oral fluid collection is convenient, noninvasive, fast, and observable, sample adulteration is not likely to occur (11).

Several oral fluid sample collection devices are available. However, neat oral fluid collected in plain test tubes contained the highest concentrations of drugs when compared to collectors containing liquid buffer. Also, when collecting saliva into a liquid buffer, using a “lollipop”-type collector, one does not know if any oral fluid is actually collected (21,22). On the other hand, spitting into a tube is not as acceptable to subjects as are the “lollipop”-type collectors.

On-Site Screening Immunoassays

The increased prevalence of drug use and abuse has prompted the development of new drug screening technology that produces results in as little time as 5 minutes. Several situations require immediate results. Hospital emergency departments need rapid detection of drugs causing overdose toxicity and psychiatric reactions. In addition, quick results are useful for monitoring compliance within drug rehabilitation programs and supervising parolees released conditionally from prison. Because these tests are designed to be performed on-site, they are performed directly in front of the person being tested or, certainly, at the collection site. All presumptive positive tests must be confirmed by a laboratory-based alternate method. On-site testing is particularly useful for preemployment screening, random testing, probable cause workplace testing, and accident-related injuries. On-site screening may also be important to conduct in safety-oriented occupations, such as public transportation, aviation, and nuclear energy plants.

Visually interpreted immunoassays do not require complex instrumentation and no special technical skills. These kits are

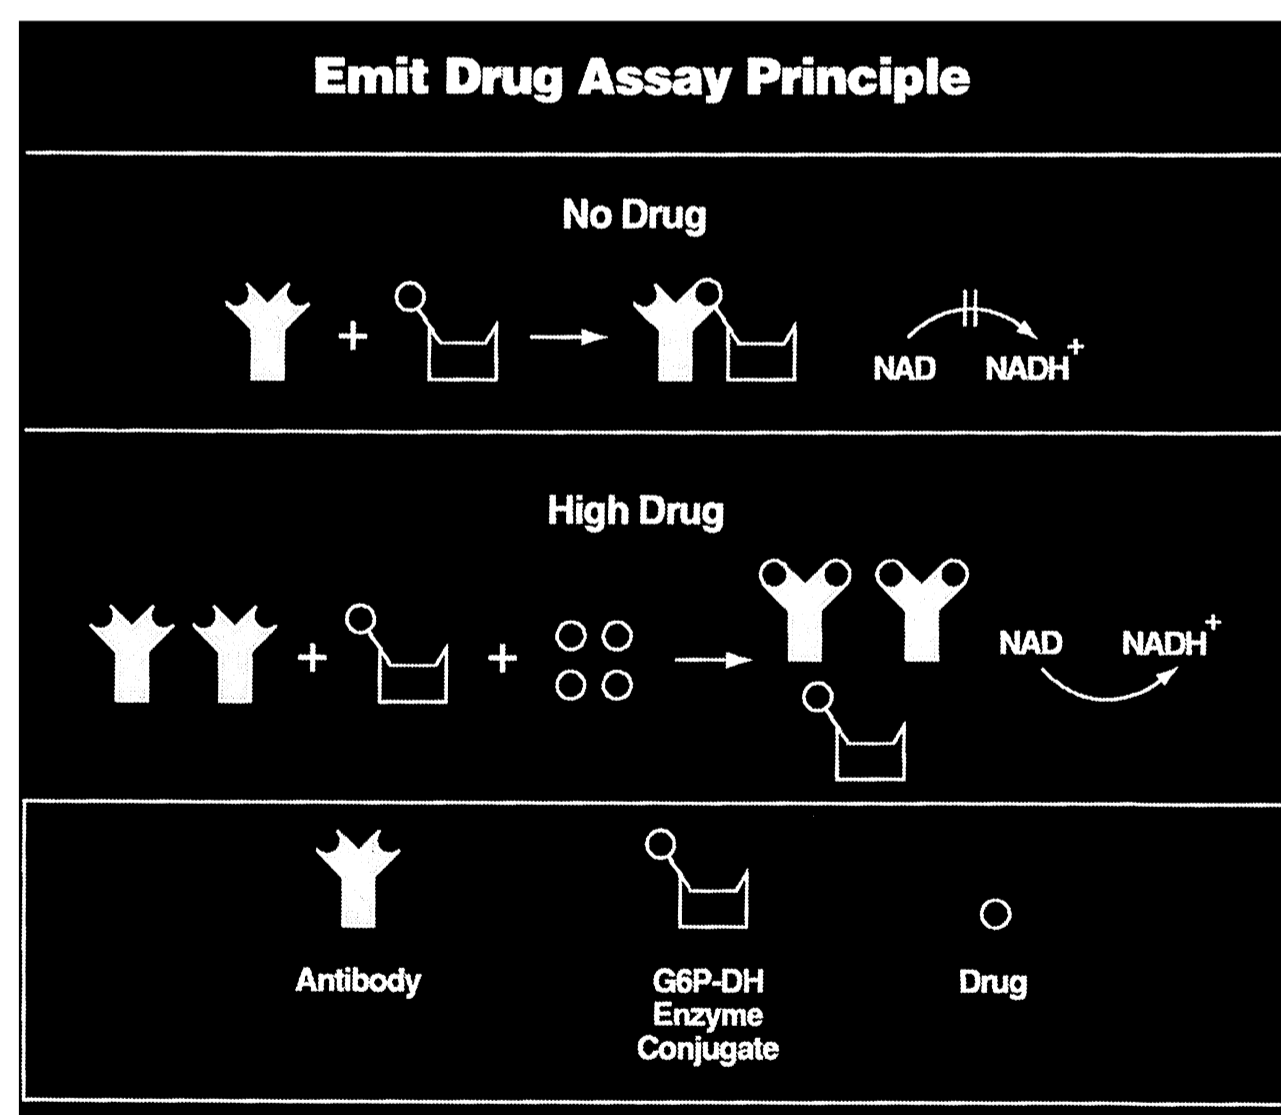

Figure 11.2. The basic principle of enzyme immunoassay (EIA) reactivity as it relates to drug detection. Molecules with similar functional groups cross-react; hence, immunoassays have less specificity than do chromatographic assays. EIA is the most popular screening procedure. G6P-DH = glucose-6-phosphate dehydrogenase; NAD = nicotinamide adenine dinucleotide; NADH = nicotinamide adenine dinucleotide (reduced form). (Reproduced with permission from Syva Company, Inc., Palo Alto, CA.)

particularly effective because there is no calibration, instrument maintenance, or downtime and no special skills needed to perform these tests. Most kits have built-in quality control zones in each panel, which ensures reagent integrity, sample validity checks, and sufficient sample size. Lastly, most on-site devices have an extended shelf life at room temperature.

There are currently many on-site kits available using simultaneous multiple drug detection capabilities. Some of the kits employ regular urine collection cups with multiple drug tests in a separate chamber in the device. Urine samples are in contact with the solid-phase, lyophilized reagents, and the reaction is allowed to continue for 5 minutes. The operator visually examines each zone for the presence or absence of a colored bar. A positive specimen produces a blank reaction in the drug detection zone. A negative specimen produces a colored bar. The method incorporates preset threshold concentrations that are set for each drug by SAMHSA.

The iScreen (Instant Technologies) in Figure 11.3 is a CLIA-waived stat screening kit, which detects 1 to 10 drugs from 15 drugs or drug classes. The device is dipped in urine and the results are visually read in 5 minutes. The iScreen also contains controls and several validity tests. It is a one-step,

Figure 11.3. iScreen is a one-step urine drug detection card. The choice is from 15 commonly abused/used drugs. The program may choose 1 to 10 drugs to be placed on the test card. A simple dip in the urine sample and read provides results in minutes. The card also contains sample validity test zones for pH, specific gravity, oxidants, pyridinium chlorochlorate, glutaraldehyde, and creatinine. (Reproduced with permission from Instant Technologies, Norfolk, VA.)

competitive, membrane-bound immunoassay. A urine sample can be evaluated for the presence of each of the specified classes of drugs. When one or more drugs are present or positive in a urine sample, the result window remains blank. Negative results are shown as a colored bar next to each result window. On-site screening kits have demonstrated greater than 97% agreement with confirmatory tests such as GC-MS (23). However, it must be stressed that these kits provide only preliminary test results, just as immunoassay tests run in a laboratory. A more specific alternate chemical method must be used to confirm presumptive positive screening results. GC-MS and LC-MS are the most specific confirmation methods.

An example of an on-site screening analyzer is the i-Cup (Instant Technologies, Fig. 11.4). The i-Cup performs two functions: It is a urine collection device ready to send out to a laboratory for confirmation of positive screen tests. Also, it is a one-step test for the rapid, qualitative detection of 3 to 9 drugs choosing from 14 drugs or drug classes in human urine. The choices are cannabinoids, cocaine/metabolite, opiates, amphetamines, PCP, tricyclic antidepressants, barbiturates, methadone, benzodiazepines, ecstasy (MDMA), methamphetamine, morphine, oxycodone, and propoxyphene.

Figure 11.4. The i-Cup is an “all in one” urine sample collector and drug testing device. It detects the presence of drugs and adulterants (if present) in 5 minutes. Also, it measures the urine temperature (90°F–100°F) to prevent dilution during collection. The choice is from 14 drugs or drug classes that can be custom ordered in 3 to 10 drug panels. Positive samples can be sent directly to the laboratory for confirmation. The i-Cup also screens for adulterants: pH, specific gravity, and various oxidants. (Reproduced with permission from Instant Technologies, Norfolk, VA.)

Gas-Liquid Chromatography and Gas Chromatography-Mass Spectrometry

GLC is an analytic technique that separates molecules by migration, similar to TLC. The TLC plate is replaced by long glass or metal tubing called columns, which are packed or coated with stationary materials of variable polarity. Figure 11.1 is an example of a GLC tracing showing separation of drugs in a mixture. The extracted analyte is carried through the column to the detector by a steady flow of heated gas. The detector responds to the vaporized drugs. This response is graphically recorded and quantified as area under the peak. The peak area is proportional to the amount of drug or metabolite present in the sample. Identical compounds travel through the column at the same speed because they have identical interaction with the stationary column packing. The time between injection and the observed response of the peak at the recorder represents the retention time. Identical retention times of drugs or metabolites on two different polarity columns constitute strong evidence that the substances are identical.

Indisputable evidence can be obtained by the use of the MS detector, which identifies substances by gas chromatography separation and mass fragmentation patterns. Figure 11.5 shows a GC-MS separation and fragmentation pattern of cocaine and its major metabolite benzoylecgonine. The separation is shown at the bottom of the figure, while the fragmentation is shown in the top two panels. Cocaine has the fragments 82, 182, and 303 masses, while benzoylecgonine has 82, 240, and 361 masses.

Not all bonds in molecules are of equal strength. The weak bonds are more likely to break under stress. In the MS detector, electron beam bombardment breaks weak molecular bonds. The exact mass and quantity of the molecular fragments or breakage products are measured by the mass detector. The

breakage of molecules results in a fragmentation pattern unique for a specific drug. The fragments occur in specific ratios to one another; thus, the GC-MS method is often called “molecular fingerprinting.” Therefore, mass spectroscopy with either GC or LC separation is the most reliable and most definitive procedure in analytic chemistry for drug identification (3).

The fragmentation pattern of unknowns is checked against a computer library that lists the mass of drugs and related fragments. Matching a control’s fragments and fragment ratios is considered absolute confirmation of a particular compound. The sensitivity of GLC for most drugs is in the nanogram range, but with special detectors some compounds can be measured at picogram levels. GLC and GC-MS can also be used quantitatively, which provides additional information helping to interpret a clinical syndrome or explain corroborating evidence in forensic cases. Tandem mass spectrometry (MS-MS) offers even greater sensitivity than GC-MS or LC-MS alone. For example, LSD confirmation by GC-MS-MS is as low as 200 pg. As the screening method’s sensitivity approaches the low-nanogram range, confirmation sometimes requires picogram-level sensitivity to confirm presumptively positive samples.

Technically, samples are introduced into MS-MS detectors from gas chromatographs, liquid chromatographs, or direct insertion probes. The choice depends on sample volatility and purity. Thus, MS-MS provides a confirmation procedure for the even more sensitive screening methods (e.g., ELISA) and is used at very low drug concentrations common in alternate matrices, such as oral fluids, sweat, and hair analysis.

HPLC is used especially for drugs that are polar or not volatile and cannot be made volatile by derivatization. Some of these drugs and glucuronidated metabolites are not amenable for analysis by GC or GC-MS. Examples of drugs

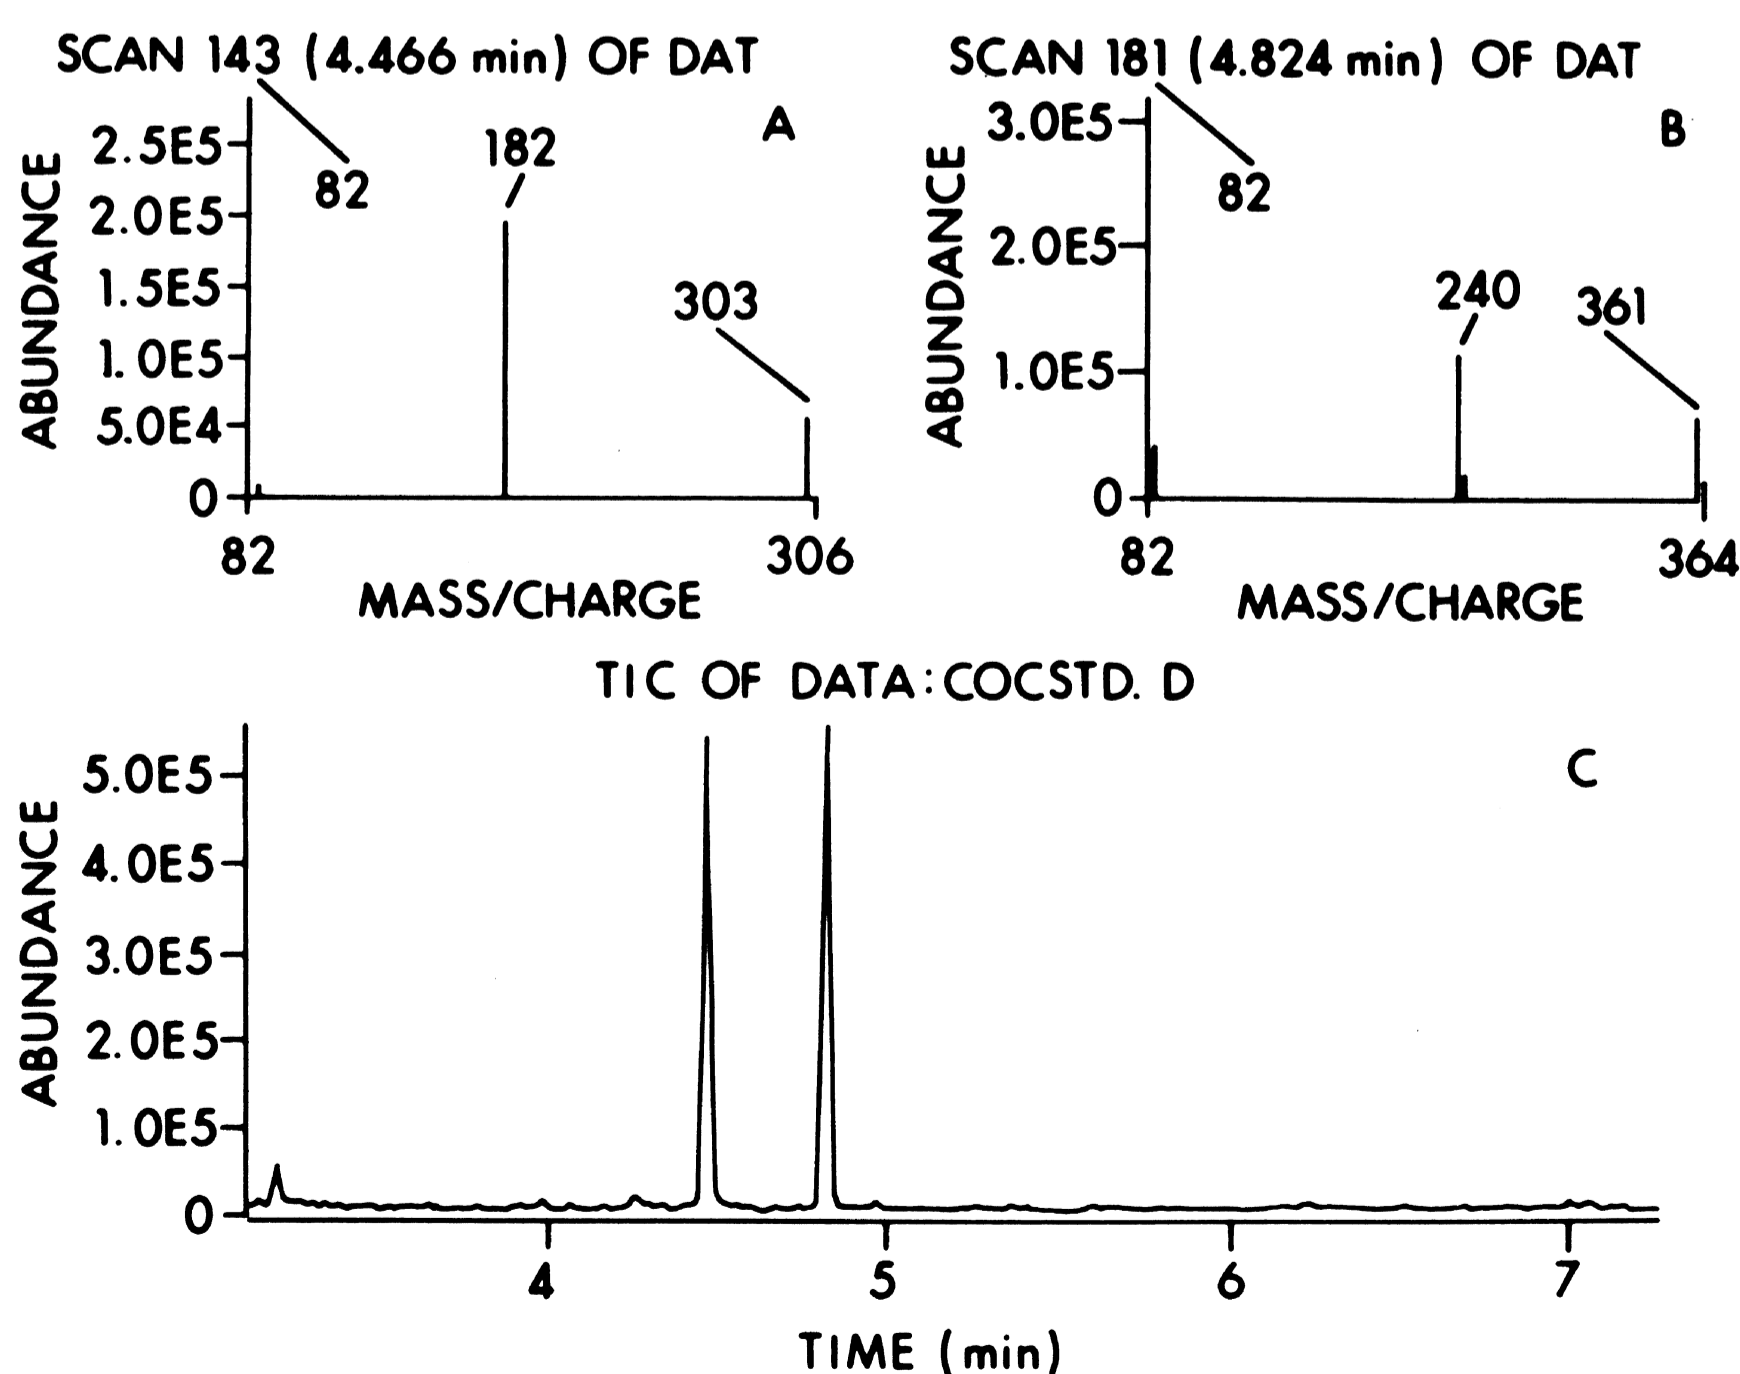

Figure 11.5. Gas chromatography-mass spectrometry showing the fragmentation pattern of cocaine (A) and benzoylecgonine (B). Total ion chromatogram (C) showing the chromatographic separation of cocaine (4 minutes 28 seconds) and benzoylecgonine (4 minutes 51 seconds). (Reproduced with permission from Drs. R. W. Taylor, N. C. Jain, and the *Journal of Analytical Toxicology*.)

TABLE 11.2 Performance characteristics of different assays for drugs of abuse

Assay	Sensitivity	Specificity	Accuracy	Turnaround time	Cost (\$)
On-site	Moderate–high	Moderate	Qualitative ^a	Minutes	4–25
EMIT, FPIA, ELISA	Moderate–high	Moderate	Low–high	1–4 hours	5–10
GC	High	Moderate	Excellent	Day(s)	20–40
GC-MS	High	High	Excellent	Day(s)	30–100
LC-MS	High	High	Excellent	Day(s)	30–100

^aResults are generally expressed only in qualitative terms (i.e., positive/negative); consequently, accuracy may be difficult to assess. Presumptive positive test results need confirmation by either GC-MS or LC-MS.

EMIT, enzyme-multiplied immunoassay technique; FPIA, fluorescent polarization immunoassay; GC, gas chromatography; GC-MS, gas chromatography-mass spectrometry; ELISA, enzyme-linked immunosorbent assay; LC-MS, liquid chromatography-mass spectrometry.

or drug groups for which HPLC is the choice of analysis are the benzodiazepines, tricyclic antidepressants, and acetaminophen, among others.

When a routine toxicology screen is ordered, the physician is often not aware that options are available for more specific screening and confirmation methods. Table 11.2 shows the performance characteristics of different types of assays for drugs of abuse identification.

CHOICE OF BODY FLUIDS AND TIME OF SAMPLE COLLECTION

Some drugs are metabolized extensively and are excreted very quickly, such as cocaine (24), whereas others, such as marijuana, stay in the body for a long time (25). Thus, success of detection depends not only on the time of sample collection after the last use, but also on the drug's characteristics and whether the analysis is performed for the drug itself or for its metabolite(s). Table 11.3 illustrates the typical screening and confirmation cutoff concentrations and the expected times of detectability for some commonly abused drugs when analyzed in urine, blood, saliva, and hair.

When drug-abuse detection is the goal, the following questions should be asked: (a) How long does the suspected drug stay in the body, or what is its biologic half-life? (b) How fast and how extensively is the drug biotransformed? Based on the rate of biotransformation, should one look for the drug itself or its metabolite(s)? (c) Which body fluid is best for analysis, and what is the major route of excretion? Intravenous use or smoking of drugs provides nearly instantaneous absorption into the bloodstream. Metabolism, tissue distribution, and excretion of the drug and/or metabolites into urine occur depending on the rate of the aforementioned processes. Oral use of drugs will result in slower absorption, but greater first-pass metabolism in the liver.

Cocaine is rapidly biotransformed into benzoylecgonine and ecgonine methyl ester. Less than 10% unchanged cocaine is excreted into the urine, and it is detectable only for 12 to

18 hours after use. What does this suggest to the clinician who wants to identify a cocaine abuser? Cocaine has a short half-life; therefore, if use is suspected within hours or the patient is under the influence of cocaine at the time of sample collection, the parent compound should be present in detectable concentrations both in blood and in urine (24). Plasma enzymes continue to metabolize cocaine to benzoylecgonine even after blood is taken from the body. Therefore, blood samples must be collected into tubes containing sodium fluoride to inactivate the plasma enzymes. Benzoylecgonine is the major metabolite of cocaine; its half-life is about 6 hours and it is excreted into urine at levels totaling approximately 45% of the dose. Thus, cocaine abuse detection is best accomplished by collecting urine and analyzing it for benzoylecgonine, which is the target compound of most assays.

Marijuana is slowly biotransformed. It is very lipid soluble. In occasional users the average time of detection is approximately 4 to 6 days. In chronic users the average detection time is approximately up to 30 days (25). As a consequence of slow biotransformation and large tissue distribution, urine tests are effective for many days to detect the major metabolite, 9-carboxy-tetrahydrocannabinol (9-carboxy-THC). The individual pharmacokinetic drug metabolism and drug excretion information is important to determine which drug or metabolite is best for detection. Many physicians prefer blood to urine for drug screening because blood levels constitute stronger evidence of recent use and are related more closely to brain levels and drug-related behavioral changes than are urine levels.

The collection of urine specimens must be supervised to ensure donor identity and to guarantee the integrity of the specimen. It is not unusual to receive someone else's urine or a highly diluted sample when collection is not supervised. Also, the laboratory tests for pH, specific gravity, and creatinine levels assure that the sample is not adulterated. As a rule, first morning urine samples are more concentrated; therefore, drugs are easier to detect than in more diluted daily samples. The decision to use blood or urine must be based on the purpose of the test and the suspected drug's pharmacokinetic,

TABLE 11.3 Drugs of abuse reference guide

Substance	Urine screening cutoff concentration (ng/mL)	Urine confirmation cutoff concentration (ng/mL)	Urine detection times	Blood/oral fluid detection times	Hair detection times
Amphetamine	1000	500	1–3 days	12 hours	Up to 90 days
Barbiturates (short acting)	200	200	2–3 days	1–2 days	Up to 90 days
Barbiturates (long acting)	200	200	2–3 weeks	4–7 days	Up to 90 days
Benzodiazepines (therapeutic use)	200	200	3 days	6–48 hours	Up to 90 days
Benzodiazepines (chronic use)	200	200	4–6 weeks	6–48 hours	Up to 90 days
Cocaine (benzoylecgonine)	300	150	2–5 days	2–5 days	Up to 90 days
Codeine	300	300	2–3 days	2–3 days	Up to 90 days
Morphine	300	300	2 days	1–2 days	Up to 90 days
Heroin (6-acetylmorphine)	10	10	Up to 24 hours		
Marijuana	50	15	Casual use: 1–3 days Chronic use: up to 30 days	Up to 24 hours	Up to 90 days
Methadone	300	300	2–4 days	2–4 days	Up to 90 days
Methamphetamine	1000	500	3–5 days	1–3 days	Up to 90 days
Phencyclidine	25	25	Casual use: 2–7 days Chronic use: up to 30 days	Up to 48 hours	Up to 90 days

metabolic, and excretion characteristics. Generally, drug levels in urine are higher than in blood; therefore, urine is the biofluid of choice for drug detection.

INTERPRETATION OF RESULTS

Psychoactivity of most drugs lasts only a few hours, while urinalysis can detect some drugs and/or metabolites for days or even weeks (24,25). Thus, the presence of a drug (or metabolite) in urine is only an indication of prior exposure, not a proof of intoxication or impairment at the time of sample collection. In some cases, quantitative data in blood or urine can corroborate observed behavior or action of a subject, especially when the levels are so high that it is impossible for the subject to be free of drug effects. Nevertheless, laboratory data and

corroborating drug-induced behavior must be interpreted by experts in psychopharmacology and toxicology with experience in drug biotransformation and pharmacokinetics (26).

Drug analysis reports, either positive or negative, may raise questions about the meaning of the results. The usual questions are as follows: (a) What method was used? (b) Did the laboratory analyze for the drug only, or the metabolite only, or both? (c) What is the “cutoff” value for the assay? (d) Was the sample time close enough to the suspected drug exposure?

False-negative results occur more easily than false-positive results, mainly because once a test is screened negative, it is usually not tested further. If the screening method was EIA, the cutoff may have been set too high, in which case, drugs present below the cutoff concentration are reported negative. It is imperative for the physician to know the cutoff for each

drug tested and, for diagnostic purposes, ask for any drug presence above the blank and below the cutoff. Another possibility for false negatives is that the sample was taken too long after the last drug exposure. Whatever the case may be, if the suspicion of drug use is strong, the clinician must repeat testing and ask the laboratory for a more sensitive cutoff level. False-positive results can also occur especially in the screening process. Most common are the so-called cross reactivity issues. This happens when drugs or chemicals with similar chemical structures react with the antibodies of the drug test. A typical example occurs with amphetamines testing. Immunoassays for amphetamine and methamphetamine may cross-react and test positive with other sympathomimetic amines, such as ephedrine or pseudoephedrine.

In general, analytic methods have improved significantly and the trend is toward further improvement. As technology advances, more drugs and chemicals will be analyzed in biofluids at the nanogram and picogram levels. However, advancement does not mean that modern methodologies are infallible or that they replace clinical judgment. Theoretically and practically, technical or human error can influence testing results. Therefore, certified laboratories, with checks and balances in their procedures, limit the occurrences of human or technical errors. With knowledge of the available analytic methods, one can interpret and scrutinize laboratory results with confidence as to their validity.

CLINICAL DRUG TESTING

Clinical drug testing has three components: emergency toxicology, rehabilitation toxicology, and diagnostic toxicology. Each has slightly different goals and requirements. Emergency toxicology requires quick analysis, responding to critical situations in overdose cases. Sometimes the clinical symptoms or the leftover drug is a sufficient clue to the laboratory for which drug to test. On-site, one-step, nontechnical kit screening is becoming more popular to provide instant results. Instrumental immunoassays are also quick and practical, but as in all screening techniques, they give only “present” or “absent” results for each drug or drug class tested. If the target drug is not on the menu, no identification is possible, and tracking down the “unknown” one by one is a slow process. However, if there is a clue to a drug’s identity, immunoassays provide quick answers. Confirmation of positive results is performed by an alternate scientific methodology, usually chromatography. It is at the discretion of the physician to request confirmation or identification of the specific drug.

In rehabilitation programs, drug testing is of foremost importance. Identified ex-drug abusers need to know that the therapist or the counselor knows objectively that they are in good standing or in danger of relapsing to drug use. In this situation, drug-abuse testing is a deterrent and an important component of the treatment process. However, from the laboratory’s point of view, testing is significantly different from emergency toxicology. The test results may not be available for at least 24 hours, and large numbers of samples need to be analyzed in a batch for the many rehabilitation clinics.

The laboratory usually performs a screening test rechecks and/or confirms positives by means of an alternate scientific method. The choice of method depends on assay sensitivity, specificity, expense, and practicality. Instrumental immunoassay methods, such as EIA and ELISA, are used most frequently for screening when large numbers of samples must be tested at a reasonable cost. An FDA-approved sweat patch aids rehabilitation drug testing. The patch placed on the skin is worn for several days, and it detects drugs used during that period; thus, use of short-acting drugs will also be detected (27–29). Urine testing is the most common; however, oral fluid testing is also becoming popular in drug treatment clinics. When direct observation of urine collection is not possible or collection of urine is difficult because the donor has renal disease or a shy bladder, oral fluid is an appropriate alternative.

Diagnostic drugs of abuse identification is another important testing with a slightly different goal. Denial is typical of drug abusers. Therefore, astute physicians are frequently testing their patients for drug use or abuse. A critical role of diagnostic testing is to prevent false negatives caused by poor timing of sample collection or poor sensitivity. From the laboratory’s perspective, sensitive methods with the lowest cutoff and a large drug panel screening must be used. Immunoassays and GLC techniques are appropriate for ultimate sensitivity.

FORENSIC DRUG TESTING

Forensic or legal drug testing has three components: workplace testing, postmortem testing (medical examiner), and criminal justice (correctional and parole) testing.

Historically, forensic drug testing developed from clinical and pathologic testing. Laboratories had to implement numerous legally acceptable procedures, and testing also needed improvement. Certified laboratories must be able to prove that positive test results are accurate and reliable and that the tests performed were from the individual listed on the report. Weak links in external and internal chain-of-custody procedures or poor standards and/or quality control in the testing process provide sufficient ammunition to defense attorneys and expert witnesses to contradict the validity of positive results. For this reason the forensic drug-testing facility must be significantly more secure and better organized than that of a clinical drug-testing laboratory.

Workplace testing is performed on subjects at their place of employment. Many industries and governmental agencies mandate testing of individuals performing critical duties. These places of employment have strict drug policies in place, informing employees that drug abuse is not tolerated and that tests are performed to protect the public interest. The different types of tests performed are preemployment, for cause, and random drug testing. Positive tests can result in loss of job or job opportunity. The consequences of workplace testing are very serious and often disputed. People’s livelihoods depend on laboratory results; therefore, sufficient safeguards must be built into the system to provide assurance that the results are reliable. In forensic testing, the usual procedure is screening

with an automated immunoassay analyzer (i.e., EIA, ELISA, and FPIA) and confirmation of positive screening tests by GC-MS, LC-MS, or MS-MS for additional sensitivity.

Other forms of forensic drug testing requiring “litigation documentation” are medicolegal cases and postmortem analysis of body fluids for the presence of drugs, alcohol, and poisons. Before workplace testing became common, even the medicolegal or postmortem toxicology testing was less stringent. Currently, very strict rules and regulations govern workplace testing. More rigorous and complete chain-of-evidence documentation and more accurate methods are required in medicolegal and postmortem testing.

Another area of drug testing is in correctional institutions and testing in the prison system. A very large percentage of the prisoners’ criminal activity is connected either to drug use or to drug trafficking. It is not unusual to find that drug abuse continues in the prisons. Consequently, correctional facilities have adopted a drug-abuse testing policy in prisons and also during parole. Although the consequences of testing are potentially punitive, testing of inmates in many states requires only screening without confirmation of positive results.

TESTING DRUGS IN ORAL FLUID

Although drug detection in oral fluid (saliva) is not a new idea, the last decade, from 1998 to 2009, has exploded with a large number of new research and scientific publications (30,31,32). Articles describing these technical advances have been described in O. H. Drummer’s excellent review articles (30,33).

In the past, blood and urine samples were preferred for drug detection, until analytic methods, especially LC-MS-MS, increased sensitivity to a desired level. This advancement opened up the possibility for oral fluid as an alternative specimen for drug detection. There are several advantages for using oral fluid for drug screening: (a) collection of specimens is noninvasive and easily observable by the collector, (b) the introduction of LC as an analytic instrument negates the often difficult and time-consuming extraction and cleanup steps needed for GC and GC-MS analyses, (c) the sensitivity of LC-MS-MS permits identification and quantitation of drugs in relatively small oral fluid samples, and (d) water-soluble drugs, conjugated drugs, and metabolites can be easily recovered from the oral fluid without extraction.

However, there are also limitations for using oral fluid for drug detection. (a) Often the collected sample is either inadequate or too small for further analysis and confirmation, if needed. (b) The detection time of drugs or metabolites in oral fluids is about the same as in blood, but shorter than in urine (34,35). The many different oral fluid collectors available when compared to each other are better for some drugs or drug classes than for others (21,22). The fact that they are not uniformly effective for some drugs may cause contradictory results just from the choice of collector used.

Conclusively, properly validated oral fluid testing performed in certified laboratories provides a reasonable opportunity for screening and confirmation of recent drug use (30). However, urine specimens still provide longer detection times

and larger sample volumes for further analysis and confirmation, if requested.

TESTING DRUGS IN SWEAT AND HAIR

Sweat is approximately 99% water and is produced by the body as a heat-regulation mechanism. Because the amount of sweat produced is dependent on environmental temperatures, routine sweat collection is difficult because of a large variation in the rate of sweat production and lack of adequate standardizations. However, cocaine, morphine, nicotine, amphetamine, ethanol, and other drugs have been identified in sweat (27,36). A “sweat patch” resembles an adhesive bandage and is applied to the skin for a period of several days to several weeks. Sweat is absorbed and concentrated on the cellulose pad, which is then removed from the skin and tested for drug content. Cone et al. (27) evaluated sweat testing for cocaine. Generally, there appeared to be a dose-concentration relationship; however, there was wide intersubject variability, which is a disadvantage of this technology. Research in this testing technology is still developing and is indicating apparent advantages of the sweat patch, such as high subject acceptability of wearing the patch for drug monitoring and the ability to monitor drug intake for a period of several weeks with a single patch (27).

Testing for drugs in hair is an alternate method to the drug-abuse detection technology (37–39). Because of the very low concentrations of drugs incorporated in hair, very sensitive methodology must be used. Screening is performed by RIA with ultrasensitive antibodies, or by ELISA, with confirmation by GC-MS, GC-MS-MS, or LC-MS-MS (40). Representatives from virtually all abused drug classes have been detected in hair (41,42). Drugs can enter the hair in various ways: (a) diffusion from blood into the hair follicle and hair cells with subsequent binding to hair strands (37) (Fig. 11.6); (b) excretion in sweat, which bathes hair follicles and hair strands; (c) excretion in oily secretions into the hair follicle and onto the skin surface; and (d) entry from the environment (37). Two controversial issues in hair drug testing are the possibility of environmental contamination that may result in false-positive test results and the difficult interpretation of dose-to-time relationships. Although it has been generally assumed that the hair strand, when sectioned, provides a long-term time course of drug-abuse history, studies with labeled cocaine have not supported this interpretation. Henderson et al. (38) concluded: “... there is not, at present, the necessary scientific foundation for hair analysis to be used to determine either the time or amount of cocaine use.” On the other hand, Cone found a good dose-response relationship and time profile of morphine and codeine in human beard (43). In spite of some controversial aspects of hair testing, this technique is being used on an increasingly broad scale in a variety of circumstances (44). This technology may be used to estimate the long-term drug-abuse habit of the patient who is in denial. Self-reported drug use over a period of several months can be compared to hair test results from a hair strand (about 3.9 cm long) representative of the same time

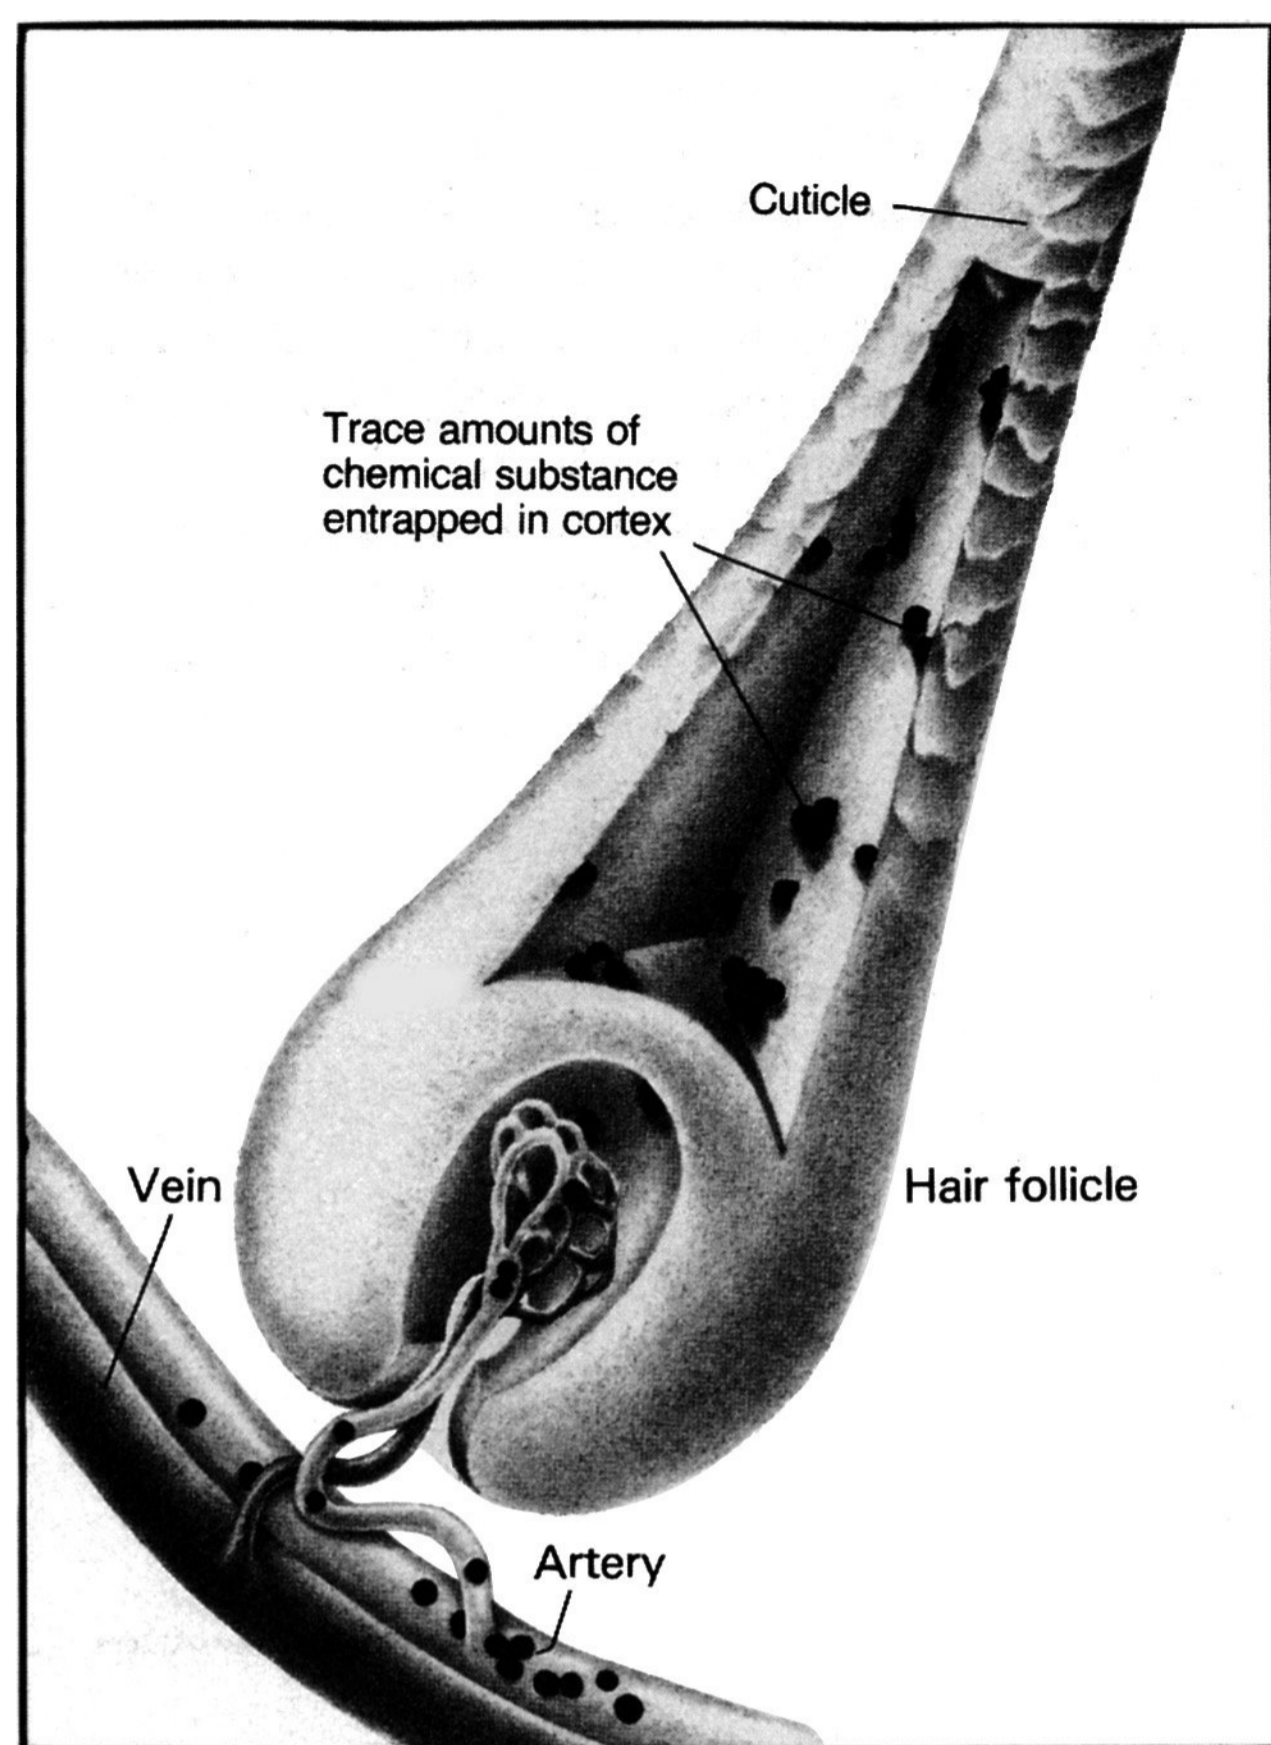

Figure 11.6. A conceptual drawing of drug transfer from the blood to hair follicle and its subsequent encapsulation in the hair shaft. (Reproduced with permission from Psychomedics, Inc., Santa Monica, CA.)

period (41,43). It is expected that this type of comparison would be more effective than urine testing because urine provides a historical record of only 2 to 4 days under most circumstances (41,43). Because denial is a major problem with drug abusers, this technology is an invaluable tool in drug-abuse diagnosis and therapy. Table 11.4 illustrates the comparison of usefulness of urine, saliva, sweat, and hair as a biologic matrix for drug detection. Advantages and disadvantages of urine, saliva, hair, and sweat are reviewed by Caplan and Goldberger (19) (Table 11.5).

ETHICAL CONSIDERATIONS

Legitimate need for drug-abuse testing in the clinical setting is indisputable. Denial makes identification of drug abuse difficult; therefore, testing is necessary both for identifying drug abusers and for monitoring of treatment outcome. Drug testing in the workplace and in sports is more controversial because positive test results may be used in termination of long-time employees or refusal to hire new ones.

Private companies believe that it is their right to establish drug- and alcohol-free workplaces and sport arenas. The opposition believes that one is ill-advised to terminate individuals for a single positive test result, even when it is confirmed by forensically acceptable procedures. A testing program is reasonable when a chance for rehabilitation is also offered. Probationary periods provide an opportunity to stop using drugs through treatment or self-help programs. Employee assistance programs, which refer employees to drug counseling, are available in larger companies and governmental organizations.

TABLE 11.4

Comparative usefulness of urine, saliva, sweat, and hair as a biologic matrix for drug detection

Biologic matrix	Drug detection time	Major advantages	Major disadvantages	Primary use
Urine	2–4 days	Mature technology; on-site methods available; established cutoffs	Detects only recent use	Detection of recent drug use
Saliva	12–24 hours	Easily obtainable; samples-“free” drug fraction; parent drug presence	Short detection time; oral drug contamination; collection methods influence pH and s/p ratios; detects only recent use; new technology	Linking positive drug test to behavior and performance impairment
Sweat	1–4 weeks	Cumulative measure of drug use	High potential for environmental contamination; new technology	Detection of recent drug use (days–weeks)
Hair	Months	Long-term measure of drug use; similar sample can be recollected	High possibility for environmental contamination; new technology	Detection of drug use in recent past (1–6 months)

TABLE 11.5 Summary of advantages and disadvantages of urine, oral fluid, hair, and sweat

Specimen	Advantages	Disadvantages
Urine	<ul style="list-style-type: none"> Drugs and drug metabolites are highly concentrated Extensive scientific basis for testing methodology Performance testing is liberally practiced Results are frequently accepted in court Uniform testing criteria (e.g., cutoffs) established Easily tested by commercial screening methods 	<ul style="list-style-type: none"> Period of detection 2–3 days No dose–concentration relationship Drug concentration influenced by the amount of water intake Susceptible to adulteration and substitution
Oral fluid	<ul style="list-style-type: none"> Useful in the detection of recent drug use Results may be related to behavior/performance Ready accessibility for collection Observed collection Detects parent drugs and metabolites 	<ul style="list-style-type: none"> Detection window may be shorter Contamination following oral, smoked, and intranasal routes of drug administration Collection volume may be device dependent Performance testing under development
Hair	<ul style="list-style-type: none"> Provides a longer estimate of time of drug use Detects parent drugs and metabolites (e.g., 6-acetylmorphine) Observed collection Ease of obtaining, storing, and shipping specimens Second specimen can be obtained from original source 	<ul style="list-style-type: none"> Inability to detect recent drug use Potential hair color bias Possible environmental contamination for some drug classes Susceptible to adulteration by treatment prior to collection
Sweat	<ul style="list-style-type: none"> Provides cumulative measure of drug exposure Ability to monitor drug intake for a period of days to weeks Detects parent drugs and metabolites (e.g., 6-acetylmorphine) Noninvasive specimen collection Collection device is relatively tamper-proof 	<ul style="list-style-type: none"> Large variation in sweat production Specimen volume unknown Limited collection devices High intersubject variability Risk of accidental removal Risk of contamination during application/removal Cannot detect prior exposure Performance testing under development

From Caplan YH, Goldberger BA. Alternative specimens for workplace drug testing. *J Anal Toxicol.* 2001;25:396–399.

It is important that this new, powerful tool—drug testing—be used judiciously as a means of early detection, rehabilitation, and prevention. Test results must be interpreted only by individuals who understand drugs of abuse medically and pharmacologically. The federal government requires that in its drug-testing program, the results go directly to medical review officers (MROs), who are supposed to be trained to interpret such reports. Improper testing or improper interpretation of drug testing data must be prevented.

CONCLUSION

As long as illegal drug use is prevalent in our society, drug-abuse testing will have an important clinical and forensic role. Testing in the clinical setting aids the physician who treats subjects with psychiatric signs and symptoms secondary to drug abuse, monitors treatment outcome, and handles serious overdose cases. Drug testing in the forensic setting will be used for workplace testing and monitoring of parolees convicted of drug-related charges.

Civil rights must be respected to protect the innocent. Names of subjects should be known only to the medical office where the sample is collected. Testing must follow strict security and chain-of-custody procedures to ensure anonymity and prevent sample mix-up during testing. Many laboratories instituted bar-code labeling of samples and related documents to ensure confidentiality. Bar coding also improves accuracy of reporting and tracking of samples and records. This system ultimately prevents sample mix-up as a consequence of human error during accessioning and processing.

The reliability of testing procedures is of foremost importance. Good laboratories institute internal open, blind, and external quality control systems to assure high quality of testing (2). Reliability depends on three major factors: well-qualified and well-trained laboratory personnel, state-of-the-art instrumentation, and logical organization of the testing laboratory.

Before issuing certification, governmental agencies require laboratories to adhere to strict standards in personnel qualifications, experience, quality control, quality assurance

programs, chain-of-custody procedures, and multiple data review prior to reporting results.

Nationally recognized agencies protect the rights of government-mandated testing programs by assuring proper procedures in forensic drug testing. The DHHS/SAMHSA administers its NLCP. Similarly, the College of American Pathologists (CAP) runs its Forensic Toxicology Inspection and Proficiency Program. In addition, numerous state and city regulatory agencies, such as the New York State Health Department, inspect and certify drug-testing laboratories. Good laboratories are easily identified by having current certificates of qualification (COQ) issued by national and/or local regulatory agencies.

Drug-abuse testing has come a long way in terms of accuracy and reliability (45). Testing started in traditional “wet chemistry” laboratories, using huge sample volumes and crude methodologies of low sensitivity. Now autoanalyzers perform hundreds of tests on minute sample volumes, accurately measuring low-nanogram, and in some cases picogram, amounts of drugs. The insecurity of physicians, counselors, and forensic investigators about drug-abuse testing should not be a concern when using properly certified licensed laboratories.

Carlos A. Hernandez-Avila ■ Henry R. Kranzler

INTRODUCTION

During the past three decades, there have been significant advances in the understanding of the neuronal basis of alcohol use disorders. Progress in neuropharmacology, genetics, and neuroimaging has yielded remarkable insights into the causes, pathophysiology, and treatment of these problems. Concomitantly, there have been significant advances in the understanding of environmental and psychological factors influencing the risk for alcoholism. In developed countries, these insights have translated into modest but gradual changes in the way that alcoholic patients are treated. From a public health perspective these developments have also been of significance, allowing interested governments and health agencies to implement effective policies aiming at reducing problem drinking and its devastating effects.

One important consequence of this progress is the emergence of a trend in which alcohol use disorders are gradually becoming less stigmatized, allowing a greater number of alcoholic patients to seek professional help. Another consequence is that rather than being restricted to addiction specialists as is currently the case, alcoholism treatment may potentially become more accepted into the routine work of primary care practitioners who generally are the first and only clinical contact for the majority of patients experiencing drinking problems.

HISTORICAL ASPECTS

Prehistoric Times

Throughout their evolutionary history, humans have been exposed to low levels of alcohol by eating fermented fruits and vegetables. For thousands of years, foods containing alcohol and alcoholic beverages have been a source of calories and water, micronutrients, and neurotransmitter precursors, all necessary for the survival of the human species.

Archeologic evidence suggests that purposeful fermentation of alcoholic beverages by humans was initiated approximately 12,000 years ago. Cultivation of grape vines suitable for wine making began about 8000 years ago in the Eurasian region currently known as Armenia (1,2). During this time, water supplies in population centers were often polluted with dangerous waste products causing lethal outbreaks of dysen-

tery and other infectious diseases. Due to their acidity and the antiseptic effects of alcohol, beer and wine are generally free of pathogens. In this context, alcoholic beverages may have been an important source, and in some instances, the only source of drinkable water in early civilization (1,2).

The Ancient Eastern World

By 4000 BC, the grapevine was used in wine making by the Egyptians, who worshipped Osiris as the wine goddess. Egyptians also believed that Osiris created beer. Although ancient Egyptians were aware of the risks of excessive drinking, they did not appear to consider inebriation a problem (1).

By 2700 BC, Babylonians worshipped several wine deities and regularly offered beer and wine to them. Around 1750 BC, the Code of Hammurabi mentioned concerns about fair trade of alcoholic beverages, but inebriation was not considered an offense (1).

In ancient China, alcohol was also considered a spiritual food with an important role in religious and civil ceremonies. Ancient Chinese believed that drinking alcohol in moderation was a “prescription from heaven” (1).

The Hellenic and Roman World

By 2000 BC, wine making reached the Greek peninsula from the Middle East, and by 1700 BC, wine was widely consumed, becoming part of the daily Hellenic diet and incorporated in most religious and civil ceremonies (1,3). In ancient Greece, wine was also consumed to remedy a variety of health problems (4). Hippocrates (460–370 BC) identified numerous medicinal properties of wine and recommended different types of wine to treat different types of ailments (5). Xenophon (431–351 BC) and Plato (429–347 BC) praised the moderate use of wine as beneficial to health and happiness, and similar to Aristotle (384–322 BC) and Zeno (336–264 BC), identified excessive drinking as problematic (1,3).

In Rome, between the founding of the empire in 753 BC and the third century BC, drinking in moderation was the norm. This ended between 509 and 133 BC, after the conquest of the Italian peninsula and the rest of the Mediterranean region. By then, traditional Roman values of temperance, frugality, and simplicity were gradually replaced by heavy

drinking, ambition, degeneracy, and corruption (1,3). Roman practices that encouraged excessive drinking included drinking before meals on an empty stomach, inducing vomiting to permit more food and wine consumption, and drinking games such as rapidly consuming as many cups as indicated by a throw of the dice (1,3).

By the beginning of the second century BC, wine became a valuable commodity and played an important economic role in the Mediterranean market. Spreading through Europe following the expansion of the Roman Empire, wine was brought to the north of Europe and England; however, regional dominant groups such as the Vikings, Saxons, Jutes, and Angles were more inclined to produce and consume ale and cider.

As the Roman Empire declined, Roman viniculture also declined. At that time and during the obscurantist period of the European Middle Ages, the Catholic Church was the only institution with sufficient resources to maintain wine production and Roman viniculture techniques (1).

The Era of Distilled Spirits

By AD 700–750, in the Mideast, a technical development occurred that radically changed the way in which alcoholic beverages were produced and consumed. The invention of distillation by Arab alchemists made it possible to produce alcoholic beverages with alcohol concentrations greater than that found in fermented beverages. By AD 1100, this method was adopted in Europe giving birth to the era of distilled spirits (2).

During the 13th and 14th centuries, the consumption of spirits rapidly spread to the rest of Europe, following the path of the Black Plague and other pandemic diseases. By AD 1500, the first printed book on alcohol distillation was published: *Liber de Arte Distillandi*, by the Alsatian physician Hieronymus Brunschwig. Although ineffective as a cure, the use of spirits as a remedy by medieval and Renaissance physicians was a common practice (2).

The American Continent

Discovery and early exploration of the American continent by European explorers such as Christopher Columbus was made feasible in part by the availability of wine and beer during their long voyages.

Available historical evidence suggests that before the arrival of Europeans most of the indigenous people of North America had limited exposure to alcohol. It appears that Native people of what is currently the southwestern United States, Mexico, Central America, and peoples of the Amazonian and Andes regions consumed fermented alcoholic beverages mainly in the context of religious ceremonies. The Pimas and Papagos in the southwestern United States extracted ferment from the saguaro cactus. The Tepehuanes and Tarahumaras, who inhabited territory in modern-day northern Mexico, fermented corn to produce *tesvino*, which they also consumed at ceremonies to mark important stages in an individual's life, such as the passage to adulthood. The Aztecs of Mexico drank pulque, which they fermented from the maguey or American aloe and the Mayas fer-

mented *balche* from bark and honey. In Mexico, after the Spanish conquest, facilities were built to produce *aguardiente* (burning water), a spirit derived from sugarcane or corn, significantly expanding the amount of alcohol available for consumption.

In other parts of North America, when Europeans met Native Americans they offered them alcohol. However, systematic trading of alcohol did not begin until the mid-17th century, when British and French colonists, using sugar produced in the West Indies, initiated the large-scale distillation of spirits, and sold it as liquor in the North American colonies (4).

After the revolutionary war in the United States, the liquor trade spread farther west affecting Native and European Americans (4).

The Temperance Movement and the “Medicalization” of Alcoholism

As early as 1784, Benjamin Rush recognized that a key component of alcoholism is the inability to control the urge to drink. He launched the first health education campaign warning the public about the risks of drinking alcohol. He has been credited as the founder of the temperance movement in North America (5).

Although the temperance movement came to be dominated by religious and puritan ideology, it was originally a health promotion movement that sought to improve the human condition.

With the triumph of the enlightenment philosophy in the western hemisphere, alcoholism and madness came to be viewed as curable diseases. Benjamin Rush identified alcoholism as a disease in which alcohol serves as a causal agent and loss of control over drinking behavior is the characteristic symptom. Similar to the mentally ill, alcoholics were to be treated away from home in inebriate asylums. Samuel B. Woodward and subsequent members of the American Association for the Cure of Inebriates wrote on the physical nature of alcoholism and proposed total abstinence as the only effective cure for intemperance. Nineteenth century physicians differentiated between chronic alcoholism and alcohol addiction. Chronic alcoholism was characterized by the physical and psychological consequences of chronic alcohol drinking, whereas alcohol addiction consisted of an uncontrollable craving for alcohol, alcohol withdrawal symptoms, and loss of control (5).

It was not until 1954, in a World Health Organization report, that Griffith Edwards turned attention back to the pharmacologic effects of alcohol as the critical factor in the disease process. This notion gained ground and was expanded in the writings of Jellinek, who linked the features of tolerance and adaptation to the “craving” to drink excessively (5).

EPIDEMIOLOGY OF ALCOHOL CONSUMPTION

International Drinking Patterns

It has been estimated that approximately 2 billion people or one half of the world's adult population consume alcoholic beverages. Although the use of alcohol is distributed unevenly

throughout the population, generally, consumption rates are greater among men (55%) than among women (34%) (6). Around the world most of the alcohol is consumed by a relatively small group of consumers with the top 30% of drinkers accounting for up to 75% of all consumption (6)

In most Western countries consumption rates of alcoholic beverages have remained stable and are expected to remain that way over the next two decades. However, in countries of the South-East Asian Region and the low- to middle-income countries of the Western Pacific Region, which include nearly half of the world's population, alcohol consumption is expected to increase during the same period (6,7).

The Dry/Wet Culture Dichotomy

Research examining international patterns of alcohol consumption has traditionally classified countries or cultures as dry or wet based on whether their per capita alcohol consumption is low or high.

In wet cultures, consumption of alcoholic beverages is integrated into daily life, with such beverages frequently consumed with meals and easily available with few legal restrictions. In countries with this cultural background, wine is the beverage most frequently consumed by a large segment of the population, usually in moderation. In these countries, wine is considered to have social, nutritional, and medicinal value. Although in this type of culture abstinence is infrequent, inebriation is uncommon. Mediterranean European countries such as Spain, Portugal, Italy, France, and Greece have traditionally been identified as wet cultures. Due to their high per capita alcohol consumption, however, these countries have a greater prevalence of alcohol-related health problems such as liver disease (6,8).

In dry cultures drinking is not prevalent in everyday life. In countries with this type of culture abstinence is common, but when drinking occurs it is likely to be at inebriating levels. Northern and Eastern European countries such as Norway, Sweden, Finland, Poland, and Russia have been classified as dry cultures. In these countries, drinking is not considered a key dietary component and distilled spirits are more frequently consumed than wine. Alcohol-related problems in these countries consist largely of accidents, public intoxication, and social disruption. In other dry countries such as Germany, Austria, Belgium, the United States, and the United Kingdom, beer consumption is predominant. In beer-consuming countries, per capita alcohol consumption tends to be lower than that in spirits-drinking countries but greater than that in wine-drinking countries (6,8).

One limitation of the wet/dry culture dichotomy is that it has focused primarily on differences among North American and European countries, representing a scale of extremes on which to measure drinking cultures. In recent decades, economic and globalization forces appear to be blurring the wet/dry culture distinction, especially in Europe, where a homogenization process of consumption rates and beverage preferences appears to be occurring. (8).

A different group of countries with low per capita alcohol consumption and low prevalence of alcohol-related problems are those with predominant or large Islamic populations such as Pakistan, Iraq, and Israel. Abstinence rates among adults in

these countries can reach 90% of the population (6). Among other factors, the large abstinence rates found in the Middle East can be attributed to the fact that consumption of alcoholic beverages is forbidden by Islam.

The greatest prevalence of high-risk drinking, as defined by consumption of 40 g alcohol per day in men and more than 20 g in women, is found in Europe and Central Asia, followed by the sub-Saharan African and Latin American countries. The lowest prevalence of high-risk drinking on the other hand is found in the Middle East and North Africa with rates lower than 1% (6,8).

Alcohol Use Disorders around the World

In 2000, 76.4 million people worldwide suffered from an alcohol use disorder (e.g., alcohol abuse or alcohol dependence). Of this number, 63.7 million were men and 12.7 million were women. Regarding lifetime prevalence of alcohol abuse or dependence, these have been seen to vary from as low as 4.5 % in Hong Kong to a high of 22% in Korea (6–8).

Alcohol Consumption in the United States

In the United States, the majority (87.8%) of the adult population (>18 years old) has consumed alcohol in their lifetime (9). Regarding rates of current drinking, slightly more than half (51.6%) of Americans aged 12 or older reported drinking at least once during the last month (9). Among them, the majority (57.7%) was male. However, among youths aged 12 to 17, the percentage of males who were current drinkers (14.2%) was similar to that for females (15.0%).

Alcohol consumption in the United States is greatest among young men 18 to 25 years old. Among older Americans, the prevalence of current drinking decreases with increasing age (9). Regarding ethnicity, the highest prevalence of drinking is found among non-Hispanic whites, followed by Native Americans and Hispanics, whereas the lowest prevalence is seen among non-Hispanic blacks and Asians (9).

In the United States, the prevalence of alcohol consumption appears to increase as a function of education level, with college-educated individuals being almost twice as likely to be current drinkers as individuals with less than a high school education (9).

Prevalence of Alcohol Use Problems in the United States

In 2008, about one quarter (23.3%) of the U.S. population aged 12 or older reported binge drinking (i.e., the consumption of five or more drinks on an occasion) at least once during the past month. The prevalence of heavy drinking (i.e., the consumption of five or more drinks on the same occasion on each of 5 or more days) during the past month was 7% (9).

Men and young adults were more likely to report these problematic patterns of consumption than women and older adults. Among U.S. ethnic groups, Hispanics, followed by Native Americans and non-Hispanic whites had the highest frequency of problem drinking, whereas Asians and non-Hispanic blacks had the lowest rates (9).

The National Epidemiological Survey on Alcohol and Related Conditions (NESARC) (10) showed that alcohol abuse or dependence, defined by the fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders* text revised (DSM-IV-TR) criteria (11) affected 8.5% of the U.S. population, with 4.7% meeting criteria for a diagnosis of alcohol abuse and 3.8% for alcohol dependence. A more recent population survey conducted in 2007 by the U.S. Substance Abuse and Mental Health Services Administration (SAMHSA) (9) showed that the past-year prevalence of DSM-IV-TR alcohol abuse or dependence among individuals 12 years old or older was 7.3%. Differences in prevalence rates between NESARC and SAMHSA studies appear to be due to differences in sampling and diagnostic methods.

The demographic predictors identified for alcohol abuse or dependence in the U.S. population are similar to those reported for heavy or binge drinking. These disorders affect men (9.7%) more frequently than women (5.1%), and are most common among adults 18 to 25 years old (9). Among ethnic groups, Hispanics, Native Americans, and non-Hispanic whites are affected more frequently than Asians and non-Hispanic blacks. The risk for alcohol use disorders is also negatively correlated with educational level and is greater among the unemployed and in urban populations (9).

CLASSIFICATION AND PHENOMENOLOGY OF ALCOHOL USE DISORDERS

Classification of Alcohol Use Disorders

The most widely used definitions for alcohol use disorders are those included in recent editions of the American Psychiatric Association DSM (11) and the International Classification of Diseases (ICD) of the World Health Organization (WHO). Studies of alcohol treatments, human genetics, and epidemiology all rely on these definitions, which constitute a near-universal reference for research and clinical practice on alcoholism.

The most recent editions of the DSM and the ICD (DSM-IV-TR and ICD-10, respectively) recognize and use similar diagnostic criteria for alcohol dependence. However, alcohol abuse is recognized only by the DSM-IV-TR. The ICD-10 includes the diagnosis of harmful drinking, which was created by the WHO to address concerns that health problems related to alcohol consumption were underreported. Harmful use is defined by alcohol consumption that causes physical and/or mental damage in the absence of alcohol dependence.

Studies consistently have showed high reliability for DSM-IV and ICD-10 alcohol dependence diagnoses but lower reliability for those of alcohol abuse/harmful use. Similarly, validity studies indicate that DSM-IV and ICD-10 alcohol dependence diagnoses have good validity, but the validity for alcohol abuse/harmful use is much lower (12).

Contrary to the notion that alcohol abuse and alcohol dependence represent two distinct disorders, recent evidence suggests that alcohol use disorder criteria may be best modeled as reflecting a unidimensional continuum of alcohol-problem severity. It is likely that changes in alcohol dependence and al-

cohol abuse diagnoses in future versions of the DSM-IV and ICD will reflect this conceptualization.

The alcohol dependence criteria in the DSM and subsequently in the ICD were adopted from the alcohol dependence syndrome (ADS) proposed by Edwards and Gross in 1976. In this tridimensional model, the biologic domain reflects the emergence of tolerance and withdrawal symptoms secondary to chronic alcohol consumption. The behavioral and cognitive dimensions reflect impaired control and the salience of drinking behavior.

In the DSM-IV-TR (11), the diagnosis of alcohol dependence requires that at least three criteria from a list of seven be present during a 1-year period and that they cause significant clinical impairment (Table 12.1). If the individual's drinking pattern does not meet criteria for alcohol dependence but there is a pattern of drinking that leads to clinically significant impairment as reflected by the presence of one or more alcohol abuse criteria, then the alcohol abuse diagnosis is considered.

Phenomenology and Natural Course of Alcohol Dependence

The clinical and phenomenologic presentation of alcohol dependence can be complex and multifaceted. Although it is difficult to describe a typical pattern that describes the course of this disorder, studies conducted in clinical samples suggest that certain clinical characteristics and progression patterns are prominent in the natural history of alcoholism.

In the early phases of the disorder, generally during the individual's early and mid twenties, the most prominent feature is daily heavy drinking or frequent binge drinking leading to significant intoxication. Early in the drinking career, individuals describe a rewarding sense of euphoria and elation that immediately follows the first drinks and is commonly described as the alcohol high or buzz. As heavy drinking persists, *tolerance* to alcohol's effects sets in, leading the individual to escalate alcohol consumption. Increased frequency and intensity of drinking may be associated with irresistible urges to drink or "craving" that are often triggered by environmental cues (e.g., bar scenes, celebratory gatherings, loud music) and/or internal cues (e.g., negative or positive mood states). Drinking may then become associated with "blackouts" or amnesia for events while intoxicated, and frequent "hangovers."

During an individual's early thirties, alcohol-related psychosocial problems may become prominent. Typically, the person experiences increasing days absent from work, frequent family conflicts, and other interpersonal and legal problems. Work, home, and/or motor vehicle accidents while intoxicated causing injury also become common.

From the individual's mid-to-late thirties, there may be a frank loss of control over drinking that is associated with a worsening of social and work-related problems and the onset of medical complications. Attention to personal care and hygiene may deteriorate, and despite the loss of personal relationships and employment, alcohol consumption can dominate the individual's life. Often, at this point, the individual's global level of functioning is further impaired by alcohol-induced cognitive deficits. In some cases, alcoholics may

TABLE 12.1 DSM-IV-TR criteria for alcohol dependence

A maladaptive pattern of drinking as manifested by three or more of the following during a 12-month period:

- (1) Tolerance, that is, either:
 - (a) a need for markedly more alcohol to achieve intoxication
 - (b) markedly diminished effect despite continued consumption of the same amount of alcohol
- (2) Withdrawal, that is, either:
 - (a) two or more signs or symptoms (autonomic hyperactivity, tremor, insomnia, nausea or vomiting, transient illusions or hallucinations, psychomotor agitation, anxiety, grand mal seizures) within several hours of stopping or reducing heavy, prolonged drinking
 - (b) consuming alcohol or a related substance (e.g., benzodiazepines) to relieve or avoid withdrawal symptoms
- (3) Alcohol is often consumed in larger amounts or over a longer period than was intended
- (4) There is a persistent desire to cut down or control drinking
- (5) A great deal of time is spent in drinking or recovering from drinking
- (6) Important social, occupational, or recreational activities are given up or reduced because of drinking
- (7) Drinking is continued despite knowledge of having a persistent or recurrent physical or psychological problem that is likely to have been caused or exacerbated by alcohol.

DSM-IV-TR Criteria 305.00.

experience feelings of remorse or guilt, which lead them to conceal their drinking. Alcoholic beverages are concealed at home or work and solitary drinking may help to avoid feelings of guilt and depression.

By the time the individual is in his or her late thirties or early forties, severe medical complications such as liver cirrhosis or chronic pancreatitis may develop, leading to frequent visits to emergency services and hospitalizations. Voluntary or involuntary efforts to stop drinking may be associated with significant symptoms of alcohol withdrawal (e.g., tachycardia, tremulousness, diaphoresis, insomnia, anxiety) that in a small group of alcoholics can be complicated by grand mal seizures and/or episodes of delirium (e.g., confusion, disorientation, hallucinations). The individual often resumes drinking to relieve or avoid withdrawal symptoms. Continued heavy drinking often exacerbates medical complications, with potentially fatal results.

Variables Influencing the Course of Alcohol Dependence

Variables that have been shown to influence the course of alcohol dependence, especially the response to treatment, include the age at onset of the disorder, severity of the disease, and presence of co-occurring psychiatric disorders. An early age at onset of alcohol dependence has shown to predict a greater severity of alcoholism and poor treatment response (13). Greater severity of alcoholism as evidenced by alcohol withdrawal symptoms is associated with a poor treatment response. A comorbid psychiatric diagnosis is also a predictor of poorer posttreatment outcomes.

In this regard, affective dysregulation may contribute to risk of alcohol dependence by promoting the use of alcohol to “self-medicate” negative affective states such as anxiety and depression. This theory is supported by research indicating an association between alcohol problems, mood disorders, and life stress. Also, deviance proneness or behavioral under-control, as indicated by hyperactivity, distractibility, sensation seeking, impulsivity, difficult temperament, and conduct disorder, appears to contribute to school failure and association with deviant peers, which then provide a context for heavy drinking and other substance use. Consistent with this, a diagnosis of antisocial personality disorder (ASPD), mood disorder, or another substance abuse/dependence diagnosis among alcohol-dependent individuals in general is associated with a poorer drinking outcome, more illicit drug use, and poorer social functioning during the posttreatment period than in alcoholics without these comorbidities (14,15).

Alcoholism Subtypes

A variety of typologies have been proposed to classify the diverse clinical presentations associated with alcoholism and to provide a heuristic framework to understand the complex interaction of the diverse etiologic factors. Cloninger and colleagues (16) studied adopted sons of Swedish alcoholics and developed a typology that differentiated between Type 1 and Type 2 alcoholism. In Type 1 or “milieu-limited” alcoholism the etiologic role of environmental factors is predominant. These individuals are characterized by a late initiation of problem drinking and rapid development of tolerance to alcohol. Type 1 alcoholics generally experience intense guilt

and anxiety associated with drinking behavior, though it is uncommon for them to experience legal problems or be involved in fights. In Type 2 or *male-limited* alcoholism, the etiologic role of genetic factors is emphasized with transmission of the disease occurring predominantly from fathers to sons. Type 2 alcoholics characteristically experience drinking problems at a young age. These individuals do not experience substantial guilt or fear concerning their drinking though they frequently are involved in fights and experience legal problems related to drinking.

Cloninger hypothesized that differences between alcoholic subtypes could be explained by differences in three basic personality traits or temperaments: novelty seeking, harm avoidance, and reward dependence. These features in turn could be explained by specific neurochemical and genetic factors. Cloninger proposed that novelty seeking, which is characterized by frequent exploratory behavior and intense pleasurable responses to novel stimuli, was modulated by the dopaminergic neurotransmission system. He hypothesized that harm avoidance, a tendency to respond intensely to aversive stimuli and their conditioned signals, was modulated by serotonergic systems. Finally, he hypothesized that norepinephrine modulated reward dependence, which is defined as resistance to extinction of previously rewarded behavior. In Cloninger's typology, high reward dependence, high harm avoidance, and low novelty seeking are characteristic of Type 1 alcoholics, and Type 2 alcoholics are characterized by high novelty seeking, low harm avoidance, and low reward dependence. Although this tridimensional personality theory and other aspects of Cloninger's typology were attractive to researchers and clinicians, studies have failed to provide empirical support for this theory (17).

Babor and colleagues (18), using statistical clustering techniques, proposed a similar dichotomous classification of alcoholics. These authors described two homogeneous subtypes: Type A alcoholics were characterized by a late initiation of problem drinking and the absence of antisocial behaviors, and Type B alcoholics were characterized by an early initiation of problem drinking and by frequent antisocial behavior typically exacerbated by inebriation.

More recently, several multidimensional empirically derived typologies of alcohol use disorders, derived primarily for research purposes, have been described (17). Using different statistical methods, these studies have consistently found as many as four homogeneous types of alcoholics: a chronic/severe type, a depressed/anxious type, a mildly affected type, and an antisocial type (17). Further research is needed, however, in order to determine the clinical utility of these alcoholism subtypes.

DETERMINANTS OF ALCOHOL CONSUMPTION

Pharmacology of Alcohol

Absorption

After alcohol is ingested, it is rapidly absorbed in the gastrointestinal (GI) tract through the wall of the stomach and small intestine. Absorption of alcohol from the duodenum and je-

junum is greater (80%) and faster than that occurring in the stomach (20%). However, when alcohol is consumed with food, gastric emptying is slowed and the stomach becomes the main site of absorption.

Alcohol absorption through the gastric and intestinal mucosa occurs by passive diffusion down a concentration gradient. The rapid removal of alcohol by efficient blood flow at the site of absorption is also necessary to maintain the alcohol concentration gradient.

The main factor governing the absorption rate of orally administered alcohol into the bloodstream is the rate of gastric emptying into the small intestine via the pyloric sphincter. This effect is due to the smaller absorptive surface area of the stomach compared with the duodenum and jejunum. Whether alcohol is consumed on an empty stomach or with food affects its rate of absorption. Food in the stomach delays gastric emptying, thereby reducing the absorption of alcohol. Foods high in fat, carbohydrate, or protein content are equally effective in retarding gastric emptying.

The amount and rate of drinking may also influence alcohol absorption. When alcohol is consumed in a single large dose rather than several smaller doses, the resulting alcohol concentration gradient is greater, potentially yielding higher peak blood alcohol concentrations. However, when alcohol-containing beverages are rapidly ingested, the irritant properties of alcohol not infrequently cause superficial erosions and hemorrhages of the mucosa, causing paralysis of the smooth muscle and reduced blood perfusion. This can reduce alcohol absorption. Other factors that influence gastric emptying and alcohol absorption include smoking, diurnal changes in blood glucose, physical activity, and medications such as ranitidine or erythromycin (19).

Due to the significant variability in rates of gastric emptying and in alcohol absorption, the time to achieve peak blood alcohol concentration is also highly variable. In one controlled study (30), the rate of absorption ranged from 14 to 130 minutes (with a mean of 57 minutes for men and 42 minutes for women) (19).

Distribution

Although alcohol shows little solubility in fat, it has the ability to cross all biologic membranes. Alcohol distributes from the bloodstream into all body tissues and fluids in proportion to their relative water content. Because of this and given that there is no binding of alcohol to plasma protein, alcohol concentration in body tissues rapidly reaches equilibrium with blood alcohol concentration.

Due to the fact that in humans there are large variations in the proportions of body fat and body water content, an equivalent alcohol dose per unit of body weight can yield different blood alcohol levels in different individuals. For example, due to lower volumes of total body water among women and the elderly, they have a smaller volume of distribution for alcohol than men and younger individuals. Thus, women and older individuals will reach greater peak blood alcohol levels than men and younger individuals when given an equivalent dose of alcohol (19).

Metabolism

First-Pass Metabolism of Alcohol Some of the alcohol that is consumed orally does not enter the systemic circulation but is oxidized in the gastric mucosa by isoforms of the enzyme alcohol dehydrogenase (ADH). This first-pass metabolism appears to be important in determining alcohol toxicity since its efficiency determines alcohol bioavailability. First-pass metabolism is reduced in women and alcoholics secondary to decreased ADH activity. This may translate into increased sensitivity to alcohol and greater blood alcohol concentrations in these populations (31). Several drugs, including histamine 2 receptor blockers such as cimetidine or ranitidine, or aspirin, decrease gastric first-pass metabolism by inhibiting gastric ADH activity. First-pass metabolism also appears to occur in the liver, particularly when the delivery of alcohol into the portal vein is slow, as occurs in the fed state (19).

Nearly all (i.e., 92% to 95%) of the alcohol that is ingested is metabolized in the liver by ADH located in the cytosolic fraction of hepatocytes. Alcohol-metabolizing enzymes are also located in the microsomal fraction of the liver, specifically CYP2E1. In the most common pathway, alcohol is first oxidized to acetaldehyde by a class I ADH. Subsequently, acetaldehyde is oxidized to acetate by the enzyme aldehyde dehydrogenase (ALDH), which is localized in the mitochondria. The coenzyme nicotinamide adenine dinucleotide (NAD⁺) is required for these two nonreversible reactions to occur. During the hepatic oxidation of alcohol, the ratio of NADH to NAD⁺ in the liver cells significantly increases. The rate-limiting step in these reactions appears to be the reoxidation of NADH to NAD⁺. It is believed that the altered reduction–oxidation (redox) state accounts for many of the metabolic disturbances and hepatotoxic effects associated with heavy drinking. Finally, the last step in alcohol metabolism occurs when acetate is oxidized to CO₂ and water in peripheral tissues as part of the Krebs cycle (19).

Alcohol is a nutrient with a caloric value of approximately 7 kcal/g. In comparison, carbohydrates and proteins provide 4 kcal/g while fat yields 9 kcal. Unlike carbohydrates and fat, which can be stored, alcohol remains dissolved in body water until eliminated. Given that alcohol is generally oxidized preferentially over carbohydrates, fat, or proteins, calories derived from alcohol usually are produced at the expense of the metabolism of other nutrients. Alcoholics often consume 200 to 300 g of alcohol per day, the equivalent of 1400 to 2100 kcal, with consumption of normal nutrients usually neglected. Another important fact is that unlike metabolism of major nutrients, which is under complex hormonal control (involving, e.g., insulin, glucagon, leptin, catecholamines, thyroid hormones), there is little hormonal regulation of alcohol metabolism or elimination. Consequently, there is a major metabolic burden on the liver to oxidize alcohol and to remove it from the body (19).

Alcohol Dehydrogenase (ADH) ADH is an enzyme with broad substrate specificity that oxidizes many primary and secondary alcohols. It also appears to be involved in steroid and bile acid metabolism. Although found in other tissues, ADH is mainly found in the liver and GI tract. ADH is

composed of two subunits (α , β , and γ subunits) or dimers with unit composition determining enzyme's ability to oxidize alcohol. In this regard seven types of ADH have been identified and classified into five classes based on similarities in their amino acid sequence and unit composition. ADH encoded by class I genes (*ADH1A*, *ADH1B*, and *ADH1C*) account for most of the oxidizing capacity in the liver (19,20). Several mutations have been identified in the *ADH1B* and *ADH1C* genes that are differentially distributed across population groups and that produce enzymes with different pharmacokinetic properties. A further discussion of this topic is reviewed in the genetics section.

Acetaldehyde Dehydrogenase (ALDH) There are two main ALDH enzymes, ALDH1 and ALDH2, which oxidize the acetaldehyde generated during alcohol metabolism. ALDH1 is found in the cytosol and ALDH2 is found in the mitochondria. ALDH1 and ALDH2 have a similar structure being 70% identical in amino acid sequence. Gene variants coding for ALDH1 and ALDH2 are differentially distributed across populations producing enzymes with different pharmacokinetic properties (19,20). A further discussion on this topic is reviewed in the genetics section.

Elimination

As discussed earlier in this section, 90% to 95% of ingested alcohol is metabolized by the ADH–ALDH enzymatic system and eliminated as water and CO₂. A small proportion of consumed alcohol (~1%) undergoes conjugation with glucuronic acid to yield ethyl glucuronide as a by-product that can be measured in urine. The remainder of the consumed alcohol (~4%) is excreted unchanged in the breath, urine, and sweat. Because the amount of alcohol expelled in the breath is proportional and in equilibrium with the concentration in the pulmonary arterial blood, alcohol breath tests can be used as a noninvasive means to estimate the blood alcohol concentration (19).

Although alcohol elimination rates vary widely, in humans the metabolic capacity to remove alcohol is approximately 170 to 240 g/day for a person with a body weight of 70 kg. This is equivalent to an average metabolic rate of about 7 to 10 g/h, which translates to about one drink per hour (19).

Effects of Alcohol on Neurotransmission

Alcohol administration appears to have effects across major neurotransmitter systems (i.e., dopaminergic, GABAergic, glutamatergic, opioidergic, and serotonergic). These systems are affected by both acute and chronic alcohol administration and they appear to play a major role in mediating the rewarding effects of alcohol (21).

In general, alcohol has been considered to have central nervous system anesthetic or depressive properties, especially when administered in large doses. However, alcohol can elicit euphoria and stimulation when given in small doses (21).

To date, alcohol-specific binding sites or receptors on neurons have not been identified. It has been hypothesized that at large doses, alcohol may disturb the fluidity of the bilayer lipid neuronal membrane. Disturbances in membrane fluidity

may indirectly modify the structure and function of neurotransmitter receptors and ion channels. It is unlikely, however, that this is the mechanism by which alcohol exerts its effects on neurons at the lower doses that normally are consumed by humans. In this regard, some evidence suggests that at blood concentrations within the range of typical human consumption, alcohol can directly affect the function of several neuronal ion channels and receptors (21).

The Dopaminergic System

The ventral tegmental area (VTA), nucleus accumbens (NAc), amygdala, and prefrontal cortex in the mesolimbic dopaminergic circuit are the major brain structures mediating the rewarding effects of alcohol (21–23). A number of studies in rodents have examined the mechanisms by which acute alcohol exposure increases dopamine tone in the mesolimbic system. Results of these reports suggest that alcohol enhances dopamine release by directly increasing the firing rate of dopamine cells in the VTA. PET imaging and MRI studies in moderate drinkers described that intoxicating doses of alcohol resulted in a significant increase of dopamine levels in the ventral striatum (21–23).

Chronic alcohol exposure and alcohol withdrawal result in profound neuroadaptive changes in dopaminergic transmission that in general are contrary to the acute effects of alcohol on this system. Using PET imaging techniques, researchers found significantly lower baseline dopamine receptor (D2/D3) density among alcoholics than controls, demonstrated by a lower binding of the D2/D3 selective ligand [¹¹C] raclopride. A significant decrease was also observed in dopamine release among alcoholic subjects after administration of the dopamine reuptake blocker methylphenidate. Together, these findings support the notion that a reduction in dopaminergic signaling among alcoholics may explain the decrease in alcohol rewarding effects during chronic alcohol consumption and the emergence of negative mood states (e.g., depression, dysphoria, anhedonia) during alcohol withdrawal (21–23).

The GABAergic System

A significant involvement of GABAergic neurotransmission in the pharmacologic effects of alcohol was initially hypothesized based on observations that alcohol had effects (e.g., anxiolysis, impaired motor coordination and cognition, anticonvulsant effects) resembling those produced by drugs known to act on the GABAergic system. It was also apparent that there was significant cross-tolerance of alcohol with GABAergic agents such as benzodiazepines and barbiturates, compounds that also are highly effective in treating alcohol withdrawal.

Alcohol effects on the GABAergic system have been mainly attributed to a postsynaptic mechanism similar to that of benzodiazepines and barbiturates, compounds that allosterically enhance GABA_A receptor function. More recently, however, it has been recognized that alcohol administration also enhances GABAergic inhibitory effects presynaptically by increasing GABA release in many brain regions including the hippocampus and the cerebellum (21–23).

Although many studies have suggested that alcohol specifically potentiates the function of the GABA_A receptor type (Criswell et al. 1993), experiments that have directly examined

the effects of alcohol on GABA_A receptors-mediated ion currents have yielded conflicting results, showing wide differences in alcohol sensitivity. An explanation for these discrepancies is that there is a rich variability in GABA_A receptors subunit composition and posttranslational processes (21–23). It appears that presence of the $\alpha 1$ subunit is critical in determining the sensitivity of GABA_A receptors to alcohol. Pharmacologic manipulation of GABA_A $\alpha 1$ receptors on mesocorticolimbic neurons of alcohol preferring rodents has been shown to modify the reinforcing effects of alcohol (21–23).

Contrary to the effects of acute alcohol administration, chronic alcohol exposure and alcohol withdrawal in rodents and humans results in decreased GABAergic tone and in symptoms of anxiety, dysphoria, and alcohol craving. Reinstatement of alcohol consumption transiently relieves such negative states, negatively reinforcing drinking behavior.

A growing number of preclinical and clinical studies have shown that several compounds such as topiramate or baclofen that enhance GABAergic inhibition, are efficacious in reducing alcohol drinking and craving in alcohol-dependent subjects (21–23).

The Glutamatergic System

Alcohol administration has important effects on the glutamatergic neurotransmitter system. Acute administration of alcohol antagonizes NMDA receptors, whereas chronic administration increases the density of these receptors (21–23). This antagonist effect of acute alcohol on glutamatergic neurotransmission has been observed in the hippocampus and bed nucleus of the stria terminalis and in many other brain regions. Alcohol has also been shown significantly to reduce NMDA-evoked currents neurons, confirming the postsynaptic nature of this effect (21–23).

Recent studies have identified specific amino acids in NMDA receptor subunits that represent a putative alcohol interaction site. Generally, alcohol has relatively minimal effects on other subtypes of glutamate receptors. However, in a few specific brain regions, alcohol has been shown to have relatively potent inhibitory effects on AMPA and kainate receptor-gated synapses.

Chronic alcohol exposure and withdrawal results in significant increases in glutamatergic neurotransmission mediated by NMDA receptors in the basolateral amygdala and in the NAc (40). This increase in NMDA receptor function during alcohol withdrawal appears to be related to the emergence of significant anxiety levels (21–23). A similar increase in NMDA receptor function also appears to contribute to seizure activity observed during alcohol withdrawal. For example, treatment with NMDA receptor antagonists effectively blocked epileptiform spike patterns in the hippocampus typically seen during alcohol withdrawal (21–23).

The Opioidergic System

Alcohol administration stimulates hypothalamic synthesis, release, and binding of endogenous opioids such as β -endorphin and enkephalin to μ -opiate receptors (24). Disturbances in opioidergic neurotransmission have been described among alcoholic patients and their unaffected adult children (24).

In comparison to adult children of nonalcoholic individuals (i.e., paternal-history-negative or PHN), paternal-history-positive (PHP) subjects have lower plasma and cerebrospinal fluid levels of beta-endorphin (24). After alcohol administration, PHP individuals show a greater increase or normalization of their beta-endorphin levels (24). Based on these findings, it has been hypothesized that offspring of alcoholics have an inherited or acquired deficiency in endogenous opioid activity that leads them to drink to compensate for the deficiency (opioid deficiency hypothesis) (24). Support for the opioid hypothesis of alcoholism is provided by the fact that opioid antagonists reliably reduce alcohol preference and consumption in different experimental paradigms and across different animal species.

In humans, several placebo-controlled clinical studies have shown efficacy of the opioid antagonist naltrexone (23,24) in the treatment of alcohol dependence. Although the specific mechanisms responsible for these therapeutic effects in humans are not fully understood, some preclinical studies have shown that naltrexone can significantly attenuate the increase in NAc dopamine associated with alcohol consumption, thereby decreasing voluntary alcohol intake (24).

The Serotonergic System

The acute administration of alcohol to rodents increases their brain concentrations of serotonin (5-HT). Direct infusion of 5-HT activates dopaminergic neurons in the VTA (40,43). In contrast, chronic exposure to alcohol reduces 5-HT concentrations in the brain, which was associated with impulsive aggression and behavioral disinhibition (21–23). Although administration of 5-HT reuptake inhibitors to alcohol preferring rodents reduced alcohol drinking behavior, it was unclear whether these compounds specifically dampened the reinforcing effects of alcohol or produced a reduction in all consummatory behaviors (21–23).

In humans, derangements in central serotonergic activity may contribute to alcohol and drug use disorders, particularly among individuals with antisocial personality. Consistent with this interpretation, antisocial alcoholics had lower basal CSF concentrations of the serotonin metabolite 5-HIAA than normal controls (21–23). Also, antisocial alcohol and drug-dependent men exhibited blunted cortisol and prolactin responses to a challenge with the 5-HT agonist fenfluramine (21–23). Additionally, children with a parental history of substance abuse and/or criminal behavior showed a reduced density of 5-HT_{2A} receptors on platelets (21–23).

There is evidence that the 5-HT₃ receptor plays an important role in the serotonergic modulation of the mesolimbic reward circuit. This receptor is unique among the 5-HT receptors in that it directly gates an ion channel that regulates rapid depolarization, causing the rapid release of neurotransmitters and/or peptides. Preclinical findings indicate that antagonism of the 5-HT₃ receptor in the VTA, NAc, or amygdala reduces alcohol self-administration and/or alcohol-associated effects. Consistent with preclinical findings, treatment with 5-HT₃ antagonists such as ondansetron attenuates the subjective effects of low alcohol doses and reduces relapse rates among early-onset alcoholic patients (21–23).

The Cholinergic System

Neuronal nicotinic acetylcholine receptors activate the release of dopamine in the CNS (21,22). Several nicotinic receptor subtypes ($\alpha 4\alpha 6\beta 2\beta 3$, $\alpha 6\beta 2\beta 3$, $\alpha 6\beta 2$, $\alpha 4\beta 2$, and $\alpha 4\alpha 5\beta 2$) are expressed on dopamine nerve terminals. The nicotinic receptors located in the soma of dopaminergic neurons of the VTA activate these neurons directly, leading to release of dopamine in the NAc. Nicotinic receptors also modulate dopaminergic reward circuits indirectly by the activation of $\alpha 7$ homomeric receptors on glutamatergic neurons. This $\alpha 7$ activation triggers release of glutamine, which in turn stimulates NMDA receptors on dopaminergic neurons, leading to dopamine release (21,22).

Studies in rodents showed that the alcohol-induced dopamine release in the NAc can be antagonized by the central nicotinic receptor antagonist mecamylamine (40). Further, pretreatment with the partial nicotine receptor agonist varenicline antagonized the dopamine stimulatory effect of acute nicotine and of coadministration of alcohol and nicotine in rodents (21,22).

In healthy humans and social drinkers, pharmacologic manipulation of the nicotinic cholinergic receptor with mecamylamine or varenicline (21,22) appears to reduce the stimulant effects of acute alcohol administration and alcohol consumption. These findings suggest that pharmacologic treatment with compounds targeting nicotinic receptors may be a useful strategy to reduce alcohol consumption among alcoholics.

Genetics of Alcohol Dependence

Family, adoption, and twin studies strongly support the involvement of genetic factors in the etiology of alcohol dependence. Family studies have shown that there is a sevenfold risk of alcohol dependence in first-degree relatives of alcohol-dependent individuals, especially among men. The observation that the majority of alcohol-dependent individuals do not have an alcohol-dependent first-degree relative underscores the fact that risk for alcohol dependence is also determined by environmental factors that may interact in complex way with genetics (25).

Adoption studies conducted during the past three decades have examined the effects of having a biologic alcoholic parent in the context of an environment provided by a nonalcoholic adoptive family. They show that there is a greater risk of alcohol dependence in adopted-away offspring from alcoholic biologic parents than in adopted away biologic children of nonalcoholic parents. The risk ratio for alcohol problems described in these studies has ranged from 1.6 to 3.6 in men and from 0.5 to 6.3 in women (25).

Twin studies have shown that the proportion of risk attributable to genetic factors (i.e., the heritability) of alcohol dependence ranges from 0.52 to 0.64 with no significant differences between men and women. Despite a rapidly changing social environment, a study conducted in Sweden that examined four birth cohorts showed that estimates of heritability remained stable over a five-decade period (25).

Linkage Studies

Linkage studies are family-based studies in which markers spaced throughout the genome are used to identify regions of chromosomes that are likely to harbor genes contributing to risk of a disorder. Linkage studies of alcohol dependence by the Collaborative Study on the Genetics of Alcoholism (COGA) group and by investigators at the National Institute on Alcohol Abuse and Alcoholism (NIAAA) have implicated a region on the long arm (q) of chromosome 4 where an ADH gene cluster has been identified. More recently, similar findings were obtained for the phenotype of alcoholism severity on chromosome 4 in a sample of 474 Irish families and among 243 Mission Native Americans from the southwest United States (25).

Among African Americans (AAs), a significant linkage between alcohol dependence and markers in chromosome 10 was also reported. This region contains numerous genes potentially relevant to alcohol dependence, such as those encoding the synaptic vesicular amine transporter and the 5-HT₇ receptor. Consistent with this finding, suggestive linkages were found on chromosomes 10, 11, and 22 for a low level of response to alcohol in a predominantly European American sample of college students (25). This trait has shown prospectively to predict an increased risk of alcohol dependence.

Other chromosomal regions of interest are those reported on chromosomes 6, 12, 15, and 16, which showed suggestive linkages with alcoholism severity and with alcohol withdrawal symptoms among Mission Native Americans (25).

Candidate Gene Studies

Candidate gene studies are population-level investigations in groups of unrelated individuals, in which genetic loci that encode proteins believed to be important in the etiology of a disorder are examined. In this approach, a statistical comparison of allele or haplotype frequencies at a candidate locus is made between affected individuals and control subjects.

ALDH Genes The influence of genetic variants encoding ADHs and ALDHs on risk of alcohol dependence in some populations is well established (20,25).

ALDH1A1 and *ALDH2* are the genes that encode ALDH1 and ALDH2. These genes have been mapped to chromosomes 9 and 12, respectively. A well-known coding variant of the *ALDH2* gene, *ALDH2*^{Q2}, encodes a substitution of lysine for glutamate at position 504. This mutation results in the coding of an ALDH2 enzyme with very little oxidizing activity (i.e., a null mutation). People with one copy of the *ALDH2*^{Q2} allele have almost no detectable ALDH2 activity in their liver, whereas people who are homozygous have no detectable activity (20,25). The inactive *ALDH2*^{Q2} variant is relatively frequent among people of Chinese, Japanese, and Korean origin but is almost absent in people of European or African descent (20,25). People with an *ALDH2*^{Q2} allele experience a typical reaction when alcohol is consumed, which is characterized by severe skin flushing, nausea, and tachycardia. This reaction among *ALDH2*^{Q2} carriers is due to the rise in the blood concentration of unmetabolized acetaldehyde. This *ALDH* gene variant that reduces or inactivates completely ALDH function has shown

to be protective against alcohol dependence especially among Asians. It is known that subjects heterozygous for the inactive ALDH2 variant have only one fourth the risk for alcohol dependence as those with two functional alleles (20,25).

ADH Genes To date, there are seven known human ADH genes: *ADH1A*, *ADH1B*, *ADH1C*, *ADH4*, *ADH5*, *ADH6*, and *ADH7*. These genes have been mapped to a small region on chromosome 4. The ADH enzymes that they encode are composed of two subunits or dimers. The seven ADH types have been divided into five classes based on similarities in their amino acid sequence and their ability to oxidize alcohol. The class I genes, *ADH1A*, *ADH1B*, and *ADH1C*, encode the α , β , and γ subunits, which can form homodimers or heterodimers that account for most of the oxidizing capacity in the liver. Several mutations have been identified in the *ADH1B* and *ADH1C* genes that are differentially distributed across population groups and that produce enzymes with different pharmacokinetic properties (20,25). There are three different *ADH1B* variants that modify the amino acid sequence of the encoded β subunit. The *ADH1B*^{Q1} allele encodes a β 1 subunit that has arginine (Arg) at positions 48 and 370. The β 2 subunit is coded by *ADH1B*^{Q2} and has the amino acid histidine (His) at position 48. This variant is frequently found among Asians. *ADH1B*^{Q3} is commonly found among individuals of African descent and encodes the β 3 subunit with cysteine (Cys) at position 370. The amino acid substitutions in both the β 2 and β 3 subunits occur at a site of the amino chain that directly interacts with NAD⁺, resulting in a faster release of NAD⁺ at the end of the reaction. In comparison to the β 1 subunit, the enzymes with these amino acid substitutions have a 70- to 80-fold greater turnover rate (20,25).

There also are three variants of the *ADH1C* gene. *ADH1C*^{Q1} encodes the γ 1 subunit with Arg at position 272 and isoleucine (Ile) at position 350. *ADH1C*^{Q2} encodes the γ 2 subunit, which has a glutamine (Gln) at position 272 and a valine (Val) at position 350. *ADH1C*^{Q3}*Thr352* encodes a subunit with threonine at position 352. The homodimeric γ 2 γ 2 enzyme has a turnover rate that is approximately 70% greater than the γ 1 γ 1 ADH enzyme (20,25). The functional significance of the *ADH1C*^{Q3}*Thr352* is still unknown.

The differences in the amino sequence encoded by *ADH1B* and *ADH1C* translate in differential rates of alcohol oxidation by the liver. It was estimated that in a person homozygous for the *ADH1B*^{Q1} and *ADH1C*^{Q2} variants, the total alcohol-metabolizing capacity would be approximately 20% lower than that of a person homozygous for both *ADH1B*^{Q1} and *ADH1C*^{Q1}. In a person homozygous for the *ADH1B*^{Q2} and *ADH1C*^{Q1} alleles, the alcohol oxidizing capacity would be eight times greater than that of the person homozygous for both reference alleles. For a person homozygous for the *ADH1B*^{Q3} and *ADH1C*^{Q1} variants, the metabolizing capacity would be almost twice that of the person homozygous for both reference alleles (20,25).

One *ADH4* variant, the -75A allele, is a promoter polymorphic site that has twice the level of activity than the -75C allele. A strong association between alcohol dependence diagnosis and *ADH4* alleles has been reported (20,25).

GABAergic Genes A variety of loci encoding proteins that play a role in GABAergic neurotransmission have been associated with alcohol dependence and related phenotypes. In a sample of families with multiple alcohol-dependent members, EEG frequency, a quantitative high-risk trait linked to chromosome 4p, was associated to *GABRA2*, which encodes the α -2 GABA_A subunit. Other groups, using case-control samples, independently replicated this finding. Although this association has been reported many times, there are studies that have failed to replicate this association and no specific causative variant or mechanism of action has been identified (25).

Interestingly, there have also been reported associations of a *GABRA2* allele with the subjective response to alcohol among healthy subjects and with drinking outcomes and the response to psychotherapeutic treatment of alcoholism (25).

Acetylcholine Receptor Genes Initial evidence that variation in the gene encoding the muscarinic acetylcholine receptor M2 (*CHRM2*) contributes to risk for alcohol dependence was independently reported. *CHRM2* maps to chromosome 7q and like the regions of chromosome 4p and 4q, it was identified by the COGA alcohol dependence linkage study as a region of interest (25).

Serotonergic Genes Genes encoding proteins in the serotonergic system have also been targeted as candidates for alcohol dependence risk. An insertion–deletion polymorphism consisting of a repetitive sequence of base pairs in the promoter region of the serotonin transporter protein (genetic locus *SLC6A4*) has been of particular interest. Compared with the “long” (L) allele, the allele with the smallest number of repeats, commonly called the “short” (S) allele, has lower transcriptional activity, leading to marked reductions in messenger ribonucleic acid (mRNA) levels, serotonin binding, and serotonin uptake in both platelets and lymphoblast. In a meta-analysis of data from 17 studies that included 3489 alcoholics and 2325 controls, presence of the S allele increased the risk for alcohol dependence by almost 20%. Moreover, the greatest association with the S allele was seen among individuals with alcohol dependence complicated by either a comorbid psychiatric condition or early-onset or more severe alcohol dependence (25,26).

Gene by environment studies have also shown that the S allele moderates the effects of various environmental stressors to increase alcohol consumption in children, adolescents, and college students. However, findings from COGA failed to replicate this moderating effect on risk of alcohol dependence. In a study examining a cohort of children at risk who were followed from birth into young adulthood, men homozygous for the higher expression L allele, when exposed to high psychosocial stressors, reported more hazardous drinking than those with the S allele or than those without exposure to stressors (25).

Opioidergic Genes A meta-analysis of studies focusing on the gene encoding the μ -opioid receptor (genetic locus *OPRM1*) failed to provide convincing evidence of association to alcohol dependence (27). Some evidence suggests, however, that an A118G polymorphism that encodes an Asn40Asp amino acid

substitution in *OPRM1* may moderate the response to treatment with the opioid antagonist naltrexone (25). Healthy individuals with one or two Asp40 alleles who were pretreated with naltrexone, reported lower levels of alcohol craving and greater alcohol-induced “high” than Asn40 homozygotes after intravenous alcohol administration. Further, pretreatment with naltrexone blunted the positive response to alcohol, an effect that was stronger among individuals with the Asp40 allele.

Among alcoholic subjects treated with naltrexone, effects of the *OPRM1* Asp40Asn polymorphism on drinking behavior have varied. Several treatment studies (25) showed that naltrexone-treated patients with one or more Asp40 alleles were significantly less likely to relapse to heavy drinking than Asn40 homozygotes. However, other studies have failed to replicate this finding (25).

In addition to the Asn40Asp polymorphism, investigators (25) have studied two other *OPRM1* SNPs, three markers in *OPRD1* (which encodes the δ -opioid receptor), and one marker in *OPRK1* (which encodes the κ -opioid receptor). No significant interaction between any of these markers and the response to naltrexone treatment was detected (25). In summary, the available evidence shows that the risk of alcohol dependence is determined by multiple genes that interact with environmental factors. To date, variants in genes encoding proteins that metabolize alcohol (ADH and ALDH genes) and GABAergic neurotransmission have consistently been found to influence the risk for alcohol dependence. Although the mechanism of the effects of genetic variation on alcohol metabolism appears to be related to the aversive effects of acetaldehyde, the mechanism of other genetic effects that have been identified remains unclear. Despite substantial evidence that a genetic component is operative in the development of alcohol dependence, the disorder is etiologically complex, with a variety of other vulnerability factors playing a substantial role (25).

EVALUATION AND TREATMENT

Conducting a detail, systematic evaluation of alcohol dependent patients allows clinician to develop an individualized plan of treatment. To determine the most appropriate level of care and the type and intensity of therapeutic interventions, clinicians should determine the severity of the disorder, the nature of co-occurring conditions, the extent of social support available, and a history of previous responses to treatment.

To build a therapeutic alliance and increase the chance of accurate reporting, it is crucial for the clinician to avoid communicating judgments that he or she may have regarding the patient’s drinking behavior, remaining neutral and empathetic.

A complete drinking history should be obtained, including specific questions on typical quantity and frequency of alcohol consumption, maximal number of drinks per drinking occasion, frequency of heavy drinking episodes, and history of alcohol-related problems such as family and interpersonal problems. Other areas of inquiry include work and legal problems, psychiatric symptoms and the nature of their relationship with alcohol consumption (e.g., precipitation or exacerbation),

and history of medical complications (e.g., alcohol withdrawal, alcoholic gastritis or pancreatitis, alcoholic liver disease).

Screening

Diverse clinical settings, including primary care practices or general hospitals, provide an opportunity to identify persons at risk for alcohol-related problems, as well as those who are already experiencing adverse effects of drinking. Evidence suggests that screening in conjunction with brief interventions (discussed below) can be very effective in prompting people whose alcohol consumption is risky or harmful to cut back on their drinking and/or to seek treatment (28). In addition to clinical settings, screening can take place in community agencies, colleges, churches, etc.

A number of self-report screening tests have been developed to identify alcoholics and individuals at risk for alcohol problems. One of the most frequently used is the CAGE, which includes four questions: (1) Have you ever felt you ought to *cut* (the “C” in CAGE) down on your drinking? (2) Have people *Annoyed* (A) you by criticizing your drinking? (3) Have you ever felt bad or *Guilty* (G) about your drinking? (4) Have you ever had a drink first thing in the morning to steady your nerves or get rid of a hangover that is, an *Eye opener* (E)?

A total CAGE score of 2 or greater (i.e., at least two of the items are endorsed as being positive) is considered highly suggestive of an alcohol use disorder.

The CAGE has shown to have a high test–retest reliability (0.80–0.95) and to adequately correlate (0.48–0.70) with other screening instruments. This is a valid screening tool for detecting alcohol use disorders in medical and surgical populations, and in psychiatric inpatients with an average sensitivity 0.71 and specificity of 0.90. However, the CAGE has not performed well among nonpregnant, pregnant women, and college students. Also, this questionnaire appears to have a poor screening efficiency in detecting low severity drinking problems (29).

Another commonly used screening instrument is the Alcohol Use Disorders Identification Test (AUDIT), which consists of 10 items. In addition to being sensitive and specific in the identification of hazardous or harmful drinkers, the AUDIT can identify alcohol-dependent individuals and may be used as the first step in a comprehensive alcohol use history (30). The AUDIT includes items examining the frequency and intensity of alcohol consumption, symptoms of alcohol dependence, and alcohol-related consequences. Using an AUDIT’s cutoff score of 8 or more yields a sensitivity ranging from 61% to 97% and a specificity from 78% to 90% in detecting alcohol use disorders (30).

A brief version of the AUDIT that includes only the first three consumption questions (AUDIT-C) has been evaluated and found to have an acceptable sensitivity (54% to 98%) and specificity (57% to 93%) in detecting drinking problems (30).

Because alcoholic patients commonly abuse or become dependent on other addictive substances, screening should include questions concerning the use of other psychoactive substances, including tobacco products, marijuana, cocaine and other stimulants, and opioids.

Psychiatric History

Given the lack of reliability in unstructured clinical diagnoses, it is highly recommended that clinicians treating patients with alcohol dependence use a structured or semistructured interview to conduct and report their diagnostic evaluations. If it is not possible to use a complete psychiatric interview, such as the Composite International Diagnostic Interview (CIDI) or the Structured Clinical Interview for DSM-IV (SCID), then the alcohol sections of these interviews can be used.

To obtain an estimate of illness severity, the number of DSM symptoms obtained during a structured interview with the SCID can be tallied. Alternatively, the total scores on the AUDIT screening test can be used to assess past-year or lifetime severity, respectively. Another useful measure of substance dependence severity is the Composite Score from the Drug and Alcohol (CSDA) section of the Addiction Severity Index (ASI).

The ASI also includes a subscale that provides an overall estimate of psychiatric severity, including the number of inpatient and outpatient treatment episodes, medication status, and lifetime and current symptoms.

It is important to obtain estimates of psychological function such as measures of depression, anxiety, and more global psychological distress. Instruments such as the Beck Depression Inventory and the Symptom Checklist 90-Revised are reliable, valid, and acceptable in a variety of health care settings.

Other measures that are useful in treatment planning for alcoholic patients include estimates of motivation and the patient’s readiness to change. The 32-item University of Rhode Island Change Assessment Scale (URICA) and the 12-item Readiness to Change Questionnaire (RCQ) are instruments designed to evaluate the stages of change across diverse problem behaviors including alcohol drinking. In some studies, the URICA and RCQ scores have shown to predict treatment outcome among alcoholics.

Physical Examination and Laboratory Findings

Physical Examination

Medical complications are a common consequence of heavy drinking and clinicians should be aware that such complications often develop in the absence of an alcohol dependence diagnosis. Conversely, early in the course of alcohol dependence, alcoholics may show no physical or laboratory abnormalities, but as the disorder progresses, most organ systems are adversely affected.

The physical examination provides essential information about the presence and extent of alcohol-induced organ damage most commonly in the GI system, the central and peripheral nervous system, and the cardiovascular system. The clinician should be alert to frequent acute alcohol-related signs, including alcohol withdrawal or delirium, intoxication or withdrawal from other drugs, and the acute presentation of psychiatric symptoms. Other systemic or nonspecific health problems associated with alcoholism include malnutrition and vitamin deficiencies, polyneuropathy, immune suppression and infectious diseases such as tuberculosis, viral hepatitis and other sexually transmitted diseases, and trauma secondary to fights and accidents.

Laboratory Tests

Laboratory testing is a valuable tool in the assessment of the effects of alcohol consumption on organ systems. Laboratory assessments can also be helpful in assessing individuals who deny or minimize their alcohol consumption or in resolving diagnostic dilemmas in patients whose self-report information and physical findings are inconclusive. Test results can also be used by the clinician to provide objective, nonjudgmental feedback to alcoholic patients on the negative medical consequences of excessive drinking, thereby enhancing the patient's motivation to reduce or stop drinking.

Another goal of laboratory testing is the early detection of relapse. Detection of relapse allows clinicians to modify the treatment plan and to implement more intensive therapeutic interventions.

Initially during the assessment phase, and during treatment, laboratory determinations should be obtained every other week, and subsequently, once a month during the follow-up period. To help patients appreciate changes in laboratory indexes, it is recommended that results be presented to them in an easy-to-comprehend graphic format that enables them to compare their findings with normal values.

Carbohydrate Deficient Transferring (CDT) The most sensitive and specific laboratory test for the identification of heavy alcohol consumption is the determination of CDT concentrations in blood. Transferrin is a globular protein that is responsible for iron transport in plasma. CDT is a collective term for a group of transferrins that lack sialic acid residues. An increase in CDT concentration is induced by heavy drinking. To date, CDT is the only laboratory test approved by the FDA for the detection of heavy alcohol consumption (31).

In differentiating heavy drinking individuals from light drinkers or abstainers, CDT has shown a sensitivity ranging from 82% to 91% and a specificity of 97% to 100% (31). CDT values also correlate significantly ($r = 0.64$) with the amount of alcohol consumed during the preceding month. Although the sensitivity of CDT appears to be comparable to that of another heavy drinking marker (gamma-glutamyl-transpeptidase—see below), CDT appears to be more specific in detecting heavy drinkers without liver disease. In this regard, CDT elevations are associated with fewer confounding conditions such as nonalcoholic liver disease or the effects of medications (31). The accuracy of this marker is poorer, however, among younger alcoholics and women. Generally, CDT concentrations return to normal levels after 1 to 2 weeks of abstinence from drinking. Among patients in alcohol treatment, CDT appears to detect relapse to heavy drinking more accurately than other laboratory tests (31).

Gamma-glutamyl-transpeptidase (GGTP) The hepatic enzyme GGTP is the most widely employed marker of heavy drinking. GGTP is a biliary canicular enzyme, the concentration of which can be elevated as a consequence of its induction by heavy alcohol consumption. GGTP concentrations are also increased as a consequence of its release into the bloodstream during acute hepatocellular damage. GGTP levels are

particularly elevated in patients with severe alcoholic liver disease, though these may be decreased during the later stages of liver cirrhosis. After the cessation of heavy drinking, the concentration of serum GGTP gradually falls by approximately 50% within 2 weeks, usually returning to the reference range over a 6- to 8- week period (31). The normalization of GGTP levels may be delayed or incomplete if there is underlying alcoholic liver disease or other medical disorders. GGTP concentrations are also elevated in a variety of nonalcoholic liver diseases such as hepatobiliary disease and in subjects consuming barbiturates or other enzyme-inducing agents. Nonetheless, elevations of GGTP occur in approximately three fourths of alcoholics before there is clinical evidence of liver disease. In comparison to CDT, an abnormal GGTP level appears to be more specific in detecting alcoholics with hepatic damage secondary to heavy drinking (31).

Whenever possible, CDT and GGTP should be used together to detect heavy drinking individuals. This approach has been shown to increase the likelihood of correctly identifying individuals with alcohol use disorders (31) and may be especially useful in diagnostically complex cases (e.g., alcoholics with a primary liver disease, those with iron metabolic abnormalities, and those being treated with anticonvulsants).

Liver Function Tests Other laboratory tests related to hepatic function, such as serum transaminases, bilirubin, prothrombin time, and partial thromboplastin time, have been used by clinicians to identify or evaluate severity of alcohol dependence. As with GGTP, elevations of the transaminases serum glutamic oxaloacetic transaminase (SGOT) and serum glutamic pyruvic transaminase (SGPT) are frequently observed when heavy drinking affects the liver. However these enzymes can also be elevated in nonalcoholic liver disease. Consequently, transaminase elevations are less sensitive indicators of heavy drinking. SGOT is elevated in 32% to 77% of alcoholics while elevations in SGPT have been observed in 50% of alcoholics. The ratio of SGPT to SGOT may provide a more accurate indicator of heavy drinking than the absolute values. Heavy alcohol consumption is more likely to be present when the ratio of these two enzymes exceeds 1.5, whereas other liver pathologies are more commonly associated with a lower ratio (31).

Mean Corpuscular Volume (MCV) Erythrocyte MCV can also be used as an objective indicator of heavy drinking. The MCV may be most useful when used in combination with GGTP or CDT. An elevation of MCV, which is caused by folate deficiency in alcoholics, is more prominent among alcoholics who are smokers. Because there is a 2- to 4- month period of abstinence required for MCV to normalize, this marker is not an efficient indicator of relapse (31).

The Alcohol Breath Test and Blood Alcohol Level (BAL) The alcohol breath test can be helpful in clinical settings such as emergency departments, or in circumstances such as driving while drinking, in which it is important to obtain a rapid estimate of the circulating alcohol concentration. This test measures the amount of alcohol in expired air, providing an

indirect estimate of the venous BAL. Although its accuracy is contingent upon the patient's cooperation in exhaling into the instrument, which is commonly limited in intoxicated patients, the alcohol breath test can be a reliable and inexpensive method to assess recent alcohol consumption. When the patient is comatose and dangerously high levels of intoxication are suspected, or for medical–legal purposes, a direct venous BAL can also be obtained. A BAL greater than 150 mg/dL in a patient showing no signs of intoxication (i.e., no dysarthria, motor incoordination, gait ataxia, nystagmus, or impaired attention) can be interpreted to reflect physiologic tolerance. In nontolerant individuals, a BAL in excess of 400 mg/dL can result in death, and 300 mg/dL indicates a need for emergency care.

Miscellaneous Laboratory Tests Another laboratory evaluation that is indicated in alcoholics is the urine toxicology screen, a test that is potentially helpful in identifying drug use among patients who may not recognize it or who deny it as a problem. The screen should include opioids, cocaine, cannabis, and benzodiazepines. Urinalysis, blood chemistries, viral hepatitis profile, complete blood count, serologic test for syphilis, and other sexually transmitted diseases, and a serum pregnancy test among women, should also be obtained routinely.

Treatment

The first step in treatment planning for a patient diagnosed with an alcohol use disorder is to determine the appropriate type, setting, and intensity of the therapeutic intervention. The clinical needs of patients affected by alcohol use disorders differ widely, so the nature and intensity of interventions must be chosen to match the patient presentation. For example, a brief intervention that provides feedback on negative consequences of excessive drinking and recommends a specific goal for reducing alcohol consumption may be sufficient to curb excessive drinking among hazardous drinkers who do not have alcohol dependence (32). However, these interventions may have a limited affect on alcohol-dependent individuals (32).

Consequently, alcohol-dependent individuals need multiple and more intensive interventions addressing both heavy drinking and associated psychosocial and medical complications. These interventions should include both psychosocial and pharmacologic interventions. An important step in developing a treatment plan for patients with a diagnosis of alcohol dependence is to establish treatment goals. Generally, the stabilization of acute medical and psychiatric conditions (e.g., severe alcohol withdrawal symptoms) has priority over other treatment goals.

Alcohol-dependent patients often have limited motivation to stop drinking, so that an important objective early in treatment is to enhance the patient's motivation for recovery. Generally, this goal can be achieved by building a therapeutic alliance, which provides the context within which recovery can occur. The presence of a trusting and encouraging relationship with a clinician can facilitate the patient's acknowledgement of alcohol-related problems and promotes motivation for treatment.

Early in treatment, clinicians should also advise patients who are alcohol dependent to establish a goal of complete abstinence. One approach to achieving this goal is through the provision of coping and relapse prevention skills training, which can include social skills training and the identification and avoidance of high-risk situations. Once established, the clinician should aim to promote the maintenance of abstinence through ongoing participation in structured treatment and/or self-help groups. In this regard, the patient should be made aware of the widespread availability of Alcoholics Anonymous (AA) and the wide diversity of its membership. A goal of moderate drinking may be appropriate for individuals who have not had multiple prior attempts to reduce their drinking to sensible limits. Such individuals may be less amenable to participation in AA, where the orientation is primarily one of abstinence.

Patients who need to change their living circumstances (e.g., to avoid frequent exposure to situations that are high-risk for drinking) may benefit from the clinician's assistance in achieving this goal. Finally, clinicians should assist patients in dealing with dysfunctional family or couples dynamics and in rebuilding supportive relationships that may help to sustain the patient's recovery efforts.

Treatment Setting

In patients with a diagnosis of alcohol dependence, it is critical to determine the severity of the disorder and whether the patient is in need of medical detoxification. Outpatient non-pharmacologic treatment is indicated when risk of withdrawal symptoms is low; however, when risk of withdrawal is moderate or high, outpatient or inpatient pharmacologic detoxification is indicated.

Several medical complications of alcoholism indicate the need for immediate admission into an inpatient treatment setting for acute stabilization. These include conditions that create a high risk for complicated alcohol withdrawal, including severe medical or surgical diseases such as hepatic insufficiency, acute pancreatitis, and bleeding esophageal varices, and severe comorbid psychiatric conditions (e.g., psychosis, suicidal intent) and/or drug dependence disorders (e.g., benzodiazepines, barbiturates) where there is a potential for serious withdrawal reactions. Psychosocial problems that commonly interfere with the completion of detoxification and/or rehabilitation such as homelessness and/or the lack of a social support network also may warrant admission into an inpatient or residential treatment setting to provide an opportunity to remediate these complicating social problems.

Research suggests that alcoholism outpatient treatment is equally effective and less expensive than more intensive inpatient treatment. However, patients who choose to be treated in outpatient settings are generally less severely alcohol dependent, less physically ill, less psychiatrically impaired, or more motivated for recovery. In this regard, patients with severe alcohol dependence and medical and psychosocial complications appear to benefit from inpatient treatment (33). Also, long-term residential treatment appears to be the only suitable option for recidivist alcoholics who frequently utilize emergency departments and/or medical or psychiatric wards, and who do not respond to more limited rehabilitation efforts.

Treatment of Alcohol Withdrawal

An important initial intervention in treating alcohol-dependent patients is the management of alcohol withdrawal symptoms (i.e., detoxification). The objectives in detoxification are the relief of discomfort, prevention or treatment of complications, and preparation for rehabilitation.

There are two approaches to the management of alcohol withdrawal. One is a nonpharmacologic approach known as social detoxification, which is indicated in patients experiencing mild symptoms. Medical detoxification, on the other hand, is indicated for patients experiencing moderate-to-severe or complicated alcohol withdrawal.

Social detoxification consists of frequent reassurance, reality orientation, monitoring of vital signs, personal attention, and general nursing care. Medical detoxification involves the use of one or more of a variety of agents that act predominantly on the GABAergic neurotransmitter system. Due to their favorable side effect and safety profile, benzodiazepines are the drugs of first choice in the pharmacologic treatment of this condition (34). Although all benzodiazepines will control alcohol withdrawal symptoms, diazepam and chlordiazepoxide appear to have a slight advantage over compounds such as lorazepam and oxazepam in preventing seizures and delirium tremens. This effect is explained by the fact that as a result of being metabolized to long-acting compounds, diazepam and chlordiazepoxide appear to self-taper. However, because metabolism of these drugs is predominantly hepatic, impaired liver function may complicate their use. Oxazepam and lorazepam, on the other hand, are not oxidized to long-acting metabolites and thus carry less risk of accumulation.

Anticonvulsants such as carbamazepine, gabapentin, topiramate, and valproate appear to be useful in the treatment of alcohol withdrawal (35). However, these medications have not shown greater efficacy, safety, or cost-effectiveness than benzodiazepines for this indication.

Although antipsychotics are not indicated for the treatment of withdrawal, these compounds can be added to benzodiazepine in cases where hallucinosis or severe agitation are present. Clinician should be aware, however, that in addition to extrapyramidal side effects, antipsychotics lower the seizure threshold, which may be particularly risky in patients experiencing alcohol withdrawal symptoms.

The prevention, detection, and treatment of common co-occurring or complicating medical conditions in alcoholics are important clinical considerations during detoxification. Good supportive care is also essential. Administration of thiamine (50 to 100 mg by mouth or intramuscularly) and multivitamins is a low-cost, low-risk intervention for the prophylaxis and treatment of alcohol-related neuropsychiatric complications such as Wernicke–Korsakoff syndrome.

Psychosocial Treatment of Alcoholism

In both residential and outpatient settings, the most commonly utilized psychosocial treatments include group or individual cognitive-behavioral psychotherapies, self-help groups (AA), family therapy, and recreational and occupational therapy. In many programs, these interventions are combined and deliv-

ered as components of an integrated rehabilitation plan under the notion that multimodal treatment potentially has a greater therapeutic effect on the multiple therapeutic needs commonly experienced by alcoholic patients.

Cognitive-Behavioral Therapies Empirical studies have consistently demonstrated the efficacy of cognitive-behavioral therapies and 12-step facilitation, which is based on the principles of AA, in the treatment of alcohol dependence (36).

Effective techniques most commonly used by cognitive-behavioral therapists are relapse prevention, social skills and assertiveness training, motivational enhancement, contingency management, cognitive restructuring, cue exposure therapy, and behavioral marital therapy (36).

Cognitive-behavioral therapies emphasize the teaching of adaptive skills aimed at changing precipitants and reinforcers (internal or external) of drinking behavior. Also, these interventions emphasize learning alternative interpersonal skills, and coping skills to deal with events, feelings, and thoughts that promote alcohol consumption (36).

Alcoholics Anonymous (AA) With more than 100,000 groups in 150 countries, AA is the most widely used source of help for people experiencing drinking problems around the world. AA and other self-help organizations are more numerous than alcohol outpatient treatment programs, particularly in developing countries, where they may constitute the only source of help for alcoholic persons. Although these self-help groups are not considered formal treatment, they are often used as an adjunct to or as a substitute for formal treatment.

Providing a strong social support for recovery, AA emphasizes the notion of the alcoholic's powerlessness over drinking and the need to endorse the existence of a higher power as a means to restore sanity and maintain sobriety. In addition to this spiritual emphasis, AA promotes the disease concept of alcoholism, in which lifelong abstinence is the only means to recovery. However, not all people with drinking problems are willing to endorse these principles.

Clinicians working with alcohol-dependent patients should be familiar with the AA philosophy and organization, taking the time to identify patients who may benefit from participation in AA. When referring patients to AA, clinicians should also take the time to follow up with the patients, monitoring their attendance at meetings and their drinking behavior. Despite the fact that AA is regarded as one of the most useful recovery resources, the empirical evidence supporting the efficacy of AA is somewhat limited.

A few large, methodologically sound studies, however, showed that participation in AA after formal alcohol treatment was associated with a greater chance of abstinence during the following 6 months (37–39). In multisite studies, patients who attended more self-help group meetings had better outcomes after 1 year than did patients who were less involved in such groups (37–39). Patients who attended more self-help groups in the first year after acute treatment were more likely to be in remission at 2 years and 5 years. Similarly, in a longitudinal naturalistic study (38), irrespective of having received formal alcohol treatment, alcoholics who participated in AA groups

for an average of 27 weeks during an initial follow-up period of 3 years showed better drinking outcomes after 16 years than did alcoholics who did not participate in AA. Interestingly, in the subgroup of alcoholics who were formally treated, the effects of treatment appeared to be enhanced by AA participation. Taken together these studies indicate that participation in 12-step self-help groups and the number of meetings attended is associated with a greater likelihood of abstinence and remission in the short and long term.

It has been argued that beneficial effects of AA may be due to greater motivation for recovery or lower disease severity among alcoholics who attend these groups. Relevant to this question is a study that assessed 2319 male alcohol-dependent veterans during a 2-year follow-up period after alcohol treatment (39). In this study, AA attendance was associated with improved outcomes but neither motivation levels nor psychopathology explained the relationship between AA involvement and outcome.

Behavioral Family Therapy Despite the fact that alcoholism has severe consequences in families, there are few studies documenting the efficacy of family interventions aimed at reducing drinking problems and/or improving family functioning. Available reports have mainly examined the effects of couples rather than family therapy interventions in alcoholics. In a meta-analysis of 12 available studies including 754 individuals, behavioral couples therapy showed to be superior than control conditions in yielding greater relationship satisfaction, greater reductions in alcohol consumption, and greater reductions in drinking consequences (40).

Self-help groups for relatives of alcohol-dependent individuals have also been integrated in many alcohol treatment programs. Although not formally affiliated with AA, Al-Anon and Alateen groups, which are for the families and the teenage children of alcoholics, respectively, have a similar structure and philosophy as AA, and they frequently hold concurrent meetings with AA.

Pharmacotherapy of Alcoholism

During the past decade, the use of medications in the rehabilitation treatment of alcohol dependence has gained increasing importance. Progress in this field has been fueled by an increased understanding of specific neurotransmitter systems involved in the modulation of alcohol consumption.

In the following section, we will discuss pharmacologic interventions that aim to reduce drinking directly by targeting specific neurotransmitter systems (e.g., the opioidergic, glutamatergic, GABAergic, and serotonergic systems), and medications such as disulfiram, which act by sensitizing individuals to alcohol, resulting in aversive effects associated with drinking. We will also discuss some medications, the use of which is intended to reduce symptoms associated with common psychiatric disorders that are thought to maintain heavy drinking, so as to reduce alcohol consumption by indirect effects.

Naltrexone Opioidergic neurotransmission plays an important role in drinking behavior (24). In rodents and humans, alcohol intake increases beta-endorphin release in brain regions such as

the nucleus accumbens, an effect that is blocked by the opioid antagonist naltrexone (24). Naltrexone and naloxone (another opioid antagonist) also suppress alcohol intake across a wide range of animal paradigms (24).

Among alcoholic patients naltrexone has shown to be more effective than placebo in delaying the time to relapse, in reducing the rate of relapse to heavy drinking, and in reducing the risk of relapse to heavy drinking in individuals who had consumed alcohol (41–43). To this date more than 20 clinical trials examining the efficacy of naltrexone in the treatment of alcoholism have been conducted (41,42). Some, but not all, of these studies (41–43) have shown that naltrexone is superior to placebo in reducing drinking. Bouza et al. (41) and Srisurapanont et al. (42) conducted meta-analyses showing that naltrexone treatment was associated with a 36% to 38% ($p \leq 0.0001$) reduction in the likelihood of relapse to heavy drinking and with a 26% greater chance, at the level of a nonsignificant trend ($p = 0.08$), of complete abstinence (41). Additionally, naltrexone treatment delayed the time to relapse and reduced the number of drinking days, drinks per drinking day, and total alcohol consumption. Such reductions in drinking were mirrored by reductions in concentrations of the liver enzymes GGT and AST (41).

Also, in a large multicenter clinical trial ($n = 1383$) (44), naltrexone in combination with medical management was as effective in reducing heavy drinking as when it was combined with a more intensive behavioral intervention. Findings from this study suggest that naltrexone may be effective when prescribed by primary care physicians to alcoholic patients. This is important because many alcoholics seek help in primary care settings.

Clinical characteristics that appear to predict a therapeutic response among alcoholics treated with naltrexone include high levels of craving, a family history of alcoholism, and medication adherence. On the other hand, increased severity of alcohol dependence and the presence of significant medication side effects were associated with a lack of treatment response (41–43). Poor adherence to naltrexone treatment commonly results from adverse effects of the medication, including nausea, which is reported by up to 15% of patients. This adverse effect is most common at the initiation of treatment and may reflect the rapid rise in plasma concentrations that occurs following the oral administration of naltrexone.

In 2006, a sustained-release (i.e., depot) formulation of naltrexone that yields detectable plasma concentrations of the drug for more than 30 days following an intramuscular (IM) injection was approved by the FDA. The relatively constant plasma naltrexone levels produced by a slow but regular release from a depot formulation may help to prevent side effects such as nausea that can lead to poor adherence and discontinuation of treatment. A monthly naltrexone depot injection could enhance medication adherence since it obviates the patient's need to remember to take the medications daily. Additionally, steady naltrexone plasma concentrations during the month following the depot injection may translate to greater exposure to this compound thereby enhancing its beneficial effects.

The FDA approval was based on the study reported by Garbutt et al. (45), who showed that patients receiving 380 mg of depot naltrexone (Vivitrol) in a large, 24-week, multicenter clin-

ical trial had a lower percentage of heavy drinking days than those getting an intramuscular injection of placebo ($p = 0.02$). A lower naltrexone dosage of long-acting naltrexone (190 mg) was also associated with a greater reduction than those receiving placebo, but this difference did not reach statistical significance. In this study, secondary analysis showed that the beneficial effect of the 380 mg dose was limited to men. Although no clear mechanism could be determined for the lack of efficacy of the naltrexone formulation in women, since the study was not designed to test the effects in women, it likely was due to chance. Additional research is needed to determine whether there are sex differences in the effects of this formulation.

Summarizing, naltrexone appears to produce a modest but clinically significant effect on drinking behavior among alcoholics. Given the modest overall effect of the medication, a variety of other factors, including medication adherence, family history of alcoholism, severity of alcohol dependence, and presence of adverse effects, have to be considered so as to optimize the treatment response to this medication.

Topiramate In an initial 12-week clinical trial, topiramate (up to 300 mg/day) was more effective than placebo in reducing heavy drinking and alcohol craving and in improving alcohol-dependent patients' quality of life. Reductions in self-reported heavy drinking in the topiramate group were confirmed by reductions in GGT plasma concentrations. Subsequently, in a 14-week, multicenter clinical trial in 371 patients, topiramate treatment, up to 300 mg/day, was more effective than placebo in reducing self-reported drinking and GGT concentrations and in increasing quality of life among alcoholics who concomitantly received a weekly brief compliance enhancement intervention (23,46). From this study, it was estimated that the magnitude of topiramate's treatment effect in reducing the percentage of heavy drinking days ranged from 0.52 to 0.63 (46), a moderate effect size and one that is greater than that estimated for naltrexone treatment (43).

In general, topiramate has a favorable adverse effect profile, with most adverse events described as mild to moderate in severity. The most frequent adverse effects include paresthesia, anorexia, difficulty with memory or concentration, and taste disturbances. Topiramate treatment is also associated with uncommon visual adverse events such as myopia, angle-closure glaucoma, and increased intraocular pressure. Generally, these problems resolve within a few days of discontinuing topiramate. To prevent or reduce topiramate's adverse effects, a slow titration to a maximal dose of 300 mg/day for 8 weeks is recommended. However, regardless of the titration schedule or final dosage, approximately 1 in 10 patients taking this medication may experience cognitive disturbances.

Among other actions that may explain the reductions in alcohol drinking associated with topiramate is the ability of this compound to antagonize alpha-amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA) receptors and kainate glutamate receptors (23). Topiramate also facilitates inhibitory GABA_A-mediated currents at nonbenzodiazepine sites on the GABA_A receptor (23). Studies in rodents have shown that a high-dose (50 mg/kg) but not a low-dose (1, 5, and 10 mg/kg) of topiramate suppressed alcohol intake in C57BL/6

mice (23). Topiramate also has been shown to reduce alcohol drinking in both alcohol preferring (P) and Wistar rats (23) and to reduce alcohol withdrawal symptoms in rodents (23).

In summary, although more research is needed to establish the efficacy of topiramate's effects on heavy drinking, available evidence strongly supports its efficacy in the treatment of alcohol dependence.

Acamprosate This amino acid derivative (calcium acetyl homotaurinate) has effects on both gamma-aminobutyric acid (GABA) and excitatory amino acid (i.e., glutamate) neurotransmission. Acamprosate appears to antagonize NMDA glutamate receptors (22,23), potentially restoring the balance between excitatory and inhibitory neurotransmission, which is dysregulated after chronic alcohol drinking. Specifically, acamprosate may modulate glutamate neurotransmission by affecting metabotropic-5 glutamate receptors (mGluR5) (22,23).

Results from human laboratory studies in healthy volunteers and alcohol-dependent individuals (23) showed no risk of liver toxicity and no interaction with alcohol. Acamprosate is not metabolized by the liver, rather it is excreted unchanged by the kidney. It is safe and well tolerated, with the most common adverse effects associated with its administration being diarrhea, nervousness, and fatigue.

A meta-analysis of the literature (47) that examined data from 17 published acamprosate clinical trials involving 4087 alcohol-dependent patients showed that continuous abstinence rates at 6 months were greater in acamprosate-treated patients (36.1%) than in those treated with placebo (23.4%) ($p < 0.001$). However, the effect size of acamprosate treatment has been shown to be small (0.14 for increasing the percentage of nonheavy drinking days and 0.23 for reducing the risk of relapse to heavy drinking) (43).

The majority of studies showing a therapeutic effect of acamprosate have been conducted in Europe, where this medication has been used for many years. In 2004, the FDA approved the use of acamprosate in the United States for the treatment of alcohol dependence, based on the evidence of the medication's efficacy provided by these studies. However, multicenter trials in the United States, Europe, and Australia have failed to detect beneficial effects of acamprosate compared with placebo in the treatment of alcohol dependence (22,23,44).

Discrepancies in the results of different studies have been attributed to differences in the use of standardized psychosocial interventions and in the severity of alcohol dependence, cognitive dysfunction, and psychological problems, as well as the prevalence of co-occurring drug abuse in most European studies compared with those conducted in the United States and Australia. Also, the small therapeutic effect of acamprosate can be difficult to detect in heterogeneous samples that are typically examined in multicenter studies.

Predictors of a favorable response to acamprosate among alcohol-dependent individuals appear to include greater levels of anxiety and physiologic dependence, a negative family history of alcoholism, a late age of alcoholism onset, and female sex. Although there is evidence suggesting that acamprosate is helpful in the treatment of alcohol dependence, effects of this com-

pound in reducing alcohol consumption appear to be small and difficult to replicate in more recent clinical trials (47).

Serotonergic Medications Another group of medications that has been examined for the treatment of alcohol dependence are serotonergic compounds. In rodent models, pharmacologic manipulation of this system has consistently shown to influence alcohol consumption, with an inverse relationship between serotonergic activity and drinking behavior (21–23). In humans, however, evidence supporting beneficial effects of serotonergic compounds on drinking behavior is less consistent (22,23).

Although several investigators have reported that treatment with the selective serotonin reuptake inhibitor (SSRI) fluoxetine (at a dosage of 40–80 mg/day) or citalopram (at a dosage of 40 mg/day) reduced alcohol consumption among nondepressed alcoholics, subsequent placebo-controlled trials showed no overall advantage of these medications on drinking outcomes (22,23).

More recent trials described that treatment with sertraline reduced the frequency of drinking only among a subset of patients with lower vulnerability/late onset of alcoholism (Babor's type A alcoholics). In contrast, among high-risk/early-onset alcoholics (Babor's type B or Cloninger's type II alcoholics) treatment with fluoxetine or fluvoxamine appeared to be associated with greater rates of relapse (22,23).

Ondansetron, a 5-HT₃ antagonist, has been found to reduce drinking among alcoholics whose onset of problem drinking occurred before age 25 (23). In this regard, early-onset alcoholics treated with low-dose ondansetron (i.e., 1, 4, or 16 µg/kg/day) had significantly more abstinent days and significantly less alcohol consumption than a control group. Among alcoholics with a later onset of problem drinking, the effects of ondansetron on drinking did not differ from those of placebo (23).

In summary, the use of SSRIs to treat alcohol dependence requires that alcoholism risk/vulnerability and age of onset be considered in evaluating treatment effects. Beneficial effects of SSRIs appear to be limited to alcoholics with lower vulnerability/late onset of alcoholism. The beneficial effects of treatment with the 5-HT₃ antagonist ondansetron, on the other hand, appear to be greatest in early-onset alcoholics. Further research examining a matching strategy based on age at onset or subtype of alcoholism is needed before these compounds can be recommended for the treatment of alcohol dependence.

Baclofen Experiments in rodents and in humans have shown that the GABA_B receptor agonist baclofen decreases voluntary alcohol consumption (21–23). Among alcoholics, open label and placebo-controlled studies have shown a therapeutic effect of baclofen (up to 30 mg/day), reducing craving and drinking and increasing abstinence rates from pretreatment levels (23,48). In one of these trials, 70% of the baclofen-treated patients remained abstinent, compared with 21.1% in the placebo group ($p < 0.005$). In addition, baclofen reduced anxiety symptoms and craving. In general, baclofen was well tolerated with no evidence of abuse liability (23,48). Reported side effects were mild and included nausea, vertigo, sleepiness, and abdominal pain (23,48). These findings suggest

that baclofen is safe and potentially effective in treating alcohol-dependent patients. More studies with larger sample size and longer treatment duration are warranted.

Disulfiram For many years, alcohol-sensitizing medications (i.e., those that induce an unpleasant reaction when alcohol is consumed) such as disulfiram have been used in the clinic. Disulfiram (Antabuse) was the first medication and is the only alcohol-sensitizing medication approved in the United States for the treatment of alcoholism.

Disulfiram binds irreversibly to ALDHs, the enzymes that metabolize the alcohol metabolite acetaldehyde, increasing acetaldehyde concentrations when alcohol is consumed. The increased acetaldehyde concentration causes the aversive reaction known as the disulfiram-ethanol reaction (DER), which is characterized by flushing of the skin, nausea, vomiting, and headache. Disulfiram also inactivates other enzymes such as dopamine-beta-hydroxylase, an effect that has been linked to reduced rewarding effects of alcohol and cocaine among individuals addicted to both drugs.

Common side effects of disulfiram independent of its alcohol-sensitizing effects include drowsiness, lethargy, and fatigue. More serious (though rare) adverse effects are optic neuritis, peripheral neuropathy, hepatotoxicity, and when prescribed in large dosages, exacerbation of psychotic and depressive symptoms in patients with schizophrenia or mood disorders.

In the United States, disulfiram approved daily dosage is 250 mg orally. However, to achieve blood concentrations sufficient to elicit the DER, some patients may need a disulfiram dosage in excess of 1 g/day. The need for greater dosages in some patients may be explained by the fact that disulfiram undergoes extensive bioactivation before it is capable of inhibiting ALDH (22,23). At the dosage that is generally used in the clinic, a reduced bioactivation of disulfiram in some individuals may yield an inadequate concentration of the active metabolite.

There are few placebo-controlled studies of the efficacy of disulfiram for the treatment of alcohol dependence. In an early placebo-controlled study, disulfiram was prescribed concomitantly with stimulus control training, role playing, communication skills training, and recreational and vocational counseling. In this context, the medication was superior to placebo in reducing drinking (22,23). However, in a multicenter trial that involved more than 600 male alcoholic veterans randomly assigned to receive disulfiram 1 or 250 mg/day, or a placebo (22,23), there were no differences in abstinence rates among treatment groups. However, patients who showed good adherence to the treatment were more likely to remain abstinent during the 1-year treatment period. Also, among patients who resumed drinking, those in the group receiving 250 mg of disulfiram had significantly fewer drinking days than patients in either of the other two groups. When disulfiram treatment was supervised to enhance adherence during outpatient alcohol treatment, patients receiving disulfiram had more abstinent days and consumed fewer drinks on drinking days than those taking placebo. These findings support the contention that supervised adherence is an important element in the successful use of disulfiram (22,23). Due to the limited evidence of the efficacy of disulfiram for the prevention of alcoholic relapse, this

medication is not recommended as a first-line treatment for alcohol dependence and should be prescribed only to patients who have not responded to other pharmacologic treatments and/or to patients in whom treatment adherence can be supervised.

Patients who are prescribed disulfiram should be warned to avoid over-the-counter preparations and food preparations that contain alcohol and medications that may interact with disulfiram. Given that substantial efforts are generally necessary to assure adherence with disulfiram treatment, this medication should be prescribed only to patients participating in treatment programs or by practitioners who make a systematic effort to enhance medication adherence.

Pharmacotherapy of Psychiatric Comorbidity in Alcoholics Clinically significant anxiety, depression, insomnia, and general distress induced by chronic alcohol consumption are common complaints among alcohol-dependent patients after detoxification. Frequently, these symptoms represent a diagnostic challenge since they are usually indistinguishable from psychiatric disorders with onset prior to the initiation of heavy drinking. Regardless of the cause, when untreated, these problems can increase the likelihood of relapse in alcoholic patients, whereas attempts to relieve emotional symptoms can translate into reduced drinking.

Pharmacotherapy of Depressed Alcoholics During the early phases of alcohol withdrawal, depressive symptoms are common; however, they tend to improve spontaneously with sustained sobriety. However, for depressive symptoms that last longer than the acute withdrawal period (which for practical purposes might best be considered 2 to 4 weeks), antidepressant treatment may be beneficial (49).

Nunes and Levin (50) reviewed data from 15 published clinical trials that examined antidepressant treatment of depressed patients with alcohol and/or other substance use disorders. Nine studies showed a moderate beneficial effect of antidepressants and six studies showed no evidence of efficacy. In the studies in which antidepressant treatment was effective in improving mood, there were reductions in alcohol and drug use. However, abstinence rates were low even in the studies in which a robust antidepressant response was seen. Seven of these clinical trials examined the effects of the selective serotonin reuptake inhibitors (SSRIs) fluoxetine and sertraline, among alcoholics with a major depression diagnosis. In these studies, patients who received the active medication generally showed a greater reduction in depressive symptoms than those receiving placebo. However, treatment with SSRIs appeared to be less effective than treatment with a tricyclic or other antidepressant such as nefazodone. Despite this, due to their favorable safety and side effect profile and lack of interactions with alcohol, SSRIs are considered the first-line antidepressant treatment among alcoholics. In summary, although it is believed that most cases of alcohol-induced depression spontaneously remit with abstinence, a significant proportion of patients continue to experience severe and persistent depression. Given the favorable safety profile of SSRIs, particularly in relation to risk of suicide by medication overdose, use of these compounds is preferable to the use of tricyclic antidepressants.

Pharmacotherapy of Anxious Alcoholics Due to the potential of benzodiazepines to produce dependence and additive CNS depressant effects when ingested concurrently with alcohol, the use of these and other brain depressants in alcoholics is probably best limited to the detoxification phase of treatment.

Bupirone, a nonbenzodiazepine anxiolytic without sedative effects or abuse potential that does not interact with alcohol, has shown to be effective in the treatment of anxious alcoholics. Although no effects on drinking were reported, initial placebo-controlled clinical trials reported greater retention in treatment and greater reductions in alcohol craving, depression, and anxiety measures among alcoholics treated with bupirone (49,51). Subsequent studies described that irrespective of a specific anxiety disorder diagnosis, a greater severity of pretreatment anxiety symptoms predicted a greater response to treatment with bupirone (49,51). Interestingly in these studies, bupirone treatment was also associated with a longer retention in treatment and longer time to relapse to heavy drinking.

In reports that failed to find differences in anxiety or alcohol consumption between bupirone-treated patients and those treated with placebo, lack of patient involvement in a psychosocial intervention program and greater severity of alcoholism appeared to explain the lack of bupirone effects (49,51).

In summary, bupirone treatment appears to be useful in the treatment of anxious alcoholics in the context of appropriate psychosocial interventions.

COMORBIDITIES AND COMPLICATIONS OF ALCOHOL CONSUMPTION

Alcoholism Comorbidity with Other Psychiatric Disorders

Community and clinical epidemiology studies suggest that in comparison to nonalcoholics, individuals diagnosed with an alcohol use disorder have a greater likelihood of having a mental health problem. Conversely, patients suffering from certain mental illnesses are more likely to experience alcohol abuse or dependence. Antisocial personality disorder, mood disorders, anxiety disorders, and another substance use disorder are the most commonly comorbid psychiatric problems in alcoholics.

Recent data from a large representative community survey examining comorbidity of past-year prevalence of alcohol use disorders and other mental health problems have been provided by the National Epidemiological Survey on Alcohol and Related Conditions (NESARC), survey that examined 43,093 household respondents residing in the United States, including Alaska and Hawaii using the DSM-IV diagnostic criteria (15,52–54).

The NESARC survey showed that among those in the community diagnosed with a current alcohol use problem, one third experienced at least another axis I disorder. This prevalence rate is two times greater than the prevalence rate of psychiatric problems observed among nonalcoholic respondents. The NESARC survey also described that in comparison to those with no diagnosis of a mental illness, those with a psychiatric diagnosis had a three times greater risk of experiencing an alcohol use disorder.

Comorbidity with Other Substance Use Disorders

NESARC described that 13.05% of persons diagnosed with an alcohol use disorder experienced a drug use disorder (OR = 9.0), whereas among persons diagnosed with drug abuse or dependence more than half (55.2%) were diagnosed with an alcohol use problem. Individuals with cocaine dependence appeared to be at the greatest risk for this comorbidity (OR = 43.0), with 89.4% of them also experiencing an alcohol use disorder. Similarly, persons who were diagnosed with hallucinogens, amphetamines, opioid, cannabis, tranquilizers, or a sedative use disorder had a greater increase in the risk for alcohol problems (52).

NESARC also described that more than half of the persons with an alcohol use disorder (58.2%) use tobacco, a rate two times higher than the prevalence observed for the use of this substance in the community. Additionally, patients with a diagnosis of alcohol abuse or dependence were more frequently found to be heavy smokers (53).

Comorbidity with Mood Disorders

In NESARC, mood disorders were diagnosed in 18.9% of alcoholics (OR = 2.6). Conversely, among individuals diagnosed with a mood disorder, 17.3% also experienced an alcohol problem. Individuals diagnosed with a mania or hypomania had the greatest risk (OR = 3.5%), with 24.0% diagnosed with a comorbid alcohol use disorder. Other mood disorders such as major depression were relatively common among alcoholics (13.7%) and were significantly associated with drinking problems (OR = 2.3) (54).

Comorbidity with Anxiety Disorders

The NESARC showed that 17.1% of persons diagnosed with alcohol abuse or dependence experienced an anxiety disorder (OR = 1.7) while in those diagnosed with an anxiety disorder, 13.0% had an alcohol use disorder. In NESARC, panic disorder with agoraphobia was the anxiety disorder with the strongest association with alcoholism (OR = 2.5), followed by generalized anxiety (OR = 1.9) and social phobia (OR = 1.7) (54).

Comorbidity with Antisocial Personality Disorder (ASPD)

The NESARC also showed that 12.3% of individuals with an alcohol use disorder met criteria for ASPD (OR = 4.8), whereas 28.7% of persons diagnosed with ASPD also had alcohol abuse or dependence (15). It is important to mention that the strong association observed between these two disorders may reflect in part substantial overlap in diagnostic criteria since antisocial behavior may be caused by alcohol intoxication.

Psychiatric Complications of Alcohol Use

Alcohol Intoxication

This condition is characterized by behavioral disturbances such as aggression or inappropriate sexual behavior, or psychological changes such as labile mood and impaired judgment that begin shortly after heavy drinking. Other clinical signs suggestive of alcohol intoxication include slurred speech, lack of coordination, unsteady gait, nystagmus, impairment of attention and memory, and in the most severe cases, stupor and coma. After large amounts of alcohol have been ingested, severe distur-

bances in consciousness and cognition can occur. This is known as alcohol intoxication delirium, a problem that generally subsides after blood alcohol concentrations decline. During the assessment of patients presumed to be intoxicated with alcohol, the clinician must rule out general medical conditions or other substance use or psychiatric disorders.

Alcohol Withdrawal

Among alcohol-dependent individuals, alcohol withdrawal occurs following a substantial reduction in drinking (among individuals who have severe physical dependence) or the abrupt cessation of alcohol consumption (in the majority of physically dependent individuals). Uncomplicated alcohol withdrawal is characterized by signs and symptoms of autonomic hyperactivity including increased heart rate, diaphoresis, tremor, nausea, vomiting, insomnia, and anxiety. The symptoms of alcohol withdrawal generally begin 4 to 12 hours after the last drink, and symptom severity generally reaches its peak after 48 hours, subsiding after 4 to 5 days of sobriety. Less severe anxiety, insomnia, and autonomic hyperactivity may last for a few weeks, though in some cases they can persist for up to 6 months in what is known as protracted alcohol withdrawal.

Approximately 10% of alcohol-dependent patients can experience episodes of alcohol withdrawal complicated by delirium and/or grand mal seizures. Alcohol withdrawal delirium, also known as *delirium tremens*, is seen in approximately 5% of the cases. This condition is characterized by severe signs of autonomic hyperactivity accompanied by a fluctuating level of consciousness and disorientation generally occurring 36 to 72 hours after the last drink. During alcohol withdrawal, patients can also experience vivid illusions and hallucinations of an auditory, visual, or tactile nature, which can also occur in a clear sensorium. Alcohol withdrawal seizures occur in approximately 3% to 5% of cases, generally within the first 48 hours after drinking cessation. A failure or delay in instituting treatment in patients with complicated alcohol withdrawal is associated with an elevated mortality risk. Predictors of complicated alcohol withdrawal include older age, poor nutritional status, co-occurring medical or surgical conditions, a history of high tolerance to alcohol, and a history of previous episodes of delirium tremens and/or alcohol withdrawal seizures.

Alcohol-Induced Cognitive Disorders

Chronic heavy alcohol drinking can result in severe folate and thiamine deficiency leading to severe neurocognitive problems such as Wernicke encephalopathy, which is characterized by confusion and disorientation, ataxia, nystagmus, and gaze palsies. Generally, this disorder responds promptly to thiamine repletion and sustained sobriety; however, if heavy drinking persists, repeated episodes of Wernicke encephalopathy can lead to a persistent alcohol-induced amnesic disorder known as Korsakoff psychosis. Although not a true psychotic disorder, a prominent characteristic of this condition is confabulation that stems from profound deficits in anterograde and retrograde memory that prevent the retention of previously learned information and/or the acquisition of new information. Despite a profound disorientation to time and place, Korsakoff's patients are unaware of their deficits.

With sobriety, improvement in the cognitive impairments usually occurs in 20% of cases of Korsakoff syndrome. However, memory deficits may remain unchanged or can be exacerbated by continued heavy drinking, resulting in an alcohol-induced persisting dementia. In addition to memory impairment, this complication is characterized by apraxia, agnosia, and disturbances in executive functioning. In addition to heavy drinking, a history of head trauma is frequently seen among individuals with this condition. Repeated episodes of Wernicke encephalopathy may also result in alcohol-induced persisting dementia. Typical neurologic findings in this condition include atrophy of the frontal lobes and increased ventricular size. As with patients with Korsakoff psychosis, continuous drinking exacerbates the dementia, whereas sobriety may improve the deficits.

Alcohol-Induced Mood and Anxiety Disorders

Chronic heavy alcohol drinking can also result in mood and/or anxiety disorders, characterized by depressed mood and anhedonia, elevated, expansive, and/or irritable affect or in the case of anxiety symptoms, indistinguishable from a primary generalized anxiety, panic, or a phobic disorder. Mood and anxiety disturbances are common, affecting up to 90% of alcoholic patients entering treatment. Alcohol-induced mood and anxiety disorders can occur during alcohol intoxication or episodes of alcohol withdrawal, and may be indistinguishable from a primary mood or anxiety disorder. Typically, the severity and duration of alcohol-induced mood and anxiety symptoms are greater than the symptoms usually attributable to alcohol withdrawal (e.g., dysphoria, insomnia, and lack of energy). However, alcohol-induced mood and anxiety symptoms generally subside fully within 2 to 4 weeks following alcohol cessation.

In the assessment of these conditions, the clinician should seek evidence that the mood or anxiety disturbances are not better explained by a primary mood or anxiety disorder. Such evidence includes the initiation of mood or anxiety symptoms before the onset of alcoholism and the persistence of symptoms during extended periods of sobriety. Given that suicide is highly prevalent among depressed and anxious alcoholics, clinicians should closely monitor the patient for emerging suicidal thoughts and/or behaviors.

Alcohol-Induced Psychotic Disorder

Hallucinations or delusions induced by chronic heavy alcohol consumption generally occur within 30 days of alcohol intoxication or a withdrawal episode. Although alcohol-induced psychosis can occur during or shortly after an episode of alcohol intoxication or delirium, hallucinations and/or delusions do not occur exclusively during the course of these conditions. However, alcohol-induced psychotic symptoms tend to subside within a few weeks of abstinence.

During the mental status exam, the patient experiencing this condition is fully alert and oriented, unaware that the symptoms are alcohol related. Evidence supporting a diagnosis of an alcohol-induced psychotic disorder include an atypical or a late age at onset of psychotic symptoms, heavy drinking preceding the onset of delusions and/or hallucinations, and

improvement in the psychotic symptoms during extended periods of sobriety.

Alcohol-Induced Sleep Disorder

Heavy drinking commonly produces disturbances of sleep architecture. Acute alcohol intoxication is associated with an increase in the density of nonrapid eye movement (NREM) sleep and a reduction in the density of rapid eye movement (REM) sleep. However, chronic heavy drinking results in a reduction in NREM sleep and a rebound in REM sleep density. These effects are clinically reflected by increased wakefulness, restless sleep, and vivid dreams, or nightmares. Alcohol withdrawal is also characterized by sleep fragmentation and an increase in REM sleep. Even after months or years of sobriety, some patients can continue to experience fragmented and unsatisfying sleep. However, generally speaking, sleep tends to improve during periods of sustained sobriety. An alcohol-induced sleep disorder is characterized by an initiation of drinking before the onset of the sleep disturbance. Although sleep problems can occur during alcohol intoxication or alcohol withdrawal, alcohol-induced sleep disorder has a longer duration and a greater severity than that typically seen during these conditions. Persistence of sleep disturbances for more than 4 weeks and/or a history of a previous sleep problem are highly suggestive of a primary sleep disorder.

Finally, it is important to notice that heavy alcohol consumption can also exacerbate other psychiatric disorders that present with sleep disturbances such as mood or anxiety disorders, or other sleep problems such as narcolepsy or breathing-related sleep disorders.

Morbidity and Mortality Associated with Alcohol Use

The World Health Organization (6) has identified heavy drinking as an important risk to global health. In 2002, 2.3 million deaths (3.7% of global mortality) were attributable to alcohol. Although there is evidence that nonhazardous drinking (which according to the National Institute on Alcohol Abuse and Alcoholism consists of ≤ 1 drink/day for women and ≤ 2 drinks/day for men) protects against cardiovascular disease, this effect appears to be confined to men 45 years old or older and postmenopausal women. Conversely, greater levels of drinking have been shown to increase mortality risk due to cardiovascular disease and other health problems. In this regard, the number of years of life lost due to drinking appears to outweigh saved years attributed to the protective effects of moderate alcohol consumption.

After accounting for its health protective effects and without considering other adverse consequences it was estimated that alcohol drinking accounts for 4.4% of the global burden of disease. Alcohol drinking is known to be associated with more than 60 health problems, most frequently alcoholic liver disease, cancer of the upper gastrointestinal track, breast cancer, fetal alcohol syndrome, immunologic impairments resulting in increased incidence of infectious diseases, seizures, and neuropsychiatric disorders.

In the United States, excessive drinking is the third leading preventable cause of death (55). In 2001, an estimated 75,766 deaths and 2.3 million years of potential life lost were attributable to the harmful effects of excessive alcohol consumption. Of the alcohol-attributable deaths, 46% resulted from chronic complications such as alcoholic liver cirrhosis and pancreatitis, whereas 54% resulted from acute complications such as injury from motor vehicle crashes and violence (55). Overall, 72% of all alcohol-attributable deaths involved men, with 75% of these involving men aged ≥ 35 years. Despite the fact that the frequency of fatal car accidents related to alcohol intoxication has declined during recent years, alcohol intoxication is still a common risk factor for motor vehicle related injuries. Also, alcohol intoxication is associated with other risky behaviors and their adverse effects, as well as to deaths attributable to suicide and homicide.

In addition to medical morbidity and mortality, heavy drinking also contributes to financial, social, and family problems. Reduced productivity and unemployment, increased criminality, and increased health care cost are highly prevalent problems related to heavy drinking. It was estimated that globally, the cost of heavy drinking amounted to more than 1% of the gross national product in high-income and middle-income countries, with the cost of social harm constituting the major proportion, exceeding those related to health care (55).

In the United States, the cost of alcohol-related problems, including hospitalization and institutionalization, motor vehicle crashes, and crime more than tripled during the past two decades, going from \$70.3 billion in 1985 to an estimated \$220 billion in 2005. In 2005, this cost was greater than that associated with other health problems such as obesity (\$133 billion) and cancer (\$196 billion).

INTRODUCTION

Terminology: Opioids and Opiates

The term *opiates* refers to two of the psychoactive alkaloids (morphine and codeine) that occur in opium and to the many similarly psychoactive compounds that can be derived from them (such as heroin and oxycodone) (1). *Opioid* is a superset of *opiates*: it additionally includes fully synthetic compounds (such as methadone and fentanyl) and endogenous compounds (such as endorphins, enkephalins, and dynorphins) that share the actions and effects of opiates (1).

Classification of Opioids through Their Actions at Receptors

Decades of behavioral research led to what might be called the classic view of the opioid analgesics, expressed here by the director of the Addiction Research Center (ARC) in 1963: “All strong analgesics clinically employed are essentially morphine-like, differing only from morphine in such characteristics as rate of onset and duration of action, routes by which they can be administered, potency, analgesic ceiling, and side effects” (2). Although this statement almost certainly needs qualification, it remains difficult to say along what lines one should split the opioids it lumps together. The classification described above—natural opiates, semisynthetic opiates, and fully synthetic opioids—is commonly encountered in textbooks, but is rarely useful. Opioids can be also classified as “long-acting” or “short-acting”; this distinction can be useful for prescribers choosing an opioid for a specific indication, although many of the available prescription opioids have fairly similar durations of analgesic action (typically 4 to 6 hours, despite differences in plasma half-life) (1).

A more “carved at the joints” classification of opioids is likely to emerge from increased understanding of their actions at receptors. The four known types of opioid receptor are mu, delta, kappa, and nociceptin/orphanin FQ peptide (NOP) receptors. Each type is G protein coupled, and although each has been suggested to have further subtypes, such variation seems to reflect posttranslational modifications (3). There are at least 20 endogenous opioid ligands, most with preferential but promiscuous affinities for receptor types (4).

Mu receptors are preferentially activated by beta-endorphin (3) and are largely responsible for the constella-

tion of effects classically associated with morphine-like drugs: analgesia, euphoria, cough suppression, respiratory suppression, pupillary constriction, and (via receptors in the gut) constipation. Studies of mu-knockout mice suggest that mu receptors are necessary for morphine-induced analgesia and for development of tolerance to morphine (5,6).

Delta receptors are preferentially activated by enkephalins (3). Delta agonists are self-administered by laboratory animals and produce conditioned place preference (4), but the extent to which this represents delta activity is unclear: seemingly selective delta agonists have turned out to be less selective than initially thought when tested in delta-knockout mice (3). Delta agonists do produce effects distinct from those of mu agonists; in laboratory animals, these include anxiolytic and antidepressant-like effects, along with proconvulsant effects (7) and only limited efficacy for analgesia (8) (though a recently developed selective delta agonist appears to be highly efficacious in rodent models of allodynia (9)). Mu but not delta antagonists produce conditioned place aversions (4), suggesting that some basal level of mu but not delta activation modulates hedonic tone. However, chronic antagonism of delta receptors reduces self-administration of mu agonists such as morphine (without reducing analgesia) (4); this and other findings suggest that delta receptors contribute to the abuse liability of opioids (10,11). This contribution may be mediated by the ability of delta receptors to dimerize or oligomerize with mu receptors—that is, to link together into complexes of two or more receptors—and such dimers or oligomers may also play important roles in tolerance and withdrawal (4,8). The clinical implication is that delta ligands might help prevent tolerance to and abuse of mu agonists without reducing their analgesic efficacy; the ligands could be delta antagonists (such as naltrindole) or bivalent ligands (which have two binding sites and a connecting spacer so that they bind specifically to dimers) (4,11–13).

Kappa receptors are preferentially activated by dynorphin A (14). Kappa agonists, such as pentazocine, cyclazocine, and salvinorin A, are not self-administered by laboratory animals; the agonists produce analgesia, but also produce a distinct profile of other effects, most notably “prodepressant” and aversive effects (15) that presumably correspond to what human users experience as dysphoria and psychotomimesis (16). (Another signature effect of kappa agonists is micturition (17).) The aversive effects of kappa agonism may be at

least partly mediated by reduction of dopamine release in the nucleus accumbens. This action might make kappa agonists clinically useful as “antagonists” of abused psychostimulants (15), or it might make kappa antagonists clinically useful to counteract the dysphoria associated with cocaine withdrawal (18). One commonly used opioid with kappa-antagonist properties is buprenorphine, though its effectiveness against cocaine use disorders is still debated (19,20). Finally, like delta receptors, kappa receptors can dimerize with other opioid receptors, and the dimers can be targeted with bivalent ligands (21).

NOP receptors (also called opioid receptor like-1 [ORL-1] receptors) are preferentially activated by nociceptin (also called orphanin FQ) (22). They are considered part of the family of opioid receptors due to structural similarities, but they appear to represent a separate branch of the family, in terms of both their pharmacology and their effects when activated. For example, in rodents, NOP agonists induce *hyperalgesia* when administered intracerebroventricularly (22), block expression of cocaine-conditioned place preference (23), and prevent behavioral sensitization to cocaine (24). NOP receptors have little or no affinity for most of the prototypical endogenous opioids (endorphins, enkephalins, and dynorphins), analgesic opioids, or the prototypical antagonist naloxone (3). One seeming exception is buprenorphine, whose partial agonism at NOP receptors may account for some of its effects at high doses, such as inhibition of ethanol drinking in rats (25). However, some investigators have been unable to confirm that buprenorphine activates NOP receptors with adequate selectiveness or efficacy to support that idea (26).

Thus, the three receptor types most relevant to a classification of abused or prescribed opioids are mu, delta, and kappa. But classification in these terms is often not straightforward: a given opioid can interact with all three types of receptors and be an agonist, partial agonist, or antagonist at each (1). This complexity is reflected in the term *mixed agonist–antagonist*, which has sometimes been used interchangeably with *partial agonist*, but now typically describes a drug that is an agonist or partial agonist at one type of receptor while being an antagonist at another type.

The existence of multiple types of opioid receptors was predicted long before the tools of molecular biology were available, based both on knowledge of the structures of opioids (27) and on behavioral data (28). Nonetheless, human laboratory studies had supported the classic view cited at the beginning of this chapter, in which mu-preferring analgesics were lumped into a single category. For example, when heroin and morphine were administered intravenously to experienced users in a double-blind fashion, the users could identify no clear qualitative differences between the two drugs—though they could discriminate between them, a finding attributed to peripheral effects such as the “pins and needles” feeling that accompanied morphine injection (29). Common wisdom was that heroin, morphine, and the mu-preferring synthetic analgesics all exerted the same pharmacodynamic effects (primarily mu agonism, with some

contribution of delta agonism later recognized) once they reached the brain.

This view leaves some clinical observations unaccounted for. For example, ostensibly similar prescription opioids do not produce complete cross-tolerance (30); in fact, practitioners treating chronic pain often rely on “opioid rotation,” switching one opioid to an equianalgesic dose of another to prevent or counteract the development of tolerance (31,32). (It seems, however, that the effectiveness of this practice has been tested only in open-label trials.) Anecdotally, clinicians sometimes find that a patient’s pain responds to only one of two similar opioids (such as oxycodone and hydrocodone) at presumably equianalgesic doses (Pasternak, personal communication, March 31, 2009). These observations could be explained by genetic variations in metabolism (as described below in the section “Differences among Users.”) or by several aspects of opioid-receptor function that are only beginning to be fully appreciated.

One such aspect is the existence of splice variants, which has been shown in mice, rats, and humans. For example, the classic mu receptor, transcribed from exons 1–4 of the 16-exon MOR-1 gene, coexists in the human brain with at least 10 alternatively spliced mu receptors; different opioids bind with equal affinity across these variants, but each opioid’s potency and efficacy at a given variant are uncorrelated with its affinity and with each other (33). In mice, disruption of exon 1 blocks the analgesic effect of morphine, but not the analgesic effect of heroin or the morphine metabolite M6G (30); disruption of exon 11 blocks the analgesic effect of heroin, M6G, and fentanyl, but not the analgesic effect of morphine or methadone (34). Thus, splice variants of the mu receptor appear to respond preferentially to morphine and methadone on the one hand versus fentanyl, M6G, and heroin (presumably acting through its active metabolite 6-acetylmorphine) on the other. In both rats and mice, these splice variants are differentially distributed in specific brain regions (30), perhaps helping to account for subtle differences in the effects of analgesic opioids. Genetic differences in expression of splice variants could help account for idiosyncratic responses to specific opioids.

Another recently appreciated aspect of opioid-receptor function is that ligands can display functional selectivity—that is, they can induce different responses at the same receptor (35). For example, mu agonists differ in the degree to which they induce responses associated with development or avoidance of tolerance, such as phosphorylation (which desensitizes mu receptors) and internalization (which protects mu receptors from desensitization, prevents compensatory superactivation of the cAMP second-messenger system, and is typically followed by receptor relocation to the cell surface (36)). In rat-brain slices, mu receptors are desensitized by morphine, methadone, M6G, DAMGO, fentanyl, etorphine, and [Met]⁵enkephalin, but, unexpectedly, not by oxycodone (37). Differences among splice variants come into play here as well: the splice variant mMOR-1C is internalized by morphine, but the splice variant mMOR-1 is not (38).

All of these findings suggest that the classification of opioids is in transition between the classic “lumping” (especially of the mu-preferring agonists) and a new “splitting” whose exact contours are not yet known.

HISTORY

History of Opioid Use

The use of opium for intoxicant purposes (including religious purposes) and analgesia appears to date back at least to ancient Greece and Sumer, where typical routes of administration were oral ingestion of opium or inhalation of its vapors from heated vessels (39). By the 8th century CE Arab traders had brought opium to China and India; between 1000 and 1300, opium use spread to Europe, and the first surviving accounts of opium addiction began to appear in all these regions. Use of opium via smoking apparently first became popular in China in the 1600s after a ban on tobacco smoking (39).

Morphine was isolated and named by the German pharmacist Friedrich Sertürner in 1806 (39); the other naturally occurring opiate, codeine, was isolated in 1832 by the French chemist Pierre Jean Robiquet (40). Heroin (diacetylmorphine, i.e., an acetylated analog of morphine) was initially synthesized in 1874 by Charles Wright in London and was tested in frogs and rabbits at the University of Edinburgh in the 1880s, but only as part of a series of studies on structure–activity relationships (41). The now-famous (re)synthesis of heroin at Friedrich Bayer and Company in 1898 occurred in the midst of the “acetylation mania” that had included Felix Hoffman’s synthesis of aspirin (42). In fact, Hoffman synthesized heroin just 2 weeks after first synthesizing aspirin; its effects were then assessed in rabbits and humans by Heinrich Dreser, head of pharmacology at Bayer (41,42). Dreser’s primary interest was in finding a cough suppressant with a more benign side-effect profile than morphine’s; his spirometry studies in rabbits quickly led him to the intriguing—and wildly erroneous—conclusion that heroin stimulated and strengthened the lungs (41,42). One historian contends that this mistaken finding led Bayer to market heroin, which otherwise seemed to have no advantages over morphine (41). Another historian notes that between 1898 and 1911, scientific and medical controversy surrounding heroin focused almost exclusively on its respiratory effects, not on its addictiveness—cases of iatrogenic heroin addiction apparently having been rare due to the use of low doses and oral administration (42).

During those same years, however, heroin became a staple ingredient in the plethora of unregulated patent medicines that already included morphine (and had probably done so since the very early 1800s) (43). Opiate-containing patent medicines were sold in nearly every conceivable

dosage form for nearly every conceivable indication, including, for gynecologic problems, heroin-impregnated tampons (42). In the medical literature, the first explicit warning about heroin abuse and addiction was probably a 1912 *JAMA* article by physician John Phillips of Cleveland, Ohio, who described three individuals’ “habits” of insufflating heroin; two of the users had initially been attempting to relieve coughs, while the other seemed to have sought out heroin for its psychoactive effects. Two of the users had also told Phillips that heroin was frequently used for euphoriant effects “in the tenderloin districts” of Ohio cities or among soda-fountain employees with daily workplace access to it (44). These patterns of use were especially notable in light of heroin’s reputation (among both laypeople and physicians) as a nonaddictive drug (44). Phillips’s article marked the start of wide public concern about heroin abuse and addiction in the United States (41). In December 1913, fully 3 years after President Taft had declared to Congress that cocaine was “more appalling in its effects than any other habit-forming drug used in the United States” (45)¹ and the *Chicago Tribune* had featured a headline about “The War Against Cocaine” (46), an article in the *New York Times* was introducing the word *heroin* to a readership still presumed to be unfamiliar with it:

Dr. C.J. Douglas of Boston ... described the ravages of the new drug which, he said, was making victims by the hundred in his own city. This is a new product of opium and its discovery has been so recent that no existing State law may be made to apply against it. This new chemical is called heroin. Its effects are like those of morphine, and it is sold so openly in one district of Boston that the vicinity of the drug store which markets it has become known as “heroin square.” The victims, who have increased by the hundreds within the last few months, hold regularly what are known as “sniffing parties,” when the drug is passed around occasionally as the chief means of entertainment (47).

The lurid tone of the *New York Times* article suggests that heroin was becoming the center of what sociologists call a “moral panic.” The moral panic may also have been stoked by growing public antipathy toward Germany in the years leading up to World War I (41).

With the 1914 passage of the Harrison Narcotic Act, access to heroin in the United States was restricted to those whose physicians would prescribe it (in federally regulated amounts), and as of 1924, heroin could no longer legally be prescribed, either (though it always remained available by prescription in the United Kingdom). By many accounts, the criminalization of heroin caused a demographic shift in the profile of those who abused or were addicted to it, whereby the middle-class misuser of patent or prescribed medicines gave way to the marginalized, “deviant” seeker of euphoriant effects. However, as the 1913 *New York Times* article suggests,

¹ Several textbooks and scholarly articles add the irresistible factoid that Taft had called cocaine “public enemy number one.” There is no evidence that Taft used this phrase, which did not enter common parlance until the 1930s (Joseph F. Spillane, personal communication, July 1, 2009). The misquotation may have arisen from a misreading of David Musto’s 1989 summary of the *gist* of Taft’s statement.

the Harrison Act may have been a *reaction* to—though also an exacerbating influence on—an already present trend in that direction (48).

History of Behavioral Research on Human Opioid Use and Addiction

Human behavioral research² on opioids in the 1900s can be considered in terms of at least three major strands: the psychiatric and clinical-pharmacology approaches taken at the ARC in Lexington, Kentucky from 1930s to the 1970s (48–50); the behavioral-pharmacology approach taken by experimental psychologists at Johns Hopkins and other universities from the 1950s onward (50); and the sociologic approaches taken by Chicago School theorists and others, beginning in the 1930s and becoming influential from the 1950s onward (48).

Psychiatry and Clinical Pharmacology at the Addiction Research Center (ARC)

The ARC was established as an independent entity within a unique federal narcotics hospital/prison in which inmates had access to ostensibly therapeutic farm work and were asked to participate in research studies (50). The published output of the ARC from the 1930s through the 1950s shows the movement of addiction research from psychodynamic concepts to behavioral ones (49). Lawrence Kolb, the ARC's first medical director (48), organized some aspects of the program with a psychodynamic typology of addicts he had developed in the 1920s (50). In 1948, Abraham Wikler, associate director of the ARC, developed a theory of addiction through a study consisting of psychoanalytic interviews with one especially articulate user during readdiction to and withdrawal from morphine (50,51). Yet the theory, which Wikler called a "pharmacodynamic" theory, was ultimately more behavioral than psychodynamic: although Wikler ascribed the initial misuse of opiates largely to personality defects, he ascribed ongoing addiction to "factors of little or no symbolic significance"—specifically, the avoidance or termination of withdrawal symptoms (52). Later, Wikler would discuss the theory in exclusively behavioristic terms (53,54), but even in 1953, Wikler invoked processes and concepts that remain important to current scientific thinking about addiction:

... a "conditioning" process may play a role in relapse, particularly in the case of addiction to opiate drugs. A number of opiate addicts have stated that experiences akin to that of the opiate abstinence syndrome, including intensified "craving" for such drugs, may occur long after "cure," when opportunities to obtain narcotics present themselves (52).

Harris Isbell, director of the ARC from 1945 to 1962, discussed Wikler's conditioning theory in terms that comport even more closely with current thinking:

The instantaneous relief of this [withdrawal-related] suffering afforded by opiates serves to heighten the addict's esteem for

this class of drugs and causes him to use the drug for the relief of discomfort from any cause. In a sense, the addict becomes "conditioned"—any unpleasant situation calls for an injection. A pleasurable experience, such as meeting an old friend, also requires a celebration, using drugs as a means of heightening the pleasure already experienced (55).

In the same article, Isbell endorsed a harm-based definition of addiction to which physical dependence was not essential, and acknowledged that personality dysfunction could be either a cause or consequence of opiate addiction (55). Isbell had also published the first findings indicating that withdrawal from methadone could be preferable to withdrawal from morphine (56); methadone was thereafter used at the ARC to manage withdrawal symptoms (50), though maintenance treatment was apparently not discussed, except insofar as to point out that the Harrison Act seemed to forbid it (57). Treatment with mu antagonists such as nalorphine was discussed (58).

Other important advances during the early days of the ARC occurred in a laboratory directed by Clifton Himmelsbach, where careful characterization of the opiate-withdrawal syndrome (59) was used to develop methods for addiction-liability testing of new drugs (50,60,61).

From 1963 to 1977, ARC research was directed by William Martin (50). As mentioned in the previous section, Martin used behavioral and physiologic data to infer that there were multiple types of opiate receptors (28). Martin also postulated a syndrome of "protracted abstinence" lasting up to 30 weeks, characterized by subtle physiologic signs and, he hypothesized, associated with vulnerability to relapse (62); this syndrome continues to be investigated. Martin, and later Donald Jasinski, continued to test opioid antagonists as maintenance treatments (63–65). Charles Haertzen developed the Addiction Research Center Inventory (ARCI), a subjective-drug-effects questionnaire refined by factor analysis in the tradition of personality inventories (66). The ARCI has become a standard measure for characterizing experimental drugs in terms of their resemblance to known classes of drugs.

In the 1970s, as the ethical acceptability of research with prisoners was increasingly called into question, the ARC moved to a medical campus in Baltimore, becoming part of the National Institute on Drug Abuse (NIDA) (50). The campus was already home to the Behavioral Pharmacology Research Unit (BPRU) of Johns Hopkins University; this geographical proximity led to an entwinement of the ARC's research traditions with those of another strand of research: behavioral pharmacology.

Behavioral Pharmacology

Although views of opioid addiction at the ARC became less psychodynamic and more behavioral over the decades, the branch of behaviorism embraced at the ARC (as in Wikler's conditioned-withdrawal theory) was largely Pavlovian. In the 1950s and 1960s, investigators primarily interested

² For a brief review of the history of molecular research on opioids and their receptors, see Ref. 39.

in Skinnerian (operant) conditioning established the field of behavioral pharmacology. Among the clearest contrasts between the two schools of thought was that behavioral pharmacologists tended to doubt the value of the kinds of self-report data collected by clinical pharmacologists at ARC (67). Behavioral pharmacologists also favored single-subject designs in which the individual's behavior was intensively analyzed (50)—this at a time when ARC director Harris Isbell was stating, at a 1963 conference, that “all new suggested programs for opiate addiction should be evaluated by rigidly controlled clinical trials” (49). Human research at the ARC relied heavily on what was uniquely human—the ability to provide self-report data—whereas research in behavioral pharmacology usually involved applying a given methodology across species (and was thus necessarily oriented toward nonverbal behavior). Thus, even this brief summary of human research needs to include some discussion of laboratory-animal research.

The first major achievement for behavioral pharmacology in the study of opioid addiction occurred in the late 1950s at the University of Maryland, where Joseph Brady had been developing high-throughput behavioral screens with rats to study the effects of new drugs (68). Brady's students, Charles Schuster and Travis Thompson, fortuitously discovered that monkeys would self-administer morphine (68; 69). Although self-administration research helped confirm Wikler's assertion that morphine use could be induced by cue-induced withdrawal (70), some ARC investigators initially doubted that such work was relevant to addiction (68). Perhaps this reflected their awareness of its implications: self-administration work allowed addiction to be conceptualized in terms of principles of behavior analysis (a point made by Fischman and Schuster (71)). This meant that causal attribution for drug use and misuse began to change from antecedents (such as users' psychiatric defects) to consequences (68)—which could be similar for anyone in a given environment.³

From 1963 to 1968, Schuster ran a behavioral-pharmacology laboratory at the University of Michigan that came to include James Woods, Chris-Ellyn Johanson, and Maxine Stitzer. Schuster and Woods showed that morphine self-administration (in monkeys) could be maintained at doses that did not require physical dependence (73); such findings are reflected in the current criteria for opioid addiction, which hold that physical dependence is neither necessary nor sufficient for the diagnosis (74).

From 1968 to 1974, Schuster and Marian Fischman ran a behavioral-pharmacology laboratory at the University of Chicago (75), where self-administration techniques began to be more frequently applied to human research. One project completed there was a study of human self-

administration of methadone, codeine, and pentazocine, showing that pentazocine's abuse liability was lower than those of methadone and codeine (76). During approximately the same years, Travis Thompson ran a behavioral-pharmacology laboratory at the University of Minnesota, where his trainees included George Bigelow and Roland Griffiths; Thompson and Bigelow continued the self-administration work with monkeys (67).

In the 1970s, many of these investigators converged back in Maryland, this time at Johns Hopkins University. By 1974, Bigelow, Griffiths, and Stitzer had named their Hopkins laboratory the Behavioral Pharmacology Research Unit (BPRU) (77). Bigelow and Ira Liebson studied the effects of behavioral treatments in methadone patients (78); this and related work at BPRU (79) were the genesis of contingency-management treatment. As mentioned, in 1974 the ARC (by then part of NIDA) moved from Lexington to BPRU's Hopkins campus; by 1986, the former gulf between the ARC and behavioral pharmacologists had been eradicated in a more than symbolic way, as NIDA's director was now Charles Schuster.

Also in 1974, behavioral pharmacologists Jack Mendelson and Nancy Mello established the Alcohol and Drug Abuse Research Center at McLean Hospital in Boston (80). Mendelson had attended Johns Hopkins and the University of Maryland (80), but was not directly associated with the investigators who formed the BPRU. At the Mendelson and Mello laboratory in Boston, investigators did further work with heroin self-administration in humans, showing that sequential self-administrations of heroin produced ever smaller phasic increases in euphoria against a tonic background of increasingly intense dysphoria (81). This observation—that self-administration continued despite demonstrably diminishing reward—presaged the idea of a dissociation between wanting and liking (82), which would become an influential hypothesis in addiction research.

Mendelson and Mello also showed that human self-administration of heroin is suppressed by buprenorphine (86); this finding was instrumental in the development of buprenorphine for treatment. Perhaps reflecting the blurring of the lines between clinical and behavioral pharmacology, the abstract from the report of this study includes a distinctly un-Skinnerian emphasis on subjective responses to the test medication: “The subjects liked buprenorphine and indicated that it was preferable to methadone or naltrexone.”

Sociology and Ethnography

A third strand of human research on opioid use and addiction consists of work done by sociologists and ethnographers. These investigators have been more geographically disparate

³ By the 1970s, the social implications of these findings were being openly expressed by behavioral pharmacologists and neuropharmacologists. For example, the neuropharmacologist Avram Goldstein wrote: “This [opioid self-administration] is not the anomalous behavior of a few, but the predictable behavior of all. Thus, on fundamental biologic grounds, we may infer that were it not for countervailing influences in human society, narcotic addiction might well be the norm rather than an aberration” (72).

than the ARC and BPRU investigators, and it is accordingly more difficult to summarize their history in a few paragraphs.⁴

The roots of this body of work can be traced to a doctoral dissertation completed in the 1930s by University of Chicago sociologist Bingham Dai, who conducted in-depth interviews with heroin addicts in order to supplement epidemiologic data; although his conclusions placed heroin addiction in a social context, he still emphasized the etiologic role of individual addicts' psychiatric pathologies, much like his contemporaries at the ARC such as Kolb (48). Dai's fellow student Alfred Lindesmith, who completed similar fieldwork at the same time, explicitly rejected Kolb's conceptualization of heroin addiction as a manifestation of psychopathology (48), formulating a "sociologic theory of addiction"—but Lindesmith's sociologic theory was in many ways a cognitive theory, stressing the etiologic importance of recognizing and labeling one's own withdrawal symptoms (43).

In the 1950s, a "second Chicago School" emerged, including Howard Becker, whose studies of deviance in drug users influenced later sociologists such as Dan Waldorf (86,87), Bruce Johnson (88), and Charles Faupel (89). Each of the latter three discussed heroin addicts' long-term trajectories of use in terms of "using careers," implying that addicts function (often adaptively) within a particular social system and have some degree of mobility within that system. Becker has stated that he and Lindesmith were hostile or indifferent toward most of the accounts of addiction emerging from the ARC and from behaviorists and that the feeling seemed reciprocal (90).

Nonetheless, the intellectual descendents of the first and second Chicago Schools produced work that has radically reshaped scientific thinking about addiction in general. Probably the most celebrated example is the work of Lee Robins, who showed that heroin-addicted U.S. soldiers returning from Vietnam defied expectations by overwhelmingly reverting to abstinence (or moderate use) without treatment or participation in self-help programs (94–98). Following up on Robins' surprising findings on natural recovery from heroin addiction, ethnographers Dan Waldorf and Patrick Biernacki suggested that the seemingly uncontrollable pull of addiction can be defeated by "the pulls of 'the good life', as exemplified by the dominant value system—work, stable life, and high levels of consumption" (96). Another implication of Robins' findings—that addiction is determined largely by social setting—was fleshed out in the work of psychiatrist Norman Zinberg, whose in-depth interviews provided evidence that certain subcul-

tural norms can support chipping, the long-term recreational use of heroin or other opiates in the absence of addiction (97–99).

History of Methadone Maintenance

For opioid addicts who did need treatment, the early 1960s saw what remains the major breakthrough: methadone maintenance, pioneered largely by Vincent Dole and Marie Nyswander at Rockefeller University Hospital in New York City.⁵ Their initial report on methadone maintenance included data from only 22 patients (101), yet remains a remarkably informative primer. Their follow-up work with a larger sample of methadone-maintained patients showed multiple indicators of treatment success, including reductions in criminality (102).

Methadone maintenance and other agonist treatments, despite being surprisingly straightforward approaches to a problem of such theoretical complexity, have never existed in isolation from the research that preceded and followed them. The theoretical roots of methadone maintenance can arguably be traced back to laboratory-animal self-administration studies done by behavioral pharmacologists (this argument was made by Fischman and Schuster (71)). Once methadone maintenance was established, it was used as a platform for behavioral studies, such as a study of self-regulation of methadone doses (103).

Dole and Nyswander themselves did not present methadone maintenance in a theoretical vacuum. They argued that the unexpectedly good psychosocial outcomes of their first few hundred patients militated against notions of inherent and intractable psychiatric dysfunction (104). Dole and Nyswander did state that methadone maintenance should be accompanied by psychotherapy or psychosocial case management, but when they discussed how those aspects of treatment should be individualized, they wrote in terms that might have come from the Chicago School-influenced sociologists:

[T]he social problems of the street addict will continue to disable him unless effective social helps are also given. The slum-born, minority-group addict was underprivileged before he became addicted, and these social problems remain with him after his heroin use is stopped This may not be true of the middle-class addict who presents psychiatric rather than social problems (105).

This idea—that opioid addiction might be a different "disease" for addicts of different socioeconomic classes—is rarely stated so plainly in current research literature.

⁴ One criminologist, John Ball, worked at the ARC in the early 1960s, characterizing the population there, but he worked more from an epidemiologic standpoint than an ethnographic one; for example, he compiled statistics on all Asian patients, all patients who died, and all patients whose primary addiction was to methadone (84). He later coauthored a classic book on correlates of outcome in methadone programs (85).

⁵ This breakthrough was not without precedent. Between 1919 and 1923, the Shreveport Morphine Maintenance Clinic successfully maintained 762 patients until state and federal pressure caused its closing (100).

The success of Dole and Nyswander's work helped to change U.S. federal policy toward addiction, though in some ways the change was transient. Under President Nixon, federal funding for addiction treatment came to exceed federal funding for enforcement, but this change had already been reversed before Nixon's administration ended, long before the emergence of the better-known punitive drug policies of the 1980s (48). Similarly, Don Des Jarlais (who in the 1970s had published treatment-outcome research with Dole and Nyswander) provided evidence in the 1980s for the effectiveness of needle exchange and community outreach (106), yet most of his findings have not been incorporated into federal policy (48).

A more encouraging interaction among research, treatment, and policy can be seen in the history of buprenorphine treatment; this is discussed in Section 6 of this book.

EPIDEMIOLOGY OF OPIOID USE AND DEPENDENCE

Prevalence and incidence of opioid use in the United States can be gleaned from the National Survey on Drug Use and Health (NSDUH), which reports on the use of illicit drugs, alcohol, and tobacco in respondents aged 12 and older (107). In 2007, the most recent year for which data are available, the survey included interviews from a sample of 67,870 people, selected to be representative of the civilian, noninstitutionalized population of the United States, with demographic minorities oversampled to facilitate reliable extrapolation. Opioid use is reported under two categories, "heroin" and "pain relievers"; the latter is a subset of the "prescription-type psychotherapeutics used nonmedically."

Heroin Use

Prevalence

The number of current heroin users (defined as those who have used in the past month) in the United States is not trivial in absolute terms, but is small as a proportion of the general population: extrapolation from NSDUH data suggests that in 2007, 153,000 persons 12 years or older were current heroin users (107). This is a decrease from the 2006 number of 338,000 and corresponds to a decrease in current heroin use prevalence from 0.14% to 0.06% of the U.S. population. The decrease from 2006 to 2007 was consistent across most demographic groups: among females 12 years or older, the rate decreased from 0.06% to 0.02%; among adults 26 years and older, from 0.14% to 0.05%; and among youth, from 0.06% to 0.01%.

Incidence

In 2007, an estimated 106,000 persons aged 12 or older had used heroin for the first time within the last 12 months. The average age of first use was 21.8 years, which was unchanged from 2006 (107).

Nonmedical Use of Pain Relievers

Prevalence

In 2007, an estimated 5.2 million persons aged 12 or older (2.1% of the U.S. population) had used prescription-type pain relievers nonmedically in the past month; this rate was similar to the rate seen in 2006. Sources of the drug (among those who used nonmedically in the past 12 months) often included a friend or relative, either through free access (56.5%), purchase (8.9%), or theft (5.2%); in addition, the drug was obtained from doctors (18%, who reported that they got the drug from just one doctor), drug dealers or other strangers (4.1%), and Internet sources (0.5%). Rates of past-month use of OxyContin were similar among males (0.2%) and females (0.1%).

Incidence

Among past-year illicit drug initiates, 19% initiated with non-medical use of pain relievers. Pain relievers tied with marijuana as the two illicit drug categories with the largest number of past-year initiates among persons aged 12 or older; each had an estimated 2.1 million. These estimates were not significantly different from those seen in 2006. The number of new nonmedical users of OxyContin aged 12 or older was 554,000, and 24 years was their average age at first use.

Opioid Use among Youth

Trends in drug use among youth can be gleaned from Monitoring the Future, a long-term study of American adolescents, college students, and adults through age 50 (108). The 2008 national sample included approximately 16,300 8th graders, 15,500 10th graders, and 14,600 12th graders, for a total of approximately 46,000 students in 386 secondary schools.

Youth Prevalence

In 2008, the lifetime prevalence of heroin use with a needle was 0.9%, 0.7%, and 0.7% in grades 8, 10, and 12 respectively; without a needle, the corresponding prevalences were 0.9%, 0.8%, and 1.1%. Lifetime prevalence of use of narcotics other than heroin (assessed in 12th graders only) was substantially greater: 13.2%. The annual prevalence of heroin use for all three grades (8th, 10th, and 12th) fluctuated between 0.7% and 0.9% from 2005 through 2008. During this same time period, the annual prevalence of use of narcotics other than heroin by 12th graders fluctuated between 9.0% and 9.2%. The annual prevalence of use of OxyContin and Vicodin specifically among 12th graders between 2005 and 2008 fluctuated between 4.3% and 5.5% (OxyContin) and between 9.5% and 9.7% (Vicodin) (108).

Youth Attitudes

Perceived Risk and Disapproval of Opioid Use In 2008, a small majority (55.5%) of 12th graders perceived trying heroin once or twice as a "great risk," and a larger majority (86.4%) perceived taking heroin regularly as a "great risk." Among 12th graders, 93.3% "disapproved" of trying heroin once or twice, and 94.2% "disapproved" of trying

heroin once or twice without using a needle; these percentages were not appreciably different from those seen in 2007 (108).

Almost 60% of youth reported that they had talked in the past year with a parent about the dangers of drug, tobacco, or alcohol use (108).

Opioid Availability Heroin was said to be “fairly easy” or “very easy to get” by 25.4% of 12th graders in 2008; this was a modest but statistically significant decrease from 2007 (29.7%). Similar decreases in availability were seen with some other opioids (including methadone and excluding heroin), which were said to be “fairly easy” or “very easy to get” by 37.3% of 12th graders in 2007 and 34.9% in 2008 (108).

Opioids and Emergency Department (ED) Visits

Drug-related ED visits in the United States are monitored by a public health surveillance system called the Drug Abuse Warning Network (DAWN) (109). DAWN estimates for 2006, based on a national sample of general, nonfederal hospitals operating 24-hour EDs, suggest that 113 million ED visits occurred, and that just over 1.5% of these (1,742,887; Confidence Interval (CI): 1,451,086 to 2,034,688) were drug related. Of these drug-related visits, approximately 11% (189,780; CI: 119,525 to 260,035) were related to heroin; this is likely an underestimate, because some heroin use is misclassified as an “unspecified opiate” use. Accounting for population size and margin of error, ED visits involving heroin were higher for males than females and highest in patients aged 21 to 54. There were no significant changes in rates or proportions of heroin-related ED visits between 2004 and 2006. Of the ED visits made by patients seeking detoxification, 29% were specifically for heroin detoxification.

The DAWN data include a separate category for “nonmedical use of prescription or over-the-counter pharmaceuticals or dietary supplements”; there were approximately 741,425 (CI: 674,198 to 808,652) such visits, of which approximately 33% involved opioid analgesics. From 2004 to 2006, visits involving opioid analgesics increased 43%, with some of the largest increases seen in visits involving “hydrocodone/combinations” (44% increase), “oxycodone/combinations” (56% increase), and “unspecified opiates” (60% increase). Of the ED visits made by patients seeking detoxification, 26% were specifically for detoxification from opioid analgesics.

Opioid Abuse or Dependence and Treatment

In 2007, 213,000 persons aged 12 or older met *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition (DSM-IV)* criteria for heroin abuse or dependence (74). A much larger number—1.7 million—met *DSM-IV* criteria for pain-reliever abuse or dependence; this was second only to cannabis (3.9 million). The estimate for pain relievers has remained unchanged between 2002 and 2007. These diagnoses (the criteria for which are discussed in the Section Phenomenology of use and withdrawal, and criteria for opioid-use disorders of this chapter) reflect not merely physical dependence, but patterns of use with broad adverse psychological or interpersonal consequences.

Past-Year Treatment for an Opioid-Use Problem

In 2007, an estimated 335,000 aged 12 or older had received treatment in the past year for drug problems involving heroin, and an estimated 558,000 people had received treatment in the past year for drug problems involving pain relievers. The latter figure represents a substantial increase over the preceding 5 years (2002: 360,000 persons) (107).

An estimated 21 million people (8.4% of the U.S. population aged 12 or older) needed but did not receive treatment for a problem with illicit drugs or alcohol in 2007. An estimated 1 million people perceived a need to be treated, but only 28.5% of them made an effort to get treatment. The most commonly reported reasons for not receiving treatment (combining data from respondents who did and did not seek treatment, from 2004 to 2007) were: lack of health coverage or ability to pay (35.9%), not being ready to stop using (26.6%), ability to handle the problem without treatment (12.5%), lack of transportation or convenient access (10.5%), concerns about negative opinions from neighbors/community (8.9%), lack of type of treatment needed (8.1%), concerns about negative effects on employment (7.0%), and lack of knowledge of where to go for treatment (6.9%).

Treatment Admissions for Opioid Problems

Treatment facilities that are licensed or certified by state substance-abuse agencies provide data for the Treatment Episode Data Set (TEDS) (110). TEDS data from 2007 show that 13.6% of all treatment admissions for substance abuse were related to heroin and 5% were related to other opioids. Of the individuals admitted for heroin-related problems, 68.5% were male, 52.3% were white (non-Hispanic), 22.1% black (non-Hispanic), 22.4% Hispanic, and 6.6% of other races/ethnicities; the average age at admission was 36 years. Of the individuals admitted for problems related to other opioids, 53.4% were male, 88.6% were white (non-Hispanic), 3.7% black (non-Hispanic), 4.1% Hispanic, and 3.5% of other races/ethnicities; the average age at admission was 32 years. The plurality of those admitted for heroin problems had had five or more prior treatment episodes, while the plurality of those admitted for other opioid problems had had no prior treatment episodes. Admissions for opioids other than heroin increased from 1% of all admissions in 1997 to 5% in 2007.

Longitudinal Course of Opioid Dependence

Given that heroin use disorders are relatively rare among substance use disorders (107), heroin users seem to be overrepresented among treatment admissions for substance use disorders (110). The high treatment numbers almost certainly reflect the fact that agonist maintenance is among the most effective addiction treatments ever developed. Nonetheless, there has long been a relatively hidden population of individuals who recover from addiction to heroin or other opioids without formal treatment (or attendance at self-help groups).

In 1962, Charles Winick reviewed official records from the Federal Bureau of Narcotics and found that by age 35 to 40

years, individuals tended to drop out of the files, a phenomenon he attributed to their “maturing out” of their substance use problems (111). The “maturing out” hypothesis has received only partial empirical support: a recent review concluded that there is “no particular age at which the probability of becoming abstinent either increases or decreases” and that periods of use and abstinence tend to be cyclical (112). Users who do achieve long-term abstinence tend to be those who, as ethnographer Dan Waldorf had suggested (96), have or establish hallmarks of a conventional lifestyle, such as employment, good social relationships, and a variety of leisure activities (112,113).

For users who do not achieve abstinence, health consequences seem to be cumulative over decades (114). A 33-year longitudinal study of 581 male heroin addicts, with a mean age of 25 years at enrollment, showed a mortality rate of nearly 49% (115). This statistic would be easier to interpret if it had been accompanied by data on the expected mortality rate in demographically matched men without heroin addiction. One clear aspect of the findings, however, was that 45 (8%) of the men had died of heroin overdose.

PHENOMENOLOGY OF USE AND WITHDRAWAL, AND CRITERIA FOR OPIOID USE DISORDERS

Phenomenology of Use

A study by Mirin and colleagues, mentioned in the “History” section of this chapter, evocatively describes the behavioral sequelae of *ad libitum* heroin use in a laboratory setting:

With the onset of heroin use, behavior typical of addicts in a more natural setting was clearly in evidence. Quarreling, sarcasm, verbal hostility, and threats of assault were more frequent, both among themselves and with staff. Complaints about the quality of the heroin were voiced even while subjects were “nodding out.” ... When asked if their attitudes or behavior differed in any way from previous cycles of addiction, most volunteered that “this is the way I get.” Despite the negative clinical and social effects of prolonged heroin use, the subjects continued to work for and self-administer increasingly larger doses of the drug (80).

A first-person description of heroin effects notes that heroin can initially be a social lubricant and euphoriant, at least for some users:

The unglamorous truth is that it’s not that pleasurable or interesting a drug—except at the beginning The first time I snorted heroin, I couldn’t believe it had such bad press: I felt absolutely wonderful and consummately able to conduct all essential life activities—talk, write, listen to music. Sex, it turned out, wasn’t so great, but you can’t have sex all the time anyway. I liked heroin much better than alcohol and didn’t notice a physical downside: my coordination was okay and nothing was blurred or confused. The high felt ... like nothing so much as happiness itself (116).

On chronic use, these positive effects become unreliable: “Sometimes you can do dope all night and function the next day; other times hours of vomiting replace the evening partying you had in mind” (116). Eventually, the effects of heroin use may become, at best, emotionally numbing:

What passes for interaction is so much more minimal on dope A non-drug-using friend called some of my junkie pals “holograms,” as in: “they’re not really there, you can’t talk to them.” But that’s just the point; heroin may not warm a cold world, but it lowers your comfort zone to the reptilian average. Heroin loses its savor once you start seeing this numbing effect as a negative rather than an advantage. Used regularly, heroin is mainly a way of lowering one’s expectations Among users, heroin is proverbially what you do when you really must organize your files or your house; it lends itself to cushioning activity that’s deadening and inherently repetitious (116).

Phenomenology of Withdrawal

Withdrawal from opioids produces a flu-like syndrome that is not life threatening (117). The syndrome has been described in medical literature as either “subjectively severe but objectively mild” or “objectively mild but subjectively severe,” presumably depending where the writer wanted to place the emphasis. For users, the subjective severity tends to be paramount. Even an objective onlooker would be unlikely to describe the behavioral manifestations of unaided withdrawal as “mild.” Isbell and Harris (118) noted that even prodromal symptoms of withdrawal are sufficient to drive ongoing use of morphine. In our own treatment-research clinic, we have noted that anticipatory anxiety about an eventual dose taper (sometimes called “detoxification phobia” (119)) can hinder patients’ acceptance of a sufficiently high maintenance dose of methadone.

Abrupt discontinuation of relatively short-acting mu agonists such as heroin (but not methadone) typically leads to onset of symptoms in 6 to 8 hours; the most prominent are yawning, watery eyes, runny nose, chills, muscle aches, nausea/vomiting, diarrhea, and fever. Eating is disrupted for approximately 7 days; sleeping is increased on the first day, but disrupted for at least 15 days; fever peaks on the third day and may persist for approximately 15 days (120).

Abrupt discontinuation of methadone leads to symptoms that are slower in onset (usually starting after 24 hours), longer in duration, and possibly milder (117). In clinical practice, methadone is typically tapered over 8 to 24 weeks, depending on the maintenance dose. Some patients state that methadone withdrawal (even during a taper) is at least as severe as heroin withdrawal, and there is some evidence to support this contention, at least when street-methadone addicts were compared with heroin addicts in a 10-day open-label taper from methadone (121). A double-blind, double-dummy study would be needed to resolve the issue.

Ten patients’ perceptions of lengthy individualized methadone tapers (11 months on average) were described in detail by Eklund and colleagues (122):

Among the individual psychological symptoms, sleeping disturbances, fatigue, and insecurity were judged to be the most discomfiting. Various forms of sleeping disturbances are ... the symptom the patients mention as being the most discomfiting. Insecurity was reported high, and several of the subjects say that they particularly experience a general feeling of insecurity in different social situations, for example when they run errands in town, go out shopping, or meet acquaintances (122).

Eklund and colleagues noted that insecurity had not been specifically reported in other studies of methadone withdrawal, but “nervousness” had. Proneness to other psychological symptoms, such as depression, varied across individuals. As for physiological symptoms:

only excessive sweating, yawning, diarrhea, and muscular aches increased significantly from the first to the second half of the withdrawal process. Of these, the greatest change is noted for excessive sweating and yawning. These symptoms thus escalate in later parts of the dose reduction process and have caused considerable problems for a couple of the subjects. For example, Subject 7 ... suffered from excessive sweating mainly in the face and armpits for a long time after conclusion of withdrawal, which can be very embarrassing, particularly on the job Two years after the last methadone dose, Subject 7 still reports abnormal sweating, although the problem has gradually diminished. Regarding yawning, this is also a common sign of abstinence and can be discomfiting owing to the fact that it is deeper and more frequent than ordinary yawning (122).

Eklund and colleagues also noted an “almost total absence of cramps”; abdominal cramps seem to be much more common during abrupt withdrawal of shorter-acting opioids than during a methadone taper. Finally, Eklund and colleagues noted some potentially positive changes: “Many methadone patients during withdrawal report that they become more awake, alert, and active, their senses are intensified, and they are more in touch with their emotions” (122).

Some of the clinically observable signs of opioid withdrawal (such as increased blood pressure, increased metabolic rate, and lowered body weight) may take approximately 6 months to resolve (123), an observation that has been discussed in terms of a subtle “protracted abstinence syndrome” (62) in which such signs are accompanied by dysphoria and vulnerability to relapse. There is evidence that the severity of cue-induced craving for heroin in a laboratory setting becomes and remains elevated for at least 6 months after a methadone taper (123).

Criteria for Opioid Use Disorders

In both of the major diagnostic systems for substance use disorders—the *DSM-IV* (74) and the *ICD-10* (124)—the criteria are generic, applying across substances. These criteria are discussed in Chapter 10. What bears emphasis here is that, in either system, physical dependence (tolerance or withdrawal) is neither necessary nor sufficient for diagnosis of an opioid use disorder. This is consistent with observations made as long ago as 1949 by ARC investigators: “[A]ddicts repeatedly relapse to the use of morphine long after withdrawal,

not because they are suffering with any physical distress, but because they desire the euphoria produced by the drug or the relief of the psychic and emotional discomfort which it gives. This is simply another way of saying that habituation is more important in addiction than in physical dependence” (117).

The *DSM-IV* provides for diagnoses of dependence (a term intended to replace *addiction*) or abuse. The intended distinction between dependence and abuse is that dependence reflects adverse psychological or medical consequences of use, while abuse reflects adverse social, legal, or interpersonal consequences; in other words, the two categories are meant to be logically independent of each other (125). Nonetheless, a diagnosis of abuse is not made if criteria for dependence are met. In either case, the pattern of use must be “maladaptive”; thus, criteria for a disorder will not be met by chronic-pain patients for whom opioids improve quality of life, nor by occasional users whose use remains nonproblematic.

The *ICD-10* provides for diagnoses of dependence and harmful use. The dependence diagnosis reflects mostly the same set of criteria as the *DSM-IV* dependence diagnosis, though it also incorporates a “sense of compulsion” as one possible (not required) criterion. The “harmful use” diagnosis reflects patterns of use that damage physical or mental health without otherwise meeting criteria for dependence (124).

DETERMINANTS OF USE

Drug-Related Determinants

Receptor Activity

Among the numerous factors that determine the degree to which a given drug is abused, the most fundamental is the interaction between the drug and endogenous receptors. Upon binding to a receptor, a drug may be a *full agonist* (fully activating the receptor), a *partial agonist* (activating the receptor to a lesser degree than a full agonist), or an *antagonist* (blocking the receptor). In the presence of a full agonist, a partial agonist can produce the behavioral effects of an antagonist. Some drugs, termed *mixed agonist–antagonists*, can act at more than one receptor with differing degrees of agonist and antagonist activities. Small differences in structure can result in substantial differences in receptor activity (126,127).

Drugs that act as full agonists at the mu-opioid receptor are more likely to be abused than those with activity at other opioid receptors. In fact, all of the most highly abused opioids are mu agonists, including morphine, heroin, hydrocodone, oxycodone, hydromorphone, fentanyl, and methadone (1,128). When administered to experienced drug users, these drugs produce positive mood effects, described as euphoria, along with a wide range of other subjective and physiologic effects such as nausea, vomiting, itching, dry mouth, and respiratory depression. With repeated administration of mu agonists, tolerance and physical dependence develop. Development of tolerance to the positive mood effects of mu agonists may play a role in the dose escalation that frequently occurs during opioid dependence. On abrupt discontinuation of use of mu agonists following repeated administration,

there is a characteristic abstinence syndrome, characterized by muscle cramps, chills, vomiting, and malaise (59).

Drugs with kappa-agonist activity, such as cyclazocine, ketocyclazocine (after which the kappa receptor is named), and enadoline, produce a different profile of subjective effects, including sedation and effects described as psychotomimetic or dysphoric (16,129–131). Abrupt discontinuation of repeated administration of kappa agonists produces an abstinence syndrome distinct from that of mu agonists (132,133). Kappa-agonist activity is associated with low abuse liability. In fact, although kappa agonists have been investigated for analgesia and other potential benefits such as neuroprotection in ischemia, their unpleasant subjective effects have so far prevented their successful development as medications.

The group of drugs that act at multiple-opioid receptors are often referred to as the agonist–antagonist opioids. Some of these are marketed as analgesics, such as pentazocine, butorphanol, nalbuphine, and buprenorphine. Pentazocine, butorphanol, and nalbuphine have varying degrees of mu- and kappa-agonist activities (1,134,135). Each of these three drugs can be distinguished from mu agonists such as morphine using subjective-effect questionnaires (cf. 133) and human drug-discrimination procedures (137–140). In fact, the differences in subjective effects between prototypic mu-opioid agonists and the agonist–antagonist opioids, respectively, described as morphine-like and nalorphine-like in early work, were a partial basis for the development of the multiple-opioid-receptor theory (28). Nalorphine was one of the first agonist–antagonists studied in animals and humans. It was originally marketed as an antagonist to treat opioid overdose until the more selective opioid antagonist naloxone became available. Pentazocine, butorphanol, and nalbuphine precipitate withdrawal when administered to individuals who are physically dependent on mu agonists (141–143), an attribute that limits abuse. In general, agonist–antagonist opioids have been less abused than prototypic mu agonists (128), though, as noted below, they have been abused under some circumstances.

Buprenorphine differs from the other agonist–antagonists in having partial mu-agonist activity without kappa-agonist activity; its activity at the kappa receptor is as an antagonist. Buprenorphine's subjective effects are very similar to those of the full mu agonists (144–146). Without the abuse-limiting kappa-agonist effects of the other agonist–antagonists, buprenorphine has some history of diversion and abuse (147). However, its abuse by chronic users of full mu agonists (such as heroin, oxycodone, or methadone) is naturally limited because it blocks the acute effects of full mu agonists and can thereby precipitate withdrawal in individuals who are physically dependent on them (144,148). Also, because buprenorphine is only a partial agonist at mu receptors, it is relatively unlikely to produce respiratory depression, even at high doses (145,146). However, deaths have occurred with buprenorphine, especially when it is taken in combination with benzodiazepines (149).

Opioid antagonists that lack agonist effects, such as the opioid antagonists naloxone and naltrexone, are generally devoid of subjective effects except at high doses (64), although

one early study in healthy volunteers suggested that intravenous naloxone (10 mg/mL) can block “thrills” elicited by nondrug stimuli such as music (150). These drugs have little or no abuse liability. Indeed, although naltrexone has been available for the treatment of opioid dependence for several decades, its clinical utility is severely limited by low adherence by patients (151).

Some opioids have additional activity at nonopioid sites, which can affect their abuse liability. Examples include tramadol, which produces analgesia through both mu-agonist activity and blockade of noradrenergic reuptake transporters (152), and meperidine, which has both mu-agonist and anticholinergic activities (153). Meperidine has a long history of abuse, sharing many subjective effects with more selective mu agonists, but it also has a distinctive profile of adverse effects that appear to limit its abuse relative to those drugs (128,154,155). Tramadol has not been widely abused despite its wide availability in a variety of dosage forms (156,157), perhaps because it is less potent in producing positive mood effects than in producing analgesia (158).

Overall, opioids with selective mu-agonist activity have somewhat higher abuse liability than those with mixed actions and much higher abuse liability than those without any mu-agonist activity.

Pharmacokinetics

The abuse liability of opioids is influenced by the numerous factors that determine their bodily distribution, metabolism, and excretion. One important factor is the speed with which the drug is delivered to the central nervous system. In general, abuse potential is enhanced by speeding the delivery of drug to the brain, thus shortening the interval between drug administration and the perceived onset of pharmacodynamic effects (159). One likely reason for the popularity of heroin over morphine is that its onset is faster than that of morphine. Also relevant, of course, is the fact that heroin is approximately twice as potent as morphine (and can thus be transported at a lower volume per unit dose) (160).

Although the pharmacokinetic profile of a particular opioid is largely determined by its physical/chemical attributes, the route of administration can also have a substantial impact on speed of delivery. For most drugs, the rank order for routes of administration from slowest to fastest delivery is typically as follows: oral < intranasal < intramuscular \approx subcutaneous \lll intravenous \leq inhalation (e.g., smoking). Opioids that can be inhaled or injected intravenously will likely have greater liability for abuse than those that can be used only orally. Methadone is typically dispensed as a liquid (e.g., cherry-flavored syrup) in maintenance programs in part to reduce the likelihood that it will be used by a parenteral route of administration.

Nonpharmacological Drug-Related Factors

The abuse liability of opioids is also affected by at least two nonpharmacological factors that are nonetheless related to the drug itself: availability and formulation.

The availability of heroin is not evenly distributed around the world, and rates of use and abuse can follow changes in availability. For example, India, the largest

producer of licit raw opium, also has the highest illicit opium use, a fact attributed in part to diversion of licit opium production (161). Heroin trafficking from the point of production to major markets can also increase local heroin use (and the attendant adverse consequences such as HIV infection) along the route (162,163). Temporary decreases in heroin supply can decrease the rate of initiation of new heroin users (164).

Abuse of prescription opioids has been increasing somewhat disproportionately to the number of licit opioid prescriptions (165). Availability partly determines which specific opioids are abused. For example, when availability is limited to hospitals, the opportunity for abuse of even highly abusable opioids will obviously be reduced; even within hospitals, availability and opportunity play a role in rates of abuse, as evidenced by the greater prevalence of substance abuse among anesthesiologists than among other physician groups (166,167). In contrast, even the least desirable opioid may be abused if it is widely available. An example of this is the over-the-counter cough suppressant dextromethorphan, with activity at sigma and PCP receptors. Early studies of dextromethorphan showed that it did not produce morphine-like subjective effects and was not liked by experienced opioid users (168,169). Nevertheless, dextromethorphan has been abused, mostly by teenagers either specifically seeking a dissociative/hallucinogenic experience or simply seeking any intoxicating effect (170).

Increasing the availability of a medication with a low rate of abuse can substantially increase the incidence of abuse. For example, abuse of both fentanyl (a potent mu agonist with high abuse liability) and butorphanol (a mixed agonist–antagonist with moderate abuse liability) increased when each drug was approved for prescribed use in outpatients, despite the use of formulations that might have been expected to minimize abuse liability (170). In the case of fentanyl, until 1990, reports of abuse usually involved health care providers with access to the intravenous formulation in hospital settings. After 1990, when fentanyl became available to outpatients (in a transdermal-patch formulation), abuse spread to a much broader population, mostly individuals who were not legitimate patients. Butorphanol was an unscheduled, injectable analgesic available primarily for acute administration in hospitals with only sporadic reports of abuse until another (intranasal) dosage form was approved for outpatient use in 1991. Reports of overuse and physical dependence began to appear soon after-ward, leading to the scheduling of butorphanol by the DEA in 1997. In contrast to the pattern seen with fentanyl, many of those who overused butorphanol were patients taking the medication for treatment of migraine headaches and trying to avoid rebound of migraine symptoms, despite not liking the subjective effects of the butorphanol (170).

Formulation changes were probably not the direct culprit in increases in fentanyl or butorphanol abuse, given that a transdermal or intranasal formulation is generally less reinforcing than an intravenous formulation. The role of for-

mulation becomes clearer when users devise a way to self-administer a drug by a route other than that intended by the manufacturer. For example, sustained-release formulations designed to deliver a low, constant dosage of medication over an extended period should have lower abuse liability than immediate-release formulations. However, if the slow-release formulation can be defeated, making the entire contents of the product rapidly available, abuse liability can be increased, particularly if the preparation contains large quantities of drug. The best-known example is that of OxyContin, a time-release formulation of oxycodone hydrochloride, which abusers found that they could crush to release the medication rapidly. Abuse of OxyContin became widespread; at least one study found the prevalence of its abuse greater than that of other formulations of oxycodone, methadone, morphine, hydromorphone, fentanyl, or buprenorphine (171). There is also evidence that buprenorphine tablets intended for sublingual administration are abused intravenously (172). Transdermal systems developed to deliver medication slowly for extended periods of time have been prime targets for subversion and misuse (173).

Formulation-based strategies have sometimes been used to decrease the abuse liability of prescription opioids. Naloxone, which is far more bioavailable when injected than when taken orally, has been added to pentazocine and buprenorphine tablets to decrease the likelihood that they will be dissolved and injected by opioid-dependent individuals. Sustained-release products that resist manipulation are also being considered. Further development of abuse-deterrent formulations must meet criteria for both risk-benefit and cost-effectiveness. Meeting patients' pain treatment needs while suppressing illicit use is a complex problem that is under investigation (174,175).

Work is also underway to devise early detection monitoring systems for drug diversion problems (156,171). The goal of these systems is to prevent epidemics of abuse of prescription medications through rapid detection and intervention.

Differences among Users

Genetics

The role of common allelic variants in modifying opioid effects was recently reviewed in depth by Rollason and colleagues (176); the review focused on implications for individualized prescription of analgesics. The variants of interest occur in genes coding for the following: a drug-clearing cell-membrane transporter (P-glycoprotein), phase I drug-metabolizing enzymes (specifically, cytochrome P450 enzymes in the liver), phase II drug-metabolizing enzymes (such as UDP-glucuronosyltransferase, which facilitates urinary excretion of drugs), and opioid receptors. Rollason and colleagues noted that a given allelic variant—for example, duplication of the CYP2D6 allele, resulting in an “ultrarapid metabolizer” phenotype—could increase sensitivity to one opioid (such as oxycodone) while decreasing sensitivity to another opioid (such as methadone). Genetic differences could also have implications for nonmedical use of opioids.

A recent case-control study of single-nucleotide polymorphisms at sites representing 130 candidate genes suggested small associations between heroin addiction and several variants in noncoding regions of genes for mu, delta, and kappa receptors (177). Genetic differences like these might lead to individual differences in splice variants of opioid receptors, the significance of which is discussed in the section Classification of Opioids through Their Actions at Receptors of this chapter.

Cognitive Factors

The process of social learning, initially described by Becker (178) to explain how seemingly unpleasant effects of marijuana or LSD could be reinterpreted by users as desired effects, can apply to opioids as well. For example, a user's first nonmedical experience with an opioid often includes nausea and vomiting, but the user may learn from experienced peers that these symptoms are an intrinsic part of a desirable experience (43,89). Thus, the phrase “pleasant sick” is among the standard clinical descriptors for opioid effects; one user in an ethnographic study described her early heroin experiences by saying, “The more I puked, the higher I got” (89).

Social learning may also play a role in defining oneself as an addict and behaving accordingly: some addicted users report that they had initially interpreted their withdrawal symptoms as flu symptoms until experienced users told them otherwise, leading them to seek more opioids for relief (179). We have heard similar reports from patients in our treatment-research clinic.

As discussed below, environment is a strong determinant of patterns of opioid use—yet not everyone in a high-risk environment uses opioids or becomes addicted to them. One possible explanation is that individuals' differing *perceptions* of identical environments lead to different outcomes. To address this issue, Nurco and colleagues (180) interviewed adult heroin addicts about their perceptions of deviance in their neighborhoods of origin and compared their responses to those of two never-addicted control groups: the addicts' childhood peers and nonpeers, all from the same neighborhoods of origin. The neighborhoods were perceived as having been more deviant by the addicts than by their nonpeer controls. However, perceptions were fairly similar between the addicts and their peer controls. Thus, perceptions of the neighborhood seemed to explain only a small amount of variation in outcome among childhood peers. Perhaps such variation will be better explained by some combination of peer interactions and genetic predispositions, as has been argued for personality development in general (181).

Environmental Determinants

Peers and General Environmental Setting

As mentioned in the section History of Behavioral Research on Human Opioid Use and Addiction, addiction to opioids in exceptional circumstances, such as war, often resolves when the circumstances change (94–98). In this section, we discuss opioid use and addiction in more typical circumstances.

The archetypal pusher who distributes free samples of heroin to snare nonusers is largely a myth (182). Ethnographic studies indicate that initiation of heroin use typically occurs with peers, is often serendipitous, and is attributed retrospectively to curiosity (89,179). However, in some recent small studies, addicts report having been tricked into their first use of heroin by peers who said that the heroin was cocaine or referred to it with unfamiliar slang (179). These claims are difficult to dismiss, because some addicts have acknowledged perpetrating such tricks (183). It is not clear whether being tricked into heroin use is common; it was first described in a study of a rural area, where high heroin prices had led many users to sell heroin to support their own use and to seek buyers proactively (183). It remains likely that the modal circumstance of first exposure involves a combination of availability and curiosity.

Initiation of opioid use is sometimes said to be causally related to prior use of marijuana or other drugs; this is the strong version of the gateway hypothesis. This hypothesis would be difficult to prove or disprove, but is not necessary to explain epidemiological data. The observations that underlie the gateway hypothesis—association and temporal sequencing of marijuana use and opioid use—can be fully accounted for in a computer model incorporating only two rules: differing individual propensities to use drugs in general, and temporally staggered availabilities of different drugs (184).

Once nonmedical opioid use is established, environmental factors seem to be prime determinants of whether it progresses to addiction or remains at the level of chipping (regular but nonproblematic, noncompulsive use). For illicit drugs in general, the likelihood of addiction, given use, increases with low educational background (185,186), low income, and minority-group membership (185), but the surveys from which these statistics were drawn do not disaggregate opioid addiction from other drug addiction. The classic work on determinants of opioid addiction, given use, is ethnographic rather than epidemiological: Norman Zinberg (99) interviewed 61 opioid (mostly heroin) chippers and 30 addicts, all of whose patterns of use had been stable for several years. The modest size of Zinberg's sample limits the ability to draw negative conclusions from it, but permits large effects to be observed. Zinberg found few or no differences between chippers and addicts in terms of opioid of choice, route of administration, initial responses to opioids, neighborhood availability of opioids, family background, or personality. The clearest differences were these: the chippers had more friends than the addicts; the chippers chose to remain friends with other chippers and to shun former friends who became addicts (whereas the addicts had frequently been shunned by former friends); and the chippers tended to adhere to specific rules about opioid use, such as planning use in advance, budgeting funds for use, and buying opioids only under certain circumstances (for example, only from personally known sellers). Zinberg interpreted these findings as evidence of a healthy form of social learning in which subcultural rules and rituals keep continued drug use under control, much as

societal norms regarding drunkenness keep most adults' drinking under control despite the legality and ubiquity of alcohol (99). Unfortunately, for most nonmedical opioid users, social networks tend to become increasingly narrow (179)—so even if selection of the right peer group can facilitate nonproblematic use of opioids, most nonmedical users may have difficulty finding such a peer group.

Specific Opioid-Associated Cues

General aspects of the environment affect individuals' overall propensities toward opioid use, abuse, and addiction. Specific opioid-associated cues seem to contribute to ongoing use, and to lapses and relapses, among established users. As described above, Wikler (184) theorized that environmental cues associated with past use of opioids (or with opportunities to obtain opioids) induce conditioned responses that can occur long after the last use of opioids, can include withdrawal symptoms and craving, and can play a role in relapse. Wikler's theory was based largely on anecdotal reports from users. Later laboratory work by Charles O'Brien and colleagues showed that signs and symptoms of opioid withdrawal could be induced in five of eight users by cues (an auditory tone and the odor of peppermint) that had been paired with a prior experience (187). The prior experience in this case was not opioid use, but naloxone-precipitated withdrawal. The clinical relevance of this phenomenon—exposure to cues associated with prior withdrawal—was not supported by opioid users' retrospective accounts of relapse, despite interviewers' specific probes (188). However, further work by Anna Rose Childress (in collaboration with O'Brien and Tom McLellan at the University of Pennsylvania) demonstrated that cues previously paired with opioid *use* could induce craving and “high-like feelings” as well as withdrawal symptoms and that each cue-induced response could occur independently of the others (189). The conditioned responses occurred in a variety of settings (laboratory, clinic, and home), but their exact precipitants and manifestations varied across users and across occasions. Childress and colleagues suggested that the variability of the responses hampers users' ability to recognize cue-elicited opioid seeking as a general phenomenon in daily life (189). The daily-life relevance of opioid cues was supported by findings from an ecological momentary assessment study by our group, in which opioid-dependent patients maintained on methadone reported on their heroin use and surroundings: the results showed a significant linear increase in cue-exposure reports in the 5 hours preceding episodes of heroin craving in daily life (190). The increase in cue-exposure reports was much less robust in the hours preceding episodes of actual use; our speculative explanation for this was that methadone maintenance partly decoupled craving from use (190).

If cue-elicited craving and withdrawal do contribute to relapse, it might seem encouraging to note that they can be extinguished in a laboratory setting (188,191). Unfortunately, efforts to parlay this finding into an extinction-based treatment have been thwarted by the failure of extinction to generalize outside the environment in which it occurs

(192,193). In fact, the context-specific nature of extinction is the basis of an animal model of relapse (194).

COMPLICATIONS OF OPIOID USE AND COMORBID DISORDERS

History and Physical Examination in Patients with Opioid Use Disorders

History

Like all clinical medicine, evaluation and treatment of opioid use disorders requires the development of a therapeutic relationship based on trust and a two-way exchange of information. Patients with opioid use disorders should undergo all elements of a basic medical history (chief complaint, history of present illness, past medical history, medications, allergies, and review of systems). Additionally, special attention should be paid to the patient's social history; this should include a complete assessment of substance use and HIV risk factors (Table 13.1).

The medical history in patients with opioid use disorders should also include a screening for depression and anxiety and an assessment for personal safety in regard to both living situation and personal relationships.

Physical Examination

A complete physical examination is warranted in all patients with opioid use disorders. In addition to the standard elements, the physical examination should include special attention to signs and symptoms related to opioid use and its complications (Table 13.2).

Complications of Opioid Use

Chronic use of pure opioid analgesics does not produce frank signs of toxicity in any major bodily organ, though it may be immunosuppressant to a degree whose clinical significance is not clear (195). Nonetheless, chronic misuse of opioids usually has considerable medical sequelae, many of them attributable to the associated lifestyle and to the routes of administration employed.

Heroin is most often taken by sniffing, intravenous injection, or “skin popping” (subcutaneous injection); these routes are also sometimes used for other opioids (such as crushed OxyContin tablets). Each route of administration has accompanying complications (Table 13.3). Injection can result in the entry of organisms from the skin, injection works, or perhaps the drug itself (197) into the surrounding soft tissue and the bloodstream. This can result in a localized infection such as cellulitis, abscess, wound botulism, or necrotizing fasciitis. It can also result in more widespread systemic infection such as endocarditis and septic emboli. Injection drug users are more likely than nondrug users to be admitted to the hospital for infection (198). Treatment should be driven by culture and sensitivity of the offending organism, with incision and drainage or debridement as necessary. Of note, “classic” findings are not always evident

TABLE 13.1 Elements of a substance use and HIV risk factor assessment

Sexual practices	
■	Number of sexual partners
■	Kinds of sexual contacts (one-time, anonymous, groups, exclusively with one partner, etc.)
■	Type of sexual activity (receptive or insertive, vaginal or anal intercourse, oral–genital, oral–anal, manual–anal, etc.)
■	Condom/barrier use and negotiation of safe-sex practices with partner
■	Use of drugs or alcohol to enhance sexual encounters
■	Sex in exchange for money, drugs, or shelter
■	Sex with someone known or suspected to have HIV/AIDS
■	History of sexually transmitted infections
Drug practices	
■	Drugs used
■	Routes of drug administration (smoking, huffing, sniffing, injecting, etc.)
■	Source of needles (pharmacy, needle exchange, street, shooting gallery, etc.)
■	Sharing of needles, works, cottons, cookers, rinse water, or any other injection equipment
■	Sharing of straws or other material to sniff drugs, etc.
■	Cleaning injection equipment with bleach

Data from Cherubin CE, Sapira JD. The medical complications of drug addiction and the medical assessment of the intravenous drug user: 25 years later. *Ann Intern Med.* 1993;119(10):1017–1028. (196)

in physical examination or laboratory tests of injection drug users, so providers should have a low threshold for initiating workup and treatment when otherwise clinically indicated.

Sniffing opioids can result in pulmonary complications including granulomatous responses, hemoptysis from airway irritation, and emphysema. There may also be nasal irritation, chronic sinusitis, and septal perforation.

As might be expected, overdose is a common adverse event among opioid misusers; it has been estimated that for every fatal overdose involving opioids, there are roughly 30 nonfatal ones (199). Most opioid misusers acknowledge having witnessed a nonfatal overdose, many acknowledge having witnessed a fatal one, and many also acknowledge having experienced a nonfatal overdose themselves (200,201). The mechanisms of overdose death are unclear (202); it has been argued that most such deaths involved synergistic effects of opioids and other drugs (203).

Because opioid misusers are often reluctant to summon help for peers who have overdosed in their presence, and because many also hold inaccurate beliefs about resuscitation methods (204), a case has been made for providing take-home naloxone with appropriate training for emergency use. Initial arguments against take-home naloxone included an anecdotal report of recreational “flatlining,” a practice in which “one drug user stands guard with naloxone while another uses opiates in a dose that far exceeds tolerance” (205). This fear was not borne out in any of several subsequent pilot programs in several different cities (206–210). In one of the programs, bystander-administered naloxone was shown to be effective when administered as a nasal spray, eliminating the risks associated with injection (209).

Primary Care and Substance Use–Related Comorbidities

All patients with opioid use disorders should undergo the age-appropriate preventive health measures that are recommended for the general population (screening for breast, cervical, colon, and prostate cancer and for elevated cholesterol) as outlined by the United States Preventive Services Task Force. In addition, these patients should be screened for the following substance use–related comorbidities: hepatitis, HIV, sexually transmitted infections (STIs), and tuberculosis (TB). Treatment and management of comorbidities should be undertaken as indicated.

Hepatitis C Virus (HCV)

Hepatitis C is the most common bloodborne infection in the United States, with a prevalence of almost 2% (211). In some case series, HCV infection is seen in more than 80% of injection drug users (212,213). In HIV-infected injection drug users, the prevalence of HCV is 50% to 90% (214). HCV is primarily spread by contact with infected blood or blood products. In the United States, the main routes of transmission are blood transfusions and shared, unsterilized injection equipment.

All individuals with substance use disorders should be tested for HCV. The initial screening test is the anti-HCV enzyme immunoassay (EIA). False positives are possible, so confirmatory testing of positive EIAs should be performed for HCV RNA with polymerase chain reaction or transcription-mediated amplification. In immunocompromised individuals, anti-HCV EIA tests may produce false negatives due to lack of antibody production, so in these individuals, testing for HCV RNA is recommended if clinical suspicion is high (215).

Among individuals with chronic HCV, 50% report chronic fatigue and abdominal discomfort and over 40% have elevated serum transaminases either intermittently or persistently. Treatment of HCV in injection drug users should be based on individual risk-benefit assessments (216).

Other Hepatidides

Injection drug users have elevated rates of hepatitis A, and approximately 50% of injection drug users have serological evidence of exposure to hepatitis B. Individuals with opioid use disorders who test negative for hepatitis A and/or hepatitis B should be vaccinated against them.

HIV

Current guidelines from the Centers for Disease Control and Prevention (CDC) are that HIV screening should be performed routinely for all patients aged 13 to 64 years and that screening should be annual in patients at high risk for HIV infection, including patients with substance use disorders (217).

Rapid HIV tests have been FDA approved and facilitate early detection. These tests can detect antibodies in blood obtained by venipuncture or finger stick or in oral fluid in about 20 minutes. All positive HIV screening tests should be confirmed with supplemental HIV testing.

A study in our treatment-research clinic (218) is among many that have shown decreases in drug-related and sex-related risk behaviors during methadone maintenance treatment.

Sexually Transmitted Infections (STIs)

In a study by Sullivan and Fiellin (219), individuals who inject drugs were found to be at higher risk for STIs, probably due to increased involvement in trading sex for drugs and also due to the disinhibition caused by drug use. The authors recommended that all drug-injecting patients receive syphilis screening and that women and symptomatic men receive screening for gonorrhea and Chlamydia. CDC Guidelines for screening and treatment of STIs can be found at <http://www.cdc.gov/std/treatment/2006/toc.htm>.

Syphilis—Testing for syphilis is done with the rapid plasma reagin test or the Venereal Disease Research Laboratory (VDRL) test. However, these tests are often falsely positive in injection drug users due to increased immune activation and should therefore be confirmed by a treponemal test (fluorescent treponemal antibody test, FTA-Abs) or microhemagglutination test. Positive syphilis tests need to be followed by patient education and appropriate antibiotic treatment (<http://www.cdc.gov/std/syphilis/default.htm>).

Gonorrhea and Chlamydia—*Neisseria gonorrhoeae* and *Chlamydia trachomatis* can be detected with a urethral culture in men, a cervical culture in women, or urine testing in either (first 10 to 30 mL for nucleic acid amplification test). Testing should be done annually in all sexually active patients, and more often as indicated in high-risk patients such as injection drug users (220). Positive results are a marker for high-risk behavior and warrant-enhanced counseling, treatment, and contact tracing (<http://www.cdc.gov/std/chlamydia/default.htm> and <http://www.cdc.gov/std/Gonorrhea/default.htm>).

Tuberculosis (TB)

Rates of TB are high in injection drug users (221) and the emergence of multidrug resistant strains is rising. Patients with opioid use disorders should be screened for TB annually with a purified protein derivative (PPD) skin test. Known or suspected cases of active TB must be reported to the U.S. Public Health Service, and state and federal laws require follow-up and treatment in individuals with known exposure to an active TB case. A positive PPD test (>10 mm in general population and >5 mm in HIV positive individuals) requires follow-up with a chest radiograph. Providers should be aware of the signs and symptoms of TB including fever, weight loss, fatigue, night sweats, and persistent cough, and should be prepared to follow up, assess, and manage as appropriate. Complete guidelines for TB screening, classification, and management are available from the CDC (<http://www.cdc.gov/tb/>).

Other Medical Comorbidities

In a cross-sectional study of substance-dependent patients without primary care. De Alba and colleagues (220) found that such patients had a significantly lower mean score on the physical component summary from the short-form health survey (SF-36) than the U.S. general-population norm (44.1 vs. 50, $p < 0.001$). Furthermore, 47% of study participants reported at least one chronic medical condition, 20% reported two or more, and 35% had had an episodic medical condition in the last 6 months. Eighty percent of study participants had been hospitalized for medical reasons one or more times (mean 3.9 times per patient), 21% were being prescribed medications for a chronic medical illness, and 61% had experienced a medical problem in the last 30 days.

In a study of methadone-maintained patients over the age of 50, 58% of respondents reported fair to poor physical health, with high rates of past-year health problems, including arthritis (54%), hypertension (45%), heart conditions (18%), chronic lung conditions (22%), stomach ulcers or irritable bowel syndrome (21%), cirrhosis (14%), hepatitis C (49%), diabetes (11%), and tobacco use (87%) (223). Heroin use has also been shown to be independently associated with greater insulin resistance, and methadone maintenance has been shown to be independently associated with previously diagnosed diabetes (224).

These findings show that the opioid abusers develop chronic medical comorbidities much like those of the

general population in addition to more specific comorbidities. Management and treatment of these chronic medical comorbidities should be addressed in the primary-care setting and, if possible, incorporated into substance-abuse treatment.

Polysubstance Use

Polysubstance use is common in patients with opioid use disorders. For example, at the most recent time point in a 33-year longitudinal study of heroin-dependent individuals, past-year prevalence of drug use was 67% for tobacco, 22% for daily alcohol, 36% for marijuana, 19% for cocaine, 10% for crack, and 12% for amphetamines. Even in the subset of individuals who had been heroin-abstinent for 5 or more years, past-year prevalences were 50% for tobacco, 15% for daily alcohol, 25% for marijuana, 4% for cocaine, 3% for crack, and 4% for amphetamines (115). Issues concerning these drugs are addressed more completely in the other chapters of Section 4 in this book.

In patients with polysubstance use disorders, assessment of medical complications needs to include consideration of each substance and of possible interactions. Special attention should be paid to use of alcohol and sedative-hypnotics such as benzodiazepines or barbiturates: these substances are sometimes used by opioid abusers in an effort to minimize opioid withdrawal or enhance a high (225). In addition to presenting more serious withdrawal complications than opioids do, they can synergistically exacerbate the respiratory depression and sedation induced by opioids.

Co-occurring Disorders (CODs)

“Co-occurring disorders” (CODs) refers to the co-occurrence of substance use disorders with mental-health disorders. CODs are common: among adults aged 18 or older in the United States, an estimated 5.4 million have a co-occurring serious psychological disorder and substance use disorder (107). CODs also entail elevated medical risks: when compared to individuals with only one or the other type of disorder, individuals with CODs had the highest adjusted odds for heart disease, asthma, gastrointestinal disorders, skin infections, and acute respiratory disorders (226). Additionally, individuals with COD have higher rates of hospitalization and inefficient use of health care services (227). For a detailed discussion of CODs, see Section 7 of this book.

EVALUATION APPROACHES

Overview of Screening and Evaluation

In January 2008, the United States Preventive Services Task Force concluded that there are reliable and valid standardized questionnaires for screening the use and misuse of illicit drugs, but also warned that there is not yet sufficient evidence to assess the “balance of benefits and harms” associated with such screening, whether in adolescents, pregnant women, or a general population of adults. Nonetheless, some

of these questionnaires are widely used in primary-care settings (228).

There is no standard tool for the evaluation of candidates for opioid-addiction treatment. A consensus panel convened by the Center for Substance Abuse Treatment had recommended that treatment programs develop their own tools and methods for assessment based on their patient population and their own infrastructure (225). We will review some of the available tools.

Tools for Screening and Evaluation

Addiction Severity Index (ASI)

The fifth edition of the Addiction Severity Index (ASI) is a 161-item multidimensional clinical and research instrument administered as a semistructured face-to-face interview. It addresses two timeframes—lifetime and past 30 days—and assesses functioning in seven domains: Medical, Employment/Support Status, Alcohol, Drug, Legal, Family/Social, and Psychological. The ASI is designed to provide basic diagnostic information on an individual before, during, and after treatment for substance use–related problems, and is thus useful for assessment of treatment outcome (229). The numeric summary data generated by the ASI—the composite scores and especially the interviewer severity ratings—have been criticized in terms of their reliability, validity, and suitability for clinical decision making (230); examination of individual items from the ASI may be of greater value.

Drug Abuse Screening Test (DAST)

The DAST is a 28-question self-report measure used to screen and evaluate individuals in both clinical and research settings. Each question is dichotomous (yes/no) and valued at one point, resulting in a score from 0 to 28. A cutoff of 6 is generally used to indicate drug abuse or dependence (231). The DAST has been found to have moderate-to-high levels of test–retest, interitem, and item–total reliabilities, moderate-to-high sensitivity and specificity, and acceptable criterion, construct, and discriminative validity (232).

ICD-10 Symptom Checklist for Mental Disorders

ICD-10 Symptom Checklist for Mental Disorders Psychoactive Substance Use Syndromes Module is a 10-question instrument that asks about symptoms associated with heroin or other opioid use in the time period immediately before admission to current treatment. The symptom list corresponds to the ICD-10 criteria for substance dependence or harmful use (233).

NIDA-Modified ASSIST

The NIDA-Modified ASSIST (Alcohol, Smoking and Substance Involvement Screening Test) was introduced in April of 2009 as part of NIDAMED, a collection of research-based screening tools and resources (available at: <http://www.drugabuse.gov/NIDAMED>). The package also includes a reference guide and a resource guide for clinicians. The NIDA-Modified ASSIST is based on the World Health Organization ASSIST, Version 3.0 (available at: <http://www.wo.int/>

[substance_abuse/activities/assist_v3_english.pdf](http://www.wo.int/substance_abuse/activities/assist_v3_english.pdf)) that has been shown to have good concurrent, discriminative, and construct validity (234).

Severity of Dependence Scale (SDS)

The SDS is a 5-item questionnaire that takes less than a minute to complete. Each question is scored on a 4-point scale (0–3); the total score is an opioid dependence severity score (the higher the score, the higher the level of dependence). The SDS has been shown to satisfy several criteria for reliability and criterion validity (235).

TREATMENT APPROACHES

Overview of Treatment Approaches

Opioid addiction, like all addiction, is considered a chronic relapsing disorder, and as such, its treatment is a long-term process. Detoxification (the management of opioid-withdrawal symptoms that occur when an individual discontinues use) addresses the “physical” component of addiction (we use quotation marks here to avoid suggesting that psychological factors have no physical basis) and can be an initial step in treatment. However, detoxification should be followed by long-term treatment to address the full syndrome of addiction. Maintenance therapy, when administered correctly, addresses the full syndrome by providing long-term opioid replacement and supportive psychosocial treatments. Combining several treatment modalities is more effective than giving stand-alone treatment, but no specific combination has been shown to be superior to all other possible combinations, so treatment approaches should be individualized based on the patient’s needs. The best approach is the one that works for that particular patient at that particular time. Of paramount importance is respecting that abstinence is achieved in different ways by different individuals (96,236).

Detoxification

The goal of detoxification is safe management of withdrawal symptoms while the patient adjusts to an opioid-free state. Gerstein and colleagues (237) demonstrated that repeated detoxifications in the absence of subsequent treatment are neither cost-effective nor helpful. This is because detoxification addresses only the acute physiological effects of opioid withdrawal, not the emotional, cognitive, behavioral, and social aspects of recovery. Detoxification in and of itself does not constitute treatment for opioid dependence (238–240). Rather, it should be considered a precursor to treatment, or a first stage of treatment, and should be followed by formal assessment and referral (241).

Detoxification has high utilization rates because it is quick and comparatively inexpensive, qualities that appeal to patients and third-party payers alike. Detoxification can occur in several settings and with various approaches. Some individuals attempt detoxification on their own without specialized treatment assistance. Self-detoxification methods include

abrupt cessation of opioids (going “cold turkey”), detoxification with benzodiazepines, detoxification with opioids, avoidance, and distraction—and all of these methods have low success rates (118). Detoxification with assistance can occur in inpatient settings (either psychiatric or medical), residential settings, or outpatient settings (such as substance-abuse clinics, primary-care offices, and prisons). Use of detoxification programs is associated with increased rates of initiation of long-term treatment for addiction (including methadone maintenance and other forms of addiction treatment) (242).

Traditional Detoxification Methods

Traditionally, opioid detoxification consisted of a methadone taper. This method has been criticized by providers and patients alike for the long duration of withdrawal symptoms associated with it. The method has been improved with the use of adjunctive medications for symptomatic relief; these include alpha-2 adrenergic agonists such as clonidine and lofexidine. An alternative to methadone-assisted detoxification emerged when the FDA approved buprenorphine for the same indication (“medically supervised withdrawal”). Buprenorphine tapers over 7 days appear to be safe and well-tolerated (243).

Comparison of Traditional Detoxification Methods

Methadone and buprenorphine have been shown to be comparable in suppressing signs and symptoms of opioid withdrawal and in their adverse-event profiles and rates of treatment completion (244,245). In a systematic review comparing buprenorphine to clonidine, buprenorphine was found more effective in decreasing signs and symptoms and was associated with greater treatment retention and fewer adverse events (245). When given as a stand-alone treatment for opioid withdrawal, clonidine provides considerably less reduction of subjective symptoms than of autonomic signs (246); given that the problematic aspect of opioid withdrawal is the distress associated with symptoms rather than any medical risk associated with autonomic signs, clonidine is probably best used as an adjunct to a methadone-assisted or buprenorphine-assisted taper.

Detoxification under Anesthesia

For approximately 20 years, detoxification under anesthesia has been advertised as a quick and painless way of opioid withdrawal. However, this approach is expensive, generally not covered by insurance, carries significant medical risks, and lacks evidence of effectiveness. Collins et al. (247) conducted a randomized controlled trial of 106 treatment-seeking heroin-dependent patients comparing three detoxification methods: anesthesia-assisted rapid opioid detoxification with naltrexone induction, buprenorphine-assisted rapid opioid detoxification with naltrexone induction, and clonidine-assisted opioid detoxification with delayed naltrexone induction. Results showed that mean withdrawal-severity scores, rates of inpatient detoxification completion, and treatment retention over 12 weeks were comparable across the three treatments—

but that in the anesthesia group, there were three potentially life-threatening adverse events not seen in the other two groups. The authors concluded that the anesthesia procedure conveys “no benefit ... over a safer, cheaper, and potentially outpatient alternative using buprenorphine as a bridge to naltrexone treatment” and that “general anesthesia for rapid antagonist induction does not currently have a meaningful role to play in the treatment of opioid dependence.”

Detoxification and Coordination of Care

Chutuape and colleagues (248) found that after a 3-day hospital-based inpatient detoxification, patients had significant decreases in drug use and drug-related activities over three follow-up evaluations (1, 3, and 6 months). There was a significant decrease in mean days of use of heroin, cocaine, alcohol, and multiple drugs in the last 30 days, and a decline in the percentages of opioid-positive and cocaine-positive urines. At the three follow-ups, 15% to 24% of patients reported current enrollment in treatment; their self-reported days of heroin and alcohol use, and their percentages of opioid-positive and cocaine-positive urines, were significantly lower than those of the patients who were not in treatment. This and other studies highlight that detoxification is most successful when followed by additional treatment. Efforts to coordinate aftercare following detoxification are of paramount importance.

Maintenance

Maintenance combines pharmacologic therapy with psychosocial interventions and support services and has the greatest likelihood of success in most patients. The pharmacological therapies include methadone, buprenorphine, and naltrexone and are described more fully in Section 6 of this book.

Methadone Maintenance

Methadone is a long-acting synthetic opioid that blocks the effects of heroin and other opioids by binding with mu receptors found in the brain and periphery. It is dispensed as an oral solution, liquid concentrate, tablet/diskette, or powder. Treatment with methadone is usually conducted in specialized settings (e.g., methadone-maintenance clinics). The goal of methadone maintenance is to find a methadone dose that balances positive effects (such as preventing opioid withdrawal and decreasing heroin use and craving) with possible negative effects (such as constipation and sedation). Determination of the appropriate methadone dose is patient-specific. Like most medications, methadone requires especially careful monitoring and dosage adjustment in patients who are taking other medications or who have other chronic medical conditions (249).

LAAM (Levo-Alpha Acetyl Methadol) Maintenance

LAAM is a full mu-opioid agonist that, like methadone, blocks the euphoric effect of opioids while controlling opioid

craving. When it was in clinical use, it was dispensed as an oral solution that was noted for its long duration of action, suppressing opioid-withdrawal symptoms for up to 72 hours (250). However, due to reported LAAM-related disturbances in cardiac function, Roxane Laboratories withdrew LAAM from the U.S. market in 2004 (251).

Buprenorphine Maintenance

Buprenorphine received FDA approval for the treatment of opioid addiction in October 2002. Buprenorphine has two sublingual formulations: one with buprenorphine alone and another that is a combination of buprenorphine and naloxone; the addition of naloxone is intended to deter abuse by injection but to be of no consequence when the medication is taken sublingually. In maintenance treatment, buprenorphine is as effective as, but no more effective than, methadone; however, it may be better tolerated than methadone or clonidine in detoxification (252). From a legal standpoint in the United States, buprenorphine differs from methadone in that it can be prescribed in a specially licensed physician's private office rather than only in a counselor-staffed addiction-treatment clinic.

Abuse rates for buprenorphine in the United States are low. Smith et al. (253) counted abuse cases of sublingual buprenorphine and sublingual buprenorphine/naloxone in 18 regional poison-control centers for 2003 to 2005 and found 77 reported cases, an average quarterly ratio of abuse cases per 1000 prescriptions dispensed of 0.08 (SD \pm 0.09) for buprenorphine and 0.16 (SD \pm 0.08) for buprenorphine/naloxone.

Naltrexone Maintenance

Naltrexone is a pure opioid antagonist that comes in an oral tablet and was approved for opioid dependence treatment by the FDA in 1984. Naltrexone has a higher affinity for mu receptors than heroin, morphine, or methadone and will displace these drugs from the receptors, blocking their effects. This action precipitates withdrawal symptoms in individuals who have not been abstinent from short-acting opioids for 7 days and longer-acting ones for at least 10 days (254). Naltrexone has no abuse potential and produces no withdrawal symptoms when discontinued. The main barrier to its effectiveness as a maintenance treatment is poor adherence by patients (148).

Heroin Maintenance

Heroin maintenance is the provision of prescribed heroin as a harm-reduction mechanism to chronic heroin-dependent individuals who have failed other treatments. In a 2006 systematic review of four randomized controlled trials of heroin maintenance, the findings were inconclusive in regards to retention in treatment, relapse to street-heroin use, criminal activities, and social functioning, due to the heterogeneity of interventions and measures (255). A multisite randomized trial in Canada was substantially compromised by political

and regulatory barriers (256). Nonetheless, the results from that trial showed that heroin maintenance produced better outcomes than methadone maintenance in terms of nondrug criminal behavior, employment, family and social relationships, and medical and psychiatric status (257). This finding is surprising considering that oral methadone requires less frequent dosing than intravenous heroin and is far less likely to produce acute intoxication. However, the trial was conducted in patients for whom at least two prior attempts at treatment (including at least one attempt at methadone maintenance) had been unsuccessful; heroin maintenance may be indicated in such cases.

Other Pharmacological Approaches

Montoya and Vocci (258) reviewed novel antiaddiction medications, including new formulations of already FDA-approved medications such as buprenorphine and naltrexone, off-label uses of FDA-approved medications such as clonidine and tramadol, and not-yet-FDA-approved medications such as antagonists at N-methyl-D-aspartic acid (NMDA) receptors or corticotropin-releasing hormone (CRH) receptors.

Long-acting formulations of buprenorphine, such as subcutaneous depot injections, provide effective buprenorphine delivery for several weeks, with therapeutic effects persisting even at fairly low plasma concentrations of buprenorphine (259). Sustained-release injectable formulations of naltrexone are also being studied and are showing promise in regard to treatment retention and prolonged opioid abstinence (260). Also under study is an implant formulation of naltrexone; individuals given a naltrexone implant in a Norwegian study had naltrexone blood levels above 1 ng/mL for at least 6 months and less heroin and opioid use than controls, with a low rate of adverse events (261).

The alpha-2 adrenergic agonists lofexidine and clonidine are not FDA-approved as treatments for opioid withdrawal but have been shown to be effective (262). The mixed-action opioid tramadol produces some suppression of withdrawal symptoms, but further studies are needed to determine what role, if any, it might play in treatment (263).

NMDA-receptor antagonists such as memantine, ketamine, dextromethorphan, and phencyclidine have been shown in laboratory-animal studies to suppress the development of tolerance and dependence to the analgesic effects of morphine, and may be useful in treating opioid craving in humans (264). Antagonists at receptors for CRH have been shown in animal models to lessen opioid withdrawal (265), block withdrawal-induced conditioned place aversion (266), and prevent stress-induced reinstatement of opioid seeking (267); thus, they may have a role in treatment.

Another treatment approach being tested is the use of oral naltrexone at ultralow doses for a seemingly paradoxical effect: although naltrexone is an antagonist, ultralow doses eased withdrawal symptoms during a methadone-assisted taper (268), perhaps by preventing or counteracting some of the receptor changes associated with chronic agonist use.

Vaccines

Immunotherapies are appealing for their lack of addiction liability, minimal side effects, and potential for long-lasting protection against drug use (269). Immunotherapies can also potentially be combined with existing pharmacological interventions and behavioral therapies for a multipronged approach to addiction treatment. Vaccines against morphine were first created and tested in the early 1970s (270), around the same time that methadone maintenance was becoming more widespread. In the developing world, where methadone treatment is expensive and often not well accepted, there has been a recent resurgence of interest in vaccine development (271).

Anton and Leff (272) described the initial development of a bivalent vaccine against morphine/heroin. The vaccine produced a high-titer antibody response with equivalent specificities for heroin and morphine but not other opioids. In an animal self-administration model, vaccinated rats developed antibodies against heroin that blocked its reinforcing effects. To date, research with this vaccine has been conducted in rodents and rhesus macaques, but not in humans. Even a successful antidrug vaccine will not be sufficient as a stand-alone treatment for addiction, because it will not address the problems that initially led to the addiction, nor the problems that resulted from the addiction.

Behavioral Therapies

Behavioral therapies encourage cessation of opioid use and teach patients to function without drugs, handle cravings, avoid drug-using people and drug-associated places, and cope with lapses and relapses. They are most effective when used in conjunction with pharmacological treatments, but when this is not possible, they are also effective alone. Behavioral treatment can be delivered in both residential and outpatient settings and may include individual counseling, group or family counseling, contingency management, and cognitive-behavioral therapies, among others. Below is a quick overview of a few behavioral therapies utilized in the treatment of opioid addiction; more detail is provided in Section 6 of this book.

Contingency Management

Contingency management—that is, clinician control of the contingencies (consequences) associated with patients' behaviors—is typically implemented as a voucher-based approach in which patients earn credit for achieving treatment goals. These goals could be opioid-negative urine-toxicology results, meeting goals for clinic attendance or counseling attendance, attending job training, and so on. The earned vouchers can be exchanged for goods and services in the community consistent with treatment goals. The goods and services might include workplace-appropriate clothes, bus passes, payment of utility bills, a down payment on a car, or a security deposit for an apartment. Much of the clinical research underlying contingency management for treatment of opioid dependence was performed with patients maintained on opi-

oid agonists, and the results have shown that contingency management has an important place in treatment of opioid addiction, although barriers involving cost and social acceptance need to be surmounted (273).

Cognitive-Behavioral Therapy (CBT)

In CBT, the patient and counselor work to identify problems related to drug use and practice coping skills to modify drug use behaviors. Specific techniques include exploring the positive and negative consequences of continued use, self-monitoring to recognize drug cravings early on and to identify high-risk situations for use, and developing strategies for avoiding or coping with high-risk situations and the desire to use (274). In cocaine addicts, the benefits of CBT have been shown to emerge months after completion of treatment (275).

Needle Exchange

Access to needle-exchange programs (NEPs) in the United States is inadequate. Wodak and Cooney (276) conducted an international review of the literature and concluded that NEPs are both clinically effective and cost-effective in reducing HIV, and that there is no convincing evidence for unintended negative consequences (e.g., increases in the initiation, duration, or frequency of illicit drug use or injection). Furthermore, there is evidence that NEPs might increase entry into drug-treatment programs and contact with primary health care (277). Given the evidence, NEPs should be seen as an important component of an evidence-based approach to reducing the spread of HIV and other bloodborne infections.

Access to Treatment

Methadone maintenance, which is available only through highly regulated methadone clinics, reaches only an estimated 15% to 20% of the people needing treatment for opioid addiction (225). The Drug Addiction Treatment Act of 2000, signed into law by President Clinton, eased access to treatment by legalizing office-based opioid maintenance treatment by physicians in private practice (278).

In 2008, the Paul Wellstone and Pete Domenici Mental Health Parity and Addiction Equity Act was passed by Congress and signed into law by President George W. Bush. This law is intended to improve access to treatment for behavioral and psychiatric problems, including addiction, by prohibiting treatment limits and other discriminatory restrictions.

Linkage of Care

Despite the high prevalence of comorbidities in individuals with opioid use disorders, treatment for comorbid conditions often occurs in an uncoordinated, parallel fashion. This parallel approach interferes with communication between the players in what should be a multidisciplinary collaboration (279). The resultant fragmentation of care may result in premature treatment termination, relapse, criminal involve-

ment, and preventable use of high-cost resources such as EDs and inpatient admissions (280,281).

A 2005 report from the Institute of Medicine advocated coordination of care among primary-care providers, mental-health specialists, and addiction specialists. Such coordination, which should emphasize a patient-centered approach, can occur on a spectrum from straightforward formal agreements among providers to clinically integrated practices (282).

Linking substance-abuse care and primary care has many benefits, such as broadening access to both types of care, reducing the stigma associated with addiction medicine among some medical providers, and creating support for reimbursement parity for substance-abuse services (279). To some degree, linkage can also reduce health care costs by increasing efficiency. For example, on-site delivery of primary care reduced use of EDs and hospitals among methadone-maintenance patients and long-term residential-facility patients (though not among nonmethadone patients) (283). Off-site referral for primary care reduced use of EDs (though not hospitalizations) in long-term residential patients (283).

Reimbursement for Treatment

In January 2008, two new American Medical Association Current Procedural Terminology codes for screening and brief intervention (99408 and 99409) went into effect. These codes afford health care providers a mechanism to report and receive reimbursement for structured screening and brief intervention for substance use disorders (http://www.whitehousedrugpolicy.gov/dfc/files/sbi_codes.pdf).

CONCLUSIONS

Opioids, and the use and misuse of opioids, are more complex than they might seem. For example, as we have discussed, opioids that could once be mentioned in the same breath as mu-preferring analgesics with differing pharmacokinetics (morphine, heroin, oxycodone, methadone) might act quite differently from each other at different mu-receptor variants, with behaviorally and therapeutically significant consequences. Newly selective agonists may disaggregate aspects of opioid-induced analgesia (for example, delta agonists may relieve allodynia without producing more general analgesia). New types of mixed or bivalent ligands, or new ways of administering antagonists (such as ultralow-dose regimens with seemingly paradoxical effects), may open new possibilities for prevention or treatment of physical dependence. At the same time, physical dependence is increasingly understood not to be the defining feature of opioid addiction. And opioid addiction, given use, is increasingly understood to be determined in large part by cognitive and sociocultural factors, despite lore that emphasizes the irresistibility of intoxication and the hellishness of withdrawal.

These insights have emerged from disciplines as remote from each other as ethnography and molecular biology, as well as the behavioral sciences that in some respects bridge the two. Continued work in all of those disciplines should increase the

proportion of good outcomes from therapeutic use of opioids, and should also expand the already good range of treatments available for opioid use disorders. One important challenge is to ensure that these treatments, most of which were developed in the context of heroin addiction, are applied effectively to the growing problem of addiction to prescription opioids.

INTRODUCTION

Viewed as a gift from the gods, the coca leaf was to the Incas of ancient Peru both mood and performance enhancing—it could lift spirits and increase stamina over long days of back-breaking labor. Today our lives are more sedentary, our age has been described as self-indulgent, and rather than a gift cocaine is seen by many as a curse from the devil. In this chapter we will address many aspects of cocaine abuse and addiction, prominently including discussion of crack cocaine. The following key points are emphasized throughout:

- Cocaine addiction results frequently from exposure to the highly concentrated, potent forms of cocaine now available on the streets of most American cities and towns, and it is difficult to treat successfully; partial responses to treatment and lifelong morbidity are common.
- Cocaine addiction is a particularly virulent disease because it involves a potentially lethal combination of sensitization of the brain's primary "pleasure centers" (to which the cocaine molecule has direct access) *and* powerful reinforcement of drug pursuit behaviors. Together these effects greatly increase the likelihood of use despite catastrophic consequences. Ironically, the pleasure associated with continued use often decreases.
- The mainstay of cocaine treatment is an integrative approach with thorough consideration of all medical, psychological, and social factors that may be perpetuating active addiction; cognitive-behavioral therapy (CBT) and other forms of "psychological" intervention, including tried and true 12-step programs, feature prominently.
- Better understanding of the neurobiology of cocaine addiction is opening up new possibilities for pharmacologic interventions which target different facets of the disease, greatly increasing the prospects for long-term treatment success.
- Prolonged use of cocaine frequently results in severe medical and neurologic complications that lead to deterioration of health, disintegration of personality, and lost integrity of the higher cognitive centers necessary for full recovery. Early, effective intervention is therefore imperative.

HISTORY: FROM COCA LEAVES TO CRACK

The amount of cocaine ingested by the Incas was probably quite low. It is estimated that the average user chewed 60 g of coca leaves in a day. Given that the cocaine alkaloid content

of a coca leaf is approximately 0.5% and that only a portion of the alkaloid is absorbed in digestion, the total dosage would probably have been 200 to 300 mg over a 24-hour period (1). In contrast, a similar or greater dose may be delivered to the brain after just a few "hits" from a crack pipe.

Word about cocaine spread from the Andes to Europe through reports first by explorers and later by naturalists and botanists. By 1860, essays and medical testimonies inspired makers of various tonics to add the newly isolated active ingredient of coca leaves to their formulations. The French chemist Angelo Mariani produced inexpensive Bordeaux fortified with coca leaves, a product so popular that it was endorsed by none other than Pope Leo XIII, who is reported to have carried around a supply of the elixir in a hipflask. Within 15 years people could also buy snuff that contained pure cocaine, touted as a remedy for asthma and hay fever. Cocaine was also a common ingredient in "toothache drops." These new cocaine preparations, the much higher daily doses, and routes of administration marked the first change in the pattern of cocaine use in more than 4000 years.

Prominent medical men of the late 19th century fraternized with cocaine, often with tragic results. A famous essay by Sigmund Freud published in 1884 ("Uber Coca") advocated therapeutic use of cocaine as a stimulant, an aphrodisiac and virtual tonic for a variety of disorders. Freud prescribed it to alleviate the symptoms of withdrawal from alcohol and morphine addiction. Not surprisingly, some patients who used cocaine as a substitute for alcohol or morphine became dependent on it, as did Freud. Likewise, the brilliant American surgeon William Stewart Halsted, who pioneered the use of cocaine as a local anesthetic, became seriously addicted.

Atlanta druggist John Pemberton devised a patent medicine during the mid-1880s that contained two naturally occurring stimulants, cocaine and caffeine. Pemberton advertised his product as an "intellectual beverage," a "brain tonic," and a "temperance drink" due to the fact that it contained no alcohol. This product eventually became known as Coca-Cola and until 1903, contained approximately 60 mg of cocaine per 8-ounce serving. In response to public pressure and news reports about the dangers of cocaine, the maker voluntarily removed cocaine from the formulation. The Coca-Cola Company still uses an extract of the coca leaf, minus the active ingredient.

The beginning of the 20th century thus marked a turn in public and professional attitudes about cocaine. The American Medical Association, seeking to raise the standards of medical

practice, lobbied to curb the sales of patent medicines, including those containing cocaine. The Harrison Narcotic Act of 1914 (which mistakenly listed cocaine as a narcotic) banned the use of cocaine in proprietary medications and tightened the restrictions on the manufacture and distribution of coca products. As a result of these restrictions, and for other reasons, drug users turned to amphetamines and other centrally stimulating drugs, a trend documented abundantly in the beatnik literature of the 1950s. These drugs were easily substituted for cocaine because they cost less, were more widely available, and induced a sense of euphoria that lasted longer. They were also more deadly. By the late 1960s, the drug-using subculture recognized the danger in amphetamines, as reflected in the contemporary slogan “speed kills.” Eventually amphetamines were listed as Schedule II drugs (drugs with a high abuse potential and prescription limitations), making them much more difficult to obtain.

Stimulant abusers searching for a “safer” recreational euphoria soon rediscovered cocaine in the mid- to late 1970s. As described in detail in the following section, cocaine abuse skyrocketed well into the 1980s, especially among middle- and upper middle-class populations, trendsetters, and disco queens, where it became known as “the champagne of pharmaceuticals.” The warnings of cocaine’s dangers from past generations had been forgotten. During the 1970s, cocaine was usually administered intranasally in a powder form, and individual doses were usually moderate. A typical user bought 1 g of cocaine for approximately \$150 and insufflated (snorted) the drug from a tiny “coke spoon,” a “tooter,” or even a fingernail cultivated for the purpose. A “line” of cocaine inhaled through a straw or rolled bill delivered approximately 25 mg and typical users would repeat the dose in both nostrils. The general perception among users was that cocaine was safe and nonaddictive, and the medical literature of the time did little to contradict this false perception. Writing in the 1980 edition of the *Comprehensive Textbook of Psychiatry*, Grinspoon and Bakalar stated: “Chronic cocaine abuse usually does not appear as a medical problem” (2). People willing or prone to misuse drugs interpreted these and other similar statements from medical “experts” as a license to try, and then to use, cocaine freely.

A newer method called “freebasing” began in the late 1970s, became popular in the mid-1980s, and was made notorious by the late comedian Richard Pryor who was severely burned when the ether used to extract cocaine alkaloid ignited. Freebasing made cocaine “smokable,” allowing rapid self-administration of much higher doses than ever before in the form of a dense vapor, often dozens of times greater than that achieved by snorting. Another form of smokable cocaine appeared in the United States in the mid-1980s and opened a particularly tragic chapter in the history of the drug. Essentially mass-produced freebase cocaine, crack was low priced (as little as \$2 per dose), making it available to younger and poorer users and sending the average age of the user spiraling down. Crack is named after the characteristic crackling sound that the “rock” makes when heated. This

newest and most deadly formulation of cocaine is remarkably addictive.

The association between cocaine, and crack in particular, and violence is compelling. Just being shot appears to be associated with the presence of cocaine in the blood. Commission of a felony is highly associated with the presence of cocaine in the body of the perpetrator. Our report from 1995 correlated illicit drug use with carrying weapons and violence among 6th through 12th grade students, and there is little to indicate that this has changed much over the past 15 years (3). For example, in 2001, cocaine was the most frequently reported drug in emergency room visits nationwide, with 76 visits per 100,000 population; 24% of the emergency mentions in the report were attributed to crack. Rates in some metropolitan areas far exceeded the national rates. In 2006, the Drug Abuse Warning Network (DAWN) survey estimated 548,608 emergency department (ED) visits involving cocaine, which was by far the most common illicit drug to be involved in emergency care presentations (57% of all illicit drug-related ED visits); a greater number of these 2006 presentations appeared to be linked with crack cocaine than in 2001 (4). Cocaine is consistently among the top three drugs mentioned in mortality data from DAWN, and cocaine or cocaine in combination with alcohol is extremely common in association with suicides (5).

In summary, dramatic changes in the patterns of cocaine use, the typical dosage, and the route of administration have combined to produce deadly epidemics of addiction to a drug once touted by medical experts as “safe.” Despite declines in the percentage of the population initiating cocaine use, the percentage of adults who are chronically using cocaine on a regular basis, a large percentage of whom are addicted to crack, is staggering. Approximately 75% of these individuals are likely to meet the *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition (DSM-IV)* criteria for cocaine dependence. There are high rates of recidivism and tens of thousands of Americans seeking rehabilitation at any given time.

EPIDEMIOLOGY: THE EVOLVING COCAINE “EPIDEMICS”

To be most effective in clinical practice, it is essential to understand the “cocaine problem” from the widest possible perspective. Fortunately, a number of valuable information resources are available to the clinician (6–9). Cocaine abuse in the United States had reached truly epidemic proportions by the late 1970s. When at its peak in the mid-1980s, over 6 million Americans, about 20% of whom were under the age of 18, were using cocaine repeatedly, and many more had tried it at least once. It is estimated that in 1980 alone, nearly 1.5 million Americans were initiated to cocaine use, and that as many as 30 out of every 1,000 young adults were using cocaine. Fortunately, by 1990 the National Household Survey on Drug Abuse (NHSDA) found cause for hope, documenting a dramatic decline in the number of current cocaine

users—people who had used the drug within the past 30 days—from 5.8 million in 1985 to 1.6 million in 1990 (6). By 1993, the rate of initiation of cocaine use had dropped to less than half the rate in 1980 and because of increased awareness of the dangers of cocaine, interdiction efforts, or a combination of factors, the rapid “infective” phase of America’s worse cocaine epidemic seemed to have subsided. However, the dramatic decline in overall cocaine use from the peak years of the early 1980s should not be viewed as a decrease in the seriousness of the cocaine problem for the following reasons:

1. Although casual experimental use of powder cocaine undoubtedly decreased from the mid-1980s, the introduction of “crack” cocaine around the same time, a much more addictive smokable form of the drug, marked the beginning of a trend in which a core population of frequent, heavy, persistent users began to appear, initially in major urban centers. Obviously, not all compulsive cocaine users are addicted to crack, but it is now well established that even though “only” about 25% of regular cocaine users smoke crack, this comparative minority represents the majority, perhaps as much as 75%, of those entering some form of treatment for cocaine abuse or addiction. With the advent of the crack subepidemic there has been a protracted wave of violence and crime, a burgeoning of serious medical complications, child neglect, increased demand for treatment and, tragically, jail space.
2. By the late 1990s current overall use of cocaine among Americans 12 years and older appeared to be increasing again, with the NHSDA estimating 1.7 million cocaine users, 406,000 of whom (about 23%) were current users of crack in 2001. The best available evidence suggests that this second wave of the cocaine epidemic mostly reflected a moderate increase in use mainly among 18 to 25 year olds. In our 2006 surveillance report on cocaine use in

Florida, there was evidence of a renewed epidemic among students and the more affluent, with striking increases in per capita cocaine-related deaths (7).

3. On the one hand, the most recent data from the national surveys suggest that overall use of illicit drugs (other than marijuana) has not continued to increase significantly in the young adult demographic, and in children may have decreased somewhat over the years since 2001. For example, the percentage of 8th and 10th graders reporting lifetime, past year, and past month use of any illicit drug—other than marijuana—has decreased substantially since 2001, according to the most recent reports from the National Institute of Drug Abuse, “Monitoring the Future Survey” (8); if this trend is sustained, it may represent the beginning of a welcome new phase of the cocaine epidemic. However, it should be kept in mind that the rates of initiation and current use of cocaine among youths still remain much higher than those estimated from the 1970s. Furthermore, abuse of prescription and illicit manufactured psychostimulants (e.g., methylphenidate and methamphetamine) by youths and young adults has clearly increased over the past 10 or so years, representing to some extent a “substitute epidemic.” Figure 14.1 shows a timeline of usage.

Another important phenomenon to note is that, unlike other drugs of abuse, where rates are highest among adolescents and very young adults, a remarkably high rate of regular (past month) use of cocaine in individuals 26 years and older has been well documented in recent years. Record numbers of middle-aged and even elderly patients are appearing in treatment centers with cocaine abuse as their chief problem. Illicit drug use in general has increased rather dramatically in persons aged 50 to 59 in recent years, with an uncertain contribution from persistent or reinitiated use in aging baby boomers. In 1995, only 37% of drug treatment admissions primarily for problems with smoked cocaine

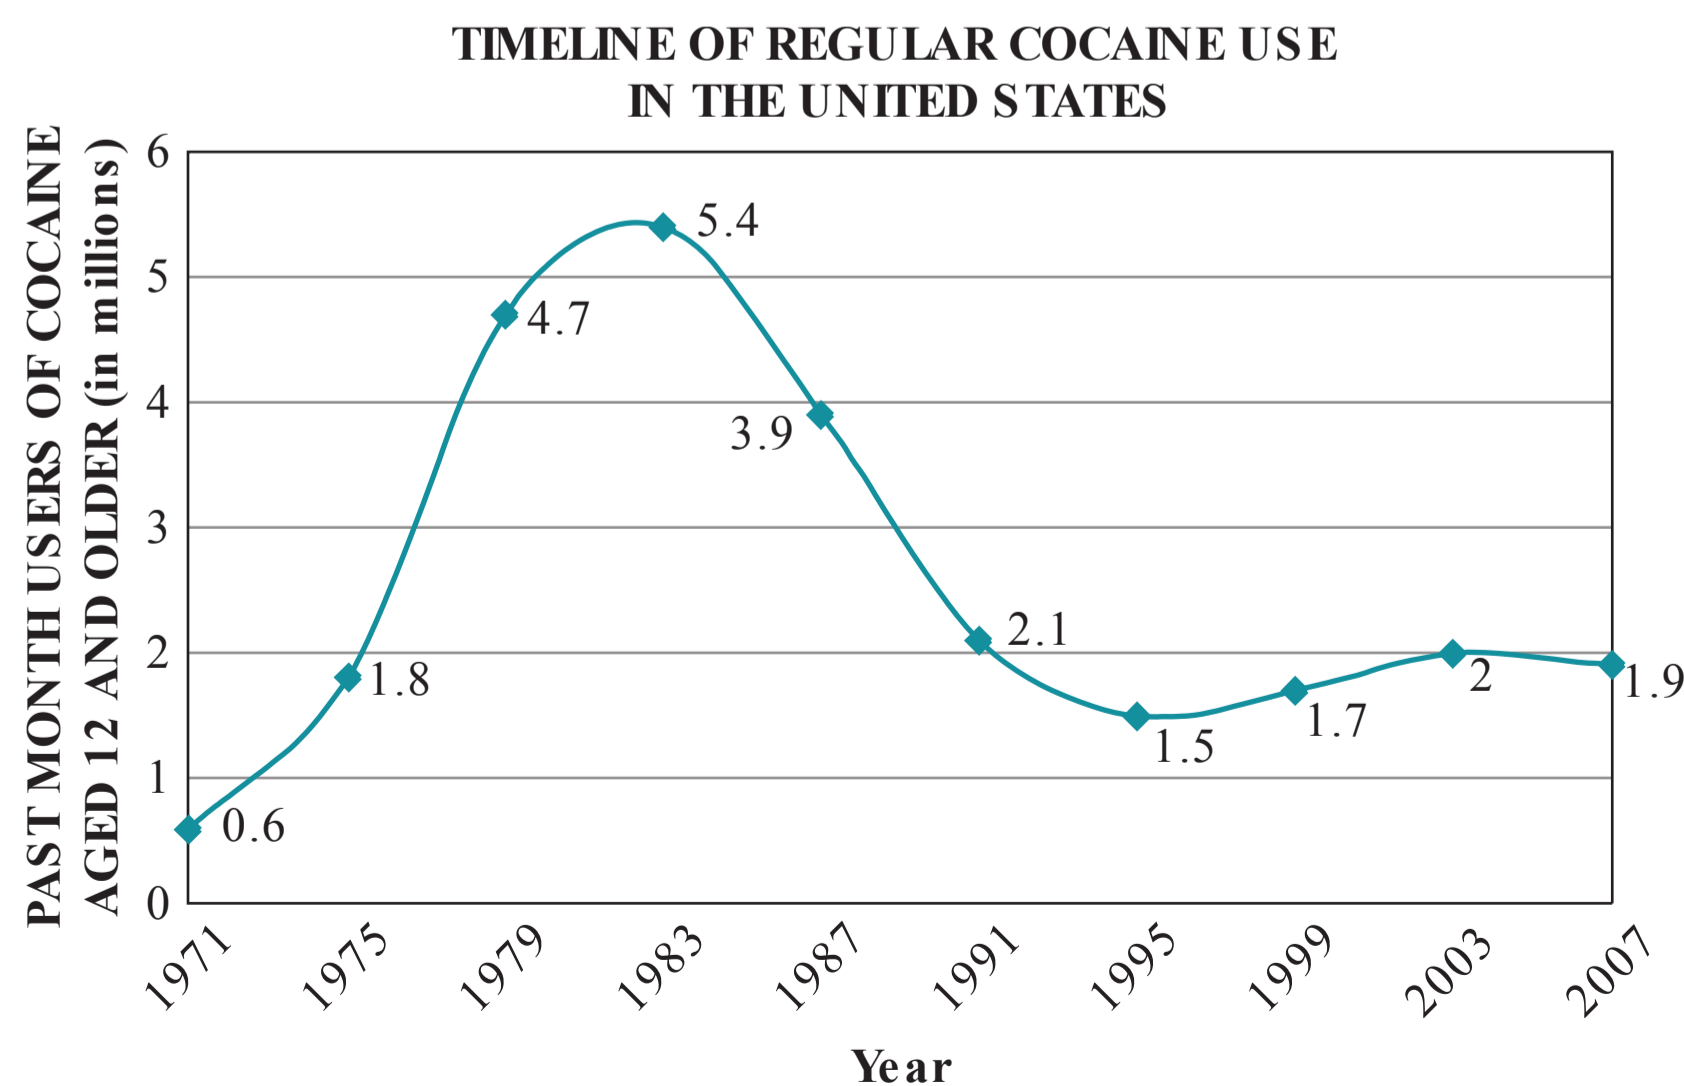

Figure 14.1. Timeline of regular cocaine use in the United States. Estimates of regular cocaine use (number of past month users aged 12 and older in millions) abstracted from the NHSDA and NSDUH reveal striking changes over the past four decades. Although cocaine use has decreased dramatically since the mid-1980s, between 1.5 and 2 million Americans have continued to use frequently in recent years, a substantial percentage of whom are addicted to crack cocaine.

were over the age of 35, but by 2005 68% were in this age group (9).

Beginning in 2002 the National Survey on Drug Use and Health (NSDUH) replaced the NHSDA and, applying more rigorous methodology and much larger sample sizes, brought forward more fine-grained demographic data focusing on current use of cocaine. A brief review of the highlights of the NSDUH-reported trends from 2002 to 2007—the most recent analyzed data set available—is instructive (6). Current cocaine use appears to have been holding steady over most of the past decade at between 0.8% and 1.0% of Americans aged 12 years and older, with approximately 2% of 18 to 25 year olds using cocaine currently. The most recent NSDUH suggested the possibility of a decline in current cocaine use in young adults (from 2.2% in 2006 to 1.7% in 2007), but it will take several more years to see if this, as with the data from the youth surveys noted above, is the beginning of a persistent downward trend. To place current cocaine use in context, current use of marijuana in the young adult demographic has held steadily at a rate six to eight times that of cocaine use over the same time period, while current use of heroin was about half as frequent, the latter perhaps declining slightly. A consistent 20% to 25% of current cocaine users have been identified as users of crack and, although precise estimates are not currently available, most instances of frequent cocaine use—persons using cocaine more than 51 days out of the past year—and most daily or nearly daily use appears to be crack related. In 2007, the NSDUH estimated that there were 610,000 current users of crack ages 12 and up (approximately 0.23% of that demographic), a figure that has not changed appreciably over the past decade. As noted above, crack cocaine users represent a disproportionately high percentage—approximately 75%—of those cocaine users entering treatment. However, from a clinician’s perspective it is important to note that a large number of court-sanctioned referrals skew these treatment figures.

The stable rates of overall cocaine use belie the dramatically elevated rates of current use in certain subgroups. For example, over the past decade, unemployed adults have been shown consistently to be about 1.5 to 2.0 times more likely than a full-time employed adult to be a current user of illicit drugs, and an adult without a high school diploma has been shown consistently to be about twice as likely to be a current user than a college graduate. Young adults in the criminal justice system (parolees or on probation) have had current illicit drug use rates as much as four times those of age-matched adults over the past 10 years. Youngsters who smoke cigarettes regularly are well documented to have rates of current illicit drug use as much as 15 times higher than that of nonsmokers, even higher if they regularly use alcoholic beverages.

In summary, a nuanced view of the various trends and subtrends of the cocaine epidemics exposes the complexity of the social factors that the clinician must consider in dealing effectively with the addict or potential addict. Rates of

initiation of use and rates of compulsive, regular use vary across age groups, and within any one age group there is considerable variation depending on social status, race, educational achievement, contact with the criminal justice system, and concurrent use of other mind- or mood-altering substances.

PHENOMENOLOGY

Most people try cocaine out of curiosity but those who pursue it seek the unique experience of cocaine intoxication. Although chronic addicts will often relate that they never quite obtain the same subjective “highs” that they did when they first started using, there is nonetheless anecdotal evidence that the typical cocaine user experiences with reasonable consistency a combination of intense, brief pleasure and related enhancements of sensation and perception that are generally outside the scope of normal everyday human experience (10). Patients may develop brisk speech, strained facial expressions, darting eyes, fidgeting, and pacing. Sexual interest and sensitivity is often piqued, and some users describe the experience as akin to a “full body orgasm.” The feeling of increased alertness reported subjectively with cocaine can be confirmed by electroencephalographic recordings, which show a general desynchronization of brain waves after cocaine administration. Such desynchronization, which indicates arousal, reveals widespread involvement of the cerebral hemispheres through brainstem and thalamic relays which mediate conscious awareness, attention, and wakefulness. Despite the feeling of arousal, individuals using cocaine usually do not gain superior ability or greater knowledge. Their sense of omnipotence is a temporary delusion; they tend to misinterpret their enhanced confidence and lowered inhibitions as signs of enhanced physical or mental acuity. Taken together, these symptoms, signs, and sensations can be referred to as the euphorogenic and psychostimulant effects of cocaine, and they can be characterized in human functional imaging studies and sometimes inferred in animal models of addiction. Not all people appreciate or continue to pursue these effects; for some they can be intensely dysphoric and therefore undesirable.

The precise psychological and behavioral effects of a cocaine dose—desirable or not—depend on many factors: the purity of the drug, route of administration, chronicity of use, the personality and mental health of the user, past and present use of drugs and alcohol, the environment in which the drug is used, and whether other drugs are taken simultaneously (11). In addition to the subjective experiences already mentioned, acute intoxication with moderate-to-high doses of cocaine may be associated with rambling speech, headache, transient ideas of reference, hypersensitivity to low frequency sounds, and tinnitus. There may also be frank paranoid ideation, auditory hallucinations in a clear sensorium, and tactile hallucinations (“coke bugs”), which the user usually recognizes as effects of cocaine. Visual illusions are common, but true visual hallucinations less so,

and when they do occur this is usually indicative of very high or protracted dosing, often in combination with sleep deprivation. Extreme anger with threats or acting out of aggressive behavior may occur. Mood changes such as depression, suicidal ideation, irritability, anhedonia, emotional lability, or disturbances in attention and concentration are common.

The initial experience of cocaine differs widely between people. Interestingly, clinical surveys in both the United States and Europe suggest that only about 10% to 20% of persons who use cocaine become dependent on it, but precise data as to how many of the remainder of those who have tried cocaine subsequently remain casual abusers over long periods of time (as opposed to “turned off” and fully abstinent) are not available. Durable features of personality such as a tendency toward risk taking have been linked with greater likelihood of cocaine abuse and dependence, as have specific psychiatric disorders, including but not limited to attention-deficit hyperactivity disorder (ADHD), schizophrenia, and affective disorders (especially bipolar disorder). In schizophrenics, where tobacco abuse is almost the rule, concurrent use of cocaine may represent a form of self-treatment as, paradoxically, the user may report a temporary calming effect on the psyche, not unlike the calming effect

of prescription psychostimulants (e.g., methylphenidate and dextroamphetamine) in persons with ADHD. However, despite the high coincidence of enduring psychopathology in cocaine abusers compared to the general population, it is important to note that many people seeking help will not have identifiable major psychiatric illness or personality disorders; behavioral, cognitive, and emotional abnormalities may resolve dramatically with long-term abstinence and successful treatment.

Not long ago many medical experts assumed that cocaine was not addictive; however, *DSM-IV* now acknowledges that cocaine use can most definitely lead to addiction and establishes criteria for dependence (see Table 14.1). Self-motivated or externally imposed abstinence in cocaine-dependent individuals may or may not be accompanied by signs of withdrawal, although cocaine rarely, if ever, produces physiologic dependence, as is common with addiction to opiates, alcohol, and barbiturates. At the extreme ends of the spectrum cocaine withdrawal may manifest with minimal degrees of dysphoria or produce frank anhedonia with psychomotor retardation (12). Patients may have limited interest in the environment, limited ability to experience pleasure, and severely decreased energy. Elopement from treatment and relapse are very common within the first several days postcessation of use.

TABLE 14.1 Clinical criteria for cocaine dependence

The *DSM-IV-TR* defines cocaine dependence as “a maladaptive pattern of use leading to clinically significant impairment or distress.” Three or more of the following clinical features, occurring within a 1-year period, are needed to make the diagnosis:

1. Tolerance. There is a need for more cocaine to achieve the desired effect or the experiences markedly diminished effect with continued use of the same amount.
2. Withdrawal. After cessation of heavy or prolonged cocaine use, the patient may experience pronounced dysphoric mood and one or more of the following: fatigue, unpleasant dreams, insomnia or hypersomnia, increased appetite, psychomotor retardation, or agitation. The symptoms above cause clinically significant impairment of functioning and are not accounted for by another mental disorder.
3. Loss of control over use. Large amounts of cocaine are taken or it is used over a longer period of time, especially when the person did not “intend” to use as much as they actually did.
4. Persistent desire to change or control use, including unsuccessful or aborted efforts to quit.
5. Preoccupation with obtaining or securing supply; inordinate time using the substance or recovering from intoxication.
6. Reduction or elimination of important social, occupational, or recreational activities because of use.
7. Continued use despite serious adverse consequences. Ongoing use despite major physical, psychological, or social consequences.

Criteria 3 through 7 are highlighted. The emphasis is on lack of control over use and continued use despite what are often devastating consequences. According to revisions in the *DSM-IV*, it is not necessary to manifest (1) tolerance or (2) withdrawal in order to be diagnosed with substance dependence. With this modified definition, cocaine is recognized as addictive even though there are often no major physical withdrawal symptoms, and tolerance is quite variable.

The *DSM-IV-TR* formally acknowledges this change in diagnostic criteria by specifying the following modifiers:

- Dependence with Physiological Dependence—evidence of tolerance or withdrawal (i.e., item 1 or item 2 is present).
- Dependence without Physiological Dependence—no evidence of tolerance or withdrawal (i.e., neither item 1 nor item 2 is present).

DETERMINANTS OF USE

Elements that influence susceptibility to cocaine addiction include the speed of onset and duration of elevated blood levels, genetically determined differences in pharmacodynamic response, postdrug effects and social–environmental setting. The particular roles of each of these factors have been elucidated at various levels of detail and certainty over the past 30 years, and animal models of addiction have been of tremendous value in parsing them. A full account of each is well beyond the scope of this chapter, but a few of the more important considerations most relevant to clinical practice are briefly addressed.

Pharmacologic Considerations

Cocaine—benzoylmethylecgonine—is a naturally occurring crystalline alkaloid of the tropane family that also includes atropine and scopolamine. It does not exert notable anticholinergic effects. As described in more detail in the following section, cocaine’s primary neuropharmacologic effect is to block the uptake of monoamines released into synapses of the central nervous system. However, cocaine also has sympathomimetic actions in peripheral tissues and quinidine-like anesthetic/type I antidysrhythmic properties. As a local anesthetic, cocaine’s main effect is to block sodium channels in excitable tissues, and in high doses it can also interfere with certain potassium channels and induce a profound failure of electrical transmission in the heart and central nervous system, as may be seen with accidental massive overdoses (e.g., a smuggler who “bodypacks,” or “bodystuffing” during a police raid).

Cocaine is a relatively small (molecular weight 303) lipophilic molecule that is well absorbed through mucous membranes and alveoli. About one-third of an oral or nasal dose of powder cocaine, and up to 95% of an inhaled dose of freebase or crack cocaine may be bioavailable. Once in the blood, it readily penetrates the blood–brain barrier. Binding of cocaine to plasma proteins is minimal and volume of distribution is low; blood to plasma concentration ratios are typically close to unity. At the doses typically seen in clinical practice, ingestion of cocaine can be viewed as a multitoxic exposure because enzymatic and nonenzymatic hydrolysis produce a number of metabolites, some of which have the same or greater effects as cocaine. Active metabolites may intensify or prolong cocaine euphoria. As a testimony to the desperation that may accompany compulsive use of cocaine, there are case reports of addicts injecting cholinesterase-inhibiting insecticides to attempt to enhance their highs. Benzoylecgonine, a neuropharmacologically active and cardiotoxic agent, is produced rapidly by enzymatic (hepatic carboxyesterases) and nonenzymatic hydrolysis and is usually the major metabolite of cocaine, but when cocaine is smoked there may be relatively greater production of ecgonine methylester. The latter is generally considered the least toxic of the major metabolites and is formed readily by the action

butyrylcholinesterases in plasma, brain, and lung. Bacterially derived choline esterases and mutant forms of human butyrylcholinesterase, both of which have orders of magnitude greater activities than native enzymes, are under active investigation as “antidotes” for the emergency management of life-threatening overdose situations. These modified enzymes can facilitate rapid metabolism of cocaine to the less toxic ecgonine methylester. Under conditions that inactivate butyrylcholinesterases or activate hepatic N-demethylation, benzoylecgonine and norcocaine may be produced in considerably larger metabolic amounts than their usual 50% and 5%, respectively. Inactivation conditions may be extremes of age or presence of medications with cholinesterase inhibitory action; examples of activation conditions are pregnancy or elevated progesterone and testosterone. The latter is neuropharmacologically active and is also a potent vasoconstrictor. Tiny quantities of several other metabolites are produced to varying extents under varying conditions, but these are usually of no clinical significance. Very little cocaine is passed unchanged in the urine and stool.

The purer the drug, the greater its effects, but as a rule, pure cocaine is unavailable on the street. Cocaine is typically heavily adulterated with other substances such as mannitol, lactose, or glucose to add weight, and caffeine, lidocaine, amphetamines, quinine, or even heroin to add taste and to provide additional central nervous system stimulant effects. The typical concentration of cocaine in street preparations ranges from 10% to 50%; rarely, samples can contain as much as 70% cocaine. Both the cocaine concentration and the adulterants affect the user’s response to the drug and the potential complications of use, particularly venous irritation and pulmonary insults in intravenous (IV) and smoked cocaine users, respectively.

Routes of administration that deliver drug rapidly to the brain are intensely euphoric, most rapidly addicting, and also the most sensitizing to the effects of future cocaine use (11,13). In other words, a person who has used crack in the past is more likely to experience pronounced psychological and physical effects to even moderate future dosing than a person who has used a comparable dose of cocaine through insufflation. Rate of administration appears to influence the extent to which long-lasting changes in brain cell function, including expression of immediate early genes and neurotransmitter receptor populations, may occur (14). Generally, cocaine tends to be less addictive if the dose is small, the peak plasma levels low, the onset of activity slow, the duration of action long, and the unpleasant withdrawal effects absent or very mild. If cocaine is taken by means of chewed coca leaves, through oral ingestion, or through nasal insufflation, consequences are generally slow to develop. The latter consideration is part of the justification for the not unreasonable but controversial suggestion that oral cocaine in the form of tablets or tea may be used to treat people who have become addicted to cocaine delivered more rapidly to the brain.

IV cocaine use ranks high on the addiction potential scale. The onset of the IV cocaine “rush” is within 30 to 45 seconds,

and the drug's effects last for 10 to 20 minutes. One hundred percent of an IV dose is delivered to the circulatory system, compared with perhaps 20% to 30% of a relatively poorly absorbed oral or intranasal dose, and peak blood levels after an injection can be more than twice those that occur following intranasal ingestion. Nevertheless, for many reasons—pain of injection, difficulty of finding and using needles and syringes, risk of infectious disease—IV administration is less appealing to most cocaine abusers than other administration methods and is considerably less common than insufflation or smoking. When it is seen in clinical practice, patients often concurrently use opiates such as heroin (“speedballing”), in part to enhance the high, in part to offset the undesirable adrenergic effects and paranoia that can attend IV injection of cocaine.

Cocaine in any smokable form, whether coca paste, freebase, or crack, probably has the highest addictive potential. The resulting high is intense and the onset is extremely rapid (15). Only 8 to 10 seconds elapse before the user experiences the high, and peak brain concentrations occur more rapidly than following IV use since the venous side of the circulation is bypassed. Anecdotal data suggest that cocaine smokers are twice as likely to fail to complete their treatment program as are intranasal abusers. Crack cocaine is frequently used in combination with alcohol. As with coadministration of an opiate in the IV cocaine user, the effects of alcohol tend to blunt the undesirable effects and may prolong the high. People who simultaneously abuse cocaine and alcohol may be susceptible to heightened morbidity related to cocaethylene, a cardiotoxic metabolite that also possesses some stimulant effect. Also contributing to the high addiction potential of crack is the fact that the effects of the drug last only 5 to 10 minutes. After the high is over, the crack user feels extremely anxious and depressed. Such a rapid shift between the drug's positive and negative effects makes users immediately crave the euphoria they felt just moments before. Most troubling to the addict (and clinician) is the dysphoria and drive for a cocaine remedy that they know can be achieved by a “hit.” The intellectual knowledge that the resolution of dysphoria will not last is often overwhelmed by the intensity of the cravings that form a distinct part of the cocaine withdrawal syndrome.

One of the enduring mysteries of addiction medicine is the extent to which different people, apparently with similar initial drug exposures and opportunities for ongoing drug use, will respond so differently to those experiences. In the past, the differences between an experimenter who promptly quits, a chronic abuser, and an addict may have been attributed more to social and moral factors than to biologic ones. While the former may play some role in the broad scheme of things, 30 years of medical research unquestionably points to a powerful biologic foundation of cocaine addiction and addictions more generally (16,17). Animal models, including those involving nonhuman primates reared in naturalistic settings, clearly indicate that genetic and social–environmental factors dramatically alter the biology of brain regions intimately involved in

establishing and perpetuating addictions (18,19). There is compelling evidence that animals—and presumably also humans—inclined to self-administer cocaine may have both quantitative and qualitative differences in receptor populations and, perhaps even more interestingly, apparent differences in the fundamental intracellular signaling events that proceed from receptor binding (20). Some of these changes appear to be fixed features of the genetic endowment, and others may actually reflect changes in brain cell function induced by the social environment, including the social context of cocaine use. The following subsection provides a brief overview of some of the compelling themes from recent research into the neurobiology of addiction.

Neurobiology

Cocaine addiction has been described as a disease of the brain's “pleasure centers”—neural networks subserved primarily by the monoamine neurotransmitter dopamine (DA) (16). However, recent insights have broadened the concept of pleasure center to include not only the dopaminergic connections between the brainstem and the structures of the basal forebrain (prominently including the nucleus accumbens [NAcc]), but several frontal cortical regions, and an increasingly important role for nondopaminergic neurotransmission. The latter prominently includes but is certainly not limited to amino acid neurotransmitters (both excitatory [glutamate] and inhibitory [gamma-aminobutyric acid, GABA]), serotonin, endogenous opioids, endocannabinoids, and proximal components of the hypothalamic–pituitary–adrenal (HPA) axis. The hippocampal formations, amygdalae, prefrontal cortex, and anterior cingulate regions—all components of the limbic system—play prominent roles in this enriched and more differentiated view of pleasure center circuitry and are the current focus of intensive research (Fig. 14.2).

There is also growing appreciation of the extent to which the brainstem's DA centers and their projections are anatomically differentiated and profoundly influenced by other neurotransmitter and neuromodulatory molecules. For example, more lateral groupings of DA-producing cells in the ventral tegmental area (VTA) of the midbrain project mainly to the more superficial shell of the NAcc. The shell region mediates reinforcement effects that increase the efficiency of acquisition behavior after initial exposure to cocaine. Cells of the NAcc core appear to be more intimately involved in the long-term plasticity that appears to underlie craving and cue-sensitive relapse behaviors. The magnitudes and patterns of release of DA from neurons originating in the VTA are in turn modulated by reciprocal, largely GABA-inhibitory projections from the NAcc and by excitatory glutamate projections from limbic prefrontal cortex (21). DA neurotransmission is generally facilitated by the effects of endocannabinoid receptor activation (22), and endogenous opioids produce mixed effects (23,24). Compounds that activate kappa-opioid receptors

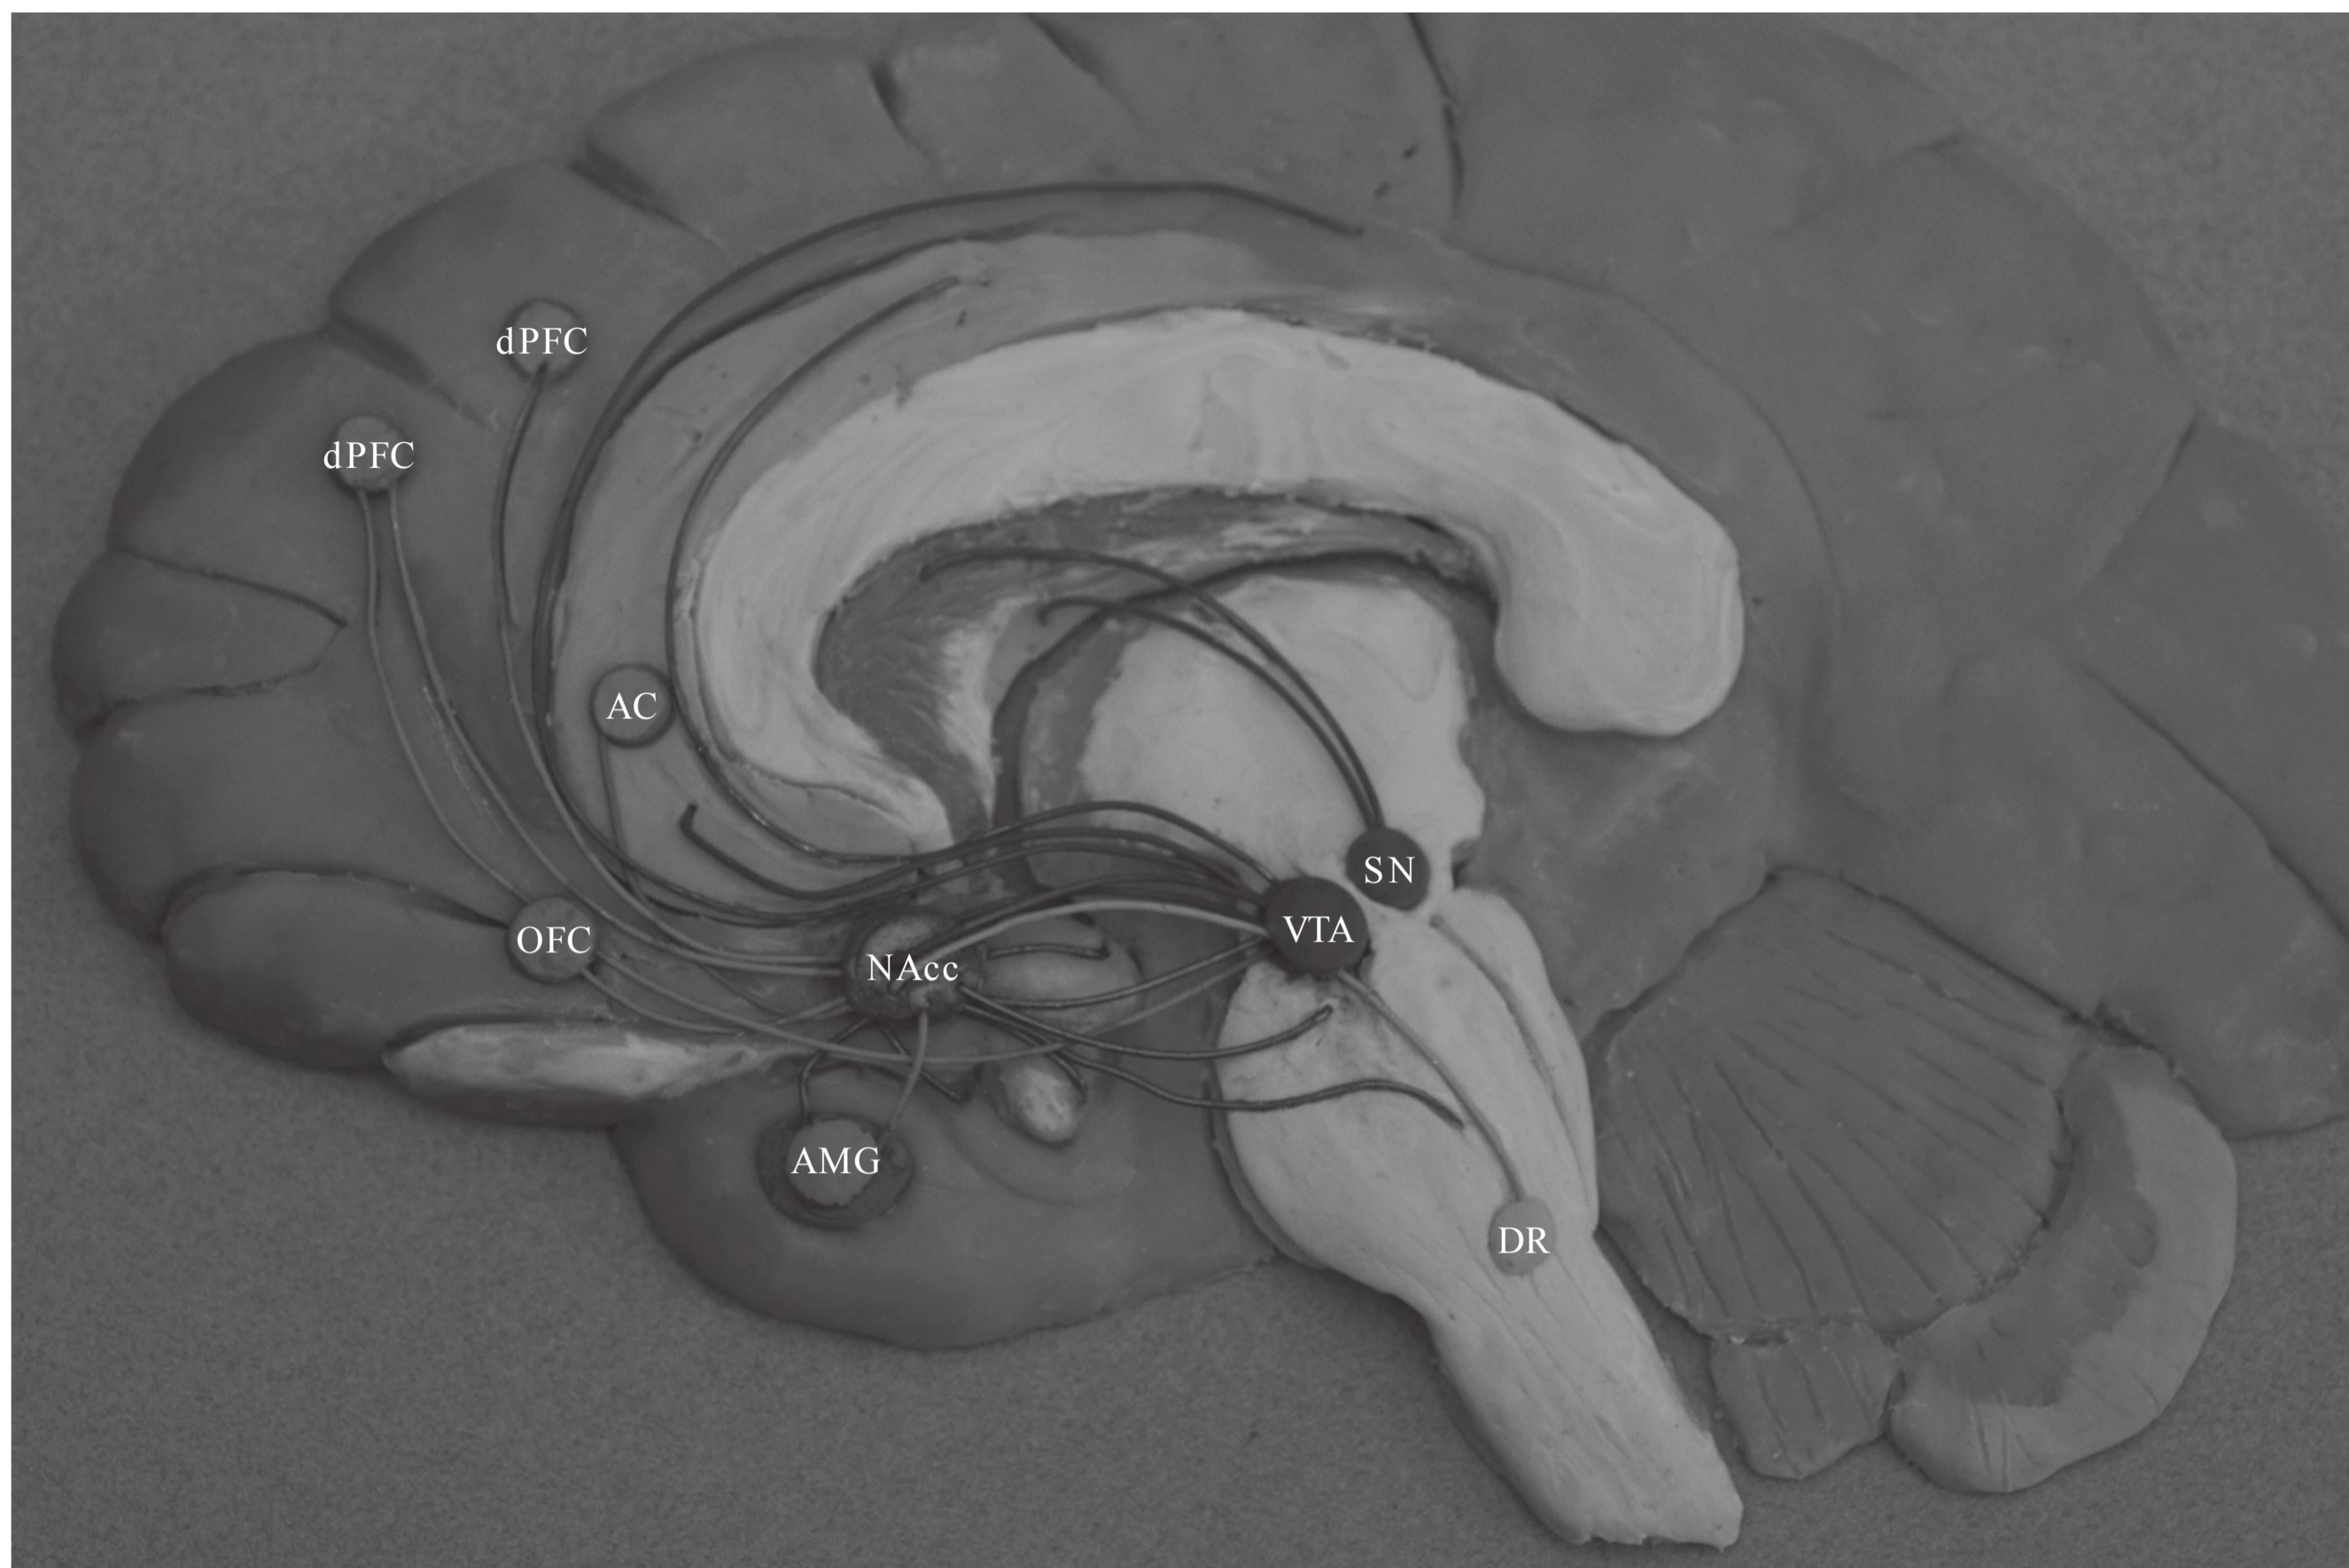

Figure 14.2. The functional anatomy of cocaine addiction can be represented as multiple neural circuits working in conjunction, providing both positive and negative feedbacks at key points of interaction. Dopamine-producing cells in the ventral tegmental area (*VTA*) and substantia nigra (*SN*) project to the nucleus accumbens (*NAcc*; part of ventral striatum) and to the dorsal-motor striatum, respectively. Serotonin-producing cells of the dorsal raphe nuclei (*DR*) also project to *NAcc*. In turn, GABA-producing medium spiny neurons of the *NAcc* project back to brainstem dopamine and serotonin centers, completing the negative feedback loop of a mesoaccumbal circuit. Dopamine projections to the ventral and dorsal striatum exert excitatory (mostly through D1 receptors) and inhibitory (mostly through D2 receptors) effects, with D3 receptors also abundantly expressed in the *NAcc*. GABAergic cells of the *NAcc* frequently coexpress the neuromodulatory peptide dynorphin. GABA-dopamine interactions are now also thought to be powerfully modulated by the hypothalamic-pituitary-adrenal axis and by endocannabinoids acting through CRF-1 and CB-1 receptors, respectively (not shown in figure).

A second circuit comprises direct projections from dopamine-producing cells of the midbrain to the amygdala (*AMG*) and multiple limbic cortical sites, prominently including dorsal prefrontal cortex (*dPFC*), orbitofrontal cortex (*OFC*), and anterior cingulate (*AC*). Cortical and *AMG* neurons in turn project back to the *VTA* and *NAcc* primarily using the excitatory neurotransmitter glutamate completing a mesocortical circuit. Glutamate-producing cells, which also frequently coexpress dynorphin and other neuromodulatory peptides, act through a multitude of ionotropic and metabotropic glutamate receptor subtypes that are expressed throughout the basal ganglia and brainstem. Metabotropic glutamate receptors in particular have been implicated in the long-term plasticities that accompany chronic use of cocaine.

A third integrating circuit establishes connections in a series from limbic cortex to *VTA*, *VTA* to *NAcc*, *NAcc* to discrete regions of the ventral pallidum, and thenceforth to the dorsomedial nucleus of the thalamus, which in turn projects to prefrontal cortical regions, completing a corticostriatopallidal circuit. In addition to ventral pallidum, medium spiny cells in the *NAcc* also send GABAergic projections to the hypothalamus, lateral preoptic area, and more caudal regions of the brainstem.

Recent data also support an important role for the dorsal-motor striatum in cocaine addiction. Acting through polysynaptic connections between the shell region of the *NAcc* and midbrain dopamine centers, the dorsal striatopallidal system may prominently influence the transition from conscious pursuit of cocaine to more automated habit-like behaviors. (Illustration by RP Paczynski and Jennifer Koller.)

(most notably dynorphin) tend to counteract mesolimbic DA neurotransmission, while those that activate mu-opioid receptors tend to facilitate it. Subjects with robust brain dynorphin expression in the setting of cocaine use may be at less risk of addiction. In contrast, there is strong evidence that long-term reinforcement of cocaine self-administration is difficult to induce in experimental animals with deficient mu-opioid receptor functions.

A receptor for cocaine has been identified, a high-affinity binding site on the DA transporter (DAT) in presynaptic elements of dopaminergic nerve terminals. By attaching to and reversibly inactivating these membrane-bound transport proteins, cocaine blocks the reuptake of DA when it is released and thereby produces an acute but *relatively* sustained increase in synaptic DA availability. Increased DA receptor binding occurs as a consequence. In contrast, most other drugs of abuse and many nondrug pleasure-producing stimuli appear to influence DA availability indirectly by modulating the excitability and firing patterns of DA-producing cells in the VTA. Cocaine is not a selective DAT blocker, however, and it is well established that it also impairs reuptake of serotonin and norepinephrine. It is interesting to note that in DAT “knockout” mice, cocaine may still induce increases in DA levels in the brain and still produce its primary reinforcing effects; it is believed that in these genetically altered brain serotonin reuptake transporters may in a sense “takeover” the interplay of presynaptic DA release and reuptake. The acute surpluses of monoamine neurotransmitters produced by cocaine also activate responses within the sympathetic nervous system, producing such effects as pupillary dilation, vasoconstriction, and acute increases in heart rate and blood pressure, addressed in greater detail in the discussion of comorbidities and complications of use.

Some of the best evidence for a general theory of addiction centering on DA comes from classic experiments utilizing animal models of cocaine self-administration (25). Kalivas and Duffy placed dialysis probes in the VTA projections that terminate within the NAcc, providing direct evidence for specific roles of these structures in sensitization to cocaine’s effects in self-administration paradigms; Petit and Justice, using microdialysis in the NAcc, demonstrated that extracellular DA levels are increased during cocaine self-administration, with behaviors directed toward attaining specific, almost optimal, DA levels. DA levels attained were dose dependent and correlated with increased cocaine intake. However, DA projections from the VTA to NAcc are certainly not the only elements involved in increasing DA neurotransmission in response to cocaine. The pleasurable effects of cocaine are probably also related to increases in DA and serotonin in the cerebral cortex through extensive mesocortical projections (26). In addition to the relatively sustained increase in DA levels related to transporter blocking effects, it has recently been demonstrated that cocaine induces phasic surges in DA release within the NAcc and other structures on a subsecond timescale. These phasic changes are highly dynamic and have been related by Cheer et al., and other investigators, to the

links between cocaine self-administration, environmental cues, and other contextual information (27).

Acute administration of cocaine clearly results in increased levels of synaptic DA. However, it is superficial to imagine that brain DA levels remain elevated in the wake of repeated cocaine exposure; the opposite may be the case (28). Using binge administration paradigms, some investigators have found significantly reduced basal DA levels after chronic self-administration, and chronic exposure to cocaine may significantly alter the patterns but not the magnitude of the acute DA response to cocaine. Dopaminergic neurons appear to demonstrate tolerance and diminished responses to chronic self-administration consistent with the notion of a functional DA deficit developing over time, as suggested in our landmark work (29). There is strong evidence that postsynaptic DA receptor availability (and probably the actual density of DA receptors) changes in response to prolonged, repeated exposure to cocaine. This has been conceived as another aspect of an evolving hypodopaminergic state, but the interactions between basal DA levels, acute presynaptic responses to cocaine, DA receptor density, and receptor responsiveness are highly complex. An interesting paradox is presented by the fact that reductions in DA receptor populations, an evident feature of cocaine tolerance, may coexist with heightened sensitivity to some of the psychomotor stimulant effects of cocaine administration after chronic self-administration. A possible explanation for sensitization phenomena in the setting of reduced receptor numbers is differential expression and/or activation of subpopulations of DA receptors that may be more specifically linked with the behaviors of sensitization behaviors. These differential effects may have important therapeutic implications (30).

Environmental and Social Features

Some of the more interesting research findings in recent years address the long-standing question of why some individuals in particular circumstances seem more inclined to psychostimulant addiction. In experiments involving drug-naive monkeys, Nader et al. have provided evidence that individuals with lower D2-type dopamine receptor levels have heightened vulnerability to the reinforcing effects of cocaine (18,19). Similarly, Volkow and colleagues have reported that nonaddict human subjects with lower levels of D2 receptors were more likely to report a euphoric response to IV methylphenidate (31). In contrast, subjects with higher levels of these receptors tended to state that methylphenidate not only did not appeal to them, but made them feel awful. It is therefore difficult to distinguish between the possibilities of increased vulnerability to psychostimulant addiction stemming from DA deficiency, and relative protection from addiction based on a generous DA receptor endowment. The situation is further complicated by the fact that, at least in subhuman primates, brain DA receptor levels may change according to position in a dynamic social hierarchy (up in dominant animals, down in submissive animals). Do these findings reflect a genetic predisposition to

addiction or a vulnerability induced by social environment? The work of Nader and others demonstrate that both may be the case, raising the possibility of a “vicious cycle” of addiction risk. The suggested pathophysiology is analogous to the postulated deficit of endogenous opiate receptor functioning in heroin addicts, and the clinical implications are fascinating. Evidence of social and environmental influences on patterns of drug use is an important reminder of the dynamic nature of receptor biology.

In most animal models of cocaine dependence, drug pursuit behaviors seem to be powerfully reinforcing themselves. Brain DA levels and rapidity of reinforcement are increased in self-administration paradigms compared with circumstances where the same dose of drug is administered by the experimenter. Recent studies have tried to separate addiction from neural adaptation by comparing volitional self-administration from passive (involuntary) drug injections. Not only does addiction develop in the former, but neurochemical changes *appear to be maximized* with self-administration models. In studies of nonhuman primates, cocaine self-administration rapidly produces a progressive, spreading pattern of increased metabolic activity in the upper brainstem, mediodorsal nucleus of the thalamus, and several areas of the prefrontal cortex (26).

Pavlovian conditioned responses to environmental cues (e.g., placement preference paradigms in animal models of cocaine dependence) seem to be a major “source” of relapse. In autoradiographic studies in animals, and using positron emission tomography and functional magnetic resonance imaging in humans, a subject’s perception of drug-related cues causes limbic-connected neocortical regions to “light up.” For example, the sight of drug paraphernalia or a street corner where drugs were frequently purchased might elicit powerful craving that is accompanied by increased cerebral metabolism, particularly in the orbitofrontal cortex and portions of the anterior cingulate region (32). In fact, these cue-sensitive changes in regional metabolism provide some of the best evidence for a critical role of neocortical structures in mediating hallmark features of full-blown addiction: anticipation and craving as preludes to relapse, even after long periods of abstinence. Glutamatergic projections from prefrontal cortex and amygdalae to both NAcc and VTA likely play a key role in these aspects of addiction (21). Nondependent subjects exhibit metabolic changes in subcortical structures when they are exposed to the cocaine, but recent studies suggest that only addicts develop robust increases in regional metabolism in prefrontal and anterior cingulate cortex; these changes occur during periods of craving, with intoxication, and with compulsive use (binging), strongly suggesting that recruitment and sensitization of these higher brain centers are essential aspects of the addiction process (32).

On the other hand, in persons with established addiction to cocaine, or other psychostimulants, frontal lobe metabolism may be substantially *decreased* from baseline *during withdrawal* from a period of binge use. This finding does not necessarily conflict with the suggestion that phasic cortical activation is essential to the behaviors leading up to relapse. Perhaps not

unexpectedly, withdrawal-related hypometabolism appears to correlate with decreased dopamine receptor availability, as judged by radiotraced DA receptor studies, consistent with the aforementioned concept of a hypodopaminergic state in the chronic abuser (28). Unfortunately, frontal deficits may not always be reversible functional changes. Certain cognitive deficits and impairments of affect, particularly those related to impulse control and assignment of circumstance-appropriate salience to stimuli, may be permanent in some people. These observations from the neuropsychology literature are consistent with some of the grim findings from gross neuropathologic studies going back several decades.

There are extensive communications between the NAcc and the amygdala. While the NAcc clearly plays a critical role in the aforementioned reinforcing properties of cocaine and other stimulants, the amygdala has extensive connections with other portions of the limbic system and integrates emotional experiences—elation, fear, anger—with specific visual, auditory, tactile, olfactory, and gustatory memories. In the mind of the user, strong associations form between cocaine and the internal and external environments from the very beginning of cocaine use. The danger, allure, and sense of the streets increase the reinforcing potency of cocaine. In the setting of functional or anatomic impairment of prefrontal cortex, the amygdala may drive a less flexible, more stimulus-bound behavioral repertoire. Environmental information and memories appear to be coupled to reinforcement of cocaine self-administration through the effects of endocannabinoids, endogenous opioids, and other neuro-modulatory proteins (22–24).

EVALUATION AND TREATMENT APPROACHES

Initial Evaluation and Management

A comprehensive assessment of the pharmacologic, medical, psychological, and social aspects of the patient’s substance abuse problem is needed in all cases. For many patients, cocaine use has become the focus of their entire life. They may have become so accustomed to the mood changes, constant pursuit of supply, and the various risks involved in their lifestyle that they have all but forgotten what life without drugs is like. Thus, they come to regard the drugged state as normal and may not believe treatment is necessary (33). Consequently, many patients enter treatment only under pressure from family, friends, employers, or the judicial system. In some cases the patient may become extremely paranoid and perceive the machinations of “enemies.” Therefore, families often need guidance from medical professionals in staging an intervention on a cocaine-abusing relative.

Initial contact with a patient may occur while the patient is still intoxicated, but is more often after the “cocaine crash” and during the withdrawal phase, which may last from hours to weeks. The physician should take a complete medical, family, and forensic history to include a history of *all* drug use. However, information obtained from chemically dependent people is notoriously unreliable, and there is no substitute for

obtaining collateral information from family or other close contacts. A thorough physical and dental examination should include assessment for occult trauma. Patients ideally will have already been screened by medical personnel prior to arrival at a rehabilitation facility, but under many conditions this service may not have been afforded. In the patient with altered sensorium it is always best to assume the worst, namely that they may be under the escalating influence of one or more mind-altering drugs, manifesting an organic brain disorder, or both. One particular concern is that patients about to enter a hospital or other rehabilitation unit may have ingested large and potentially lethal doses of one or more drugs, often as part of an ill-conceived “last hurrah.” Laboratory tests, electrocardiograms, and chest x-rays may supply useful information and may help to reassure both staff and patients as to medical stability and general state of health. Any severe conditions or impending medical emergencies may necessitate transfer to the medical floor of a hospital.

Having established medical stability, the first step in treatment is, of course, to diagnose the patient’s condition accurately. Table 14.1 lists the clinical criteria of cocaine dependence and some of the features of cocaine withdrawal, based on the *DSM-IV-TR*. Importantly, the withdrawal syndrome following even heavy, frequent cocaine use may not be particularly prominent, is rarely life-threatening, and generally not the focus of the specialist in addiction medicine. It is often said that withdrawal from cocaine is primarily psychological, as opposed to the prominent physical withdrawal syndromes seen commonly with dependence to alcohol, opiates, benzodiazepines, and barbiturates. The symptoms of cocaine withdrawal syndrome are certainly of concern, however, because withdrawal-related dysphoria and intense craving increase the chances of elopement from treatment. Using the Cocaine Selective Severity Assessment (CSSA), some investigators have identified intensity of withdrawal symptoms as one of the most, if not the most, powerful predictors of treatment failure. The CSSA has also been suggested as a means to quickly identify the so-called “Type B” patients (those with more severe withdrawal symptoms and other poor prognostic indicators) for more intensive monitoring and management. Medical treatment that helps relieve withdrawal symptoms *may* therefore improve the initial prognosis, but some of the earliest clinical trials indicated that successful amelioration of withdrawal alone appears to be of limited significance *for long-term success*. Painless and symptomless cocaine withdrawal was often followed by relapse and return to active addiction, just as in the past clonidine detoxification was followed by opiate relapse, and initial success with the nicotine patch is frequently followed by return to smoking. It is a vestige of old ways of thinking about addiction within the medical community to place too much attention on “management of withdrawal” often to the detriment of long-term treatment of the addiction process. One of the clinician’s most important roles is to assure the person in withdrawal from cocaine that their symptoms are common, transitory, not usually of major medical concern, and, perhaps for some, part of the process of recovery.

Regardless of the initial (provisional) diagnosis, toxicologic analysis of body fluids should be made. Testing confirms the clinical impression and may help identify concomitant use of other drugs. Negative testing may help identify numerous other disorders that can mimic all or most of the features of cocaine intoxication, cocaine withdrawal, cocaine delirium, and cocaine delusional disorder, all of which are detailed in the *DSM-IV*. Laboratory testing’s main value, however, is to eliminate the need to continually question the patient about current drug use and uncover occult use in the therapeutic setting. As a therapeutic relationship is established, “trust but verify” is the operative principle, and this attitude can provide a strong motivation for the patient to remain drug free. Excellent recent discussions of forensic evaluation of cocaine dependence by Liberty et al. and others are available (34). Here, we will limit comments to a few key points the importance of which cannot be over-stated: immediately following the initial physical examination, blood and/or supervised urine samples should be collected and sent for analysis; if possible, a sample of the cocaine used by the patient should also be submitted to the laboratory; all subsequent urine collections should be supervised and taken first thing in the morning; temperature and/or specific gravity should be measured to confirm that the sample has not been adulterated.

In addition to the standard urine tests for cocaine (typically an inexpensive immunochromatographic assay for cocaine and its major metabolite benzoylecgonine), analytical methods for the simultaneous determination of cocaine and its major metabolites in oral fluid and hair and in the case of crack even sweat (captured under tamperproof patches) have been developed. Hair samples provide a long window of opportunity with each half inch of hair representing approximately 1 week of history. When the distinction is clinically important, unique pyrolysis products of crack (burned cocaine) can now be detected through gas chromatography–mass spectrometry. Although expensive, gas chromatography–mass spectrometry testing is many times more sensitive and specific than either thin-layer chromatography or immunoassay drug screens.

Characterization of the patient’s pattern of use is important in assessing the extent to which the patient has progressed along the path that leads from experimental or occasional use (initiation) to compulsive, often more frequent use. The severity of withdrawal symptoms may be estimated from the pattern of use, and the chronicity of use is frequently an indirect indicator of the extent to which the patient’s life may be in disarray. Unlike the so-called functioning alcoholic, it is relatively rare for a regular cocaine user to maintain anything resembling functionality. Cocaine dependence is associated with either of two patterns of self-administration: episodic or daily (or almost daily) use. Cocaine use separated by 2 or more days of nonuse is considered episodic. Binges are a form of episodic use characterized by continuous high-dose use over a period of hours or days. Binges usually terminate only when cocaine supplies are depleted, or the user becomes so exhausted that they “pass out.” With chronic daily use, there are generally no wide fluctuations in dose on

successive days; rather, it is an increase in dose over time that indicates the development of dependence. With continuing use there is often diminution of pleasure as a consequence of tolerance, increase in dysphoric effects, and accumulation of adverse consequences. Despite these realities, with cocaine dependence use persists or may even accelerate.

Inpatient versus Outpatient Care

An accepted method for recommendations of level of intensity of treatment is provided by the American Society of Addiction Medicine (ASAM) in its Patient Placement Criteria 2-R (PPC-2R). Two sets of guidelines are provided by the ASAM PPC-2R, one for adults and one for adolescents with five broad levels of care for each group. Information from six dimensions—(a) acute intoxication and/or withdrawal potential, (b) biomedical conditions and complications, (c) emotional/behavioral/cognitive conditions and complications, (d) readiness to change (formerly treatment acceptance/resistance), (e) relapse/continued use/continued problem potential, and (f) recovery environment—is used to determine the recommended level of care. The levels of care are Level 0.5, Early Intervention; Level I, Outpatient Treatment; Level II, Intensive Outpatient/Partial Hospitalization; Level III, Residential/Inpatient Treatment; and Level IV, Medically Managed Intensive Inpatient Treatment. A range of specific types of care are found within these broad levels of service.

For several reasons, outpatient treatment is the preferred modality of care if circumstances permit. First, as noted above, use of cocaine can usually be stopped abruptly without medical risk or major discomfort, so many cocaine abusers can be treated as outpatients. Second, the goal of treatment is always to return the patient to a normal life. Third, the cost of outpatient treatment is in general lower (although some insurance companies may refuse to pay for care delivered in the outpatient setting). Fourth, many patients—particularly women with parenting responsibilities—are more willing to accept help on an outpatient basis because it carries less of a social stigma and is less disruptive to daily life. Given the life-long risk of relapse and the need for ongoing support, all cases of substance abuse will eventually need outpatient care and this is perhaps the most important consideration of all. On the other hand, recommending treatment in a hospital or residential rehabilitation center clearly conveys the impression of imminent danger. When drug use is severe, or if outpatient care is not possible or has failed in the past, treatment in a hospital or residential rehabilitation center is called for. Commonly recognized indications for inpatient care include chronic cocaine use with history of multiple relapses, comorbid dependence on another drug, serious comorbid psychiatric or medical illness, or major lack of social support. An important advantage of a treatment facility is removing patients from the environment—the home, the street—that may be contributing to their drug use. Patients under round-the-clock supervision are unable (in most cases) to obtain illicit drugs. They can take daily advantage of the many types of

therapy the inpatient or residential facility offers. Another advantage is that patients are available for full medical and psychiatric evaluations, which will reveal whether any coexisting problems exist, such as cognitive impairment, clinical depression, HIV infection, hepatitis, and so on. Suspected cognitive impairments and psychiatric problems in particular can only be confirmed after detoxification and substantive observation. Successful initial treatment in a residential setting may improve retention by facilitating the integration of the patient into self-help and social support networks. Indeed, inpatient or residential treatment may provide an ideal transition from active addiction to abstinence and daily meetings.

Current and Future Treatment

In this section we endeavor to provide a concise overview of both nonpharmacologic and pharmacologic approaches to the treatment of cocaine dependency. Nonpharmacologic approaches are discussed first because despite impressive recent advances in the neurobiology of cocaine addiction, “psychosocial” treatments are the mainstay of management of cocaine dependence in 2010. Remarkably, with the notable exception of opiate addiction, use of medicines in the day-to-day management of addictions remains quite limited when compared to the prominent role of drugs in the other two most prevalent categories of psychiatric illness, namely affective and anxiety disorders. Addictions are currently the third most prevalent psychiatric illness. Nonpharmacologic therapies play a central role in the current standard of care and they must be included in drug trials as part of the therapeutic background against which drug effects are measured. Even the most promising biological and pharmaceutical approaches to cocaine addiction are unlikely to *replace* nonpharmacologic approaches. Indeed, drugs are more likely to be used as bridge therapies during early recovery and in periods of high risk of relapse.

Most treatment facilities have adopted the chemical dependency model, which regards drug dependence as a primary condition—a disease unto itself—not a secondary problem arising from some other underlying psychopathology. Such programs take a multidisciplinary approach to drug treatment and provide a range of behavioral, cognitive, educational, and self-control techniques aimed at reducing drug cravings and the potential for relapse. The multidisciplinary/multimodal approach has evolved in light of the highly challenging, multifaceted nature of the disease of addiction. Most persons who enter treatment do so with many aspects of their lives disrupted; the multidisciplinary approach therefore seems very appropriate.

Different treatment modalities for cocaine addiction have their advocates and detractors, but some of the more durable and commonly used include the 12-step programs, CBT, the so-called contingency management, and the matrix model. These and related therapies are discussed in depth in Part 2 of this book. Recent reviews have demonstrated that psychological and cognitive behavioral approaches to addiction have response/success rates that are generally moderate, but

otherwise quite comparable to nonpharmacologic interventions for other mental health problems (35). The 12-step programs emphasize coming to terms with and “owning” addiction as a chronic disease process which is managed, never completely cured. Adherents to a 12-step program accept the individual’s powerlessness over addiction, pursue ongoing social support from people in the same boat, and maintain vigilant watch over a disease process that is as much a spiritual as a physical problem. CBT is a time-tested approach that is often used in comparison with (“control group”) or in addition to pharmacologic treatments in clinical trials. CBT emphasizes identification of factors that tend to trigger relapses, psychosocial barriers to sustained abstinence, and development of a rational plan of action steps that a patient can realistically employ. Reports of mixed results with CBT may reflect the fact that this form of treatment is highly “operator dependent.” In the opinion of the authors there is no substitute for highly motivated, socially engaging therapists (as opposed to manual-oriented provision of CBT) in achieving favorable outcomes. The “matrix model” can be described as a holistic approach that strives to provide general supportive psychotherapy while balancing positive and negative reinforcement of sober behavior, and documented abstinence. Self-help participation, drug education, and family/group therapies are emphasized. Most treatment centers offer some form of the matrix model, either as inpatient or outpatient therapy.

In some studies contingency management or the “community reinforcement approach” has shown more efficacy than traditional counseling or pharmacotherapies (36). Literally, paying for abstinence by focusing on drug- and cocaine-free urine tests rather than a more amorphous outcome can succeed where standard drug-abuse counseling has failed to retain cocaine-dependent individuals in outpatient treatment. In one early study, a surprising 85% of patients completed 12 weeks of incentive treatment (earning vouchers exchangeable for retail items) and 65% to 70% achieved 6 or more weeks of continuous cocaine abstinence across the two trials. By contrast, less than 45% of patients assigned to standard counseling completed 12 weeks of treatment.

In recent studies the effectiveness and frequency of CBT counseling sessions have been evaluated in cocaine-dependent patients. Twelve weeks of CBT has been shown to decrease cocaine craving and use, and may be effective even when used on a less intensive schedule. Efrat, Aharonovich, and colleagues have used the MicroCog computerized battery to assess cognitive performance at treatment entry and to compare cognitive functioning between completers (patients remaining in treatment at least 12 weeks) and dropouts. The results indicated that treatment completers had demonstrated significantly better cognitive performance at baseline than had patients who dropped out of treatment. Cognitive domains that significantly distinguished between treatment completers and dropouts were attention, mental reasoning, and spatial processing.

As in relapse paradigms involving experimental animals, many cocaine-dependent individuals respond powerfully to

environmental cues. In extreme cases, seemingly trivial stimuli such as the sight of talcum powder, bread crumbs, or snow may be potent reminders of cocaine. Many individuals respond with increased craving for cocaine and demonstrable physiologic arousal. Arthur Margolin and colleagues have described cue-reactivity protocols that conclude with relaxation exercises. Patients who remain abstinent often report a reduction in cue-elicited craving to below baseline levels, while in those who do not succeed in treatment, drug cues continue to produce intense craving. Cue-induced cravings are one of the most difficult challenges in weaning addicts from cocaine, and simple nonpharmacologic interventions such as relaxation exercises and acupuncture deserve in-depth study as both response markers and potential treatment modalities.

Psychosocial treatments also attempt to help patients understand their ambivalence to give up cocaine and clarify the importance of cocaine in their present life problems. At the same time, the treatment program is designed to reduce cocaine availability by encouraging patients to avoid people, places, and things associated with their addictions. The addict is encouraged to identify high-risk environments, feelings, and attitudes, and to prescribe a sponsor or group meeting rather than a relapse. The patient learns that an impulse to use need not result in an action. Just coming to a regular treatment program is a lifestyle modification that can have a very positive impact on recovery. Meetings provide an opportunity to learn and share with others and to develop new associates and coping skills. Finally, a slip does not automatically become a relapse and many intensive treatment programs manage such events by learning from them to prevent others.

Pharmacologic Treatment

Development of medications that deny the brain access to cocaine or diminish its rewarding and reinforcement effects has marked the beginning of a dramatic change in the field of addiction medicine. The National Institute of Drug Abuse’s Cocaine Rapid Efficacy Screening Trial (CREST) has recently brought attention to promising drugs that influence glutamatergic and GABAergic systems. Perhaps the greatest challenge of pharmacologic treatment is to match the robust reinforcement mechanisms outlined above with equally robust yet safe therapies that can be tolerated over the course of a chronic, relapsing disease. The most realistic approaches will likely involve targeted, relatively short-term interventions with drugs that can disrupt specific aspects of the disease process while natural “extinction” of reinforcement occurs, and new life skills and healthy habits accrue in strength. The unfortunate propensity for cocaine addicts to relapse after long periods of abstinence greatly increases the challenge of effective pharmacologic therapy (32,37).

Table 14.2 highlights pharmacologic treatments for cocaine addiction. Some of these drugs are in advanced clinical testing and many more are in earlier stages of development. Pharmacologic classes and individual agents are related to broader therapeutic goals. Although there is considerable overlap in putative mechanisms of action and beneficial

<p>Treat psychiatric comorbidity</p>	<ul style="list-style-type: none"> ■ Antidepressants (SSRIs) ■ Anxiolytics ■ Psychostimulants for ADHD 	<ul style="list-style-type: none"> ■ Pharmacologic treatment of comorbid psychiatric conditions undertaken with caution in early stages of recovery

The table highlights pharmacologic treatments for cocaine addiction. Some of these therapies are in advanced clinical testing and many more are in earlier stages of development. Pharmacologic classes and examples of individual agents are related to broader therapeutic goals. SSRI, selective serotonin reuptake inhibitor; ADHD, attention-deficit hyperactivity disorder. DA, dopamine; GLU, glutamate; MTEP, 3-[(2-methyl-1,3-thiazol-4-yl)ethynyl]pyridine]; 5-HT, 5-hydroxytryptamine

effects, the following discussion is divided into drugs that may be used for reducing brain exposure to ingested cocaine, as agonist or replacement therapies, and for relapse prevention more generally. Drugs used in treating psychiatric comorbidity are beyond the scope of this chapter and are addressed in Part 2 of this book.

Reducing Brain Exposure to Ingested Cocaine

Two of the more exciting developments of recent years have the common goal of reducing brain exposure to cocaine when cocaine is ingested. Modified enzymes capable of degrading cocaine to nonactive or less toxic metabolites include genetically engineered high-activity variants of human butyrylcholinesterase, and high-activity cholinesterases derived from bacterial species. Some of these enzymes can metabolize cocaine at rates that are orders of magnitude higher than normal, and may be useful in acute treatment of massive overdoses. The so-called immunotherapies have been designed to prevent or reduce passage of cocaine across the blood–brain barrier. The immunotherapies furthest along in development involve attachment of cocaine to larger molecules capable of stimulating an immune response, such as the inactivated cholera B toxin. In animal models, immunotherapies have reduced the behavioral reinforcement effects of cocaine and in clinical trials some subjects have reported diminished cocaine-induced euphoria. There have been promising indicators of reduced desire to pursue further use in immunized individuals. Immunotherapies have no known direct psychoactive effects and therefore no abuse liability. However, there are several important shortcomings worth noting. First, with currently available agents, mounting an effective immune response may take several weeks or even months. Second, given the variability in immune response and often low antibody titers, a dedicated addict may readily overcome the immune response by simply using more cocaine. Third, there have been concerns raised about the ethics of using a long-term immune response in socially vulnerable patient populations. Nevertheless, judicious use of cocaine immunotherapy in highly motivated addicts holds great promise.

Agonist Therapies

The so-called agonist or replacement therapies have dominated the development of drugs for cocaine addiction over the past several decades. As a general approach, agonist therapies replace some aspect(s) of the dopaminergic reinforcement mechanisms described in preceding sections, but using drugs that for pharmacokinetic or pharmacodynamic reasons may not have the same abuse potential as cocaine. In this respect they can be thought of as analogous to methadone or buprenorphine therapies for opiate addiction. A recurring concern with nearly all agonist therapies is that they may perpetuate psychostimulant reinforcement and hence prevent natural extinction of the core mechanisms of the addiction process. Some agonist therapies such as modafinil have produced modestly encouraging results

in clinical trials, but abuse potential is a substantial concern as more is learned about its effects on brain chemistry. Like cocaine, modafinil appears to bind dopamine transporter proteins, among other possible mechanisms of action (39). Illicit use of psychostimulants as performance-enhancing drugs, including many agents that have been tested as agonist therapies for psychostimulant addiction, has led to the development of an underground world of “cosmetic psychiatry.”

There are often no clear lines of demarcation that separate agonist therapies and the multifaceted agents under development for relapse prevention, but drugs that alter reuptake of dopamine or interact directly with dopamine receptors have been involved in most of the clinical trials for cocaine addiction to date. Major agonist therapy subgroups and individual agents, ranging from coca tea to methylphenidate, are listed in Table 14.2. Some of the more interesting developments are drugs such as RTI-336, a selective dopamine reuptake inhibitor, that appear to have a slower onset (and longer duration) of action than cocaine and so may limit rewarding effects. Drugs that exert selective agonist effects on D1 dopamine receptors—as opposed to D2 receptors—have been quite effective in reducing ongoing cocaine use and reinstatement of cocaine self-administration in animal models, highlighting the observation that D1 and D2 receptor systems may exert opposing effects, at least under certain conditions (26). Preadministration of D2 agonists may potentiate subsequent cocaine reinforcement, while preadministration of D1 agonists may substantially block it. Partial agonists and antagonists of the D3 dopamine receptor, expressed abundantly in the ventral striatum, also show promise in reducing responses to drug-associated cues and other aspects of drug-seeking in experimental animals. These latter compounds are in early stages of clinical development.

Relapse Prevention

There are a wide range of chemicals that interfere with one or more aspects of experimental cocaine self-administration and show substantial promise as relapse prevention agents. Animal models have focused on three aspects of the relapse process that realistically simulate clinical situations: relapse triggered by stressful conditions that activate the HPA axis, relapse triggered by drug-associated environmental cues, and relapse triggered by reintroduction of a “priming” dose of cocaine. These models are highly relevant to patient management at all stages of recovery. Drug therapies that could increase the threshold for slips or prevent full-blown relapses would be developments of enormous clinical importance. Drugs that reduce the euphorogenic impact of cocaine would also certainly fall into that framework.

A variety of drugs that show promise in relapse prevention are listed in Table 14.2. We have included those agents that have had disappointing results in early clinical trials in recognition of the fact that many of these studies have been small and inconclusive. Major themes include GABA receptor

agonists or GABA reuptake inhibitors, certain glutamate receptor modulators, HPA axis antagonists, endocannabinoid system antagonists, and kappa-opioid system agonists.

Relating new drugs (or new indications for old drugs) to specific neurochemical mechanisms of action is often fraught with contradictions. For example, agents that increase synaptic availability of GABA (e.g., vigabatrin and tiagabine) or modulate GABA receptors (e.g., baclofen and topiramate) may augment the naturally occurring negative feedback of GABAergic neurons on brainstem DA centers. However, the same drugs may produce deleterious inhibition of functions elsewhere in the brain. Likewise, a glutamate receptor antagonist may show promise in one experimental system and a glutamate agonist or partial agonist in another. Given the lack of specificity of many available agents, and the likelihood of countervailing mechanisms at the molecular level, only long-term clinical trials with clinically meaningful outcome measures (urine tests and psychosocial data) or robust surrogate markers can prevent premature acceptance or rejection of promising agents.

Disulfiram is a drug that has been available for decades as an adjunct in the treatment of alcoholism. More recently, it has shown some promise in relapse prevention in cocaine addiction independent of effects on alcohol consumption, but the data are mixed. The purported mechanisms of action and clinical features are of considerable interest. In addition to its well-known blocking effect on aldehyde dehydrogenase, disulfiram may also inhibit dopamine B-hydroxylase and one of its metabolites may influence NMDA-subtype glutamate receptors. Theoretically, disulfiram may have the properties of a functional DA agonist and a neuroprotectant. Several randomized, placebo-controlled clinical trials have demonstrated at least moderate effects on cocaine use in patients with or without concurrent opiate dependence. However, in the event of a relapse to cocaine and/or alcohol, disulfiram may increase cocaine plasma level and compound the cardiovascular effects associated with increased blood acetaldehyde.

The story of N-acetyl cysteine provides an opportunity to discuss a novel therapeutic approach as it relates to the important role of corticofugal glutamate projections to brainstem and basal forebrain in chronic cocaine addiction. Used for decades as a mucolytic agent and antidote Tylenol poisoning, N-acetyl cysteine also appears to reverse impaired cysteine–glutamate exchange within neurons and glia. Since intact cysteine–glutamate exchange is needed to maintain normal extracellular glutamate levels (which may be low in the cocaine-addicted brain), a therapeutic effect is suggested. How cocaine impairs the functioning of cysteine–glutamate exchange is complex and not fully understood, but may involve changes in the scaffolding functions of Homer proteins that maintain amino acid exchangers as functional units (21). Regardless of the molecular details, a key principle is that low basal glutamate levels can result in amplified responses to glutamate “signals” from corticofugal projections that are triggered by cocaine; the net result may be long-term potentiation of cocaine-associated reinforcement and relapses. Restoring

low basal glutamate may offset this series of events and possibly also improve baseline cortical functioning. Pilot studies with N-acetyl cysteine have been promising and controlled trials are underway. Remarkably, deletion of Homer genes in experimental animals can produce a cocaine-addicted phenotype, including complex behaviors typical of cocaine sensitization.

Numerous glutamate system modulators, and in particular group 1 metabotropic glutamate receptor antagonists, are being tested in relapse prevention paradigms. Glutamate receptor modulators will likely play a preeminent role in addiction-related pharmaceutical discovery over the coming decade. Use of a glutamate antagonist to prevent or diminish reinforcement of cocaine-seeking behavior may seem to contradict the statements above pertaining to restoration of basal glutamate levels with N-acetyl cysteine. However, the chief therapeutic target is pathologic glutamate signaling, not glutamate levels per se. A major challenge will be to develop compounds with sufficient specificity so that interference with normal glutamate-dependent brain functions may be avoided.

Recent Cochrane group meta-analyses have not found interventions involving either antiepileptic drugs or antidepressants promising enough to support their routine use in treating cocaine addiction. Recent clinical trials involving topiramate, an anticonvulsant that is also used in treating migraine headaches and bipolar disorder, have provided only weak evidence of a beneficial effect in cocaine addiction. Nevertheless, anticonvulsants are often reasonably used off-label with a rationale similar to that which justifies testing of novel GABA agonists and glutamate antagonists. The hope is that these drugs will dampen DA neurotransmission and thereby block cocaine reinforcement. D2 receptor antagonists, including commercially available antipsychotic agents, would seem to be a logical therapeutic approach, but clinical trials have been disappointing and in some cases (e.g., olanzapine), clinical decompensation of cocaine addicts has been reported. Some investigators contend that aripiprazole, with its unusual combination of dopamine receptor blocking and serotonin receptor mixed agonist properties, may have some potential in treating cocaine addiction. SSRIs, selective dopamine transport inhibitors, nonselective monoamine inhibitors, and dopamine receptor partial agonists are all under investigation as treatments for depression and restoration of cognitive deficits in patients recovering from chronic cocaine dependence. Screening for deficits and early identification of subgroups more likely to benefit from focused treatment of psychiatric comorbidity are a reasonable approach that is being pursued in many treatment centers.

The complex modulatory effects of neuropeptides relevant to addiction are beyond the scope of this chapter and are covered in other chapters of this book. However, a few comments are in order. GABA-producing cells of the NAcc often coexpress or act in parallel with cells that manufacture the important kappa-opioid receptor ligand dynorphin. Cortical components of the limbic system express dynorphin abundantly. Chronic cocaine use upregulates the kappa-opioid receptor system, and in some experimental paradigms this appears to counteract the chemistry of reinforcement. There

is some evidence from human genetic material that people possessing a “multiple-copy” version of the dynorphin gene may be less prone to develop cocaine dependence after exposure to cocaine (23,24). Dynorphin and other kappa-opioid system agonists are under intensive investigation as therapeutic agents. Cannabinoid receptors are also heavily expressed throughout the limbic system and their activation can powerfully facilitate DA release in the NAcc. According to Cheer and colleagues, cannabinoid receptors may be instrumental in the fundamental process of mesoaccumbal dopamine release (27). The cannabinoid receptor (CB-1) antagonist rimonabant can block the ability of conditioned cues to trigger reinstatement of cocaine use in experimental animals with “extinguished” drug-seeking behavior. Unfortunately, rimonabant is an anorexant with nonspecific effects on pleasure-producing stimuli that may limit its tolerability. The study of CB-1 receptor interactions more generally is an important area of pharmaceutical development.

Drugs that may diminish the impact of stress on relapse (e.g., corticotrophin-releasing factor antagonists and orexin receptor antagonists) are another example of a therapeutic approach with great promise, but because of their broad actions on the HPA axis currently available compounds are not likely to be tolerated long term. Short-term interventions along these lines during periods of peak vulnerability may nonetheless be appropriate, given the importance of social–environmental stress in predicting early relapse.

COMORBIDITIES AND COMPLICATIONS OF COCAINE ABUSE

Associated Psychiatric Disorders

Depending upon diagnostic criteria and methods of data acquisition, the lifetime prevalence of psychiatric comorbidity with cocaine abuse may exceed 75%. On the other hand, psychiatric symptoms and signs at the time of presentation for treatment will be exaggerated by the various manifestations of cocaine toxicity and withdrawal (40). The clinician must therefore be wary of overdiagnosing primary psychiatric pathology while at the same time not missing opportunities to intervene in ways that may improve long-term outcome. It is important to weigh the risk of treating newly suspected psychiatric comorbidity with psychoactive prescription drugs, potentially confounding diagnosis and patient compliance with treatment for cocaine addiction, against the risk of relapse when comorbid psychopathology goes untreated. Management philosophies and medical resources vary widely. There are no straightforward guidelines in this regard, and clinical judgment is used on a case by case basis. The heterogeneity inherent in this area of addiction medicine may account for poor outcomes in certain patient populations, and in others reports of positive responses to treatment that are tantalizing but difficult to replicate.

Certain conditions, particularly anxiety disorders and major depression with prominent anxiety symptoms, may drive the reinforcing effects of cocaine and increase the risk of

relapse. In animal models of relapse, there are numerous well-established correlates between resumption or acceleration of use and exaggerated primary HPA responses. These may reflect increased adrenergic inputs from brainstem centers or impaired inhibitory control of responses to stress by higher brain centers. Pharmacologic antagonists at various levels of the HPA response have been shown to reduce cocaine reinforcement and relapse. In a survey conducted by a national helpline, 50% of callers reported experiencing cocaine-induced panic attacks. Treatment facilities specializing in panic and anxiety disorders also report that onset of panic attacks frequently begins with cocaine use. Cocaine may increase the risk of panic through the process of kindling—lowering the stimulation threshold of the brain. Over time, and following ingestion of large amounts of the drug, such reactions may occur spontaneously, without drug-induced stimulation. Panic reactions may persist long after use of cocaine has stopped.

Some people with depression will experiment with cocaine, amphetamines, or even excessive caffeine and tobacco to lift themselves out of their fatigue, low energy, and disinterest in activities. Although cocaine may act temporarily like an antidepressant, people with major depression are likely to experience severe, often devastating dysphoria after cocaine use. Increased levels of serotonin in key brain regions may be part of the cocaine-induced high, but recurrent cocaine use may lead to long-lasting, selective disruptions of serotonin systems. This is likely to be a major part of the neurochemical basis for the mood changes that are commonly reported during cocaine withdrawal. Some surveys of people undergoing treatment for cocaine abuse reveal that half or more meet current diagnostic criteria for mood disorders. Lifetime major depression is diagnosed in approximately 50% of patients, whereas dysthymia is diagnosed in another 25% to 50%; a similar incidence of depression can be seen among opiate addicts. However, as much as 20% of cocaine abusers experience cyclothymic or bipolar disorder (manic depressive illness); the incidence of these conditions in opiate addicts is only about 1%. Such findings suggest that people who experience mood swings may prefer stimulants over other illicit drugs, as if seeking out a familiar, if unstable, comfort zone.

Another commonly seen condition among adult cocaine addicts is residual ADHD, occurring in up to 30% in some series. In both adolescents and adults with histories consistent with ADHD, it is often reported that cocaine ingestion may result in paradoxical relaxation comparable to the calming and focusing effects of therapeutic doses of methylphenidate and dextroamphetamine. However, these generalizations are harder to confirm in structured longitudinal studies, and destabilization of the patient with ADHD on cocaine is not uncommon. Methylphenidate has been used as a “substitution” therapy in cocaine addiction, similar to how “methadone maintenance” is used in heroin addiction. The predominant finding has been that the majority of the modest benefits attributable to methylphenidate occurs in those individuals who displayed moderate to severe ADHD symptoms.

Chronic cocaine abusers frequently cultivate “superstitions,” and may even experience feelings of suspiciousness

and esoteric thinking as a source of pleasure or entertainment that can play into their systems of denial. In more extreme cases, persecutory delusions may provoke violent or aggressive behavior. Acute, subacute, and chronic paranoia are commonly seen products of cocaine abuse. In its ability to induce a state resembling functional paranoid psychosis, cocaine is similar to other central stimulants, most notably methamphetamine. Like a person with schizophrenia, a person in the throes of cocaine delirium may lose contact with reality and become confused and disoriented. When the pharmacologic effects of cocaine have worn off, the delirium usually disappears. Typically, cocaine delirium with or without frank psychotic features resolves within 3 to 5 days of cessation of use; if it persists for a longer period, or if the patient becomes increasingly difficult to manage, a reevaluation of the diagnosis is indicated and an antipsychotic medication may be considered.

Perhaps more than those with any other personality disorder, people diagnosed as having antisocial personality disorder are prone to use mood-altering drugs. Alcohol is often the drug of choice in such individuals, but many also use cocaine or amphetamines or a combination of several drugs. People with this disorder are distressed, tense, unable to tolerate boredom, and agitated to the point of discomfort. Their use of drugs often removes any remaining inhibitions, increasing the risk of anger, violence, and actions that violate the rights or property of others. Because cocaine is by definition an illicit substance, use of the drug in itself constitutes a form of antisocial behavior. People with borderline personality disorder are likely to turn to mood-altering drugs for relief. They may use stimulants to induce feelings of pleasure, or depressants to reduce internal distress. Because these people are already on the edge, use of stimulants and depressants may trigger a flare-up of anger or violence.

The combined use of cocaine and alcohol is common, with reports of up to 90% of cocaine abusers also being concurrent ethanol abusers, and as many as 60% having lifetime diagnoses of alcoholism. Cocaethylene, the ethyl ester of benzoylecgonine, is produced abundantly when cocaine and alcohol are used together. Like cocaine it binds to the DA transporter and increases extracellular concentrations of DA in the NAcc, but seems to have little effect on the serotonin transporter. While similar to cocaine in producing stimulant effects, there are reports of longer half-life and increased lethality, particularly increased cardiovascular morbidity. Concurrent marijuana use is also common, and may enhance the cocaine high, not only by offsetting the anxiety and agitation of cocaine intoxication but also by altering the drug's pharmacokinetics and metabolism. In some studies marijuana pretreatment significantly reduces the latency to peak cocaine euphoria, decreases the duration of dysphoric or bad effects, and increases bioavailability of cocaine. Marijuana-induced vasodilatation of the nasal mucosa also attenuates the vasoconstrictive effects of cocaine and may thus increase its absorption.

Medical Complications

The medical complications associated with cocaine use are so numerous and complex that it would take volumes to describe them adequately. Many of the classic descriptions of cocaine toxicity produced by internists and emergency medical physicians in the 1970s and 1980s remain highly relevant, and the literature expands considerably each year. With the relatively large and rapid dose deliveries typical of today's regular user, cocaine is a frequent form of serious morbidity and mortality (41,42). However, serious medical complications, including sudden cardiac death, fatal intracranial hemorrhages, malignant hyperthermia with rhabdomyolysis, and renal failure, among others, have all been documented in association with first time use, even of moderate doses. There are obviously wide interindividual variations in both initial response and tolerance to the effects of cocaine, and the occurrence of serious medical complications does not correlate well with plasma levels of the drug at the time of presentation for emergency care.

Cardiovascular System and Pulmonary Syndromes

Cocaine rapidly triggers the physiologic responses that make up the natural "fight or flight" response to an impending threat. By affecting the release and reuptake of epinephrine and norepinephrine, cocaine causes a shift in the blood supply from the skin and the viscera into the skeletal musculature. Oxygen levels rise, as do concentrations of sugar in the blood. Tachycardia, increased cardiac contractility (beta-1 adrenergic effects), and hypertension (alpha-adrenergic effects) may be pronounced and increases in myocardial oxygen demand may outstrip supply, particularly in the presence of cocaine-induced spasm of epicardial or penetrating vessels. Persistent cocaine use has also been linked to acceleration of atherosclerotic coronary artery and renal arterial disease. Apart from the consequences of cocaine-related violence, chest pain is the most common issue prompting presentation for emergency care, 50% or more in some series.

The first detailed reports of cocaine abuse-associated cardiac toxicity appeared over 30 years ago. A review of the medical literature produced by the American Heart Association in 2008 indicates that cocaine use has been linked to virtually every type of cardiac disease imaginable, including a range of supraventricular and ventricular arrhythmias (43). Atrioventricular nodal conduction block and QTc interval widening are common; premature ventricular depolarization, ventricular tachycardia degenerating to defibrillation, and asystole are not uncommon causes of death. Some studies have found a greater acceleration in heart rate and blood pressure associated with cocaine smoking than with IV cocaine use. Direct stimulation of vagal centers in the brainstem by cocaine or indirect stimulation of baroreceptor responses may also result in severe bradyarrhythmias.

Cocaine abusers often present with atypical, sometimes bizarre presentations of chest pain, and there may be unusual

electrocardiographic findings, including those suggestive of “centrally mediated” ST segment elevations in more severe cases of cocaine toxicity. In addition to acute vasospasm or blood supply–demand mismatch in the setting of preexisting coronary artery disease, other causes of chest pain include in situ coronary embolism and coronary arterial dissections. Chronically developing myocardial fibrosis, inflammatory lesions, and other direct toxic effects on myocytes also occur and these likely contribute to the development of congestive heart failure. Cocaine toxicity should always be considered until proven otherwise when a young adult presents with chest pain or signs of congestive heart failure, with or without the presence of other risk factors. Cocaine use is also associated with acute renal failure, often in association with hyperthermia and rhabdomyolysis, and with insidious forms of chronic renal failure. An increasingly common and tragic presentation of cocaine-related vascular pathology is the middle-aged or even elderly patient who presents for emergency care with end-stage renal disease, accelerated hypertension, and positive urine tests for cocaine.

The actual incidence of myocardial infarction associated with cocaine has been controversial, but the recent Cocaine Associated Chest Pain trial, the largest prospective study of its kind ever performed, indicates that the incidence may be less than 10%, according to reports from the American Heart Association (43). The take-home message is that atypical chest pain syndromes, including a number of noncoronary ischemic presentations, need to be considered in the differential diagnosis. Mechanisms to consider, all well documented in case reports or case series, include aortic dissection in the setting of cocaine-induced hypertension, aortic thrombosis, cardiac contusions, pneumothorax, pneumopericardium, and other forms of pulmonary barotrauma. The occurrence of frank barotrauma is infrequent but by no means uncommon, and presumably relates to vigorous insufflations, Valsalva, and abnormal ventilatory patterns in smokers, with or without ischemic necrotic changes and perforations of the bronchial passages.

Shortness of breath is thought to be the second most common cocaine-related medical symptom in emergency care settings. It is well established that cocaine inhalation can cause or exacerbate asthma. The “*crack lung*” syndrome entered the medical literature in the late 1980s; people typically present with the symptoms of pneumonia: shortness of breath, atypical chest pain, high temperatures, and a negative or nonspecifically abnormal chest X-ray pattern. An eosinophilic pneumonitis may be diagnosed via bronchoscopy and biopsy, and adulterants in smoked cocaine (e.g., talc and baking soda) may be responsible for at least some of the pathology. In addition, chronic cocaine inhalation may interfere with breathing by causing telltale destruction of the nasal septum, nasal cartilage, and hard or soft palate. However, rather than pathognomonic syndromes, breathing difficulties in cocaine abusers should be thought of from the standpoint of broad differential diagnosis, as with chest pain.

Neuropathology

The spectrum of neuropathologic changes encountered in the brains of cocaine abusers is broad, but some of the most common catastrophic events include global cerebral hypoxic–ischemic insults secondary to cardiopulmonary failure, hypertensive encephalopathy, intractable seizures, thromboembolic stroke, lobar hemorrhages, and subarachnoid hemorrhages, the latter particularly in those with preexisting intracranial aneurysms or arteriovenous malformations (44). Large retrospective reviews from the neurosurgical literature indicate that concurrent use of cocaine so negatively affects outcome after a subarachnoid hemorrhage that it should be considered equal in effect to the presence of a major systemic illness such as congestive heart failure or renal disease. Accelerated atherosclerosis may occur in the cerebrovasculature just as it does in coronary, renal, and gastrointestinal vascular beds, and in some cases frank vasospasm may produce ischemic brain lesions. The relevance of cerebral vasculitis to cocaine-induced stroke has been debated in the neurologic literature for years, but postmortem pathologic studies supporting this possibility certainly exist.

Cocaine is an epileptogenic agent that can provoke generalized seizures, even after a single dose. These convulsions are typically brief and self-limited, but rare instances of status epilepticus, including difficult-to-recognize nonconvulsive status epilepticus masquerading as a toxic-metabolic encephalopathy, have been reported. Recurrent convulsions are well recognized as a poor prognostic indicator and may trigger a downward cascade including hyperpyrexia, metabolic acidosis, and rhabdomyolysis. When a witnessed or suspected seizure occurs and there is a possibility of cocaine toxicity, then appropriate diagnostic tests, vigorous hydration, and close monitoring are called for. When interictal periods are accompanied by extreme psychomotor agitation, neuroleptics should be avoided because they all, to some extent, lower seizure threshold. IV phenytoin should also be used with caution owing to its potential to induce cardiac dysrhythmias, and in most circumstances benzodiazepenes (e.g., lorazepam or midazolam) would be the anticonvulsants of choice. A rapidly deteriorating syndrome featuring premonitory signs consistent with a typical cocaine delirium, followed by seizures and cardiac arrest has been reported, sometimes within hours of first-time use of only moderate amounts. Early distinguishing features from cocaine delirium may be diminished sensorium and fever.

In addition to potentially reversible functional deficits in frontal brain regions, Volkow et al. have reported the common occurrence of multiple, small, often silent, “Swiss cheese” infarcts and neural change associated with cocaine and crack use. Our work with methamphetamine suggests reversibility should not be taken for granted and neurotoxic consequences of use may be expected. Other researchers’ work supports these findings and raises concern that persisting cerebral perfusion deficits and prefrontal cortical dysfunction may result even in patients who appear to be asymptomatic (45). In landmark studies by Tony Strickland

and colleagues, single-photon emission computed tomography, magnetic resonance imaging, and selected neuropsychological measures were used to study cerebral perfusion, brain morphology, and cognitive functioning. Widespread regions of cerebral hypoperfusion in the frontal, periventricular, and temporoparietal areas, and deficits in attention, concentration, and memory were observed. Remarkably, many of these patients were drug free for 6 months or more before their evaluations.

Following chronic cocaine use the body's reservoirs of neurotransmitters and hormones may be depleted. In addition, the drug may compromise the body's ability to regenerate these biochemicals. As a result, the chronic user may experience symptoms of withdrawal and even frank dopamine depletion. As demonstrated in our work describing the dopamine depletion syndrome, chronic cocaine abuse can result in dopamine disinhibition phenomena including increased release of prolactin; in fact, hyperprolactinemia is the endocrine abnormality most often reported in clinical studies of cocaine abusers (29). Extrapyrmidal dysfunction including akathisia, dystonias, choreiform movements, bruxism, and a peculiar combination of stereotyped movements and disordered gait (sometimes referred to as "crack dancing") may occur. These symptoms and signs are functionally analogous to the syndromes seen after exposure to dopamine antagonists (e.g., neuroleptics).

Cocaine potently stimulates the HPA axis. As noted previously, activation of corticotrophin-releasing factor (CRF) and increased glucocorticoid response to stressors have both been linked to acceleration of cocaine reinforcement in some animal models. Blocking CRF receptors, and other branch points of the HPA, may efficiently reduce reinitiation of cocaine use (46). Similar findings implicating HPA overdrive in relapse have been reported in humans. By inactivating the feeding center located in the lateral hypothalamus, cocaine also supersedes the primary drive to eat, thus leading to severe loss of appetite and loss of body weight, the latter sometimes a justification for sporadic use. Many people with eating disorders—*anorexia* and *bulimia*—take diet pills containing amphetamines or use cocaine to suppress the appetite. Some of these people progress to cocaine dependence. Muscle wasting, often associated with low-grade elevation of CPK (creatine phosphokinase), and often without clear etiology but possibly linked with central dopamine dysregulation, is common. The cocaine user's decreased need for sleep may result from the drug's effects on regulation of brainstem neurotransmitters, particularly serotonin, which plays a major role as modulator of the sleep cycle.

Impact on Sexual Function and Sexuality

Many users, particularly men, claim that cocaine is an aphrodisiac. Indeed, as mentioned earlier, the feeling of sexual excitement that sometimes accompanies cocaine use may be the result of its impact on the DA system and may produce spontaneous orgasm. Nonetheless, chronic cocaine abuse causes derangements in reproductive function, and loss of

interest in sex and poor sexual performance noted by chronic addicts may be related in part to increased prolactin release in the setting of a chronic hypodopaminergic state. These symptoms may persist for long periods after use of cocaine has stopped. In women, cocaine abuse has adverse effects on reproductive function, including derangements in the menstrual cycle function, galactorrhea, amenorrhea, and infertility. Some women who use cocaine report having greater difficulty achieving orgasm.

Infections with hepatitis B, hepatitis C, and human immunodeficiency virus (HIV) are associated with cocaine dependence as a result of promiscuous sexual behavior. HIV seropositivity seems clearly associated with crack smoking, independent of concurrent IV use. The clear association between the smoking of crack and high-risk sexual practices has been reported and linked to acceleration in the spread of the HIV virus. A recent study by Theall et al. indicated that HIV seropositivity was at least three times higher among crack smokers than noncrack smokers (47), and recent analyses of women who had sex in exchange for money or crack showed that over 30% were infected with HIV. Cuts and burns on the lips from smoking crack cocaine are also associated with positive HIV serostatus, even after controlling for the amount of oral sex. Other sexually transmitted diseases, hepatitis, and tuberculosis are also seen in cocaine abusers.

Cocaine, Pregnancy, and Fetal Development

One of the most troubling aspects of the cocaine epidemic is its use by pregnant women. "Crack babies" are not just a tragedy of American inner cities; recent reports from Australia, Europe, and South America suggest growing problems with cocaine abuse during pregnancies and at the time of deliveries. It is important to remember that many historical accounts likely underestimate fetal exposure. This "denial" is demonstrated by a recent study of over 3,000 neonates. Although 11% of the women reported using illicit drugs during pregnancy, 31% of infants' meconium tested positive for cocaine alone, plus some additional multidrug positives. Cocaine's effects on the unborn and newborn may also be related to poor nutrition, poor hygiene, and neglect. Cocaine compromises the mother or any caregiver's ability to respond to the new baby through talking, eye contact, and tactile stimulation. Such disconnection and indifference to the infant's behavioral cues create additional problems because nurturing responses are necessary for optimal intellectual and emotional development.

The available data pertaining to cocaine's teratogenicity and obstetric complications are very complex and sometimes conflicting. The least controversial findings involve impaired somatic growth. Gestational age at birth, birth weight, head circumference, and length are often decreased. Placental abruption, or premature separation of a normally implanted placenta, is thought to occur in approximately 1% of pregnancies in women who use cocaine, making the drug a significant cause of maternal morbidity as well as of fetal mortality. Women who use cocaine during pregnancy have a

high rate of spontaneous abortion, higher than that of heroin users. Pregnancy also appears to increase a woman's susceptibility to the toxic cardiovascular effects of cocaine, at least in part by the shift in hepatic metabolism of cocaine from relatively nontoxic ecgonine methylester to highly toxic norcocaine, a potent vasoconstrictor.

Neurodevelopmental consequences of exposure to cocaine in utero are heterogeneous and may be common (48). A growing experimental literature demonstrates defects of neuronal migration and dysregulation of "programmed cell death" in cortical maturation, among other effects of cocaine. Clinical and animal studies also support the concept of postnatal HPA axis hypersensitivity resulting from exposure to cocaine in utero and in early postnatal life, phenomenon with ominous implications for long-term psychological and social development.

CONCLUSIONS: REASON FOR HOPE

Recidivism among cocaine-addicted patients is high and most treatment specialists acknowledge that they offer treatment, not a cure, for addiction. Many contradictory data, some showing new therapeutic approaches with great promise, contrast with reports of abysmal relapse rates (49). Researchers have not exactly agreed on what can be termed recovery. Without long-term outcome studies that include forensic tests and rigorously collected psychosocial data, "cures" often seem based more on fashion and investigator charisma than science. Cures are a fantasy. However, there are strong reasons for hope, and as knowledge of the natural history of the relapse process and the sophistication of clinical trials increase, major breakthroughs in treatment success seem more realistic than ever. Perhaps a decade ago, only 10% to 20% of drug addicts were reported as having recovered following treatment. Some programs today report success rates of 60% to 70%, depending on definition of treatment failure (it is debatable whether brief recurrences of use—so-called slips—should constitute a relapse).

One of the major success stories of recent years has come from the management of cocaine and other addictions in health professionals. Our group has had long-standing involvement with these programs and related clinical studies. Mandatory, monitored treatment of drug addiction for health professionals can have strikingly positive long-term results and may serve as a model for treatment in the general adult population (50). The state of Florida's Professionals Resource Network (PRN) identifies, intervenes, and provides appropriate referral and case management for all physicians who are affected by chemical dependency/abuse. PRN follows individuals from evaluation through treatment and then monitors their aftercare for 5 or more years. We have recently examined outcome data from randomly selected Florida physicians who were monitored by PRN for substance abuse and dependence. Five-year recovery was documented by counselor reports, physician/psychiatrist evaluations, AA/NA attendance, return to work, and regular random urinalysis. We found that after 5 years, 92% were drug free, had attended weekly meetings, had positive counselor and physician assessments, and had returned

to work. Similarly, impressive results have been reported in evaluations of various state Physician Health Programs (PHPs). Treatment settings varied widely, but the overall results from cocaine addicts, opioid addicts, and alcoholics were comparable. None were treated with methadone or other maintenance. Recent studies extending observations over several state PHPs have confirmed the importance of 12-step programs, positive and negative reinforcement, and lengthy aftercare. These PHP results are very encouraging, but it should be kept in mind that recovering health professionals often have greater material resources and access to intensive treatment modalities that may not be available to the average person.

Treatment for cocaine addiction certainly seems to be on an upward trajectory, but preventing initiation of cocaine use should remain in the forefront, and prevention ideally begins before conception. The tragedies associated with cocaine use during pregnancy and in youth are hard to fully appreciate. While it has become fashionable to scoff at the "Just Say No" campaign of the 1980s, the prevention efforts of the federal and state governments and the Partnership for a Drug-Free America brought many of this country's best scientific, advertising, and marketing minds to the awesome task of "unselling" drugs. These educational programs and ads have helped to reduce drug use in general, but they have had an especially significant effect upon adolescents and children.

At the time of publication of this book, horrendous violence and official corruption in high places have become the calling cards of cocaine trafficking in South America and more recently through Mexico. Similar violence devastates the streets of many American cities. Faced with these realities, organizations such as Law Enforcement Against Prohibition (LEAP) have forcefully argued that legalization of drugs would reduce drug-associated violence and make addictions easier to manage. However, cocaine use is a medical problem; legal or illegal, cocaine is extremely dangerous. It is difficult to justify legalization and government control over the use of a drug such as cocaine, which is so powerfully reinforcing and fundamentally linked with escalating use, impulsive behavior, and deaths (7). Cocaine-associated violence stems from the greed and conflict of illicit drug trade, and also from activation of the "fight or flight" reaction and the disinhibitions that result from impairment of higher brain centers. Legalization and bureaucratic control of supply do not seem likely to work, at least not for cocaine.

Most organizations with responsibility for drug control policy currently advocate flexible understanding and flexible approaches to cocaine addiction/abuse. A flexible approach takes into consideration the fact that there are different phases of cocaine epidemics and that they may vary considerably on a regional basis. For example, in the rapid "infective" stages of an epidemic, initiation of use may increase exponentially as established users bring friends and associates not otherwise predisposed to use above a certain socially reinforced threshold. Interdiction operations led by law enforcement may be uniquely effective in reducing spread under these circumstances. In contrast, established users may obtain supply and perpetuate their illnesses more or less regardless of the legal

and other social consequences of continuing use. Yet, these same individuals are the most in need of medical treatment and the most likely to benefit from it.

Ideally, in the earliest stages of chemical dependency patients should have access to well-trained specialists in addiction medicine and/or addiction psychiatry. Addiction specialists are more likely to be aware of the pitfalls of early recovery, less likely to harbor judgmental attitudes and able to appreciate that recovery is a long, hard road. Cocaine abusers have often engaged in convoluted, dangerous lifestyles and have made many poor choices. It is wholly unrealistic to expect a quick turnaround from this tragic state of affairs, just as it is unrealistic for most diabetics to rapidly obtain lasting control over a chronic disease of metabolism. Most experienced clinicians have seen examples of impressive long-term success in addition to the many failures, and the medical community now seems ready to move beyond anecdotal experience to greater participation in rationally designed, fully integrated treatment programs.

Alan J. Budney ■ Ryan G. Vandrey ■ Stephanie Fearer

Cannabis is the generic and most appropriate scientific term for the psychoactive substance(s) derived from the plant, *Cannabis sativa*, and used by humans to alter their consciousness or physical state. It contains over 500 distinct chemical compounds, but the one of primary interest related to substance abuse is delta-9-tetrahydrocannabinol (THC). THC has been identified as the predominant substance in cannabis that produces the subjective “high” associated with smoking the plant. Marijuana and hashish are the most common names for cannabis used by the general population. Over the years, however, cannabis has accumulated many names (e.g., weed, pot, herb, grass, reefer, Mary Jane, dagga, dope, bhang, Aunt Mary, skunk, boom, gangster, kif, ganja, hashish, and hash oil.). In this chapter, we will use the term *cannabis* to refer generally to all the various derivatives of the *Cannabis sativa* plant used by humans, except when otherwise designated.

Cannabis is the most widely used illegal substance in the United States and most other developed countries that regulate its use. Controversy regarding its legal status, addictive potential, health consequences, and medical use has pervaded the lay and scientific communities for centuries (see below). A large component of such controversy has been skepticism regarding the dependence or addictive potential of cannabis and the perception that adverse consequences of its use are limited and relatively inconsequential. Fortunately, advances in clinical and basic science address many of these controversial aspects of cannabis use. Epidemiologic, laboratory, and clinical studies have demonstrated the existence, increasing prevalence, and clinical significance of cannabis abuse and dependence disorders (cannabis use disorders [CUDs]). Treatment research studies indicate that abstinence and relapse rates observed following treatment for CUDs are highly similar to those observed with other substance use disorders.

Scientists identified an endogenous cannabinoid system in the late 1980s that prompted research exploring the biologic underpinnings of CUD, and the potential mechanisms by which it may impact physical health and psychiatric disorders. Remarkably, such findings provide clear illustrations of similarities in the neurobiological processes involved in cannabis use and the development of CUD and other types of substance dependence (e.g., alcohol or heroin). The clinical, behavioral, and neurobiological data accumulated over the past 20 years suggest that the debate over whether or not cannabis is addictive has become obsolete. Clearly cannabis misuse and

addiction are real and relatively common phenomena that pose a significant public health issue requiring continued attention by health service providers, policy makers, and families.

This chapter will provide a comprehensive overview of cannabis and its status as a psychoactive substance with potential for misuse and addiction. A brief synopsis of the long history of cannabis use by man and its ever changing status in our society will be followed by epidemiologic data illustrating trends in cannabis use among different age, gender, ethnic, and racial groups. Description of the behavioral and cognitive experiences associated with cannabis use will precede brief reviews of the pharmacologic, neurobiological, behavioral, and environmental factors related to initiation and maintenance of cannabis use and misuse. A succinct review of the treatment outcome literature will illustrate recent progress in the development and testing of psychosocial and pharmacologic interventions and discuss their effectiveness for CUDs. An overview of specific health and psychosocial consequences associated with cannabis misuse together with a review of comorbid disorders common among those with cannabis use problems will further demonstrate the broad range of issues that warrant attention when evaluating cannabis use and the severity of CUDs.

HISTORY

Many historic accounts of the use of the cannabis plant for its fiber, as medicine, and as a mind-altering substance have appeared in the literature. For those most interested in a detailed accounting of the ancient history of cannabis, we refer you to Abel’s classic text, *Marihuana: The First Twelve Thousand Years* (1). Cannabis likely first appeared in Chinese culture 4000 to 5000 years ago and was grown primarily for its fiber (a.k.a. hemp) and used to make clothing, paper, and rope. Eventually, inhabitants of Central Asia, India, and the Middle East, and the Greeks and Romans began to use cannabis as a medicine to heal and ameliorate various ailments, as well as for its spiritual and mind-altering properties. Spiritual and religious uses of cannabis are described in ancient writings of these cultures. Indeed, over the years a number of cultures have deemed cannabis a “holy” plant because of its psychoactive and medicinal potential. Nonetheless, use of cannabis to change consciousness and its potential for misuse has repeatedly engendered controversy within most cultures, even in ancient China. The intermingling of

three issues, cannabis' value as highly utilitarian fiber, its potential for medicinal use, and its mind- and behavior-altering effects (addictive potential and consequences), has generated debate and legislation across cultures for many centuries.

Of most relevance to those interested in current perspectives on cannabis as a substance of abuse are the more recent (past 100 to 150 years) history and controversy related to science and policy. During the mid- to late 1800s many "medical papers" were written, mostly expounding the potential of cannabis for varying medical (physical and mental) conditions. Cannabis became part of the U.S. Pharmacopeia in 1870 where it remained listed as a useful medicine until 1941. Although reports from government-sponsored "studies" on cannabis (e.g., Ohio State Medical Society, 1860 and the Indian Hemp Drug Commission, 1895) suggested that cannabis was not "addictive" and had potential health benefits, the call for such studies indicated growing societal concerns about adverse effects. During the early 1900s, cannabis became a source of public controversy in the United States when the mainstream culture became concerned that "reefer" or "marijuana," purportedly being used primarily by African Americans and Mexican Americans, was negatively influencing children of the White middle and upper classes. International concerns also became apparent at this time as annual reports from the International Opium Conference and the League of Nations indicated discussion of the need to place controls on cannabis use by multiple countries and the resistance of such controls by others. In 1924, the International Opium Conference labeled cannabis a "narcotic" and called for strict controls. Yet in 1925 a U.S. report, issued in response to high rates of soldiers' cannabis use in the Panama Canal Zone, concluded that cannabis was not addictive or harmful, and recommended no restrictions on use.

By 1941, cannabis was dropped from the U.S. Pharmacopeia, the United States legislated a Marijuana Transfer Tax in response to concerns about cannabis, and Britain officially made cannabis an illegal substance. In 1944, a "scientific" report from the New York Academy of Sciences commissioned by the Mayor of New York City indicated that the public concerns about cannabis were exaggerated and that cannabis does not lead to "addiction" in the medical sense of the word. However, the report also described multiple negative aspects of marijuana smoking and associated consequences. The increase in use in the United States during the 1960s and 1970s rekindled public and scientific interest and concerns. The Transfer Tax was declared unconstitutional, but in Britain cannabis remained classified as a Class B drug, meaning any use, including use for medical reasons, was specifically banned. In reaction to the long prison terms being imposed for possession, the U.S. National Commission on Marihuana and Drug Abuse recommended in 1972 that cannabis possession be decriminalized. In that decade a number of states replaced prison terms with either civil penalties or misdemeanor fines. Also during the 1970s, the White

House Administration banned medical research on cannabis, while at the same time the state of New Mexico passed a law allowing cannabis for medical use. Similar contradictory reports, federal administrative and legislative directives, and "scientific" reports continued to appear during the 1980s. Legalization and decriminalization discussions evolved internationally with still no consensus and a resultant wide range of national and regional policies. In 1999, the Institute on Medicine released a comprehensive report acknowledging the potential negative effects of cannabis including addiction, but also provided a clear statement regarding its potential for medical benefits.

Finally, in the first decade of the 21st century, Britain downgraded cannabis to Class C status, but at the same time revised the consequences associated with possession or sale of Class C substances rendering the status of cannabis highly similar to its previous categorization. In 2009 cannabis was moved back to Class B status. Currently in the United States, cannabis remains classified under federal law as having high risk and no accepted medical use. However, approximately 13 states have passed laws "legalizing" the medical use of cannabis.

Current perception and policy in the United States and Britain reflect the history of the world's longstanding ambivalence and enduring controversy regarding cannabis use. Unfortunately, this lack of resolution has likely contributed to (a) lax attitudes toward use of cannabis increasing the probability of use and misuse; (b) reluctance of the public, scientists, and intervention specialists to consider cannabis a significant drug of abuse which may impede treatment seeking and the allocation of resources for development of effective treatment services; (c) overly severe penal consequences for possession and use of cannabis; and (d) the delay of science directed toward exploration of the potential of cannabis and/or its active compounds for treatment of physical and psychiatric disorders (2). Advances in our understanding of the addictive nature of cannabis and the mechanisms of its active compounds (to be discussed below) have provided a much clearer picture of cannabis' potential for harm, leading to a renewed emphasis on educating the public about its consequences, while continuing to explore the therapeutic potential of its chemical components. Continued debate over appropriate legal status and policy related to cannabis use will likely continue into the foreseeable future.

EPIDEMIOLOGY

Prevalence of Cannabis Use

The National Survey on Drug Use and Health (3) indicates that cannabis is the most commonly used illicit substance in the United States, with an estimated 41% of U.S. persons aged 12 and older having used it at least once in their lifetime, 10% having used it at least once in the past year, 6% having used it at least once in the past month, and approximately 2%

reported having using cannabis almost every day. These rates are similar to those seen in other developed countries, with approximately 34% of Australians and 20% of Europeans reporting lifetime use of cannabis (4). Among developing countries, use rates also appear to be increasing. Globally, an estimated 166 million people (4%) had used cannabis as of 2006 (5).

Males are more likely than females to use cannabis, with 45% versus 36% reporting lifetime use and 8% versus 4% reporting past month use (3). Use is most common among those 18 to 25 years old, with 28% reporting past-year use. Data from the Monitoring the Future Study, a survey of adolescents in the United States, indicate that 29% of 10th graders and 37% of 12th graders report having used cannabis in the past year (5). In the United States an estimated 7000 to 8000 individuals start using cannabis each day with the highest rates of initiation among those 12 to 25 years old (6). In the last decade, the risk of initiation has increased for 12 to 17 year olds, while remaining stable for those 18 years and older.

Among ethnic groups, those who identify themselves as being multiracial (two or more races) have the highest rates of use in the past year and past month, followed by African Americans, Whites, and Hispanics, respectively. Interestingly, rates of past-year and -month use among 18- to 25-year-old African Americans are lower than those of Whites, but among those 26 years and older rates are higher among African Americans, accounting for the overall disparity in use (7).

Prevalence of Cannabis Use Disorders

A review of several surveys from multiple countries estimated rates of lifetime cannabis dependence at 1% to 4% (4). The rate of abuse or dependence in the past year among those 12 years and over in the United States has remained close to 2% over the past 5 years (3), with the rate of cannabis dependence alone being 1%. The National Epidemiologic Survey on Alcohol and Related Conditions (NESARC) study observed prevalence rates of lifetime and 12-month CUD of 8.5% and 1.5%, respectively (8). Although this rate of cannabis dependence may seem a minimal percentage of the population, it is more than double the dependence rate for any other illicit drug. The high prevalence of cannabis dependence reflects the much more widespread use of cannabis relative to other illicit drugs of abuse rather than greater addictive potential.

With regard to potential demographic differences in CUD prevalence rates in the United States, compared to Whites, the risk of abuse and dependence appears to be higher among Native Americans and lower among African Americans, Asian Americans, and Hispanic Americans (8). Individuals in the Western region of the country tend to have higher rates of CUD, but there do not appear to be any differences between urban and rural areas.

Conditional Dependence

When comparing the percentage of persons who ever use a substance that then go on to develop dependence (i.e., conditional dependence), cannabis use is less likely to

lead to dependence than use of most other common illicit drugs. In the United States, approximately 9% of those who try cannabis become dependent, while 17% of those who try cocaine and 23% of those who try heroin develop dependence (6). Although lower in relative terms, the 9% conditional dependence rate observed for cannabis is still alarming given the relatively large number of people who try cannabis compared with the number who try other illicit substances. Risk of dependence is also greater for those who use cannabis more frequently, for younger individuals, for those who initiate cannabis use at an earlier age, and for those who have a family history of substance abuse (4).

Increase in Prevalence

Over the past 10 to 15 years, the prevalence of CUD has increased across adults in the United States despite stabilization of rates of use, while the rates of both use and CUD have increased among adolescents (9). Such increased prevalence of CUD may be a result of several contributing factors. First, analysis of confiscated cannabis suggests that the potency of cannabis available has increased by over 60% during the past decade, which may increase its addictive potential. Second, cannabis use is being initiated at a younger age, which is clearly related to risk of developing CUD. Of note is an observed increase in prevalence of CUD among young adult African American and Hispanic males and African American females (9). The reasons for this increased rate in CUD among minority youth are not clear, but some speculate factors such as (a) deleterious effects of acculturation on Hispanic youth; (b) growing numbers of minority youth attending college where they may experience increased exposure to cannabis use; and (c) environmental and economic factors, such as higher prices and stricter policies related to alternative substances such as tobacco products and alcohol, which may impact minority youth more than Whites.

Increase in Treatment Admissions for CUD

Paralleling the rise in CUD, treatment admissions for a primary CUD have increased both in absolute numbers and as a percentage of total admissions, from 12% in 1996 to 16% in 2007 (10). Cannabis ranks a close third, behind only alcohol (40%) and opiates (18%), among primary substances reported by individuals seeking treatment. The number of adolescents receiving treatment for CUD more than tripled from 1992 to 2002, and approximately 50% of all adolescents in substance abuse treatment report cannabis as their primary substance (Fig. 15.1).

This increase may reflect a number of factors. First, the growing number of individuals experiencing CUD simply may increase the demand for treatment, although the increase in admissions far exceeds the magnitude of the increase in prevalence of CUD. Second, it may be that, as more cannabis-specific treatments become available, the “acceptability” of seeking and providing treatment for cannabis may have increased, resulting in more individuals presenting for treatment. More generally, raised awareness of cannabis’ addictive potential may have increased the probability that users or

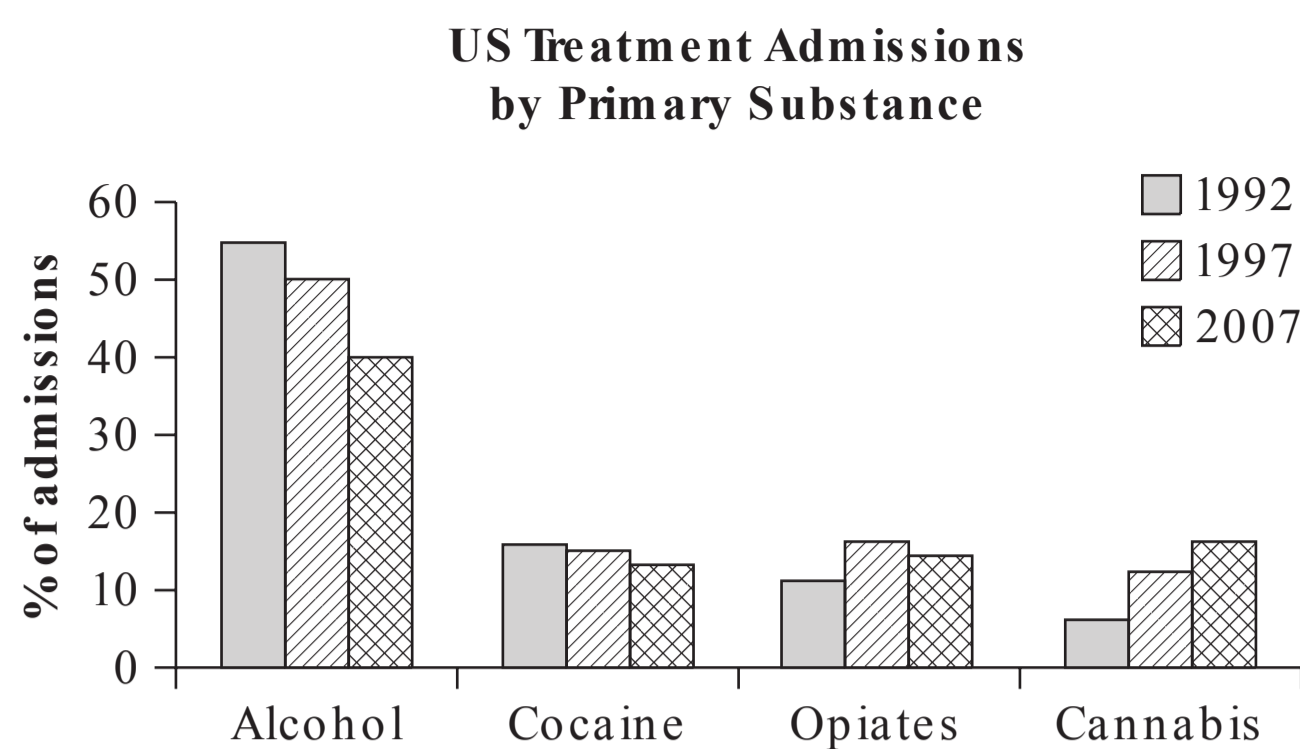

Figure 15.1. The relative increase in treatment seeking for cannabis compared with other substances over the past 15 years. (Data from SAMHSA. *Treatment Episode Data Set (TEDS) 1995–2007: National Admissions to Substance Abuse Treatment Services*. Rockville, MD: US Department of Health and Human Services; 2008.)

treatment referral sources consider the possibility that cannabis use is causing substantial problems that warrant intervention; this is most likely true among adolescents and young adults, who make up over 40% of admissions for CUD. Another factor likely contributing to the overall increase in treatment admissions is the recent advent of drug courts and other initiatives that encourage referral to treatment over incarceration for first-time or small-quantity offenders in the criminal justice system. Nonetheless, the percentage of individuals with a CUD who seek treatment remains low. Only an estimated 9.8% of individuals with a lifetime cannabis abuse diagnosis and 34.7% of those with a lifetime cannabis dependence diagnosis have ever received treatment (8).

ADMINISTRATION AND PHENOMENOLOGY

Cannabis use is associated with a myriad of behavioral, physiologic, and cognitive effects. This section reviews methods of cannabis administration and subsequent acute and chronic effects, with an emphasis placed on effects that are most likely to cause clinical concern. More detailed review of behavioral and cognitive consequences of cannabis is provided in the section “Nonpsychiatric Health Effects of Cannabis.” Tolerance and withdrawal, common features of substance abuse and dependence, are also briefly discussed.

Cultivated cannabis is sold in several different preparations that encompass a range of potency (% THC concentration). The most commonly used form of cannabis is the dried plant material which can be subdivided into preparations that include whole-plant material and those that only contain the unfertilized flowers of the female plant (often referred to as *sinsemilla*). Whole-plant cannabis typically ranges in potency from 1% to 5% THC (v/v), and *sinsemilla* typically ranges from 7% to 15% THC (v/v). Hashish refers to the resin of the cannabis plant, which typically contains 10% to 20% THC (v/v). Hash oil is derived from concentrated resin extract and usually contains approximately 20% THC (v/v), but may reach as high as 60% THC (v/v). During the past few decades

a steady increase in the potency of seized cannabis has been observed with mean % THC concentration (v/v) increasing from 3.4% in 1990 to 8.5% in 2008, but there has been little change in the range of potency encountered. Preference for type of cannabis preparation and method of smoking tends to vary by geographic region.

In most instances of acute cannabis use, the plant material is burned and the smoke emitted from the cannabis is inhaled. Methods of smoking cannabis are varied and include, but are not limited to, use of pipes, water pipes (bongs or hookahs), cigarette paper (joints), and the paper from hollowed-out cigars (blunts). Cannabis is also sometimes ingested orally, most often by dissolving cannabis or concentrated by-products of the cannabis plant into food (typically baked goods). More recently, devices have been developed in which cannabis is “vaporized.” Vaporization involves heating the plant material at a temperature high enough to release psychoactive cannabinoids for inhalation, but low enough that combustion of the plant material does not occur. The bioavailability of THC and the time course of intoxication are similar when cannabis is smoked and vaporized. Following these routes of administration, THC bioavailability is approximately 18% and cannabis intoxication typically occurs within 1 minute, reaches peak in 15 to 30 minutes, and persists for approximately 4 hours. Following oral ingestion, THC bioavailability is approximately 6% and intoxication occurs approximately 30 minutes after administration, peaks in 2 to 3 hours, and persists for 6 hours or longer.

There are several reliable effects of acute cannabis use. Subjectively, the user feels a euphoric effect or “high” that is typically characterized by a sense of relaxation or drowsiness and an increased propensity for laughter. Sense of perception is also affected such that time seems to slow down and many report an increased appreciation for music and other mediums of art. Potentially related to the latter effect, cannabis users tend to prefer engaging in nonverbal social activities (watching a movie or listening to music) while under the influence of cannabis. Feelings of anxiety, paranoia, fear, or panic may also be experienced. These effects most often occur in less experienced users or following use of higher than usual doses. In rare cases, usually involving particularly high doses, users may experience hallucinations. These effects are not life threatening, dissipate with time, and may be reduced with comfort and reassurance.

Acute administration of cannabis produces several reliable physiologic effects. The mouth becomes dry and appetite is stimulated which typically results in an increase in the consumption of food and drink, particularly high-calorie products. At low-to moderate doses, cannabis typically has antiemetic effects (reduces nausea), but can induce nausea or vomiting at higher doses or among less experienced users.

Acute cannabis use has a broad range of effects on cardiovascular function. Specifically, cannabis administration is associated with a significant (20% to 100%) increase in resting heart rate, slight increase in supine blood pressure, and increased orthostatic hypotension (dizziness or lightheadedness that results from a sudden drop in blood pressure after

TABLE 15.1 Cannabis withdrawal: signs and symptoms

- Irritability or anger
- Nervousness or anxiety
- Sleep difficulty (insomnia)—may include disturbing or strange dreams
- Decreased appetite or weight loss
- Restlessness
- Depressed mood
- Physical discomfort or symptoms (e.g., headache, shakiness/tremors, sweating, stomach pain, and chills)

Note: Cannabis withdrawal is not designated in the *DSM-IV* but recent clinical research indicates that many chronic cannabis users experience a significant withdrawal syndrome when they abruptly stop using.

standing) (11). The increased cardiac output also causes a dilation of small blood vessels, which typically results in a redness of the eyes. Case reports have been published suggesting that the acute cardiovascular effects of cannabis can contribute to myocardial infarction or acute cardiac-related fatalities, but research and epidemiologic reports suggest this is a very rare occurrence. Despite the magnitude of the acute effects of cannabis use on cardiovascular function, tolerance develops rapidly and chronic use is not clearly associated with significant cardiovascular health risks.

Controlled laboratory studies in which cannabis or oral THC has been administered indicate that cannabis can impair focused and divided attention, short-term and episodic memory, some types of complex cognitive processing, and some aspects of motor ability (12). The research on this topic is discussed in more detail below. Many of these effects are not highly robust, have not been observed consistently across studies, are dose-related, and are moderated by cannabis use history (tolerance). Generally, moderate doses of cannabis appear to have comparable effects to moderate doses of alcohol (BAC approximately 0.05%) on measures of motor ability, attention, and episodic memory.

Studies of chronic cannabis users suggest that sustained use of cannabis may impair attention, memory, and complex cognitive abilities such as problem solving and mental flexibility (13,14). Consistent with these observations, neuroimaging studies indicate that long-term cannabis users have altered brain function in the prefrontal cortex, cerebellum, and hippocampus. Chronic cannabis users have also exhibited a greater propensity for risky decision making compared with matched controls. Most research suggests that impairments associated with chronic cannabis use are likely reversed following extended abstinence. These issues are discussed in more depth in the section “Nonpsychiatric Health Effects of Cannabis.”

Pharmacologic and behavioral tolerance is fairly reliable and robust across most observed effects of cannabis (15). The severity of behavioral and cognitive impairments resulting from acute cannabis exposure is associated with the use

history of the individual. Note that some have questioned whether tolerance develops to the typical euphoric effects of cannabis, and instead have suggested that increased sensitivity to such effects occurs. However, experimental studies suggest that tolerance likely develops to these euphoric effects of cannabis, and that the perception of increased sensitivity may reflect learning to discriminate and label the effects of cannabis and learning to better titrate the dose to obtain the desired effect. In general, tolerance is lost when cannabis use is discontinued for a significant period of time.

Abrupt cessation of daily or near-daily cannabis use often results in the onset of a cannabis withdrawal syndrome. Common symptoms of withdrawal in humans include: anger and aggression, anxiety, depressed mood, irritability, restlessness, sleep difficulty and strange dreams, decreased appetite, and weight loss (16). Chills, headaches, physical tension, sweating, stomach pain, and general physical discomfort have also been observed during cannabis withdrawal, but are less common. Most symptoms onset within the first 24 hours of cessation, peak within the first week, and last approximately 1 to 2 weeks. Clinical reports and survey studies suggest that cannabis withdrawal contributes to relapse among cannabis users trying to quit. Note that a Cannabis Withdrawal Disorder is not included in the *Diagnostic and Statistical Manual for Mental Disorders, 4th Edition (DSM-IV)*; however, clinical research findings over the past 15 years suggest that withdrawal is likely to be included in the next version of the manual (Table 15.1).

DETERMINANTS OF USE

Pharmacology

The defining pharmacologic constituents of the cannabis plant are a family of compounds referred to as cannabinoids. Ninety different cannabinoids have been identified in the cannabis plant, of which THC has been identified as the primary compound responsible for the psychoactive effects of cannabis. Smoking cannabis results in rapid absorption and

wide distribution of THC throughout the body, including the brain (17). Peak plasma levels of THC are achieved within minutes of smoked cannabis administration, but are delayed to 1 to 2 hours when administered orally. THC is metabolized into 11-hydroxytetrahydrocannabinol (11-OH-THC) and 11-nor-9-carboxy-tetrahydrocannabinol (THC-COOH), which are then excreted through feces and urine. Though the subjective effects of cannabis typically last a few hours, because THC is highly lipophilic it is rapidly absorbed and stored in fatty tissues and the elimination half-life can extend for as long as 4 days. There is no indication that the presence or release of cannabinoids in fat stores results in perceptible intoxication in the user.

Neurobiology

Cannabis exerts its effects on human function primarily through an endogenous cannabinoid receptor system (18). This endogenous system has only recently been discovered, and, to date, two receptor subtypes (CB1 and CB2) and five endogenous ligands (*N*-arachidonylethanolamide [anandamide], 2-arachidonoylglycerol [2-AG], 2-arachidonylglycerylether [noladin ether], *O*-arachinoyl-ethanolamine [virodhamine], and *N*-arachydonyl-dopamine [NADA]) have been identified. The psychoactive and reinforcing effects of cannabis are primarily mediated by activation of the CB1 receptor by THC. The CB1 receptor is a presynaptic G protein-coupled receptor, activation of which inhibits adenylyl cyclase and voltage-dependent Ca²⁺ channels, and activates K⁺ channels and MAP kinase. The CB1 receptor is abundant throughout the CNS, but is expressed in the brain at the highest concentrations in the basal ganglia (reward, learning, motor control), cerebellum (sensorimotor coordination), hippocampus (memory), and cortex (planning, inhibition, higher order cognition). Changes in brain activity following administration of THC are localized mostly in these areas, which are consistent with the behavioral effects of cannabis, and imaging studies indicate that these brain activity changes are THC dose- and time-dependent effects.

A number of studies have been conducted to specifically demonstrate the neurobiological basis for cannabis abuse by focusing on the effects of THC and synthetic CB1 agonists in brain areas and systems associated with reward, reinforcement, and addiction (19). THC appears to enhance dopamine (DA) neuronal firing and synaptic DA levels in the reward pathway of the brain, and also enhances electrical brainstimulation reward. These are hallmark neurobiological features of abused drugs. Concordant with these findings, abrupt cessation of chronic THC exposure increases corticotrophin-releasing factor (CRF), decreases DA, and inhibits electrical brain-stimulation reward in the brain reward pathway. These effects have been linked to the dysphoric effects associated with withdrawal from drugs such as alcohol, opiates, and cocaine, and are thought to contribute significantly to relapse.

The pharmacologic specificity of the rewarding effects of cannabis has also been demonstrated using behavioral research. Models of human drug reward in non human species

include studies in which animals are trained to (1) self-administer THC or similar synthetic cannabinoids, (2) demonstrate drug-seeking behavior by spending time in contexts associated with drug exposure (conditioned place preference), or (3) discriminate the effects of THC from other drugs for rewards. Using these models, researchers have demonstrated that THC and similar synthetic compounds are reliably self-administered, show conditioned place preference, and are discriminated from other drugs of abuse for which the pharmacologic mechanism of action is different than cannabis (e.g., cocaine, ethanol, and ketamine). These effects can be reversed or prevented either in animals pretreated with a specific CB1 receptor antagonist or in knockout mice genetically bred to lack CB1 receptors (20).

While the reinforcing effects of cannabis are primarily mediated by the CB1 receptor, there is also evidence that the opioid receptor system is involved with these effects (21). Specifically, studies with nonhuman animals have shown that administration of the mu-opioid antagonists naloxone and naltrexone can attenuate the reinforcing effects of cannabinoids and precipitate withdrawal in animals chronically exposed to THC. Cannabinoid withdrawal effects have been shown to be attenuated in opioid receptor knockout mice. Chronic administration of THC or other CB1 agonists also has been shown to affect opioid receptor function and expression. However, the effects of naltrexone have not been replicated in humans and the functional significance of cannabis and opioid system interactions on cannabis use in humans is as yet not well understood.

Genetics

Multiple studies have firmly established that genetic influences contribute to the development of CUDs. Heritable factors contributing between 30% and 80% of the total variance in risk of CUD have been reported and genetic linkage studies of CUD and earlier stages of cannabis use (including frequency of use) further establish a genetic link to cannabis use problems (22). That said, multivariate behavioral genetic analyses suggest common genetic and shared environmental influences between cannabis and other types of drug dependence, and genome-wide research suggests a common genetic basis for adolescent substance abuse and conduct problems. These studies provide evidence for not only genetic influences, but also environmental contributions, of either the shared or unique types indicating that CUD and other substance use disorders are likely best understood as being influenced by both genetic and environmental factors, and their interaction.

In the case of adolescent substance abuse, the most common of which is CUD, genetic causality is complex. At least three sources of genotypic risk (substance specific, substance nonspecific, and environmentally modifiable) have been identified. First, substance-specific genes may impact vulnerability to the general addictive potential or the pre- and post-metabolic effects of cannabis. Second, specific genes may increase or decrease genetic vulnerability to externalizing

behavior problems in general, including adolescent experimentation and misuse of psychoactive substances. Third, certain genes may impact an individual's reactivity to environmental variables such as stress, which may influence risk for substance misuse. The contribution of genetics to substance abuse in general and cannabis use and CUD in particular remains a complex issue that will hopefully provide important contributions to the advancement of prevention and intervention in the future.

Environment

A number of different environmental factors contribute to the use and abuse of cannabis. Foremost of these is the availability of cannabis, especially considering its illicit status in most countries. Cannabis is the most widely available illicit drug in the world with a conservatively estimated 88,000 to 110,000 metric tons of cannabis being cultivated to meet market demand each year. One reason for the wide availability of cannabis is that it can be cultivated outdoors in most climates, and the development of specialized equipment and genetic strains of cannabis has also allowed for substantial production using indoor facilities.

Recently there has been a trend toward the adoption of drug enforcement policies by which cannabis remains illegal, but the law is not enforced for possession of small quantities of the drug. The most notable and liberal example of this policy is that adopted by the Netherlands where use of cannabis by adult citizens and sale of limited amounts of cannabis in registered and zoned "coffee shops" is tolerated. There is no evidence that this apparent increased availability of cannabis contributes to greater use among Dutch citizens relative to places where cannabis has not been decriminalized. This may reflect the fact that cannabis remains widely available in countries where cannabis use is not tolerated. For example, in a 2008 survey of school-aged youth in the United States, 39%, 67%, and 84% of students in the 8th, 10th, and 12th grades, respectively, indicated that cannabis was either "fairly easy" or "very easy" to obtain (23). These reports of cannabis availability are substantially higher than availability ratings for other illicit drugs of abuse (e.g., cocaine, LSD, and sedatives) and approached availability ratings for alcohol by the same cohort.

Several other important environmental and demographic factors predict cannabis use and CUD (24,25). The strongest and most consistent population-based predictors of cannabis use are (1) use of other licit or illicit drugs, (2) use of cannabis by others within one's peer network, and (3) use of cannabis by immediate family members. Delinquent/rebellious behavior, unstable or abusive home life, low socioeconomic status, other types of psychopathology, and less perceived risk of harm associated with cannabis are also associated with increased risk of cannabis use and CUD.

EVALUATION

Assessment and evaluation of CUDs should not differ remarkably from that of other substance use disorders. The important clinical features of CUDs are similar to those of

other substances of abuse (26). Guidelines and criteria for CUD diagnoses are found in the *DSM* of the American Psychiatric Association and the International Classification of Diseases (ICD) developed by the World Health Organization. Of note, the *DSM-IV* and ICD-10 use nonspecific criteria to diagnose substance use disorders, and these criteria may not discriminate cases in a manner consistent with the underlying constructs of abuse and dependence, or illustrate differences in severity level or specific symptom profiles. However, these diagnostic guidelines capture all aspects of CUD as well as they do most other substance use disorders, with the exception being that a formal characterization of cannabis withdrawal is omitted from the *DSM-IV*. Recent laboratory and clinical findings strongly suggest that cannabis withdrawal can be a clinically important phenomenon for many cannabis users, and as such should be assessed and evaluated as part of the clinical dependence syndrome (27). Structured or semi-structured *DSM-IV* diagnostic interviews (e.g., SCID or CIDI-SAM) are most appropriate for determining CUD diagnoses.

Screening and Assessment Tools

Cannabis-specific instruments for screening and assessment have been developed, and are slowly developing support as psychometrically valid instruments. The Cannabis Use Disorder Identification Test provides a short method for making a *DSM* diagnosis of abuse or dependence (28). Adult and adolescent versions of the Cannabis Problems Questionnaire provide a general measure of severity of cannabis-related problems (29,30). The Marijuana Screening Inventory (31) provides assessment of cannabis patterns and identification of clinical cases requiring more in-depth assessment and intervention. The Substance Dependence Severity Scale, a five-item scale designed to measure dependence severity across most classes of substances, has been validated for assessing dependence in cannabis users (32). Each of these measures has limitations and all are in need of additional testing to better evaluate and maximize their clinical utility.

Additional measures have been developed for use in treatment evaluation research settings such as the Marijuana Problem Inventory, which provides a summary score of specific cannabis-related consequences reported by the individual (33). This Inventory is sensitive to changes over time so as to be a useful index of response to treatment. A measure of cannabis withdrawal severity, the Marijuana Withdrawal Checklist, has been developed in the context of studies designed to characterize the syndrome (16). This measure can provide a useful list of signs and symptoms of withdrawal as well as an overall severity score, and short and longer versions have been developed. Although the Checklist is sensitive to changes in withdrawal severity over time, it has yet to undergo careful evaluation and psychometric testing to guide its use in clinical settings.

Biologic testing for evidence of recent cannabis use is a very useful screening and treatment outcome tool. In many screening and treatment settings, some individuals have

multiple reasons to be less than forthcoming about their cannabis use. The standard method of biologic screening is detection of THC metabolites in urine specimens. There are multiple methods for reliable and valid urine testing for cannabis. Rapid dipstick-type methods yield results in approximately 2 minutes, can be administered with little to no training, are inexpensive (less than \$10 USD), and provide a qualitative (positive/negative) result. Other urine toxicology methods (e.g., GC–MS and EMIT) can provide quantitative levels of THC metabolites in the urine; These methods either require access to expensive equipment and trained personnel or must be contracted to private companies. Generally, these tests are more expensive than the rapid tests, with the price varying considerably (approximate range \$3 to \$75). It is also important to note that the reliability and validity of urine toxicology testing with any of these methods for screening and evaluation is only adequate if (1) the urine specimen collection is performed under conditions that ensure the integrity of the sample, (2) the testing includes temperature check and measures of concentration and possible contaminants, and (3) the personnel have adequate training to properly interpret the test results. For example, a urine toxicology test may yield a cannabis-positive result for approximately 2 to 30 days following the last use of cannabis depending on the cutoff level used to detect the cannabinoid metabolite, the frequency, amount and duration of cannabis use prior to testing, the activity level of the individual prior to the test, and individual differences in metabolism and rate of elimination of cannabinoids (34). Many misconceptions exist surrounding the validity and interpretation of urinalysis testing for cannabis, and thus it is important that appropriate protocols are developed and adequate training provided prior to implementing a testing program for screening or treatment evaluation.

Other types of biologic screening include use of saliva and hair specimens. The technology for saliva testing is relatively new, and is continuously being improved; however, significant limitations related to the accuracy of the results and the time frame in which they can be obtained relative to cannabis use remain to be resolved. Hair testing for cannabis also has significant limitations related to determination of the time cannabis was used and the potential for false positives caused by passive cannabis smoke. In summary, to date, urine testing remains the gold standard for screening and evaluation of cannabis use. Use of any of these biologic screening methods requires comprehensive knowledge to facilitate appropriate interpretation of toxicology results.

PSYCHOSOCIAL TREATMENT APPROACHES

Systematic research on behavioral treatments for CUD began approximately 20 years ago; however, only a limited number of controlled studies have been conducted. Behavioral treatments developed and validated for the treatment of other disorders have been modified for use with CUD and shown much promise in the treatment of both adults and adolescents. Motivational enhancement therapy (MET), cognitive-behavioral therapy (CBT), contingency management (CM),

and family-based treatments have been carefully evaluated and have consistently demonstrated superior treatment outcomes (reduction of cannabis use) relative to control conditions. The cumulative findings with adults indicate that (1) each of these interventions represents a reasonable and efficacious treatment approach; (2) combining MET and CBT is probably more potent than providing MET alone; and (3) an intervention that integrates all three approaches, MET/CBT/CM, is most likely to produce positive outcomes, especially as measured by rates of abstinence from cannabis. Following is a brief description of each approach as well as a brief review of studies evaluating their effectiveness.

Interventions for Adults

MET, based on the motivational interviewing theory and technique, addresses ambivalence about quitting and seeks to strengthen motivation to change. Therapists use a nonconfrontational, empathic style of counseling to guide the patient toward commitment to and action toward change. MET is typically delivered in 45- to 90-minute individual sessions and usually involves one to four sessions. One session often focuses on providing personalized feedback on use patterns, costs and benefits of using and of quitting, and level of self-efficacy, each of which can be used as a springboard for increasing motivation for change.

CBT focuses on teaching skills relevant to quitting marijuana and to avoiding or coping with other problems that might interfere with good outcomes. Sessions involve analysis of recent cannabis use or cravings, planning for coping with situations that might trigger use or craving, brief trainings on various coping skills, role-playing or other interactive exercises, and practice assignments. CBT is typically delivered in 45- to 60-minute, weekly individual or group counseling sessions; tested CBT interventions have ranged from 6 to 14 sessions.

CM involves the systematic use of positive and negative consequences (reward and punishment) to modify a target behavior (e.g., cannabis use). The type of CM that has been tested with CUD is an abstinence-based incentive intervention adapted from a similar program for cocaine dependence (35). This program provides tangible incentives contingent on cannabis abstinence documented via once- or twice-weekly urine testing. Participants receive vouchers worth a specific monetary value for abstaining from cannabis, which are then exchanged for prosocial retail items or gift cards that can serve as alternative reinforcers to cannabis use.

Efficacy Studies

A series of four trials have demonstrated the efficacy of CBT and MET for adults with CUD (cf. 36). An initial trial showed promising results for a CBT group intervention and a social support group intervention. This trial was followed by a second trial comparing a 14-session group CBT intervention, a 2-session individual MET, and a delayed treatment control (DTC) condition. Days of use, number of uses per day, dependence symptoms, and problems related to use also decreased significantly in the CBT and MET groups compared with the

DTC group, and gains were generally maintained throughout the 16-month follow-up. No significant differences were observed between CBT and MET conditions on any outcome measures, suggesting that brief motivational interventions may be as effective as longer CBT interventions. A similar study showed that a six-session CBT and a one-session MET treatment, both delivered in individual therapy sessions, produced greater rates of abstinence than DTC, but again little difference was observed between the active treatment groups.

The largest efficacy trial ($n = 450$) was a multisite study of MET and CBT comparing nine sessions of combined MET/CBT with two sessions of MET-only and a DTC (33). MET/CBT and MET-only produced better abstinence outcomes than DTC, and MET/CBT engendered significantly greater long-term abstinence and greater reductions in frequency of use compared with MET-only, suggesting better outcomes with the longer CBT intervention. Findings generalized across three sites and were not dependent on ethnicity or gender.

Recognizing that many people overcome substance use problems only after multiple treatment exposures, one research group developed and tested a creative, chronic care model of treatment termed “marijuana dependence treatment PRN” (37). Following an initial four sessions of MET/CBT, participants could choose to attend more sessions as desired over a 28-month period. Unfortunately, enthusiasm for this PRN intervention was limited because only a relatively small percentage of participants (25%) made use of the continuing care sessions, and the PRN group did not show increased abstinence rates compared with a fixed-session comparison condition. Encouraging, however, was the observation that the individuals who did attend numerous PRN sessions showed high levels of abstinence (60%) at follow-up.

Another effort to further enhance outcomes has been to integrate CM with MET/CBT to increase rates of abstinence. An initial 14-week trial compared MET/CBT/CM with MET/CBT only, and a four-session MET intervention (38). Individuals could earn up to \$570 in abstinence-based incentives if they provided all negative urine samples throughout treatment. MET/CBT/CM clearly produced the highest abstinence rate during the 14-week treatment period. In a second trial 90 adults received MET/CBT/CM, MET/CBT, or CM alone (no counseling) (39). MET/CBT/CM and CM alone engendered equivalent abstinence rates during treatment, and both showed greater rates for abstinence than MET/CBT. During the post treatment period, MET/CB/CM evidenced greater abstinence rates than the two comparison treatments, and CM alone and MET/CBT did not differ. These findings highlight the efficacy of adding CM to MET/CBT and the importance of MET/CBT to longer term maintenance of abstinence. A third trial conducted by a different research group replicated these findings in a more diverse and larger treatment sample using a less frequent and lower magnitude reinforcement schedule (40). Again, during treatment MET/CBT/CM and CM alone produced continuous abstinence outcomes that were similar to each other and greater than MET/CBT, and, during the post treatment year,

MET/CBT/CM group sustained overall positive outcomes better than the CM group.

Two additional studies tested CM with probation-referred young adults with CUDs. Those who received a three-session MET plus an *attendance-based* incentive CM program were more likely to complete treatment (64% vs. 39%), attend sessions (2.3 vs. 1.8), and continue with treatment after completing the three sessions than those receiving only MET (41). However, no concomitant positive effects were observed on cannabis use. A second study compared MET/CBT/CM, MET/CBT alone, Drug Counseling (DC) alone, and DC+CM (42). The CM groups received incentives for attendance *and* cannabis abstinence. CM engendered higher rates of attendance, with the best attendance and completion rates observed with the combination MET/CBT/CM. Across conditions MET/CBT engendered higher rates of attendance than DC. The CM treatments engendered greater cannabis abstinence during treatment, with no difference observed between MET/CBT and DC. MET/CBT/CM showed the highest rates of abstinence throughout the post treatment period, but these rates were not significantly different from those in the other treatment groups.

In summary, MET, CBT, and CM each have empirical support for their efficacy, and CM in combination with MET/CBT has demonstrated the greatest potency in outpatient treatment for adult CUD, particularly for engendering longer periods of abstinence. Although these interventions are clearly efficacious, many individuals do not improve substantially or achieve enduring abstinence, even with the most potent treatments. As with all types of substance dependence, there remains a strong need to develop more effective treatments for CUD (Table 15.2).

Interventions for Adolescents

In clinical trials of adolescents with CUD, empirical support for the efficacy of group or individual CBT and family-based treatments has emerged (43). The CBT interventions studied are similar to CBT for adults in scope and duration. Specific forms of family-based treatment that have been tested include Functional Family Therapy (44), Multidimensional Family Therapy (MDFT; 45), Multisystemic Therapy (46), Brief Strategic Family Therapy (BSFT; 47), Family Support Network intervention (48), and Family Behavior Therapy (49). These family-focused interventions take advantage of social networks that are unique to adolescents in an effort to provide a treatment intervention that extends beyond the client–therapist relationship. These generally include efforts to address and alter maladaptive family patterns that contribute to substance use (e.g., parent drug use, parent–child relationships, and parent supervision), make use of resources in the school and criminal justice system, and address problems that might be associated with the child’s peer network. These interventions have demonstrated promise in reducing cannabis and other substance use across multiple clinical trials (43). Note however that, as with the adult CUD treatment studies, reductions in use have typically been modest and effects on

TABLE 15.2 Effective treatments for cannabis abuse or dependence

Adults (18 years and older)
■ Cognitive-behavioral therapy (CBT) (6 to 14 sessions)
■ Motivational enhancement therapy (MET) (1 to 4 sessions)
■ Contingency management (abstinence-based reinforcement)
Adolescents
■ Assertive continuing care
■ Brief Strategic Family Therapy
■ CBT (individual or group)
■ Contingency management
■ Community Reinforcement Approach
■ Functional Family Therapy
■ Family Behavior Therapy
■ MET combined with CBT (5 to 12 sessions)
■ Multidimensional Family Therapy
■ Multisystemic Therapy
Note: These treatments have been manualized and tested in randomized clinical trials.

abstinence rates have been difficult to demonstrate. Below we describe one study that illustrates the strengths and limitations of these outcome findings.

The Cannabis Youth Treatment study included 600 adolescents aged 12 to 18 referred for substance abuse treatment who endorsed at least one criterion for cannabis abuse or dependence and had used cannabis in the previous 90 days (48). Adolescents received one of the following five treatments across four clinical sites: MET/CBT5 (2 individual and 3 group sessions), MET/CBT12 (2 individual and 10 group sessions), MET/CBT12 plus Family Support Network, the Adolescent Community Reinforcement Approach, and MDFT. Significant decreases in drug use and symptoms of dependence were observed following each of the treatments. However, robust between-treatment differences in outcomes were *not* observed, which unfortunately precludes drawing strong conclusions about their efficacy. Although results were promising compared with prior treatment studies, two thirds of the youth continued to experience significant substance-related symptoms. These findings, combined with the similarly modest effects demonstrated in prior studies with the family-focused and individual therapies mentioned above, suggest a need for continued exploration and development of more potent adolescent treatment models and interventions.

As with the interventions for adults, adding CM to “standard” therapies is currently being tested with adolescents with CUD. Although a number of the aforementioned family-based interventions incorporate teaching parents to use behavioral procedures that reflect CM principles, such procedures have not been well specified, isolated, or independently evaluated. The only published randomized trial of a CM-based treatment

focused on cannabis examined an intervention with multiple CM components (50). The intervention included (a) an abstinence-based voucher incentive program of the same schedule and magnitude as that used in adult CUD trials (although incentives were earned only for documented abstinence from *all* substances), (b) a behavioral parenting intervention that focused on the development and implementation of an abstinence-based contract directing parents to provide tangible incentives for drug abstinence and to deliver negative consequences for evidence of continued use, and (c) a fishbowl incentive procedure that reinforced parents for adhering to each aspect of the parent training and CM contract. These CM components were integrated with weekly individual MET/CBT counseling and compared with an intervention that included MET/CBT, weekly educational parent sessions, and an attendance-based incentive program. Both treatments included twice-weekly urine testing with results provided immediately to the parents and the teen.

The MET/CBT/CM group demonstrated greater rates of continuous abstinence during treatment than the comparison intervention, but this effect did not clearly extend to post treatment assessments. Overall, rates of cannabis abstinence in both treatment conditions were relatively high compared with those reported in previous studies suggesting that the comparison condition might also warrant further evaluation to determine its efficacy. The twice-weekly urine testing program received in both treatment conditions, which systematically reported results to parents, was unique to this study and may be an active treatment component in its own right.

A final intervention of note involving adolescents is assertive continuing care (ACC), which was designed to

maintain treatment gains (reduce relapse) achieved during residential treatment (51). This intervention consists of adolescents being assigned a case manager for 90 days after discharge from an inpatient treatment facility. Adolescents were assigned a case manager who made weekly home visits with goals of engaging in other identified services, development of a new social support system involving prosocial activities, and generally reinforcing strategies to maintain abstinence. In a randomized trial comparing ACC to usual continuing care, the ACC intervention was more effective in increasing adolescents' engagement and retention in continuing care and resulted in longer term abstinence from cannabis (51).

In summary, a number of behavior- and family-based interventions appear effective for treating adolescents with CUD. As with adults, combining CM strategies with these interventions may enhance their efficacy. Yet it remains that many youth do not respond to even the most potent interventions tested to date including the multicomponent CM program discussed above. There remains a clear and pressing need for continued treatment development research and testing.

SECONDARY PREVENTION

“Check-up” (CU) interventions have been developed that are designed to reach cannabis users who have not sought treatment but are ambivalent about stopping or do not perceive their use to be a problem that warrants treatment (52). Such interventions have typically involved adaptations of MET approaches. In an initial trial, adult cannabis users responded to advertisements stating that up-to-date information on cannabis use and its effects was available. Those who responded were near-daily cannabis users, and ambivalent about changing their use. They received an assessment followed by either one personalized CU session, one multimedia session (providing information on cannabis and its effects), or a delayed session (choice of CU or multimedia delayed by 7 weeks). CU resulted in greater reductions in cannabis use and associated problems over the course of 12 months than the multimedia condition; however, absolute levels of change were relatively small. A second study sought to enhance outcomes by adding four sessions of MET/CBT following two CU sessions. The six-session intervention successfully engaged participants, but unfortunately did not result in greater reductions in cannabis use. These studies demonstrated that this intervention model attracted a “unique” sample of ambivalent cannabis users who may be ideal candidates for secondary interventions like the CU, but alternative CU models are needed to obtain more robust effects.

A similar CU model was tested with adolescents in grades 9 to 12 who had used cannabis at least nine times in the past month (53). Volunteers recruited with posters and health education lectures were randomized to either a two-session CU intervention or a 3-month delayed treatment condition. CU consisted of a computerized assessment and two 30-minute MET sessions. Teens in both conditions signifi-

cantly reduced their cannabis use over 3 months; however, no significant between-group differences were observed. This study showed that cannabis-using adolescents will volunteer to participate in a cannabis intervention provided at their school, which provides an important opportunity to explore alternative methods for early intervention on cannabis use. Indeed, two other interventions using brief MET/CBT have shown some promise in reducing cannabis use with adolescents outside a treatment setting (54,55).

In summary, a variety of effective psychosocial interventions have been developed to treat CUD in both adults and adolescents. Unfortunately, as with treatment for other substance use disorders, the rates of “success” are modest. Even with MET/CBT/CM, the most highly efficacious treatment for adults, only about half of those who enroll in treatment achieve an initial 2-week period of abstinence, and among those who do, approximately half return to use or relapse within a year (39,40). The treatment outcome data for adolescents paint a similar picture. Clearly, continued development of effective treatments for CUD will be required to better meet the needs of those who experience cannabis use-related problems.

PHARMACOTHERAPY

In an attempt to address the need for more effective treatments, researchers have recently sought to identify medications that could be used in conjunction with psychosocial treatments to improve outcomes for CUD. Use of medications to assist in the treatment of substance use disorders is common for the treatment of other drugs of abuse (e.g., opiates, tobacco, and alcohol). In these instances, the majority of the medications used are those known to either reduce the occurrence or severity of withdrawal symptoms or attenuate the reinforcing effects of a specific substance. Generally, evidence from other substance use disorders suggests that treatment approaches that combine pharmacotherapy and psychosocial therapy can enhance outcomes compared with use of either approach alone.

Laboratory Analog Studies

Multiple controlled laboratory studies with non-treatment-seeking daily cannabis users have been conducted to assess whether medications might have potential for clinical application. Inpatient and outpatient laboratory models have examined medication effects on cannabis withdrawal, the effects of smoked cannabis, and relapse. Here we provide a brief review of this research.

Laboratory studies of bupropion, valproate, nefazodone, clonidine, and naltrexone have not shown robust effects across multiple outcome measures that would suggest potential therapeutic efficacy, and in some cases had effects opposite of those desired (56–60). Positive laboratory findings have been observed with a few other medications. The most promising of these comes from studies targeting cannabis withdrawal with

the oral preparation of THC, dronabinol, a CB1 receptor agonist. In three laboratory studies, dronabinol significantly reduced multiple symptoms of cannabis withdrawal compared with placebo (57,61,62). This effect was dose dependent, and higher doses demonstrated almost complete suppression of withdrawal effects. Dronabinol alone, however, has not been shown to reduce laboratory models of relapse or cannabis self-administration, but did show positive effects when combined with lofexidine in a laboratory model of relapse (61). Lofexidine, an α_2 -adrenergic receptor agonist used to treat opioid withdrawal, significantly reduced ratings of chills, restlessness, and upset stomach, and improved sleep, and reduced the likelihood of relapse during a period of cannabis abstinence compared with placebo (61).

Two studies have evaluated rimonabant, a CB1 receptor partial agonist/antagonist, hypothesizing that it would block the effects of cannabis administration. Indeed in an initial study it reduced the subjective effects of smoked cannabis by approximately 40%, but the subsequent study failed to replicate this finding (63,64). Last, preliminary findings targeting sleep difficulty, a common and significant symptom of cannabis withdrawal, reported that extended-release zolpidem, an approved hypnotic, attenuated abstinence-induced sleep disturbance as measured by polysomnography in a placebo-controlled study (65).

Clinical Trials

Only three controlled clinical trials of medications for CUD have been reported. In one 6-week study, 25 participants were randomly assigned to receive either CBT plus valproate (a mood stabilizer) or CBT plus placebo (66). No effect of valproate was observed on any measures of cannabis use. A 13-week randomized trial ($n = 106$) compared individual counseling combined with one of the two antidepressant medications, nefazodone and sustained-release bupropion, or placebo (67). No effect of either medication was observed on measures of cannabis use, or on self-reported measures of cannabis withdrawal, and more than half of the participants dropped out prior to treatment completion. Last, a 12-week trial ($n = 50$) compared MET combined with either buspirone, an anti anxiety medication, or placebo (68). Non-significant positive findings were observed for buspirone on the number of THC-positive urine specimens and shorter time to first THC-negative urine specimen; however, again less than half of those enrolled completed the study. Buspirone appeared to be fairly well tolerated, but participants reported a higher frequency of dizziness, dry mouth, flushing/sweating, and cold-like symptoms.

One open-label clinical report evaluating dronabinol in two patients who had previously failed multiple quit attempts observed a period of sustained abstinence associated with dronabinol (initial dose, 30 mg/day) treatment (69). One patient was tapered off dronabinol without relapse, the other required long-term dronabinol maintenance (5 mg two to three times daily), and both received adjunct medications.

In summary, no medications have been approved for the treatment of CUD, and of the few published, controlled clinical trials, none have reported encouraging results. That said, several medications have been identified that hold some promise. Dronabinol (oral THC) appears to be the best candidate medication, and follows the agonist (substitution) therapy model that has been successful in the treatment of opioid (methadone) and nicotine (patch and gum) dependence. Controlled clinical trials are needed to determine the efficacy of dronabinol (alone and in combination with lofexidine) for treating CUDs. The attenuation of sleep dysfunction with zolpidem during the initial period of abstinence from cannabis is also positive, but additional research is needed to determine whether or not improved sleep translates to less overall withdrawal severity and reduced relapse in clinical samples.

Last, preclinical studies suggest that compounds other than THC that directly affect CB1 receptor function or endogenous endocannabinoid levels (e.g., the FAAH inhibitor URB597) may have potential as effective pharmacotherapies for CUD (70). Note, however, the only one of these compounds previously approved for clinical use, the CB1 receptor antagonist rimonabant, was removed from several markets following approval as a weight loss medication, and failed to be approved in the United States, due to the occurrence of significant psychiatric adverse events. Medicinal chemistry focusing on the development of a newer generation of CB1 receptor partial agonists, antagonists, or endocannabinoid modulators holds promise for medication development for CUD.

COMORBIDITY

Chronic cannabis use has generally been associated with impaired psychological functioning, and those with a CUD are at increased risk for concurrent substance use and nonsubstance use psychiatric disorders. The relation between cannabis use and psychotic disorders has engendered particular interest among basic and clinical scientists, with rekindled research and speculation prompted by the discovery of the endocannabinoid system. In this section, we review the literature on comorbidity of cannabis use and misuse and other psychiatric disorders with special attention to the question of causality. That is, does cannabis misuse lead to other psychopathology or do existing psychiatric problems increase risk for cannabis use or CUD?

CUD and Other Drug Use Disorders

Large general population studies indicate that individuals with past-year or lifetime CUD diagnoses have high rates of alcohol abuse (18%), alcohol dependence (40%), and nicotine dependence (53%) (e.g., 8). These rates of comorbid substance use problems are clearly much greater than observed among those without a CUD. Rates of substance abuse other than alcohol or nicotine are also likely to be

greater among cannabis abusers, but have not been estimated independently.

Among those seeking treatment for a CUD, other types of substance use are also common. For example, data from the U.S. Treatment Episode Data Set (TEDS) indicate that among adults seeking treatment in 2007 who reported cannabis to be their primary drug of concern, 74% reported problematic use of a secondary or tertiary substance: alcohol (40%), cocaine (12%), methamphetamine (6%), and heroin or other opiates (2%) (10). Among those younger than 18 years, 61% reported problematic use of a secondary substance: alcohol (48%), cocaine (4%), methamphetamine (2%), and heroin or other opiates (2%).

Prevalence of having a secondary substance use disorder diagnosis of abuse or dependence appears to be much lower than the rates of comorbid substance use listed above (10). For adults seeking treatment for a primary CUD, rates of abuse or dependence are 5% for alcohol, 7.5% for cocaine, 1% for opiates, and 7% for other substances. Most clinical trials for primary CUD have excluded participants dependent on other substances leaving few other sources to assess prevalence of comorbid secondary substance use disorders among treatment seekers. One early study, however, reported that among adults responding to advertisements offering assessment and treatment services for cannabis users, 19% reported past 90-day problematic use of any other substance, and an additional 40% reported a lifetime history of other substance abuse or dependence (71).

The TEDS data for adolescents with primary CUD indicate 2007 prevalence rates for secondary substance use disorders at 2.5% for alcohol, 5% for cocaine, 0.3% for opiates, and 5% for other substances (10). Reports from clinical trials suggest much higher rates of comorbidity among adolescents. For example, the large multisite Cannabis Youth Treatment study reported 37% of participants had an alcohol use disorder and 12% had some other substance use disorder. Differences in the prevalence of other substance use disorders across reports are likely caused by the inclusion/exclusion criteria of the various studies. For example, most clinical studies have included adolescents with cannabis abuse or dependence symptoms regardless of whether they considered cannabis their primary substance or not, while the TEDS data on secondary substance use disorders reflect only those who indicated cannabis as their primary substance.

Cannabis is also the most common, illegal secondary substance used by those seeking treatment for other types of substance dependence. Among those in treatment for primary cocaine use disorders, 35% report cannabis as a secondary or tertiary substance use problem; among primary alcohol use disorder patients, 28% report cannabis as a secondary or tertiary problem substance; and among primary heroin abusers, 16% report cannabis as a secondary or tertiary problem (10). Note that the rate of cannabis use among heroin abusers is likely much higher than the 16% who reported cannabis as a problem substance in the TEDS. These patients report high rates of alcohol and cocaine problems, and unfortunately the TEDS limits assessment to only secondary

and tertiary problem substances. Thus, the cannabis use of many of the heroin abusers may not be captured in these TEDS data because these patients are likely to use cocaine and alcohol as well and likely consider them more problematic than cannabis. Clinical trials attest to this as 50% to 85% of those seeking treatment for heroin/opiates (or cocaine) typically report regular cannabis use (72).

In summary, CUDs are experienced as significant primary problems warranting treatment intervention both with and without concurrent use or abuse of other substances. CUDs are also often observed as a secondary problem among those with a primary diagnosis of other types of substance dependence. Although such observations may appear obvious, we highlight this information here because historically many have perceived cannabis abuse to only exist as a secondary problem, typically occurring among those with other substance dependence disorders. Actually, cannabis use problems are more ubiquitous than originally believed.

Causality and the Gateway Effect

Cannabis has been designated a “gateway” drug because its use almost always precedes use of “harder” drugs such as cocaine and heroin, and frequent cannabis users have much greater probability than nonusers of using heroin or cocaine in their lifetime. Such data, in addition to the high comorbidity rates of CUD and other substance use disorders, raise the question of whether cannabis use or development of a CUD is causally related to misuse of other substances. Explanatory hypotheses for this relationship include: (a) the neurobiological effects of cannabis increase sensitivity to the reinforcing effects of other substances, (b) cannabis use increases opportunity for other substance use through increased contact with persons who use or sell other substances, and (c) common characteristics (e.g., externalizing psychopathology, neurobiological sensitivity, or environmental risk factors) exist for use of cannabis and other substances. It is likely that all of these factors contribute to a link between cannabis and other substance use. Longitudinal and genetic studies demonstrate that genes and environmental factors, and common pre-existing risk factors account for much, but not all of the relations between early initiation of cannabis use and future other substance use, supporting potential influences consistent with all three of these hypotheses (73). Thus, cannabis use does frequently precede and statistically predict use and abuse of other illicit substances, but so do tobacco use and alcohol use. More evidence is emerging that the order of initiation of substance use can vary depending on culture and geography, suggesting that substance availability may drive these relations. Cannabis use may affect neurobiological reward systems modifying effects of future substance use such that continued use of a “new” substance may be more likely. Or cannabis’ acute or chronic effects on cognitive functioning may impact decision making such that one is more likely to try a new substance. Note, however, that these possibilities are also likely true of most substances that are abused. Whether or not one can designate these relations as “causal” because

the cannabis use occurs before the other substance use is debatable.

CUD and Other Psychiatric Disorders

Cross-sectional and longitudinal studies have reported a clear association between chronic cannabis use and impaired psychological functioning (14). In particular, cannabis use has been associated with poorer life satisfaction, increased mental health treatment and hospitalization, higher rates of depression, anxiety disorders, suicide attempts, and conduct disorder.

Large general population studies also indicate that individuals with past-year or lifetime diagnoses of cannabis abuse or dependence diagnoses also have high rates of concurrent psychiatric disorders other than substance use disorders (8). Major Depressive Disorder (11%), any anxiety disorder (24%), and Bipolar I disorder (13%) appear to be the most prevalent *DSM-IV* Axis I disorders, and Antisocial (30%), Obsessive Compulsive (19%), and Paranoid (18%) are the most prevalent Axis II personality disorders among those with a past-year diagnosis of a CUD. As with other substance use disorders, the prevalence rates of these other psychiatric disorders are greater among those with CUD than those without. Clinical trials for adult cannabis treatment seekers support the observations from general population observations. Symptom Checklist 90, Brief Symptom Inventory, and Beck Depression Inventory assessments collected from these clinical samples indicate that the great majority would meet criteria for various psychiatric diagnoses, but *DSM* or *ICD* diagnoses were not obtained in most studies.

More comprehensive data are available from clinical trials assessing concurrent psychiatric disorders among adolescents enrolled in treatment for CUD. In the Cannabis Youth Treatment study, 33% of teens enrolled in treatment reported internalizing disorders (anxiety, depression, PTSD) and 61% externalizing disorders (Conduct Disorder and ADHD). Other clinical studies have reported similarly high rates of internalizing and externalizing disorders in the adolescent treatment population (74).

Cannabis is also the most common type of illicit drug used among individuals with schizophrenia and other chronic psychotic disorders, and its prevalence in this population may be even greater than those with other psychiatric diagnoses (75). Moreover, cannabis has been linked to cases of acute psychosis, typical symptoms including some combination of hallucinations, delusions, confusion, amnesia, paranoia, hypomania, and labile mood. Prevalence data on acute psychosis are limited and range from it being very rare to occurring in over 15% of cannabis users (cf. 76).

Causality and Other Psychiatric Disorders

Self-medication is a common explanatory hypothesis for the etiology of substance use disorders, including CUD, that is, persons may use the substance to self-medicate existing psychiatric disorders and symptoms. Persons with certain psychological problems or those in current mood states may

experience the initial direct effects of cannabis as either more or less reinforcing (e.g., may feel temporary relief from depressed mood or may cause increased anxious feeling in formal social situations). However, evidence from longitudinal studies particularly for the relation between cannabis and mood disorders has not supported a causal self-medication hypothesis (77,78). Whether mental health problems contribute to development of CUD, or the converse, remains equivocal. Controlling for risk factors common to both mental health and cannabis problems appears to reduce but not eliminate the positive associations between the two. Some data suggest that age of onset may relate to the direction of influence. Early onset of cannabis use is a strong predictor of later mental health problems, but such early onset also may be predicted from prior mental health problems. Psychiatric problems and early cannabis use appear to share a pathway predicted by socioeconomic disadvantage and child behavior problems; moreover, cannabis use may contribute directly to poor psychosocial outcomes.

The types of mental health problems that remain associated with cannabis use in longitudinal studies, once common etiologic factors are adequately controlled for, are primarily externalizing problems such as conduct/antisocial disorder or other drug dependence disorders. The notion that cannabis is used to “medicate” externalizing disorders is not highly tenable. Rather, the conceptualization of cannabis use and abuse as part of an externalizing syndrome that includes nondrug externalizing disorders has gathered increasing attention and support (79). In summary, cannabis use, particularly early initiation of use, can be considered a risk factor for nonpsychotic mental health problems and, as such, is a reasonable target for prevention and intervention of psychological problems.

Whether or not cannabis use can induce acute psychosis or contribute to the development of more chronic psychotic disorders (e.g., schizophrenia) also remains controversial, although data supporting such a causal relationship are emerging. Increased understanding of the actions of cannabis on the central nervous system and the functioning of the endocannabinoid system has generated increased study and concern about cannabis and its contribution to severe psychiatric disorder.

Suggestive evidence for a causal relationship between cannabis use and *acute* psychosis is primarily of two types. Clinical case reports frequent the literature with examples of patients with psychotic symptoms whose onset closely follows ingestion of cannabis; whose symptoms remit within days or, at most, a few weeks of abstinence from cannabis; and many with no previous psychiatric history. Second, experimental studies have demonstrated that cannabis administration (albeit intravenous dosing of THC) can produce psychotic-type symptoms in those without risk factors for psychotic disorders (80). Nonetheless, the literature linking cannabis use and acute psychosis includes only uncontrolled studies; thus, other causes for the psychosis cannot be ruled out. One could reasonably conclude that high doses of cannabis can precipitate psychosis in some individuals, but whether or not

a predisposition to psychotic illness or some other baseline factor is necessary for acute psychosis to occur remains unknown.

Literature reviews relying on findings from longitudinal studies and laboratory studies have posed similar conclusions regarding the relationship of cannabis use and *chronic* psychotic disorders (77,78,80). The term “component cause” has been increasingly used to describe how cannabis contributes to causing psychosis in the presence of other risk factors. Moreover, human and nonhuman basic research has established biologic plausibility related to the impact of cannabis on the DA system and the possible psychotogenic role of the endogenous cannabinoid system. Suggestive but strong evidence has emerged that cannabis use can induce a psychotic disorder in at least a subpopulation of those who have other risk factors for developing psychotic symptoms or disorders. Epidemiologic and longitudinal designs can never eliminate all confounding factors and measurement issues, but causality, defined as an increased risk for experiencing a psychotic disorder, appears to be an appropriate term to use given the current data. This said, one must be cognizant of the degree of risk. Most regular cannabis users do not experience psychotic symptoms or develop psychotic disorders, and cannabis cannot be designated the cause of most cases of psychosis. Estimates of attributable risk suggest that cannabis may play a role in approximately 1 of 10 cases (78).

Cannabis Use and the Course of Psychiatric Disorder

How cannabis use may influence the course of psychiatric disorders has obvious implications for treatment. Significant associations between drug use in general and increased use of treatment resources (hospitalizations and emergency room visits) and poor treatment compliance have been reported in general psychiatric patients. Unfortunately, the impact of cannabis use in this population has not been isolated from the impact of other types of drugs. Cannabis use has been associated with increased rates of recurrent and more severe psychiatric symptomatology and relapse among schizophrenics, but again, effects of other drug use cannot be completely ruled out in these studies. Cannabis use may also result in a misdiagnosis of cannabis-related psychosis resulting in a concomitant delay of a diagnosis and treatment of schizophrenia. As with the data on cannabis use and the development of psychotic disorders, a strong association exists between cannabis use and a negative outcome in schizophrenics. Thus, cannabis use can be considered a risk factor for schizophrenia and a predictor of poor outcome in schizophrenic patients, but its role as an etiologic factor remains uncertain.

NONPSYCHIATRIC HEALTH EFFECTS OF CANNABIS

Cannabis use impacts multiple aspects of normal human functioning including the cardiovascular, immune, neuromuscular, ocular, reproductive, and respiratory systems, appetite, and cognition/perception. Cannabinoid receptors

(CB1 and CB2), ubiquitous in the central nervous system and the periphery, suggest a broad functional role of endogenous cannabinoids in human functioning as well as possible influences of exogenous cannabinoids such as cannabis. As discussed earlier, this potential for pros and cons of cannabis use has engendered lively discussion and controversy for many years. Here we will briefly comment on the literature addressing the impact of cannabis consumption on a number of physiologic systems.

Respiratory System

Perhaps the most significant health effects of cannabis involve the respiratory system (cf. 81 for review). Chronic cannabis smoking has the potential for respiratory consequences comparable to tobacco cigarette smoking. Of concern, a large subpopulation of cannabis users smokes a combination of cannabis and tobacco in the form of blunts or cones and almost half of daily cannabis users also smoke tobacco concurring obvious additional risk for consequences on the respiratory system (3). The smoke of cannabis and tobacco contains similar respiratory toxic chemicals. Cannabis smoke can contain up to 50% more carcinogens and results in substantially greater tar deposits in the lungs than filtered tobacco cigarettes. Cannabis users smoke unfiltered material, inhale the smoke more deeply, and hold the smoke longer in their lungs than tobacco smokers, which likely contributes to the resultant high level of toxins entering the lungs.

The most significant acute effect of smoking cannabis is its action as a bronchodilator, which increases vulnerability to the smoke by decreasing airway resistance and increasing specific airway conductance. Cannabis smoking also increases absorption of carbon monoxide, resulting in elevated levels of blood carboxyhemoglobin (COHb). Increased COHb leads to reduced oxygen in the blood and impairment in oxygen release from hemoglobin that can stress a number of organs including the heart. Other short-term aspects of respiration such as breathing rate, breath depth, CO₂ production, respiratory exchange ratio, and arterial blood gases appear to not be significantly affected by cannabis smoking.

Chronic cannabis smoking increases the likelihood of outpatient visits due to respiratory illness and cannabis smokers exhibit respiratory symptoms of bronchitis at comparable rates to tobacco smokers. Airway obstruction and symptoms of chronic cough, sputum production, shortness of breath, and wheezing characterize chronic bronchitis. The cause of these symptoms, airway inflammation and tissue damage resulting in increased fluid production, cellular abnormalities, and reduced alveolar permeability, occurs before cough or wheezing begin. Cannabis smokers have substantially higher bronchitis index scores than non-smokers, and comparable scores to tobacco smokers, even at young ages and after only short histories of regular cannabis use (81).

Investigations of chronic obstructive pulmonary disease (COPD) in chronic cannabis smokers have been inconclusive. Cannabis smokers exhibit almost identical degrees of

histopathologic and molecular abnormalities associated with progression to COPD as seen in tobacco smokers but large-scale studies of COPD in chronic users do not clearly show increased risk (82).

The functional significance of cannabis smoking on the respiratory system should be taken seriously. Chronic cannabis smoking is clearly associated with similar processes and patterns of disease that lead to aerodigestive cancers among tobacco smokers, although a causal link to cannabis has not been established definitively (see the next section). Cannabis smokers tend to smoke significantly less material per day than tobacco smokers, which may slow down its comparative impact on the lungs. Individuals who began smoking cannabis in the late 1960s are now approaching the ages that are likely to be associated with aerodigestive cancers; hence, future epidemiologic studies should clarify better the risk of cancer associated with chronic cannabis use. Chronic bronchitis can be moderately debilitating and increases the risk of additional infections. Because cannabis may suppress immune system function, recurrent bronchitis may further increase the risk of opportunistic respiratory infections such as pneumonia and aspergillosis. This may be of particular concern for those individuals with already compromised immune functions such as cancer and AIDS patients.

Immune System and Cancer

The high carcinogen levels observed in cannabis smoke lead to concern of increased risk of multiple types of cancers. Chronic cannabis smoking appears to compromise the immune system, with most available information focused on its impact on the lungs as described above (82). The immunosuppressive effect occurs in a variety of immune cells including killer cells, T cells, and macrophages. Compared with tobacco smokers and nonsmokers, pulmonary alveolar macrophages of chronic cannabis smokers exhibit a reduced ability to kill tumor cells and many microorganisms, including fungi and bacteria. Cannabis smoking also appears to impair phagocytosis and cytokine function of these macrophages. Additional concern has been raised that THC may have direct cancer-fostering properties related to acceleration or increased replication of viruses related to certain cancers (e.g., herpes virus), cancer cell proliferation, and tumor growth. Note that data and arguments for potential anti cancer impact of cannabis have also appeared in the literature. For example, cannabidiol, a nonpsychoactive constituent of cannabis, has demonstrated tumor-reducing effects in rodents (83).

The functional consequences (development of cancers or other immunosuppressive-related diseases) of cannabis' effects on the suppression of the immune system in humans are not well understood. Epidemiologic, cohort, and case control studies have yielded mixed findings regarding associated risk with head and neck, lung, oropharyngeal, and testicular cancer (cf. 84,85). Nonetheless, clinical findings suggest that such effects warrant some concern. Chronic

cannabis smoking is associated with increased bronchitis and other respiratory illnesses (see the section 'Respiratory System'). Chronic use may also increase risk of exposure to infectious organisms, as cannabis and tobacco plants are often contaminated with a variety of fungi and molds including aspergillus (86). Lung illnesses in cannabis smokers have been attributed to fungal infection. Decreased immune system response could increase the vulnerability and risk of developing these respiratory illnesses and lung diseases. A better understanding of the functional significance of cannabis' effects on the immune system is imperative as attempts are made to develop safe and effective models for the medical use of cannabis and cannabinoids.

Reproductive System and Perinatal Effects

Cannabis smoking can affect some female and male reproductive hormones, but the functional significance of these effects is unclear. Unfortunately, research examining the effects of cannabis use on reproductive function in women or men has been sparse.

Pregnant women who use cannabis expose the fetus to THC, as it is known to cross the placenta. Ten to 20% of women may use cannabis during pregnancy, yet studying cannabis use during pregnancy has proven difficult, as pregnant users generally have many additional risk factors for adverse effects such as tobacco smoking, alcohol use, other illicit drug use, poorer nutrition, and lower socioeconomic status, and the validity of self-reports of cannabis use in this population is suspect. Risk of major congenital anomalies does not appear to be increased by cannabis use in pregnant women; however, some reports suggest there may be some risk associated with developing minor anomalies related to the visual system, but such data are not robust (87). Studies have reported mixed findings regarding the effects of cannabis use during pregnancy on birth weight, length, and duration of gestation (88).

Cognitive and behavioral effects of prenatal exposure to cannabis are perhaps best gleaned from the Ottawa Prenatal Prospective Study (OPPS) that has produced multiple reports over the past 20 years (89). This study collected birth data on 700 women and has periodically assessed the children of a subsample of 150 to 200 comparing those who used cannabis during pregnancy with controls who did not. Adverse effects of prenatal cannabis use were observed during the first month, with important signs including increased tremors, decreased visual habituation, exaggerated startle, and increased hand-to-mouth behavior. However, at 1, 2, and 3 years of age, no cannabis-related effects were observed. Age 4 assessments revealed performance decrements on verbal and memory tasks, which are similar findings to those reported in a separate study of 3 year olds with prenatal exposure to cannabis (90).

The OPPS group suggests that these "delayed" effects of prenatal cannabis might reflect difficulty in detection of subtle effects on complex processes in young children. However, assessment at 5 and 6 years did not reveal these

same deficits, but did show deficits in sustained attention in the 6 year olds. At 9 and 12 years deficits were observed in higher order or executive functioning involving visual analysis, problem solving, hypothesis testing, and impulse control. Continued deficits were observed at ages 14 to 16 years on tests of visual memory, analysis, and integration, which are similar to deficits in chronic adolescent and adult cannabis users (see the section “Brain Function and Cognitive Performance”). Another research group has observed similar effects at age 10 with these youth showing increased hyperactivity, impulsivity, inattention, and delinquency (91).

In summary, the effects of prenatal cannabis use on cognitive functioning appear subtle, and determining causality is difficult since genetic predispositions and multiple environmental factors cannot be ruled out. The functional importance of the observed deficits is also unclear. The types of impairment observed could impact behavioral and cognitive performance of various tasks. Such data indicate that concern is warranted regarding prenatal cannabis use and its effects on human offspring.

Cardiovascular System

Most research examining cannabis and the cardiovascular system has focused on acute effects that occur when cannabis is ingested, and suggest a limited cardiovascular health impact. The primary acute effect is tachycardia with an observed dose-dependent increase in heart rate that diminishes when tolerance develops (92). Cannabis can also produce small increases in supine blood pressure and impair vascular reflexes. Note that the inhalation of carbon monoxide associated with smoking cannabis and subsequent increase in COHb in combination with tachycardia increases the work required of the heart.

Although these findings show clear changes in cardiovascular functioning due to cannabis use, the effects have not been associated with short- or long-term cardiovascular or cerebrovascular injury or disease. Case reports suggest that regular cannabis smoking may increase risk for some potentially serious cardiovascular events or disorders, but no controlled studies support these reports. For most healthy young cannabis smokers, the stress to the heart does not appear clinically detrimental. However, for individuals with cardiovascular or cerebrovascular disease, the additional cardiac stress may increase the risk for chest pain, heart attack, or stroke. Additional research is needed to elucidate the effects of chronic cannabis use on cardiovascular health, including interactions with other risk factors.

Brain Function and Cognitive Performance

A large literature has accumulated examining the effects of cannabis on cognitive functioning and performance (93). Cannabis acts on the endogenous cannabinoid system in the central nervous system and cannabinoid receptors are located in areas of the brain that suggest impact on memory, attention, and other cognitive functions. A growing neuroimaging

literature suggests that chronic use of cannabis alters the cannabinoid system, but structural damage and serious impairment is not apparent. Administration of cannabis or THC increases activation in frontal, prefrontal, and paralimbic regions and the cerebellum, which is consistent with some of the behavioral and cognitive effects associated with cannabis (cf. 94,95). In chronic cannabis users, fMRI studies show alterations in the activation of brain areas involved in higher cognitive (executive) functions. Early initiation of cannabis use has been linked to a number of brain structure abnormalities and brain function patterns during performance of cognitive tasks (cf. 96). Such findings have increased concern regarding adolescent cannabis use and its impact on brain development. However, more research is needed to better understand and interpret the functional and long-term significance of these observations.

This literature generally indicates that cannabis use can lead to selective cognitive impairments, although the magnitude and functional significance of such deficits is difficult to assess. The ability to organize and integrate complex information appears compromised, most likely due to effects of cannabis on memory and attentional processes. Here we provide a brief review and discussion of both acute (direct or intoxicating) effects and chronic (long-term use) effects of cannabis use. Most controversial and difficult to assess has been the long-term effects of cannabis use and the extent to which deficits are recovered following cessation of use.

Acute Use

Demonstrating acute effects of cannabis on *psychomotor performance* has proven more elusive than might be expected. THC-induced effects on response speed and accuracy, tracking ability, body sway, and reaction time have been observed in some studies, but not in others (14,97). As one would expect, THC dose accounts for some of the variation in findings with dose-response effects observed in some studies, and moderately strong evidence that cannabis (THC) can impair performance on some psychomotor tasks at higher doses (e.g., 98,99). Tolerance (cannabis use history) also impacts the degree of impairment from acute doses of cannabis with regular heavy users showing less performance decrements than novice or less frequent users (100). This literature does not indicate a pervasive response slowing, such as decrements on simple reaction time tasks. Rather, affected tasks appear to be those that require more attention, motivation, and impulse control.

The literature also indicates that acute cannabis or THC ingestion, dose dependently, produces adverse effects on a number of *cognitive functions*, which are likely moderated by cannabis use history (tolerance). Effects have consistently been observed on short-term memory, particularly immediate memory and recall and retrieval following a lapse of time. Note, however, that when retrieval cues are available, these deficits may be obviated, suggesting that adverse effects on attentional or learning processes are likely involved. Cannabis has been shown to disrupt the ability to learn novel tasks, and adversely impacts performance on divided and sustained

attention tasks. Cannabis intoxication also affects the subjective perception of time. Time estimates are shorter and time productions are longer in subjects after smoking cannabis.

Experimental studies have also demonstrated that cannabis can adversely impact decision-making and executive function, although findings have produced somewhat mixed results. Increases in response perseveration, and impairment in motor impulse control, divided attention, response adaptation, and working memory have been demonstrated with higher doses (99–101).

Chronic Use

The cognitive impairments observed in acute administration studies of cannabis have also been observed when studying long-term or chronic use of cannabis. Although these chronic effects have been difficult to pinpoint and replicate due to numerous methodological difficulties in studying long-term effects, multiple reports strongly suggest that cannabis users show cognitive and behavioral performance deficits even when not under the influence of cannabis. A series of studies showed that regular cannabis users' performance on an auditory selective-attention task was significantly worse than that of matched controls, suggesting compromised ability to filter out complex irrelevant information (102). Severity of the deficits was associated with years of cannabis use and reduction in event-related potentials (P300 amplitude), a purported marker of cognitive processing. Other studies suggest significant deficits such as increased perseveration, decreased verbal learning and memory, and deficits in complex reaction time, complex reasoning, and short-term memory (103–105). These effects have been characterized as deficits of the attentional/executive system involving mental flexibility, working memory, learning, and sustained attention. Similar to the recent findings on the impact of cannabis on brain function, a number of studies suggest more impairment in those who initiated cannabis use at an early age suggesting the possibility of increased vulnerability during early adolescence (104).

Permanent or Temporary Deficits

Evidence addressing the permanence of the cognitive impairments observed in chronic cannabis use has been mixed (93). One report indicated that ex-cannabis smokers continued to show impairment in their ability to filter out irrelevant information, although some evidence of partial recovery was noted (102). Another study observed continued impairment on multiple measures following 28 days of abstinence that was positively related to the severity of their cannabis use (106). In contrast, a similar study reported that heavy cannabis users showed signs of impairment for at least 7 days post-abstinence, but observed no cannabis-associated deficits by day 28 of abstinence (107). Much of the research on the chronic effects of cannabis use is limited by multiple confounding variables such as possible acute intoxication, testing during cannabis withdrawal states, variable use histories, unknown cognitive abilities prior to cannabis exposure, concurrent use of other drugs, demographic influences, and comorbidity with other mental or physical illnesses. Although

recent studies have made strong efforts to control for many of these variables, important limitations remain.

Notwithstanding the methodological issues inherent to this research, the literature strongly suggests that chronic cannabis use can impair performance on various types of cognitive tests, specifically those thought to involve complex cognitive processes. These deficits may increase in form and severity in relation to the duration of exposure to cannabis, and early initiation of cannabis use may increase the adverse consequences. Future research is needed to better elucidate the processes that cause performance deficits and to determine their functional significance. Because most cognitive and performance tests are affected by attentional and motivational processes, understanding how cannabis affects these factors is necessary for understanding its influence on cognitive processing.

Functional Significance

The functional significance of the cannabis-associated cognitive and behavioral performance deficits discussed above is of most concern to the individual and society at large. Here we briefly discuss three potential areas of impact: driving performance, academic achievement, and motivation.

Driving The literature on the impact of cannabis intoxication on driving performance and risk of accident has been difficult to interpret, but some are concerned that it has become as great a public health risk as driving after drinking alcohol (108). Studies using driving simulators and road tests have produced mixed results (e.g., 109,110). Cannabis intoxication has been shown to adversely affect performance in emergency situations perhaps due to an increase in brake latency and worsened ability to attend to extraneous stimuli. Some have suggested that cannabis adversely impacts more well-learned, automatic driving behavior rather than skills that require more attention and conscious action. Interestingly, cannabis use appears to decrease risk-taking behavior in simulated and on-road driving situations, perhaps suggesting some awareness of and compensation for impairment. In summary, adverse effects on driving skills and behavior seem most evident when assessed in close temporal proximity to cannabis ingestion, are dose dependent, and are moderated by the individual's history of cannabis use (tolerance).

Of additional importance is the impact on driving of the combination of cannabis and alcohol, a common pattern of use among youth and young adult populations. This combination clearly increases risk of unsafe, risky driving performance (109,110). Although impaired cannabis smokers may try to compensate by using risk reduction strategies, use of alcohol likely obviates such efforts. Alcohol and cannabis use produces greater deficits than using either substance alone; even inconsequential doses of each substance can produce impairment when combined.

Epidemiologic studies also show somewhat mixed findings, but the results tend to support observations from the laboratory. Some culpability studies have reported a reduced risk of *fatal* accidents with cannabis alone (no other substances)

compared to alcohol-alone or drug-free accidents, but an increased risk with the combination of alcohol and cannabis. Failure to find that use of cannabis alone increases risk of automobile crashes in these types of studies has been attributed to the method of cannabis detection. Studies that rely on indicators of very recent use of cannabis rather than simply indicating cannabis use at some time in the past show a clear increased risk of crash compared with drug-free drivers (109). The probability of being responsible for an accident increases with greater plasma levels of THC. Case control studies have been fewer in number, but have provided more clear evidence for an association between cannabis use and increased risk of crash. A recent longitudinal study reported an increased risk of crash related to self-reported cannabis use among young adults aged 21 to 25 after controlling for multiple potential confounding factors (108).

Unfortunately, epidemiologic studies have several important limitations. Measurement of cannabis levels is difficult to relate to recency of use and behavioral impairment. Also, some studies exclude cases that involve cannabis and another illicit substance, yet the combination of cannabis and other substances, including alcohol, is the most common finding in accident reviews. Moreover, when these cases are assessed, the relative contribution of cannabis to the accidents cannot be readily determined. Last, most studies do not consider the base rates of cannabis use in comparable populations (young adults) and the concomitant accident rates in that population. Overall, the data from experimental and epidemiologic studies strongly suggest a positive relationship among acute cannabis use, driving performance impairments, and accidents. Although these data are not without limitations, driving under the influence of cannabis warrants caution and much concern, particularly for younger users who may have less tolerance, greater cognitive impairment, less driving experience, and more driving distractions (e.g., peer passengers) than adults.

Academic Achievement Although one would expect that the adverse effects of cannabis use on attentional and complex cognitive processing would have direct influence on optimal academic performance, the extent of this influence is unknown. Cannabis use has been linked to low grade-point averages, decreased academic satisfaction, negative attitudes toward school, poor overall performance in school, and absence from school (111,112), with early cannabis use (prior to age 16) associated with dropping out of high school and failure to complete college. Studies that have statistically controlled for the multiple confounding influences have reported mixed results (113). Because cannabis users tend to have multiple risk factors that are associated with poor academic performance, it is most difficult to demonstrate causality. Of note, in addition to its impact on cognitive performance, cannabis may also adversely affect motivation (see section below). A negative impact on motivation to achieve in an academic setting evidenced through decreased efforts directed toward school work (see below) would likely have an even greater impact on academic performance than

the subtle cannabis-related deficits in complex processing observed in the laboratory studies. Both influences are probable. In addition, poor academic performance in the early school years is also a risk factor for initiation of cannabis.

Motivation Cannabis use has long been associated with an “amotivational syndrome” reflecting lethargy, inactivity, loss of motivation, and decreased goal-directed behavior. Evidence for this amotivational syndrome comes primarily from case studies and clinical reports. Some chronic cannabis users attribute impaired vocational or academic performance and loss of ambition to their cannabis use, and procrastination and impaired motivation are commonly reported as the consequences of using cannabis and as reasons for quitting. Controlled field studies have failed to provide clear evidence of an amotivational syndrome although this research is weakened by limitations relating to sample selection and definitions of motivation. For example, many chronic users appear to be underemployed based on their education and abilities, yet well integrated with their families and community. Many of these cannabis users attribute these circumstances to a lifestyle choice rather than an adverse effect of cannabis use on motivation.

Laboratory studies examining the effect of cannabis on work performance demonstrate what could be termed amotivational behavior. These studies suggest that cannabis affects sensitivity to reinforcement, and that motivational effects of cannabis intoxication are determined by environmental context and contingencies (114). That is, performance deficits operationalized as decreased rates of working and decreased earnings are observed when participants are under the influence of cannabis; however, these effects can be countered when monetary rewards are strategically arranged (115). Adults, given a choice to work on a high-demand task that earned monetary reinforcement or switch to a no-demand task that earned a lower level of reinforcement, chose to spend less time working on the high-demand task when under the influence of cannabis than when given placebo. This effect appeared dose dependent and was partially reversed by increasing the magnitude of the reinforcement in the high-demand task. This suggests that the amotivational effects of cannabis intoxication may occur by impacting the effects of reinforcement on various types of operant behavior (e.g., change sensitivity). A similar amotivational effect of cannabis has also been observed in an experimental study with adolescents (114). Adolescents who regularly used cannabis chose to switch to a nonwork option more quickly than matched controls that were not cannabis smokers, which resulted in earning less money suggesting reduced motivation. Moreover, quicker switching to the nonwork option was related to measured cannabinoid levels in these adolescents. The interaction among the behavioral effects of cannabis and environmental variables needs further study to better understand the relation between cannabis and motivation.

Although laboratory studies indicate that acute cannabis use can engender what appears to be less motivated behavior, the link between chronic cannabis use and an *amotivational*

syndrome that is unrelated to acute cannabis intoxication has not been clearly established. Additional laboratory studies that compare chronic users with nonusers on performance of various work-related tasks, while controlling for acute intoxication effects, may provide more important information and address the validity of an enduring effect of cannabis on motivational processes. Of note, the acute effects of cannabis on operant performance observed in the laboratory indicate that motivation (i.e., effort) should be considered when interpreting studies that examine the effects of cannabis on any cognitive or behavioral performance tasks.

SPECIAL CONSIDERATIONS AND CONCLUSIONS

Two commonly discussed issues related to cannabis, its potential for medicinal use and legalization, warrant comment prior to concluding this chapter. Regarding the medical use of cannabis debate, the 1999 comprehensive report from the Institute on Medicine (116) acknowledged the importance of initiating additional scientific study of the risks and benefits of the use of cannabis and cannabinoids for specific medical conditions, and in particular mentioned investigation of smoked cannabis. The compounds in cannabis clearly have potential beneficial effects for a number of medical conditions. The oral form of THC is approved by the U.S. Food and Drug Administration and by regulatory bodies in other countries for AIDS wasting syndrome and cancer patients receiving chemotherapy. Likewise, the synthetic cannabinoid, nabilone, is approved for use in cancer patients undergoing chemotherapy, and the oromucosal form of a cannabis extract, which contains cannabidiol in addition to THC, is approved to manage spasticity and neuropathic pain in multiple sclerosis.

The interest in the benefits of smoked cannabis in contrast to oral THC arises primarily from differences in the pharmacokinetics of these two routes of administration. Through the oral route, THC absorption is slow and variable, and therefore clinical effects have a slower onset and longer duration than smoked cannabis. In addition, smoked cannabis not only delivers delta-9-THC, but also other compounds (e.g., delta-8-THC and cannabidiol) are absorbed that may have direct or interactive effects of therapeutic interest. That said, smoked cannabis also has multiple disadvantages when considering it for use as a prescribed medication. The adverse effects of smoked cannabis on the respiratory system and its carcinogenic impact have been reviewed earlier. Determination and administration of therapeutic doses through smoking the plant material also poses many hurdles. In addition, its psychoactive effects and multiple adverse consequences associated with its use raise additional concerns. These issues have limited the amount of research completed on smoked cannabis, and to date, there remains very limited controlled clinical research about its efficacy and side-effect profile for medical indications.

The burgeoning of science directed toward understanding of the endocannabinoid system has greatly increased optimism for the use of cannabinoids (cannabis-like compounds)

as medicine. Efforts are underway to develop alternative cannabinoid medications that could reproduce the desired effects of cannabis, without the potentially problematic effects of smoked cannabis such as abuse potential, sedation, disruption in psychomotor performance, problems with memory and other cognitive processes, carcinogenicity, and respiratory system complications. Positive findings from studies evaluating the therapeutic potential of such cannabinoid-like compounds or from compounds that can manipulate the endogenous cannabinoid system clearly indicate growing promise of medicinal value in areas such as treatment of pain, neuromuscular and neurodegenerative disorders, eating or appetite disorders, autoimmune diseases, and other psychiatric disorders (2). As such, it is likely that these novel compounds that interact with the endocannabinoid system, and not smoked cannabis, will eventually be determined effective and safe for medical use. Unfortunately such scientific advances in medicine are sometimes slowed down by certain advocates, the lay public, and legislators who are concerned that demonstrating the therapeutic potential of a class of drugs might diminish the perceived risk of a drug's addictive potential and potential for harm, and lead to increased misuse of a drug. The error of this perspective is evident in the case of the opioids, which have provided both a large and important medical benefit to society and are recognized as a class of drugs that poses a significant drug problem.

The issue of legalization of cannabis is tied closely to concerns about perceived harm, and concerns about increased availability of substances with potential for abuse and harm. As discussed above, cannabis is the most widely used illegal substance in the United States and most other developed countries that regulate its use. Controversy regarding its legal status has proliferated since the early part of the 20th century. Pro-cannabis groups have led an ongoing effort to decriminalize or legalize cannabis use, and many respected scientists and medical professionals have joined the argument by calling for the legalization of cannabis for medical use. Anti-cannabis legalization proponents raise the concerns about the psychosocial, health, and psychiatric consequences associated with cannabis misuse and addiction reviewed earlier in this chapter.

Many who argue for the legalization of cannabis point to the data showing that alcohol use and abuse is clearly more detrimental to the individual and society than cannabis use. Like all other substances including alcohol that have addictive potential, most individuals who initiate cannabis use do not experience significant consequences, but others misuse, abuse, or become dependent and experience adverse outcomes. The argument that cannabis has legitimate medical benefits has also been used to support the call for legalization and decriminalization, but one must recognize that "medical potential" could be claimed for most other substances that are abused and currently illegal. In addition, arguments abound related to the impact of changing its legal status on issues such as: cost and availability of cannabis, tax benefits to society, prevalence rates of

abuse and dependence, effects of advertising and marketing, costs related to criminal prosecution and prison housing, and the impact of criminal records related to cannabis possession on the individual.

Of course elements of the arguments proposed by both sides of the legalization debate have merit. The task of creating policy that balances protection of civil liberties and protection of the public (including children) is most difficult and requires much speculation. Currently, many U.S. states have reduced penalties for possession of small amounts of cannabis and have legislation legalizing the medical use of cannabis under very stringent conditions. At the same time, many schools and work places have adopted mandatory drug testing policies that include cannabis in the list of drugs that are not tolerated, and federal regulations remain strict.

Unfortunately, the ongoing debate over the medical use and legalization of cannabis has spawned distrust and confusion regarding the scientific data that inform our understanding of cannabis and its consequences. A reasonable perspective is to acknowledge that some level of cannabis use can and does result in harmful effects. However, while we have much to learn about the parameters of cannabis use that result in adverse consequences, a wealth of new knowledge has accumulated during the past two decades. Cannabis misuse, abuse, dependence, and withdrawal are real and relatively common phenomena with significant associated consequences that reflect a clear public health problem. In addition, scientific discoveries related to the endocannabinoid system have revealed the ubiquitous nature of cannabinoids and their complex interactions with other neuro-biologic systems, suggesting multiple avenues by which they might be used to treat clinical disorders in the future. Our hope is that this chapter provides the reader with an informed and thoughtful understanding and appreciation of cannabis and its impact on human functioning.

Kevin P. Hill ■ Roger D. Weiss

The number of Americans meeting *Diagnostic and Statistical Manual of Mental Disorders, 4th Edition (DSM-IV)* criteria for amphetamine abuse and dependence has increased substantially in recent years due to the popularity of methamphetamine, a derivative of amphetamine made from readily accessible chemicals. Communities across the United States are working to prevent additional growth in methamphetamine use while trying to treat those already dependent on the drug.

In this chapter, we review the use and abuse of amphetamines. Amphetamines may be used as medications or as drugs of abuse. First, we will review the history of amphetamine use and its importance to particular population groups who have viewed amphetamines as performance-enhancing agents. Next, we will explore the epidemiology of amphetamine use in the United States and abroad while discussing the public health implications of amphetamine dependence. We then discuss the pharmacology of amphetamines, from the literature on preclinical studies that suggest future clinical treatment targets for amphetamine dependence to the physiology of these drugs that makes them appealing yet potentially harmful to users, to current clinical indications for amphetamines as medications. A significant portion of the chapter is devoted to the treatment of those with amphetamine dependence. We review the evidence addressing the effectiveness of popular behavioral interventions as treatments for amphetamine dependence. We then cover the array of medications that have been studied as treatments for amphetamine dependence. A discussion of pharmacogenetics as a new tool that may improve the effectiveness of treatments for amphetamine dependence follows. Finally, we summarize our findings and look to the future of amphetamines and treatment of amphetamine dependence.

HISTORY OF AMPHETAMINES

Stimulants have been used as medications for thousands of years. Ma-huang, or ephedra, is a stimulant that has been used as a herbal remedy in Chinese medicine for the past 5000 years (1). In 1887, Nagayoshi Nagai determined that the active agent in Ma-Huang was ephedrine. That same year in Berlin, amphetamine was synthesized by Lazar Edeleanu (2). Amphetamines' actions on the central nervous system (CNS)—euphoria, heightened alertness, increased energy, and intensified emotions—were described in 1933, when an

amphetamine inhaler was marketed as a decongestant (3). Feelings of euphoria, improved performance, and anorexia were key factors in the reports of abuse that soon followed; these effects continue to be important reasons for the widespread abuse of stimulants today.

Amphetamine abuse peaked in the United States in the late 1960s. Stimulant pills were readily accessible; at that time, far more stimulant pills were manufactured than were prescribed. The U.S. government shifted its philosophy in response to this oversupply. From 1969 to 1971, the government oversaw an 80% reduction in production of amphetamines, alerted physicians to the addictive potential of these agents, and reclassified amphetamines as Schedule II drugs through the Food and Drug Administration, in order to closely monitor their distribution (2). Since amphetamines became Schedule II drugs, physicians have been more cautious about their clinical use.

Amphetamine-type stimulants (ATS) fall into three main groups: amphetamine, methamphetamine, and methylphenidate (Table 16.1). Amphetamine formulations are often prescribed for attention-deficit hyperactivity disorder (ADHD) but have high abuse potential because of their powerful effects. Methamphetamine can be synthesized from readily available chemical components and is the most commonly abused ATS. Methylphenidate formulations are the most commonly prescribed ADHD medications, although, like amphetamine formulations, they are sometimes misused, usually by those for whom they are prescribed. When misused, ATS are highly addictive; amphetamine-dependent individuals require increasing amounts of amphetamine to achieve the desired effect, they are often unable to stop using on their own, and consequences result in multiple spheres of their lives including their relationships and work.

While there have been surges in amphetamine use in general, the appeal of amphetamines has remained consistent among three groups: the military, athletes, and students. Amphetamines appeal to these groups primarily because of the increased energy and improved performance associated with amphetamine use. Amphetamines have been used by members of the military since World War II to enhance alertness and to combat fatigue. After amphetamines were distributed by the United States and Great Britain to its military and the German and Japanese military supplied methamphetamine during World War II, use by military forces continued to grow (4).

TABLE 16.1 Common types of stimulants

Stimulant	Street names	Form	Route of administration	Duration of action	Detection	Common false positives
Amphetamine (dexedrine, adderall)	Speed, uppers, bennies, black beauties	Tablets, capsules	Snorted, swallowed	4 to 12 hours	Urine: 1 to 3 days Blood: 12 hours Hair: ≤90 days	Cold medications containing pseudoephedrine, phenylpropanolamine, phenylephrine; herbal supplements containing ephedra
Methamphetamine (desoxyn)	Chalk, crank, glass, ice, meth	Tablets, powder, crystals	Swallowed, smoked, snorted, injected	8 to 12 hours	Urine: 3 to 5 days Blood: 1 to 3 days Hair: ≤90 days	Same as amphetamine
Methylphenidate (Ritalin, Concerta)	MPH, r-ball, vitamin R	Tablets, capsules	Swallowed, snorted, injected	2 to 12 hours	Urine: 1 to 3 days Blood: 12 hours Hair: ≤90 days	Not common as methylphenidate; requires a specific test

Bower and Phelan (5) characterized the effects of amphetamines on military performance into two categories: performance enhancement and performance maintenance. Performance enhancement occurs when amphetamines are thought to improve one's maximum performance level for a given task. Performance maintenance is the use of amphetamines to restore skills that may have degraded as a result of sleep deprivation or normal circadian rhythm-associated decrements. Military units and pilots who work long hours with little sleep have relied on amphetamines to perform at a high level without fulfilling their biological sleep requirements. Because of concerns about side effects of amphetamines such as hypertension and tachycardia as well as adverse reactions including paranoia, military forces are evaluating nonamphetamine stimulant drugs such as modafinil as possible alternatives to amphetamines in combat settings (6).

Athletes have used amphetamines to improve performance for many years, dating back in the United States to the 1940s for football and the 1950s for other sports (7). An early study by Smith and Beecher (8) showed that administration of amphetamine improved the performance of college swimmers when they were fatigued. While these findings were not supported by other studies, athletes often are willing to pay more attention to positive rather than negative results when considering risks and benefits, especially if they believe that they will gain a competitive advantage by using amphetamines. Thus, although evidence supporting positive effects of amphetamine or naturally occurring ephedra alkaloids on athletic performance is equivocal, ATS continue to be used

because of their perceived positive effects on attention, energy, self-confidence, mood, and aggression (9).

Amphetamines have been used by athletes in a variety of sports, from contests requiring speed and power to those requiring prolonged concentration. In the 1960s and 1970s, amphetamine use in professional football and baseball was noted to be rampant (10). Deaths of athletes have been attributed to amphetamine misuse by (1) an increase in blood pressure caused by increased exercise and peripheral vasoconstriction that hampers the body's ability to cool itself, leading to heatstroke, and (2) cardiac arrest (11). Amphetamines may mask the warning signs of fatigue that usually result in athletes' decreasing their effort; as a result, injury may occur. Adverse events resulting from amphetamine use led to its presence on the first list of substances banned by the International Olympic Committee in 1968 (12). As with the military, athletes use nonamphetamine drugs with stimulant properties like modafinil and adrafinil in an attempt to receive the perceived competitive advantage received from taking stimulants; this can unfortunately be accompanied by the hypertension and tachycardia that result from amphetamines (9,13). Increased use of modafinil and adrafinil by athletes has led to its ban by the World Anti-Doping Agency as a performance-enhancing drug (14).

Students and professionals also use amphetamines to increase productivity. Many students believe that amphetamines and other stimulants improve concentration, increase alertness, and assist with studying (15). Prescription amphetamine and methylphenidate formulations are commonly misused by this group. The National Survey on Drug Use and Health

(2009) demonstrated that full-time college students aged 18 to 22 were twice as likely as their age-matched counterparts who were not full-time college students to abuse amphetamines (16). Students report improved academic performance stemming from an ability to work at a high level for an extended period of time (17). Along with risk for developing dependence on these stimulants, students who use these medications in an attempt to improve performance report higher rates of binge alcohol consumption, cannabis use, and cocaine use (18). Students or professionals who use amphetamines and other stimulants in this context also are at increased risk for heart attack and stroke (19). In an effort to identify potentially safer alternative medications with more favorable side-effect profiles, these population groups have also used stimulant-like medications such as modafinil to prolong alertness and reduce their need for sleep. Interestingly, despite increased use and abuse of modafinil in such settings, Randall et al. (20) demonstrated that modafinil has limited effect on mood, bodily symptoms, or cognitive performance in individuals without sleep disorders.

EPIDEMIOLOGY OF AMPHETAMINES: SCOPE OF THE PROBLEM

Amphetamine misuse remains an enormous problem worldwide. The United Nations Office on Drugs and Crime (UNODC) *World Drug Report 2009* estimates that as many as 51 million people around the world regularly use amphetamines, in comparison to approximately 21 million users each of cocaine and opioids (21). Methamphetamine is the most widely available and most commonly misused type of amphetamine; the UNODC estimates that methamphetamine users comprise 54% to 59% of amphetamine users globally. The UNODC estimated that between 230 and 640 metric ton of ATS was manufactured in 2007. The spread of illicit manufacture to new countries each year suggests that amphetamine use disorders (AUDs) will remain a problem in the coming years. Different use patterns of ATS are evident in different regions of the world. Smart and Osborne (22) compared drug use in 36 countries and found that, after cannabis, ATS are the illicit drugs most likely to be used by high-school students, suggesting that amphetamine misuse will remain a concern in the coming decades.

Diversion of prescribed amphetamines is a concern. While the prevalence of AUDs has remained steady globally, amphetamine consumption and prescription rates are increasing at a proportion that suggests that diversion may be occurring. Consumption estimates in the United States from 1995 to 2006 by the World Health Organization (WHO) and prescription rates during the same time period have both increased linearly (23). The WHO estimates that consumption of amphetamines has more than tripled, from approximately 5 to 18 daily doses per 1000 persons. The number of prescriptions per year, in contrast, has only doubled, from 15 to 30 million. The larger increase in consumption in comparison to number of prescriptions suggests that prescribed amphetamines may be diverted to meet the consumption demand.

Methamphetamine dependence remains an important problem in the United States in particular. Most of the reported methamphetamine production operations globally occur within the United States, with the United States accounting for 82% of the methamphetamine laboratories seized in 2007 (21). Methamphetamine production laboratories are increasing in size, sophistication, and production yields, as organized crime groups see methamphetamine as a source of income (21). While methamphetamine use was focused primarily in the western part of the United States in the early 1990s, the problem has spread across the country in the past 15 years (24). As a result, the United States has enacted several policies aimed at suppressing production of methamphetamine by restricting access to precursor chemicals. Policies have targeted precursor chemicals in forms used by those producing methamphetamine on both large and small scales. Regulations affecting large-scale producers of methamphetamine, such as improved monitoring of bulk purchases of ephedrine and pseudoephedrine, have been beneficial by contributing to a reduction in purity of methamphetamine available in the United States (25). Policies designed to combat small-scale methamphetamine production, however, such as the limitation and tracking of pharmacy purchases of ephedrine and pseudoephedrine, have had little or no effect (25).

The prevalence of methamphetamine use has remained relatively constant since 2002, with 1.3 million Americans using methamphetamine in 2007. However, severity of use is increasing (26); the number of methamphetamine users in the past month meeting criteria for drug abuse or dependence during the past year more than doubled from 27.5% in 2002 to 59.3% in 2004 (27). Similarly, methamphetamine users progress more quickly than cocaine users from first use to regular use to entrance into substance use disorder treatment (28). In the United States, emergency room visit diagnoses mentioning amphetamine or methamphetamine increased 54% between 1995 and 2002 (29). Despite efforts to reduce access to the chemical precursors of methamphetamine, it is likely methamphetamine will remain accessible and inexpensive, and public health costs associated with increased use will continue to rise (30).

AUDs are associated with other psychiatric disorders. Those who use methamphetamine chronically are more likely to experience psychiatric symptoms including drug-induced psychotic symptoms that may persist over time (31). Zweben et al. (32) found that 27% of treatment-seeking methamphetamine users reported a previous suicide attempt, and 43% reported violent behavior problems. Those who misuse stimulants are more likely to misuse other illicit drugs as well. Wu et al. (33) showed that the lifetime prevalence of cocaine/crack and heroin use in a representative sample of youths and young adults aged 16 to 25 who regularly use amphetamines was several times higher than the prevalence in the general population.

Psychosis resulting from amphetamine use is similar to psychoses resulting from cocaine use or other psychotic disorders such as schizophrenia. McKetin et al. (34) found that 13% of 309 Australians actively using amphetamines screened positive for acute psychosis. Acute amphetamine psychosis is

difficult to distinguish from acute schizophrenia (35), with hallucinations, ideas of reference, paranoia, and agitation (36,37). Amphetamine-induced psychoses usually resolve quickly with removal of the amphetamine, while psychotic symptoms resulting from schizophrenia do not. Amphetamine psychoses may be chronic, though, with some individuals experiencing persistent psychotic symptoms even after removal of amphetamine. Others have recurrence of the psychotic state with even minimal re-exposure to amphetamine. Psychotic symptoms resulting from amphetamines are treated with antipsychotic medications just like psychotic symptoms of other etiologies (38).

AUDs have significant public health effects as well. Clandestine in-home methamphetamine laboratories have resulted in environmental costs as well as increased pediatric deaths and emergency room visits from burns and poisoning (39,40). Fetal exposure to methamphetamine leads to multiple prenatal complications (41). Methamphetamine use has also been associated with higher rates of hepatitis C and HIV (42,43). AUDs are associated with criminal justice costs as well. Cartier et al. (44) demonstrated that methamphetamine use is highly predictive of violent criminal behavior and recidivism among parolees; 82% of methamphetamine users returned to custody with 12 months, as opposed to 54% of nonusers.

DETERMINANTS OF USE

Pharmacology

Amphetamines activate the CNS, by increasing synaptic concentrations of the monoamines dopamine (DA), serotonin (5-hydroxytryptamine [5-HT]), and norepinephrine (NE) (45,46). ATS are known as “releasers” because they bind to transporter proteins and increase monoamine levels by a transporter-mediated exchange or the disruption of neurotransmitter storage in vesicles via vesicular monoamine transporter (VMAT)-2 (45,47). The rapid efflux of intravesicular monoamines results in high concentrations of cytosolic monoamines. High levels of intracellular monoamines reverse monoamines in the cell membrane, ultimately causing a movement of monoamines into the extracellular space.

Considerable evidence suggests that the mesocorticolimbic dopaminergic system mediates the rewarding effects of amphetamines (48–50). This system, which originates from the ventral tegmental area (VTA) of the midbrain and targets a number of limbic and cortical structures, including the nucleus accumbens, amygdala, and prefrontal cortex, has been shown to play an essential role in stimulant reward (50). The noradrenergic system helps to mediate the cardiovascular effects of amphetamines, and mounting evidence also suggests that the noradrenergic system is critical in mediating amphetamine’s rewarding effects in preclinical models of addiction (51). The noradrenergic system, together with the dopaminergic system, may also contribute to withdrawal symptoms that occur with stimulant discontinuation (52,53).

Changes in mood associated with stimulants result in part from activation of the serotonergic system, but 5-HT may also play a role in modulating the rewarding effects of stimulants through its impact on the DA system (54).

Preclinical Target Systems

Extensive preclinical work has played an integral role in developing ATS as medications for the aforementioned indications. Researchers hope that ongoing preclinical work will identify additional clinical indications for ATS as treatments. In addition, several potential therapeutic target systems for the treatment of amphetamine dependence have been identified using preclinical models of drug dependence, including amphetamine self-administration, reinstatement of amphetamine use, and both behavioral and locomotor sensitization to amphetamines. We will provide a brief overview of relevant preclinical studies in the study of these target systems (Table 16.2).

Dopaminergic

The dopaminergic system plays a critical role in mediating the reinforcing effects of amphetamines. Both D₁- and D₂-like receptors have been proposed to mediate acute and chronic effects of stimulants. The D₁-like family of receptors, including the D₁ and D₅ receptors, stimulates cyclic AMP formation. The D₂-like family of receptors, including the D₂, D₃, and D₄ receptors, inhibits cyclic AMP formation. The D₂-like receptors also function as autoreceptors reducing DA release (55). As a result, agents modulating DA release have been studied in several behavioral models. Tyrosine, an amino acid precursor of both DA and NE, has been shown to decrease amphetamine self-administration in rats exposed to amphetamine for 4 to 6 months (56). The dopamine transporter (DAT) inhibitor GBR 12909 nearly eliminates the DA-releasing effects of methamphetamine in rats (57). Izzo et al. (58) studied terguride, a partial D₂ agonist, due to the variations in dopaminergic tone that result from the use of psychostimulants like amphetamine. In a progressive ratio schedule, terguride acted as a functional DA receptor antagonist, attenuating intravenous self-administration in rats in a similar fashion as the D₂ antagonist eticlopride. The D₃ receptor antagonist U99194 was shown to inhibit the development of locomotor sensitization to amphetamine (59). Finally, the D₁ agonist SKF-38393 reversed the stereotypy associated with behavioral sensitization (60). Behavioral sensitization, in which repeated exposure to amphetamine produces increasingly robust motor responses and stereotyped behavior, is thought to underlie drug craving and relapse (61).

GABAergic

Dopaminergic effects are modulated by gamma-aminobutyric acid (GABA) and glutamate, the main inhibitory and excitatory neurotransmitters in the brain. Dopaminergic activity is decreased by GABA and increased by glutamate, suggesting that alteration of either GABA or glutamate

TABLE 16.2 Preclinical investigations of potential treatments for amphetamine dependence

Drugs	Year	Authors	Effect on primary outcome
Dopaminergic			
■ Tyrosine	1986	Geis et al. (56)	Attenuated amphetamine self-administration

■ N-Acetyl-L-cysteine	2004	Fukami et al. (189)	Attenuated methamphetamine-induced behavioral sensitization

transmission is a possible strategy in the development of a new medication for stimulant dependence (62,63). GABA effects are mediated through two types of GABA receptors: GABA_A and GABA_B. GABA_A receptors increase chloride influx and mediate the fast inhibitory responses to GABA. In contrast, GABA_B receptors, found both pre- and postsynaptically, mediate the slow inhibitory response to GABA (64). Thus, both GABA_A and GABA_B receptors are potential treatment targets for new medications for stimulant dependence (63,65). Baclofen, a GABA_B agonist, has been shown to produce a dose-dependent reduction in intravenous self-administration of both methamphetamine and D-amphetamine (66,67). Similarly, baclofen also attenuates the development of both conditioned place preference and behavioral sensitization following administration of D-amphetamine (68,69). The ability of 2-hydroxysaclofen, a GABA_B antagonist, to reverse the effects of baclofen on the discriminative stimulus effects of D-amphetamine in the conditioned taste aversion procedure also supports a role for GABA in modulating the effects of stimulants (70). The irreversible GABA-transaminase inhibitor, gamma-vinyl GABA, which increases synaptic GABA levels, reduced methamphetamine-induced increases of DA in the nucleus accumbens (71).

Glutamatergic

Glutamate acts on two varieties of highly specialized receptors: ionotropic and metabotropic receptors. *N*-Methyl-D-aspartate (NMDA), kainite, and alpha-amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA) receptors are called “ionotropic” receptors due to their action as ion channels. While ionotropic glutamate receptors are widespread and mediate fast synaptic transmission, metabotropic receptors are coupled to G-proteins and mediate the slow, neuromodulatory effects of glutamate. Pharmacological antagonism of glutamate transmission has been shown to block stimulant effects in preclinical paradigms of addiction. Glutamatergic drugs that act on the VTA block stimulant sensitization and reward (62). The metabotropic glutamate agonist LY379268 also prevented the enhanced self-administration associated with amphetamine sensitization (72). Consistent with these findings, riluzole, which decreases glutamate release, has been used in several preclinical paradigms to underscore the role of glutamate in amphetamine addiction. It blocks amphetamine-induced conditioned place preference, moderately attenuates amphetamine-induced locomotion, and attenuates the expression of amphetamine-induced behavioral sensitization (73–75). Although preclinical evidence for sensitization may outweigh research in humans currently, sensitization to amphetamine may be important clinically (76). Chronic amphetamine use may make it more difficult to maintain abstinence, increase the likelihood of amphetamine-induced psychosis, and worsen prognosis (77,78). These behavioral findings are supported by cellular studies demonstrating riluzole’s effectiveness in blocking DA release in the striatum and other brain areas involved in dependence (79).

Adrenergic

Noradrenergic axons project widely throughout the brain and the noradrenergic system contributes to an array of psychological processes including affective regulation, learning, memory, sleep, and reinforcement, as well as physiological responses including regulation of heart rate and blood pressure (80). These functions are mediated by α - and β -adrenergic receptors and their subtypes (53,81). Multiple preclinical studies have demonstrated that adrenergic receptors are critical in development of amphetamine dependence. Drouin et al. (82) showed that pretreatment with the α_1 -antagonist prazosin reduced the acute locomotor effects of D-amphetamine in rats, and concomitant administration of prazosin and the 5-HT_{2A} antagonist SR46349B produced a complete blockade of these effects along with the development of behavioral sensitization. The α_{2A} -antagonist atipamezole attenuated both locomotor hyperactivity and behavioral sensitization following D-amphetamine administration (83,84). Similarly, treatment with a β -antagonist timolol prevented the development of behavioral sensitization to amphetamines in rats (85). These studies suggest that α - and β -adrenergic antagonists may have promise as medications for amphetamine dependence.

Serotonergic

Neurons containing 5-HT project from the raphe nuclei to nigrostriatal and mesolimbic neurons containing DA, prompting study of the relationship of 5-HT to DA-mediated amphetamine effects. Multiple preclinical models have demonstrated the role of serotonergic neurons in amphetamine self-administration, indicating that 5-HT may attenuate the reinforcing effects of methamphetamine (54,86,87). Tricyclic antidepressants (TCAs), which affect monoamine reuptake and have anticholinergic activity as well, restore hypoactive intracranial self-stimulation in rats exposed to chronic amphetamine administration (88). Acute injection of fluoxetine, a selective serotonin reuptake inhibitor (SSRI), attenuates the self-administration of D-amphetamine in rats (86,87). Other studies have built upon these findings to investigate the relationship between serotonergic and noradrenergic systems. Salomon et al. (89) demonstrated that both the α_1 -antagonist prazosin and the 5-HT_{2B} antagonist SR46349B attenuate the development of amphetamine-induced behavioral sensitization. Repeated administration of D-amphetamine produced a hyperactivity of NE and 5-HT neurons that was blocked by antagonist pretreatment, suggesting an uncoupling of NE and 5-HT that occurs with chronic amphetamine dependence administration. Recent studies also suggest that reduced serotonergic neurotransmission may contribute to amphetamine withdrawal states. In rats, the serotonin selective reuptake inhibitor paroxetine, combined with a 5-HT_{1A} antagonist, p-MPPI, attenuated the reward deficit associated with amphetamine withdrawal (90). These findings suggest that the serotonergic system, by modulating both amphetamine reinforcement and withdrawal, may prove to be a promising target for new treatments for amphetamine dependence.

Cannabinoid

Evidence linking the endocannabinoid system to the reward circuit has encouraged study of the effects of this system on amphetamine-induced behaviors (91). A link between the cannabinoid and dopaminergic systems is suggested by the induction of sensitization to amphetamine-induced hyperlocomotion by Δ^9 -tetrahydrocannabinol, the psychoactive ingredient of marijuana (92). Similarly, the cannabinoid CB1 receptor antagonist SR14176A blocked the reinstatement of methamphetamine-seeking behavior induced by drug-priming and drug-associated cues (93). In this study, Δ^8 -tetrahydrocannabinol attenuated methamphetamine-induced reinstatement. Another CB1 receptor antagonist, AM251, was shown to attenuate amphetamine-induced behavioral sensitization (94). These findings suggest that cannabinoid antagonists may be developed as potential medications for amphetamine dependence.

Acetylcholinergic

Nicotinic and muscarinic cholinergic receptor types mediate acetylcholinergic effects. While few studies have examined a possible role for cholinergic receptors in treatments for amphetamine dependence, some studies have yielded promising results. Hiranita et al. (95) showed that systemic nicotine and donepezil, an acetylcholinesterase inhibitor, attenuated the reinstatement of methamphetamine-seeking behavior. Additional experiments by this group using muscarinic and nicotinic antagonists indicated that donepezil's effects were mediated by the nicotinic, not muscarinic receptors (95). Lobeline, a nicotine agonist that decreases DA release via inhibition of VMAT-2, also attenuates intravenous self-administration in rats (96). Additionally, lobeline reduces the DA-releasing effects of methamphetamine, suggesting that lobeline has unique properties at the DAT and VMAT-2. These studies suggest that nicotinic receptors may be promising targets for the treatment of amphetamine addiction (97,98).

Opioid

Opioid and dopaminergic neurons interact in the VTA, substantia nigra, striatum, and limbic areas of the brain (99,100). In addition, the endogenous opioid release following acute administration of amphetamines suggests a functional connectivity between dopaminergic and the opioid system (101). This connectivity has been illustrated in multiple behavioral studies as well. The opioid antagonist naloxone attenuated the locomotor response to amphetamine as well as the corresponding increase in extracellular DA (102). Similarly, pretreatment with naloxone decreased methamphetamine-induced conditioned place preference (103). Chiu et al. (104) demonstrated that naltrexone, the nonselective opioid antagonist, attenuated methamphetamine-induced behavioral sensitization. Naltrexone also inhibited reinstatement of drug-seeking behavior by methamphetamine-associated cues (105). It is important to note, however, that naltrexone did not affect reinstatement induced by priming with methamphetamine in this study, and earlier work has already documented that naltrexone has no effect on methamphetamine

self-administration (106). Another recent study, however, showed that naltrexone attenuated reinstatement of amphetamine self-administration (107).

Nitroergic

Nitric oxide (NO) is a lipid-soluble, short-lived second messenger that plays a role in diverse functions including learning and memory, neurotransmitter release, and cell death (108). NO serves as a second messenger for NMDA receptors and is released by neuronal nitric oxide synthase (nNOS) following NMDA-type glutamate receptor activation (109). Several studies have supported the role of NO in mediating the psychomotor sensitization and reinforcing effects of stimulants. Pretreatment with 7-nitroindazole, an NOS inhibitor previously shown to attenuate signs of opioid withdrawal, attenuated the development of methamphetamine-induced behavioral sensitization in mice (110–112). Acute minocycline treatment attenuated amphetamine-induced psychomotor activity and striatal (DA) release in rats (113,114). Consistent with these findings, a recent positron emission tomography imaging study in monkeys demonstrated that minocycline treatment protected against methamphetamine-induced neurotoxicity by attenuating the reduction of DAT in the striatum of monkeys pretreated with methamphetamine (115). The mechanism by which minocycline interacts with dopaminergic and glutamatergic neurotransmission has not been clarified, but it may be due to minocycline's capacity to inhibit inducible NOS and the resultant inhibition of NO release (116). These studies suggest that NO might be a significant treatment target for the development of medications for amphetamine addiction.

In summary, studies that focus on preclinical models of amphetamine will continue to serve an important purpose in the identification of new treatment targets for pharmacotherapies for amphetamine dependence. In addition, preclinical studies of medications acting on DA, GABA, glutamate, cannabinoid, nicotinic, and opioid receptors all have produced findings warranting further study.

Physiology

Amphetamines have a long duration of action. They produce an initial "rush" of euphoria, heightened alertness, increased energy, decreased appetite, and intensified emotions (117). Euphoria may be experienced in as little as 5 minutes with intravenous or smoked amphetamine and lasts 8 to 12 hours (118). Amphetamine half-lives range from 4 to 5 hours for methamphetamine to 7 to 31 hours for amphetamine (119,120). Amphetamines, therefore, produce powerful, long-lasting effects that many people find appealing; this allows amphetamines to compare favorably to other illicit drugs in terms of cost (121).

Not all effects of amphetamines are desirable, however. Acute adverse effects of amphetamines include insomnia, restlessness, hyperthermia, and even seizures. In addition to abuse and dependence, chronic use can result in agitation, paranoia, mood disturbances, psychosis, and cognitive impairment (122). After prolonged use of amphetamines, some

users experience unpleasant physical side effects or a withdrawal syndrome marked by depression, irritability, anxiety, fatigue, and aggression (123). Unpleasant withdrawal symptoms during the initial days of abstinence from chronic amphetamine use can contribute to relapse or even suicidal ideation (124). Finally, the safety of prescribed stimulants was called into question recently, as Gould et al. (125) demonstrated an association between the use of stimulants and sudden unexplained death among children and adolescents. The potential for abuse and the side-effect profile of ATS underscores the prescribing clinician's responsibility to educate patients about these medicines.

AMPHETAMINES AS MEDICATIONS

Clinical Indications

Amphetamines and ATS have proven to be effective treatments in a variety of clinical situations. They are FDA-approved as pharmacotherapy ADHD and narcolepsy (126,127). ATS such as methylphenidate, mixed amphetamine salts, dextroamphetamine, and lisdexamfetamine are first-line treatments for ADHD. Amphetamines can also be used to augment antidepressant medications in treatment-resistant depression (128,129). Other uses of ATS include treatment of symptoms associated with traumatic brain injury and stroke (130). There is also evidence supporting the use of ATS as treatment for HIV-related neuropsychiatric symptoms (130). Use of ATS for weight loss is not encouraged by physicians largely due to the potential for dependence.

AMPHETAMINES AS DRUGS OF ABUSE

Evaluation and Treatment Approaches

A variety of evidence-based psychotherapies and pharmacotherapies have been used for amphetamine dependence. We will briefly summarize the support for these treatments in the following section.

Behavioral Interventions for Amphetamine Dependence

Trials of behavioral interventions for amphetamine dependence have produced promising results warranting further study. Both cognitive behavioral therapy (CBT) and contingency management (CM) have been shown to reduce methamphetamine use. CBT involves examining learning processes in order to reduce amphetamine use. The patient receiving CBT becomes skilled at recognizing situations associated with use, avoiding them when possible, or coping with them when necessary. CM provides tangible incentives like money-based vouchers or prizes, based on objective measures of drug abstinence. CBT is a prominent component of the Matrix Model, a 4-month, manualized, intensive outpatient therapy that combines CBT, psychoeducation, 12-step program participation, and positive reinforcement for behavioral change and treatment adherence (131). In a multisite clinical trial of 978 methamphetamine-dependent subjects, Rawson et al. (131) found that the Matrix Model was more

effective as a 16-week treatment for methamphetamine dependence than standard treatments, as evidenced by increased treatment retention, methamphetamine-free urine drug screens, and periods of abstinence.

Four recent clinical trials suggest that CM has promise as a behavioral intervention for amphetamine dependence. CM, using voucher-based reinforcers, was shown to improve treatment retention and increase periods of continuous abstinence when compared to standard CBT in a 16-week trial of 162 methamphetamine-dependent gay and bisexual men, demographic groups affected by methamphetamine's recent surge in popularity (132). In another study of methamphetamine-dependent subjects that evaluated CM in conjunction with CBT and sertraline, subjects in the CM arm were significantly more likely than those not receiving CM to achieve a 3-week period of in-treatment abstinence (133). In a large 12-week study of 415 subjects dependent on methamphetamine or cocaine, CM outperformed treatment as usual with respect to treatment retention and abstinence in a community treatment setting (134). Similarly, in a 16-week study of a group of 171 subjects dependent on methamphetamine or cocaine, CM was shown to be more effective than CBT with respect to treatment retention and abstinence (135). Interestingly, the combination of CM and CBT did not produce an additive effect. This study demonstrated the potential of CM for engaging methamphetamine-dependent patients and helping them stay in treatment while achieving abstinence. The aforementioned clinical trials have produced intriguing results that necessitate further study.

Pharmacotherapy

Despite promising results from preclinical studies, clinical studies have not produced reliably efficacious treatments for amphetamine dependence. Translation of preclinical models for amphetamine dependence into effective treatments has proven difficult, and the positive signals seen in animals have, for the most part, not been reproduced in humans. In addition, the inability to develop effective pharmacotherapies for amphetamine dependence makes it difficult to assess the validity of preclinical models. Many research groups have worked to develop medications for amphetamine dependence since methamphetamine use surged in the 1980s following the cocaine epidemic. Thus far, randomized controlled trials (RCTs) of multiple classes of medications have generated inconclusive results. The classes of medications evaluated in these trials were influenced, perhaps, by previous trials of medications studied for cocaine dependence. In addition to RCTs, open-label studies have been done with a variety of medications; these studies provide hope for the eventual identification of an effective medication for amphetamine dependence. We briefly summarize the results from clinical trials of medications for amphetamine dependence.

Antidepressants

Antidepressants, including SSRIs and TCAs, have been studied as potential pharmacotherapies for amphetamine dependence for two important reasons. First, preclinical

studies of amphetamine self-administration suggest that medications blocking the reuptake of 5-HT may attenuate the reinforcing effects of amphetamine (58,87). Second, blockade of the 5-HT and NE reuptake can combat some of the depressive symptoms experienced in amphetamine withdrawal such as depressed mood, fatigue, and anhedonia, which may lead to relapse (136). Other medications with effects on 5-HT, NE, and DA have been studied as well. Although antidepressants have not been shown to be efficacious as medications for cocaine dependence, several studies evaluating this class as treatments for amphetamine dependence have been done.

Unfortunately, trials of both SSRIs and TCAs have had limited success in identifying an effective medication for amphetamine dependence. The SSRIs fluoxetine, paroxetine, and sertraline failed to distinguish themselves from placebo as treatments for methamphetamine use (133,137,138). Galloway et al. (139) showed that treatment with 150 mg imipramine improved treatment retention in 32 methamphetamine-dependent subjects attending an outpatient detoxification program, but did not differ from a 10 mg imipramine control group in negative urine drug screens, depression scores, days since last use of methamphetamine, attendance of study visits, or craving. This study followed a case series showing increased treatment retention in two subjects taking desipramine for amphetamine dependence (140).

Antidepressants with mild stimulant properties have been studied as well. Amineptine, a DA reuptake inhibitor, alleviated symptoms of depressed mood, decreased energy, increased appetite, and craving for sleep in patients experiencing amphetamine withdrawal (141,142). Bupropion, a DA and NE reuptake inhibitor, has been shown to be safe in methamphetamine users (143) but was no more effective than placebo in two studies whose primary outcomes were proportion of subjects having a methamphetamine-free week (144,145). Post hoc analyses, however, suggest that bupropion may be effective as a treatment for methamphetamine dependence in at least a subgroup of men using low-to-moderate amounts of methamphetamine (144,145). The monoamine oxidase B inhibitor selegiline has been shown to be safe for use as a treatment for methamphetamine dependence, producing minimal changes in the subjective responses of subjects to methamphetamine (146). Serotonergic antagonists have also been examined; mirtazapine, a 5-HT₂ and 5-HT₃ antagonist, was shown to be more effective than treatment as usual for methamphetamine withdrawal (147), and ondansetron, a 5-HT₃ blocker but not an antidepressant, has been shown thus far to be safe as a treatment for methamphetamine dependence (148).

GABA Enhancers

Preclinical studies showing the ability of GABA agents to attenuate drug-seeking behavior have prompted clinical investigations of these medications (149). These results led to positive studies of GABAergic agents as medications for cocaine dependence and provided a rationale for trials of these agents as medications for amphetamine dependence (150,151).

Clinical trials of GABAergic agents have provided preliminary evidence that such medications may be useful in the treatment of amphetamine dependence. Topiramate, a GABAergic anticonvulsant, did not have an adverse effect on cognitive processes in 10 methamphetamine-dependent subjects in a 27-day crossover study. Topiramate's effects on cognitive processes were mixed; it improved attention and concentration in subjects while worsening psychomotor retardation (152). In a 16-week, randomized, placebo-controlled, double-blind trial, neither gabapentin, a GABA-transaminase inhibitor, nor the GABA_B agonist baclofen produced significant differences relative to placebo on standard treatment outcome measures (153). Post hoc analyses, however, showed a significant treatment effect for baclofen versus placebo in a subgroup that was highly compliant in taking study medication. Another GABA-transaminase inhibitor, gamma vinyl-GABA (GVG), was shown to be a safe treatment for methamphetamine dependence in an open-label, 9-week safety study (154). In this study, 15 of 27 methamphetamine-dependent subjects completed the study and at least two-thirds of these subjects were drug-free for at least 4 weeks of the study. In a separate placebo-controlled study, GVG did not alter amphetamine levels or cardiovascular effects of amphetamine, nor did it attenuate the positive subjective effects of methamphetamine in nontreatment-seeking methamphetamine-dependent volunteers (155). Thus, further investigations of these medications, or longer acting or more potent GABA agents, have potential to identify an effective treatment for amphetamine dependence.

Antipsychotics

Atypical antipsychotic medications have been investigated as treatments for methamphetamine dependence in part due to the effects of DA and, to a lesser extent, 5-HT on amphetamines. Medications with dopaminergic and serotonergic function, such as risperidone and aripiprazole, have been shown to block some of the behavioral effects of amphetamines that contribute to their abuse (156,157). Preliminary studies of these medications have been conducted. A 4-week open-label trial demonstrated that treatment with risperidone, a D₂ and 5-HT_{2A} antagonist, produced significant reductions in episodes of methamphetamine use and psychiatric symptoms (158). A human laboratory study of the D₂ and 5-HT_{1A} partial agonist and 5-HT_{2A} antagonist aripiprazole demonstrated moderate reductions in abstinence-related and cue-induced methamphetamine craving (159). These studies provide a basis for additional investigations of medications with dopaminergic and serotonergic action for amphetamine dependence.

Calcium Channel Blockers

Dopamine's role in the rewarding effects of stimulants has led to the study of medications that modulate midbrain DA systems. The ability of calcium channel blockers to attenuate cocaine-induced DA output in the striatum has

led to investigation of this class of medications in models of amphetamine dependence (160). The calcium channel blocker isradipine, for example, has been shown in preclinical studies to suppress amphetamine-induced conditioned place preference and locomotor activity in rats (161).

Two clinical studies have followed this promising preclinical finding. Isradipine attenuated some of the subjective effects of and craving for D-methamphetamine in a human laboratory study of 18 healthy volunteers (162). However, a double-blind, randomized, placebo-controlled trial of another calcium channel blocker, amlodipine, did not produce positive results. Eight weeks of amlodipine treatment was not significantly different from placebo on measures methamphetamine use, depressive symptoms, and craving (163).

Stimulant-Like Medication

Another strategy for treating stimulant dependence is to employ medications that produce some of the same positive effects as the stimulant being abused. Modafinil, for example, is a wakefulness-promoting agent that is approved by the FDA for the treatment of narcolepsy. It has some pharmacological effects similar to amphetamines, such as increases in heart rate and blood pressure, but it is marketed as having less abuse potential than amphetamines (164–166). A small open-label trial has reported preliminary findings on modafinil as a pharmacotherapy for methamphetamine withdrawal. Treatment with modafinil attenuated subjective and observer-reported withdrawal severity when compared to treatment as usual (148). Subjects in the modafinil group reported less hypersomnia, fewer night-time awakenings, and deeper sleep than subjects receiving treatment as usual during methamphetamine withdrawal. Sofuoglu et al. (167) evaluated the effects of the NE transporter inhibitor atomoxetine on acute physiological and subjective responses to D-amphetamine in healthy volunteers. Atomoxetine, which is FDA-approved for the treatment of ADHD, attenuated some of the standard physiological responses to amphetamine and some of the positive subjective effects as well.

In summary, preliminary clinical trials of several classes of medications have yielded mixed results (Table 16.3). However, findings from some of these studies warrant additional investigation.

Agonist Pharmacotherapy

Another therapeutic approach, the replacement of amphetamine with agonist pharmacotherapy, has not been studied extensively, perhaps due to the lack of an established agonist pharmacotherapy for cocaine dependence (168). Several studies of amphetamine substitution, using retrospective and uncontrolled designs, describe promising results (169–172). In the lone randomized, controlled trial of amphetamine substitution treatment, Shearer et al. (173) showed the feasibility of urine toxicology screens for distinguishing between medication compliance with a prescribed amphetamine and changes in illicit methamphetamine use. The treatment group

received dextroamphetamine, in addition to counseling, and improved on several outcome measures, but failed to distinguish itself from the control group that received only counseling.

Genetic Mechanisms Underlying Differences in Amphetamine Response among Animals

Although progress has been made in the development of psychotherapeutic and pharmacological treatments of amphetamine dependence, the efficacy of available treatments is limited. One possible explanation for the lack of success of these treatments is the heterogeneity of populations dependent on amphetamine. This heterogeneity likely results from a variety of factors, including genetics and psychosocial factors such as addiction severity, treatment history, and chronicity of use. Genotypes, the specific composition of genes coding for the phenotype, may offer information about patients' potential response to treatment.

Preclinical work has supported the concept of functional polymorphisms. Animals with risk polymorphisms display increased amphetamine effects compared to wild-type (WT) organisms, while those with protective polymorphisms show decreased amphetamine effects compared to WT organisms. Spielewoy et al. (174) showed that knockout mice lacking the DAT demonstrated a decreased locomotor response to amphetamine; this locomotion was decreased in a dose-dependent manner by the SSRI fluoxetine as well. In an investigation targeting the DA second messenger pathway, a quantitative trait locus (QTL) for methamphetamine-induced activity was identified in a region of chromosome 15 containing the casein kinase 1 epsilon gene (*Csnk1e*) (175). The casein kinase 1 gene positively regulates the activity of dopamine-and-cAMP-regulated-phosphoprotein-32 kDa (DARPP-32), a prominent component of the dopaminergic second messenger pathway that regulates the locomotor response to stimulants (176). A 10-fold difference in the expression of this gene in the high-activity mouse line compared to the low-activity line was shown. They identified an expression QTL that comapped to both the QTL for methamphetamine-induced activity and physical location of *Csnk1e* in the mouse genome, suggesting that this expression locus was responsible for differences in methamphetamine-induced activity. Mice without the α_{2A} -adrenoreceptor exhibited greater acute amphetamine-induced hyperactivity after administration of D-amphetamine than WT mice (85). However, the knockout mice displayed less amphetamine-induced hyperactivity after repeated administration of D-amphetamine than WT mice. These findings point to a complex interaction of α_{2A} -adrenoreceptor subtypes in the regulation of amphetamine-induced hyperactivity and the development of behavioral sensitization to repeated amphetamine administration.

Human Gene Polymorphisms and Associations with Amphetamine Dependence and Treatment Outcome

Pharmacogenetics may be a useful tool in the development of treatments for amphetamine dependence by helping to individualize therapies. This approach has been applied in

TABLE 16.3 Randomized controlled clinical trials of medications for amphetamine dependence

Drugs	Year	Author	Dose (mg/day)	N	Controls	Effects on primary outcome
Antidepressants						
■ Imipramine	1996	Galloway et al. (139)	150	22	10	Improved retention in treatment. No differences in urine toxicology, depressive symptoms, or craving
■ Fluoxetine	2000	Batki et al. (137)	40	NR	NR	No improved outcomes
■ Paroxetine	2003	Piasecki et al. (138)	20	20	NR	Only 15% completed study; no statistical analyses performed
■ Ondansetron ^a	2004	Johnson et al. (148)	Maximum 4 mg bid	152	NR	Safety study only
■ Bupropion	2005	Newton et al. (143)	300	10	10	Attenuated subjective effects of MA and craving
■ Bupropion	2008	Elkashef et al. (144)	300	79	72	No difference from PLA on primary outcomes. Post hoc analyses suggest increased MA-free urine screens for light users
■ Bupropion	2008	Shoptaw et al. (145)	300	36	37	No difference from PLA on primary outcomes. Post hoc analyses suggest increased MA-free urine screens for light users
■ Selegiline	2005	Newton et al. (146)	10	5	4	Slightly increased methamphetamine-associated “bad effects”
■ Sertraline	2006	Shoptaw et al. (133)	100	120	109	No improved outcomes
GABA enhancers						
■ Baclofen	2006	Heinzerling et al. (153)	60	25	37	No main effects, but significant treatment effect for baclofen in group most compliant with medication
■ Gabapentin			2400			
Calcium channel blockers						
■ Amlodipine		Batki et al. (163)	Up to 10	51	26	No improved outcomes

^aNot an antidepressant but has effects on the serotonergic system (5-HT₃ receptor antagonist).

Bid: twice daily; NR: not reported.

several other clinical areas, primarily in two ways (177,178). First, pharmacogenetics can be used to identify new treatment targets for medications, such as particular neurotransmitter systems. Second, these studies may improve the efficacy of pharmacotherapies currently being used, either by describing subgroups of patients more likely to respond to a given treatment or by providing improved dosing recommendations.

Progress made in using functional polymorphisms to inform treatment in other substance use disorders and studies employing these polymorphisms in relation to amphetamine dependence continue to be described. Several studies have documented genetic effects on the subjective responses to amphetamine. Following the aforementioned DAT variable number tandem repeat (VNTR) studies, Lott et al. (179) showed variations in subjective responses to D-amphetamine in 101 healthy controls. Those with the nine-repeat DAT allele had decreased subjective responses to acute amphetamine administration on the Drug Effects Questionnaire (DEQ), the Profile of Mood States (POMS), and the Addiction Research Center Inventory (ARCI), suggesting less of a risk of amphetamine dependence in these individuals. In addition, the promoter-region gene-linked polymorphic region (5-HTTLPR) and the VNTR in the second intron of the serotonin transporter gene (5-HTT) were shown to contribute to the acute subjective responses to D-amphetamine in this cohort. The same group showed that a single-nucleotide polymorphism (SNP) in the *Csnk1e* region was associated with increased feeling of drug effect on the DEQ (180). Similarly, Dlugos et al. (181) showed that healthy volunteers with certain polymorphisms in the NE transporter (*SLC6A2*) gene had increased mood and elation responses after receiving 20 mg of D-amphetamine. Brain-derived neurotrophic factor (BDNF) potentiates neurotransmitters strongly linked to substance abuse. Flanagin et al. (182) showed that healthy adult volunteers homozygous for the val allele of the BDNF G196A gene experienced more pronounced subjective responses and a less pronounced physiological response from a single moderate dose of amphetamine than genotypic groups. A functional polymorphism for the catechol-*O*-methyl transferase (COMT) gene has also been demonstrated in a functional magnetic resonance imaging (fMRI) study; amphetamine enhanced efficiency of prefrontal function during a working memory task in those with val/val genotype, but had no effect on those with met/met genotype, suggesting this group may be at increased risk for adverse response to amphetamine (183). Finally, increased feelings of anxiety on the POMS after amphetamine administration are associated with the 1976C/T and the 2592C/T_{ins} polymorphisms of the adenosine receptor gene in 99 healthy volunteers (184). Stimulation of adenosine receptors antagonizes DA function, providing another potential substance abuse treatment target.

Other studies describe vulnerability to adverse drug effects, such as psychosis resulting from amphetamine use. Ujike et al. (185) studied four exonic polymorphisms of the DAT gene and did not find a difference in genotypic and allelic distribution of the four polymorphisms between methamphetamine-dependent subjects and healthy volunteers. However, those

experiencing methamphetamine psychosis on discontinuation of methamphetamine were significantly more likely to possess excess nine or fewer repeat alleles of the DATVNTR, supporting the findings of Gelernter et al. (186). Similarly, the met allele frequency of the COMT gene is associated with patients who experience methamphetamine psychosis and relapse into methamphetamine use, suggesting that patients with a met allele appear to be at increased risk of an adverse response to methamphetamine. Another polymorphism associated with extended methamphetamine psychosis has been found in the promoter region of the quinone oxidoreductase (NQO2) gene in a Japanese sample (187). This gene is involved in protection from methamphetamine-induced oxidative stress and neurotoxicity, suggesting a role for the NQO2 gene in prolonged methamphetamine psychosis.

CONCLUSIONS

Around the world, people continue to abuse amphetamines, often with significant negative consequences. Although there is variation in patterns of use in different parts of the world, amphetamine dependence can be associated with great personal and societal costs. Methamphetamine dependence, for example, is exacting a tremendous toll on many communities within the United States. While there are currently no effective pharmacotherapies for amphetamine dependence, strides are being made in multiple areas of research directed toward this goal, from preclinical studies to randomized, controlled clinical trials. Preliminary findings in a variety of areas require additional investigation. Although progress has been made in the development of behavioral treatments for amphetamine dependence, the need for effective medications has propelled exciting preclinical and clinical research.

Pharmacogenetics research appears to be a promising new approach that may speed the development of treatments for amphetamine dependence. Ultimately, genotypic information may allow clinicians to tailor treatment to each individual through consideration of polymorphisms affecting treatment response. Effective pharmacotherapies may become integral components of successful comprehensive treatment strategies for amphetamine dependence.

INTRODUCTION

The defining characteristic of sedative–hypnotics is their ability to inhibit neurotransmission in the nervous system, primarily, but not exclusively, through their action on γ -aminobutyric acid (GABA) receptor systems. Most have an established role in medical practice, although their liability for abuse, tolerance, and toxicity may restrict their use. The risk for dependence on these agents varies substantially among different agents, with those used commonly in clinical practice having relatively lower potential for misuse than those agents used purely for their hedonic effects. Abuse liability of these agents is best viewed on a continuum that takes into account the characteristics of the individual using the drug, even in a therapeutic context. This chapter first presents an overview of the sedative–hypnotics and then discusses individual agents and chemical classes in greater detail.

HISTORY

In the early 1900s barbitol and phenobarbital were the first barbiturates introduced into medical practice. These drugs are derivatives of barbituric acid, which was synthesized by von Baeyer in 1864. The barbiturates are still used in modern medicine as general anesthetics, anticonvulsants, and sedatives, and in combination with other medications in products used to treat headaches, asthma, and gastrointestinal disorders. Barbiturates have a risk of lethality in overdose, tolerance, dependence, abuse, drug interactions, and a life-threatening withdrawal syndrome after abrupt discontinuation of high doses.

Given the limitations of the barbiturates, the introduction of meprobamate in 1955 and the benzodiazepine, chlordiazepoxide, in 1957 was embraced by clinicians. Meprobamate was widely prescribed as an antianxiety agent but its use declined as practitioners found that it was more likely than barbiturates to lead to a withdrawal syndrome on discontinuation, which was often severe in nature and associated with seizures. The therapeutic index also proved unfavorable, with fatalities associated with doses as low as 12 g (typical therapeutic doses are between 1.2 and 1.6 g daily, with a maximum of 2.4 g daily). Chlordiazepoxide and other benzodiazepines became the dominant antianxiety agents and hypnotics with established efficacy and less risk of lethal overdose or drug interactions. The use and availability of other sedative–hypnotics

such as chloral hydrate, ethchlorvynol, glutethimide, and methprylon also declined, because they were more toxic and less effective than the benzodiazepines. Newly developed nonbenzodiazepine hypnotics, commonly referred to as the “Z-drugs,” were introduced in the 1990s. These include zopiclone, eszopiclone, zolpidem, and zaleplon. These hypnotics may have subtle differences from the benzodiazepine hypnotics, although clinical experience is limited compared to benzodiazepines. The Z-drugs are associated with abuse liability, dosage escalation above recommended levels, and associated toxicity, including seizures and a withdrawal syndrome. On the other hand, some studies suggest a low risk for tolerance, physical dependence, and rebound insomnia when Z-drugs are administered as hypnotics in therapeutic doses. Another type of sedative–hypnotic is gamma-hydroxybutyrate (GHB). In the United States GHB is marketed as Xyrem and approved by the FDA for the treatment of cataplexy and excessive daytime sleepiness in narcolepsy. Its abuse liability is equivalent to ethanol and flunitrazepam (one of the most reinforcing benzodiazepines). Administration of GHB at high doses for prolonged periods in animals produces physical dependence. Human cases of dependence and life-threatening withdrawal syndromes have been reported. Most GHB use appears to be limited to intermittent use by individuals between 16 and 23 years old in social settings, although regular use may be common in other countries and specific subgroups in the United States.

EPIDEMIOLOGY

While public concern about benzodiazepine dependence has declined over the past decade, clinicians remain divided about appropriate prescribing practices. On the one hand, there is a substantial database suggesting that abuse of benzodiazepines is not a significant health problem. Supporting this position are the results of the 2008 SAMSHA National Survey of Drug Use and Health. Figures 17.1 to 17.4 from the NSDUH demonstrate that sedatives (1) are rarely the first drug abused by an individual, (2) have the lowest rate of abuse compared to other commonly misused drugs, (3) are rarely responsible for initiation of a treatment episode, and (4) when compared to marijuana (56.6%), pain relievers (22.5%), and even inhalants (9.7%), the sedatives (3.8%), and tranquilizers (3.2%) are very rarely the specific drug used when initiating illicit drug use. Benzodiazepines

are not often the primary drug of abuse leading to treatment, and when they are involved it is usually in combination with other drugs such as marijuana, opioids, and alcohol.

In addition to SAMSHA data, other survey data and expert reports show that the number of U.S. prescriptions for benzodiazepines has steadily declined from a peak of 87 million in 1973. As expected, the “Z-drugs” have increased numbers of U.S. prescriptions, but remain at relatively modest levels. The percentage of the U.S. population taking a benzodiazepine at least once during a given year varies from 7.4% to 17.6%. More consistent rates are found when duration of treatment is included. Only about 1% of the U.S. population takes prescription benzodiazepines for longer than 1 year, which is consistent with European studies reporting 1 year of medical use of 1.7% and 6-month use of approximately 3%. Long-term medical use is more common among the elderly, women, and individuals with chronic health problems or psychological disorders.

The highest rates of use and misuse occur in patients with comorbid addictions such as opioid or alcohol dependence. Approximately 15% to 20% of alcoholics presenting for treatment are also taking benzodiazepines. This is partially explained by self-medication of alcohol withdrawal and the high prevalence of substance-induced anxiety disorder in this population. Methadone patients also have very high rates of urine samples positive for nonprescribed benzodiazepines (30% to 90%). About 30% of psychiatric patients are prescribed benzodiazepines, most commonly those with long duration of illness, affective disorders, and who are frequent users of medical services. Anxiety disorder patients, as a group, do not misuse benzodiazepines, and tend to decrease the dose over time. Benzodiazepine prescriptions for anxiety disorders have declined, supplanted by the use of selective serotonin reuptake inhibitors as a first-line treatment in several types of anxiety. Patients with chronic pain also tend to use

prescribed benzodiazepines in higher amounts than the general population.

COMORBIDITIES AND COMPLICATIONS OF USE

The toxicities of benzodiazepines and barbiturates differ more in severity than in the pattern of adverse consequences. All agents are CNS depressants, which at low doses produce sedation and at the highest doses may result in obtundation, coma, and death. At typical initial therapeutic doses problems with oversedation, motor impairment, slowed cognition, and amnesia may occur. At higher therapeutic doses slurred speech, ataxia, and impaired gag reflex may be observed. As a general rule when doses are kept within a therapeutic range, tolerance to many of these adverse effects occurs. For example, while initial treatment with a benzodiazepine may produce anterograde amnesia, learning difficulties, and impairment of attention and concentration, tolerance usually occurs with continued treatment. The scientific literature in this area is contradictory. Some studies have found that long-term benzodiazepine treatment does not impair cognitive function while others have seen persistent problems in learning, psychomotor function, concentration, and motor skills. Some of these contradictory findings are attributable to studies of populations taking different doses, various benzodiazepines, unknown duration of treatment, and heterogeneity of risk factors in the group studied (e.g., young vs. elderly). Elderly patients may be at risk for both cognitive difficulties and falls, although it is unclear whether these drugs present greater risks to the elderly than other sedative psychotherapeutic agents. Cognitive impairment is likely to persist in the elderly although most patients do not recognize it or feel that it does not impair their daily functioning. A somewhat unusual adverse effect has been seen with high doses of the Z-drugs. There have been several reports of Z-drug-related amnesia

associated with sleepwalking and odd nighttime behavior, such as driving, eating, shopping, and hallucinations.

Early studies suggested that there was a risk of cleft palate when benzodiazepines were prescribed during pregnancy. These studies found that the risk of cleft palate doubled from 0.06% in the general population to 0.12% in pregnant woman exposed to the benzodiazepines. These studies have been highly criticized based on different methodologies, failure to control for specific benzodiazepines, dose administered, duration administered, and concurrent medications used. At present, the best evidence indicates that monotherapy with a benzodiazepine during pregnancy is not associated with major congenital anomalies. Sedative–hypnotics administered during pregnancy may lead to a withdrawal syndrome in newborns or the floppy baby syndrome, in which the neonate has low APGAR scores, poor sucking, poor reflexes, hypotonia, and apnea. Congenital abnormalities resulting from barbiturates are difficult to distinguish from those associated with other anticonvulsants because phenobarbital is usually not given as a monotherapy. When phenobarbital is given alone or in combination with other anticonvulsants, higher rates of major malformations are reported compared to mothers with a history of epilepsy who took no anticonvulsants during pregnancy.

OVERVIEW OF DETERMINANTS OF ABUSE

Sedative–hypnotics have a potential for misuse if the agent has strong euphoric or mood-altering effects, tolerance develops to its primary therapeutic effect, or the severity of the withdrawal syndrome is such that discontinuation of the drug is difficult.

Among the commonly used sedative–hypnotics, barbiturates produce the greatest pleasant mood alterations, although others, such as flunitrazepam and GHB, may be similar. Among the benzodiazepines, there are differences in the ability to induce mood enhancement associated with abuse. Theories that attempt to explain differing effects are not entirely satisfactory. The most common explanation is that drugs with a rapid onset of action, followed by a rapid termination of single-dose effects, are associated with higher abuse liability *in vulnerable populations*, such as recovering alcoholics and methadone maintenance patients. It is unlikely that pharmacokinetics explains the acute mood effects of benzodiazepines entirely; we know that binding to subtypes of the alpha subunit of the receptor may influence a variety of actions, including sedation, anxiety, memory, anticonvulsant, and perhaps hedonic effects. With respect to acute euphoric effects, immediate-release alprazolam and flunitrazepam are consistently rated by experienced substance abusers as producing a high that they like. This is consistent with clinical experience, but any sedative–hypnotic may be abused by high-risk individuals.

Tolerance to barbiturates and benzodiazepines is well established. Some evidence suggests that temazepam and the Z-drug, eszopiclone, are not associated with the development

of tolerance to their hypnotic effect and have low risk of rebound insomnia when the drugs are discontinued. With respect to treatment of anxiety, patients develop rapid tolerance to sedative effects, incomplete tolerance to impairment of coordination, memory, and muscle relaxant effects, and little or no tolerance to antianxiety effects. In the treatment of seizures with clonazepam, partial tolerance develops. Clinicians should discuss the issue of tolerance with all patients, and caution them against unauthorized increases in dose or abrupt discontinuation of the medication. Information about the withdrawal syndrome and the risks of dependence on all sedative–hypnotics should be discussed prior to initiating therapy. The signs and symptoms of sedative–hypnotic withdrawal syndromes and treatments are discussed in detail in Chapter 35. In the sections below we describe the pharmacology of the individual agents in greater detail, emphasizing mechanisms of action that produce clinical effects, tolerance, and dependence.

BENZODIAZEPINES

Pharmacology

GABA_A receptors act as the primary mediator of inhibition of neurotransmission in the mammalian brain. The GABA_A receptor systems play a major role in mediating the actions of most of the sedative–hypnotic agents in current use. GABA_A receptors are ligand-gated chloride channels that are commonly formed by five subunits. The subunit composition of these receptors, in conjunction with their precise location in the neuronal tissues, determines their functional and pharmacologic properties. Nineteen types of GABA_A subunits have been identified and can be divided into seven distinct families. The α , β , δ , and λ families combine to form the receptors that are the primary targets of the sedative–hypnotic agents. There are six members of the α family (α_1 to α_6), four members of the β family, and three of the λ family. The subunit composition of GABA_A receptors in the brain most frequently consists of two α subunits and two β subunits that exist in association with a γ or δ subunit. Receptors with the $\alpha_1\beta_2\gamma_2$ mix of subunits occur with the greatest frequency in the brain.

GABA binds at the interface between the α and β subunits of the GABA_A receptors. Benzodiazepines bind at the interface of α and γ subunits. Binding of GABA to the GABA_A receptor opens a chloride channel, which results in most instances in hyperpolarization of the neuron. The binding of benzodiazepine produces an allosteric modification in the GABA binding site. This modification usually leads to an increase in the frequency of the opening of the chloride channel.

GABA_A receptors that are sensitive to the benzodiazepines contain α subunits 1, 2, 3, or 5, combined with two β subunits and a γ subunit. GABA_A receptors containing the α_4 and α_6 subunits may be insensitive to the effects of benzodiazepines (1). This may be of significance because the α_4 and α_6 subunits in combination with δ subunit may localize primarily

in extrasynaptic regions of the neuron, and may consequently act to regulate the tonic inhibitory as opposed to the synaptic phasic inhibitory effects of GABA (2). There is now increasing evidence that tonic currents play a major role in controlling neuronal excitability. The ability of drugs to interact with receptors that regulate tonic currents may determine the extent to which they can influence seizures, sleep, and other brain activity.

Data from animal studies suggest that GABA_A receptors containing different types of the α subunit appear to mediate distinct behavioral effects of benzodiazepines and other benzodiazepine receptor agonists. Receptors containing the α_1 subunit have been implicated in the production of sedation, amnesia, antiseizure effects, and ataxia (3). The presence of the α_2 and α_3 subunits is associated with the anxiolytic and muscle relaxant-inducing effects of the benzodiazepine receptor agonists (4). The behavioral effects of benzodiazepine agonist stimulation of the α_5 subunit containing receptors remain to be elucidated. However, it has been shown that learning and memory functions appear to be enhanced in animals missing the α_5 subunit suggesting that benzodiazepine might produce impairment of cognition by interacting with receptors that have this subunit (5).

Determinants of Abuse

Abuse liability of benzodiazepines has been assessed in animal models, human laboratory studies, and surveys of substance abusers, patients, and the general population. With respect to animal models, the most consistent finding indicating abuse liability is produced by models using continuous drug access, that is, drug self-administration models. Other models such as place preference show weaker signals; however, diazepam and barbiturates do exhibit reinforcing effects in these models. Human laboratory studies rely on two basic models: (1) self-administration of sedative–hypnotics and placebo by individuals with a history of substance abuse and (2) determination of subjective mood effects such as “high” or “liking” after a single dose of drug. In addition, surveys of clinical populations of individuals being treated for addictive disorders ask subjects to rate the abuse liability of a variety of drugs. In general, all of these models consistently show that the benzodiazepines have a moderate potential for abuse that is substantially lower than that of methaqualone, barbiturates, and older sedative–hypnotics, such as chloral hydrate. Among the benzodiazepines themselves the preponderance of evidence suggests that flunitrazepam, diazepam, lorazepam, alprazolam, and triazolam have higher abuse potential than chlor-diazepoxide or oxazepam. It is unclear whether these research findings have practical clinical significance because the abuse of this class of drugs depends more on patient characteristics than benzodiazepine-induced acute subjective effects. Individuals at high risk include alcoholics, opioid addicts, and individuals with mixed substance abuse problems. In clinical situations, tolerance to the therapeutic action may result in unauthorized dosage escalation.

Evidence of tolerance to the benzodiazepines includes the observation that diazepam-induced chloride influx into cortical membrane vesicles is reduced after chronic exposure to this drug (6). Several mechanisms have been implicated in the development of tolerance to the benzodiazepines. Exposure to these benzodiazepines leads to uncoupling between the benzodiazepine and GABA receptor sites, that is, there is a decrease in the allosteric interactions between these sites (7). This, in part, may be the result of the internalization of GABA_A receptors originally located on the surface of neurons.

Chronic treatment with benzodiazepines may result in the modification of the subunit composition of brain GABA_A receptors. For example, animal studies suggest that proteins for the hippocampal and cortical α_1 and β_3 subunits may be reduced by chronic benzodiazepine treatment (8). Hippocampal α_5 subunits may decrease in density following prolonged treatment with benzodiazepines (9), but increases in the messenger RNA (mRNA) for this subunit have been observed in the cortical tissues of rats treated chronically with diazepam (10). Withdrawal from chronic diazepam exposure, in contrast, results in the upregulation of α_4 subunit mRNA in rat cerebellar tissue (11). Changes in GABA_A receptor subunit composition may be one of the factors that contribute to development of tolerance to benzodiazepines.

In addition to effects on GABA_A receptor systems, chronic benzodiazepine exposure alters the activity of other systems that are involved in the regulation of neuronal activity. Voltage-gated calcium channels help to regulate the influx of calcium ions into the neuron, which serve as major signaling ion within these cells. Prolonged exposure to benzodiazepines may lead to the upregulation of L-type high voltage-gated calcium channel subunits and voltage-gated channel currents are increased during chronic benzodiazepine treatment (12). Coadministration of the L-type calcium channel antagonist, nimodipine, with benzodiazepines blocks the development of tolerance in GABA_A-mediated synaptic currents (12).

Prolonged treatment with benzodiazepines also alters the activity of amino-3-hydroxy-5-methyl-4-isoxazole (AMPA), which mediates the effects of the excitatory neurotransmitter glutamate. Chronic benzodiazepine exposure also increases hippocampal AMPA receptor currents and AMPA receptor binding sites (13), an effect that is blocked by pretreatment with nimodipine (12). These increases are correlated with increases in anxiety during withdrawal from benzodiazepines. Benzodiazepine-induced increases in AMPA receptor currents and withdrawal anxiety can be attenuated by the concurrent administration of nimodipine.

Most benzodiazepines undergo rapid and extensive absorption after being administered orally. Up to 50% of midazolam, however, may be metabolized in the liver by the cytochrome P450 enzyme CYP 3A5 following oral administration of this drug. The highly lipophilic benzodiazepines, such as diazepam, readily cross the blood–brain barrier to exert their effects in the brain, but then may quickly redistribute into other tissues. The onset of action of less lipophilic agents, such as lorazepam, may be somewhat delayed.

TABLE 17.1

Benzodiazepine and Z-drugs, active metabolites of these drugs, $T_{1/2}$ (half-life in hours) of parent drugs, and known major P450 cytochromes implicated in mediating the hepatic metabolism of these agents

Drug	$T_{1/2}$	Active metabolites	p450 cytochrome
Benzodiazepines			
■ Alprazolam	12 to 15	α -Hydroxy-alprazolam	CYP3A4&A5
■ Clonazepam	19 to 60	Inactive only	CYP3A4
■ Chlordiazepoxide	10 to 30	Desmethylochlordiazepoxide, demoxepam, nordazepam, oxazepam	
■ Clorazepate	Prodrug	Nordazepam, oxazepam	
■ Diazepam	20 to 70	Nordazepam, oxazepam	CYP2C19, CYP3A4
■ Estazolam	16	1-Oxo-estazolam	
■ Flurazepam	74	<i>N</i> -Hydroxyethyl-flurezapam <i>N</i> -Desalkylflurazepam	
■ Lorazepam	10 to 20	Inactive only	
■ Midazolam	1 to 4	α -Hydroxy-midazolam	CYP3A4&A5
■ Oxazepam	5 to 10	Inactive only	
■ Quazepam	39	2-Oxo-quazepam <i>N</i> -Desalkylflurazepam	CYP2C19, CYP3A4
■ Temazepam	10 to 15	Oxazepam	
■ Triazolam	2 to 4	α -Hydroxy-triazolam	CYP3A4
Z-drugs			
■ Eszopiclone	6	(<i>S</i>)- <i>N</i> -Desmethyl zopiclone	CYP3A4, CYP2E1
■ Zaleplon	1	Inactive only	CYP3A4
■ Zolpidem	2.1	Inactive only	CYP3A4, CYP1A2, CYP2C9

Most of the benzodiazepines in use undergo biotransformation in the liver in reactions catalyzed by a variety of cytochrome P450 enzymes. Active metabolites of the benzodiazepines are shown in Table 17.1 as are the known cytochrome enzymes implicated in their metabolism. Because a variety of drugs can alter the activity of the cytochrome P450 enzymes, the pharmacokinetic properties of the benzodiazepines that undergo hepatic metabolism have the potential of being involved in adverse drug–drug interactions. There is also a possibility that impairment of liver function as may occur in aging or a number of hepatic disorders may place patients at risk for developing benzodiazepine toxicity.

Benzodiazepines and their metabolites are frequently conjugated with glucuronide prior to their being excreted in the urine. A few benzodiazepines including lorazepam and oxazepam only undergo glucuronidation prior to being excreted. These drugs offer the advantage being unlikely to interact with other drugs and of being safer to use in individuals with compromised hepatic function.

Alprazolam, midazolam, and triazolam are hydroxylated prior to being conjugated with glucuronide. In addition to hydroxylation benzodiazepine metabolites may also be the

product of demethylation and nitroreduction. Clonazepam undergoes nitroreduction, catalyzed by CYP 3A4 to form inactive metabolites. Some of the older benzodiazepines including chlordiazepoxide, diazepam, and flurazepam may be transformed into a variety of active metabolites that may greatly extend the duration of action of these drugs. Diazepam, for example, is converted to nordazepam, which has a half-life of between 50 and 180 hours.

Z-DRUGS

Several nonbenzodiazepine drugs have been developed that share many of the pharmacologic actions of the benzodiazepines. These agents include the cyclopyrrolones, zopiclone and its *S*-enantiomer, eszopiclone, the imidazopridine, zolpidem, and the pyrazolopyrimidine, zaleplon. Although these agents do not form a single specific class of drugs, for convenience this group of drugs can be designated as being the “Z-drugs.” These drugs are able to induce sleep at doses that produce lower levels of residual sedation and residual functional impairment in cognitive and psychomotor tasks versus barbiturate or benzodiazepine hypnotic agents. As compared

to the barbiturates and the benzodiazepines, the Z-drugs do not produce marked undesirable changes in sleep architecture (14). There is, however, some evidence that zopiclone may produce modest suppression of REM sleep (15), but this drug did not significantly alter REM sleep when used in a therapeutic dose in a clinical trial (16). In addition to sedative–hypnotic effects, these drugs have amnesic effects, anticonvulsant actions, anxiolytic activity, motor-impairing effects, and muscle relaxant effects (17,18). The Z-drugs show less pronounced amnesic and antianxiety effects than do the benzodiazepines (17).

Zaleplon and zolpidem may produce alterations in vision that may include altered color perception, pulsating of light, and room spinning. Common adverse effects associated with the use of zolpidem include headache, somnolence, dizziness, and nausea. This drug may produce hallucinations when administered concurrently with serotonin reuptake inhibitors. Eszopiclone and zopiclone, in addition to sedation, may produce dry mouth and a metallic taste (14). Complex behaviors during sleep including sleepwalking, driving, eating, and cooking have been reported to occur in patients being treated with Z-drugs.

Pharmacology

The Z-drugs may activate the benzodiazepine receptor site located on the GABA_A receptor complex. The actions of these drugs are antagonized by the administration of the benzodiazepine receptor antagonist flumazenil. Eszopiclone, zopiclone, and zolpidem have been demonstrated to bind in the region of the benzodiazepine binding site, but they may differ from the benzodiazepines and from each other with respect to precisely which amino acid residues within this site are essential for their activity.

The Z-drugs all potentiate GABA-mediated currents in neurons containing GABA_A receptors. This action produces an increase in chloride ion conductance. Binding studies, however, suggest that these agents may differ in their affinity for GABA_A receptors with different α subunit compositions than do the benzodiazepines (19). Electrophysiologic studies indicate these differences may have functional significance. Like the benzodiazepines, the Z-drugs have a low affinity for GABA_A receptors that contain the α_4 and α_6 subunits. Zolpidem is between 5 and 10 times more selective for α_1 -containing GABA_A receptors than it is for α_2 - and α_3 -containing receptors, while having extremely low selectivity for receptors containing the α_5 subunit. Zaleplon has two- to threefold greater selectivity for α_1 -containing receptors as compared to those having α_2 and α_3 subunits. This drug has minimal actions on GABA_A receptors that have α_5 subunits. In contrast to zolpidem and zaleplon, zopiclone has almost equal selectivity for α_1 - and α_5 -containing receptors, while having between four and eight times less selectivity for those receptors with α_2 and α_3 . Compared to benzodiazepines, then, the Z-drugs have modest degree of selectivity for receptors containing α_1 subunits as compared to those with α_2 or α_3 subunits.

Evidence from animal studies is consistent with the idea that zolpidem acts selectively on GABA_A receptors containing α_1 subunits to produce its behavioral effects. These findings include the observations that the hypnotic, sedative, motor-impairing, and anticonvulsant effects of this drug are attenuated by either selective genetic deletion of the α_1 subunits or the administration of select α_1 subunit antagonists (3).

Animal studies indicate that zolpidem and, to a lesser degree, zaleplon have greater potency as hypnotic agents than as muscle relaxants (19). Zopiclone, in contrast, produces its hypnotic and muscle relaxant effects at similar doses. The modest differences in the selectivity of the Z-drugs for GABA_A receptors containing α_1 subunits may not be great enough to completely explain the minimal residual adverse effects seen after these agents have been used to treat insomnia.

The effects of the Z-drugs on receptor systems other than the GABA_A systems have not been extensively explored. Zaleplon has been shown to have little affinity for dopamine, muscarinic, noradrenergic, opioid, and serotonergic receptors. Zopiclone can inhibit the activity of both nicotinic receptor and *N*-methyl-D-aspartate (NMDA) receptors, which mediate the effects of excitatory amino acids, such as glutamate (20).

The receptor changes that occur after chronic Z-drug treatment have not been thoroughly studied. In the rat repeated zolpidem administration is associated with an increase in cortical mRNA levels for the α_4 and β_1 GABA_A receptor subunits after 7 days and a decrease in mRNA for the α_1 subunit after 14 days (21). Chronic exposure to either zaleplon or zolpidem of cell cultures containing rat cerebellar granule cells results in an elevation in mRNA for the α_4 subunit and a reduction in mRNA for α_1 and γ_2 subunits during withdrawal from either zolpidem or zaleplon (22).

Animals treated chronically with flurazepam show tolerance to the inhibitory effects of zolpidem in the hippocampus (12). Administration of the L-type calcium channel blocker, nimodipine, did not block the development of flurazepam-induced tolerance to the inhibitory effects of zolpidem in the hippocampus. This suggests that in contrast to the benzodiazepines, L-type voltage-gated calcium channels may not be implicated in the development of tolerance to zolpidem.

The pharmacokinetic properties of the Z-drugs may be one of the factors that explain the lower incidence of residual adverse effects that are associated with their use. The elimination half-life of zolpidem is approximately 2 hours while that of zaleplon is 1 hour (see Table 17.1) (17). Eszopiclone has comparatively longer half-life of 4 hours, which can reach up to 7 hours in elderly individuals (14). Both zolpidem and zaleplon are metabolized in the liver into inactive metabolites (17). Zopiclone is metabolized to *N*-oxide zopiclone and desmethylzopiclone. The *N*-oxide metabolite has some activity. The oxide metabolite of eszopiclone, (*S*)-zopiclone-*N*-oxide, does not bind to GABA_A receptors while the (*S*)-desmethylzopiclone metabolite of this drug may have anxiolytic effects.

Because zopiclone and eszopiclone are more slowly eliminated than are zolpidem or zaleplon, they can help to maintain sleep throughout the night. Zopiclone has been shown to produce psychomotor impairment 7 hours following its administration. A sustained-release formulation of zolpidem is currently being marketed and a sustained-release formulation of zaleplon is in development. These sustained-release formulations are designed to allow patients to maintain sleep throughout the night when being treated with either zaleplon or zolpidem for insomnia.

Determinants of Abuse

There are a number of case reports of Z-drug-related abuse and dependence. In many instances extremely high doses of drugs may be self-administered. Doses of zolpidem in cases of abuse are often in the range of hundreds of milligrams being administered daily. This is in comparison with a therapeutic dose of zolpidem of about 10 mg daily.

Many individuals who misuse zolpidem have reported using the drug not for its sedative effects, but rather for its anxiolytic, euphoric, or stimulant effects. Human laboratory studies of the effects of Z-drugs indicate that these drugs may produce stimulus effects that present some risk for abuse. In social drinkers zolpidem administration increased ratings of drug liking, but did not elevate scores on the Addiction Research Center Inventory-Morphine Benzodrine Group subscale (ARCG-MBG), a subscale that is sensitive to drug-induced euphoria (23). The drug-liking effects of zolpidem in these subjects were not found to be additive with those of alcohol. Subjects with a history of sedative abuse reported greater liking of triazolam and zolpidem than placebo (24). In subjects with a history of alcohol and drug abuse, higher doses of zolpidem produced elevations in scores for drug-liking and good effects (25). Zolpidem administration also resulted in elevations in rating of drug high and good effects in healthy subjects, who found triazolam and pentobarbital to have similar stimulus effects to those of zolpidem (25).

The results of several studies suggest that the risk for the development of tolerance, physical dependence, and withdrawal is low when therapeutic doses of the Z-drugs are used to treat insomnia. For example, no tolerance to the sleep-inducing effects of either zaleplon or zolpidem was seen when administered for several weeks. Tolerance was not observed to the hypnotic effects of eszopiclone or a sustained formulation of zolpidem when subjects were treated with this agent for primary insomnia over a 6-month period (26,27). Several studies also indicate that no rebound insomnia was observed after discontinuation of the Z-drugs. In contrast, there are some studies that indicate that modest increases in anxiety and reduced sleep were observed in subjects treated with immediate-release formulations of zaleplon, zopiclone, or zolpidem (28,29). This has also been observed in individuals being treated with a sustained-released formulation of zolpidem (30). Overall, results from sleep trials suggest that dependence and withdrawal may not

be problematic for patients being treated for insomnia with therapeutic doses of Z-drugs.

Animal studies have been conducted to determine whether Z-drugs can produce physical dependence with prolonged administration of these agents. Chronic administration of zolpidem did not result in physical dependence in mice (31). In contrast, work in primates has demonstrated that Z-drugs can produce physical dependence. In monkeys, the discontinuation of chronic zopiclone administration resulted in symptoms of withdrawal including apprehension, hyperirritability, and motor impairment (32). Flumazenil-induced withdrawal from zolpidem produced withdrawal signs that were moderate in severity in baboons that included tremor, jerk, and rigid posture (33).

Several case reports have been published that suggest that problems of dependence and withdrawal may occur in humans receiving Z-drugs (34). Seizures have been observed after the discontinuation of zolpidem in individuals using extremely high doses of this agent (34), as have other signs of withdrawal including tremor, agitation, and anxiety.

BARBITURATES

Barbiturates are barbituric acid derivatives. Prior to the introduction of the benzodiazepines, the barbiturates were extensively used as sedative-hypnotic agents. They also have been administered for their anticonvulsant effects and as anesthetic agents. The therapeutic indices of the barbiturates are comparatively low and toxic reactions, sometimes resulting in death, were frequent occurrences associated with the use of these agents. It, also, has been evident since the early 1950s that the use of these drugs is associated with a high risk of abuse and forms of dependence that can lead to severe, sometimes lethal episodes of withdrawal.

As with the benzodiazepines, barbiturates have been used in the treatment of insomnia, seizure disorders, and anxiety disorders and to produce sedation and to induce anesthesia. Barbiturates with short to intermediate ranges of duration of action, that is, from 3 to 12 hours, including amobarbital, butobarbital, pentobarbital, and secobarbital, are currently used as sedative-hypnotic agents. Butalbital is used as a sedative component of antimigraine combination agents that also contain caffeine and either aspirin or acetaminophen. Long-acting, less lipophilic barbiturates such as mephobarbital and phenobarbital are used primarily as anticonvulsant agents. The highly lipophilic, ultrashort-acting barbiturates, methohexital and thiopental, are used in the induction of anesthesia.

The barbiturates produce depression of central nervous system activity that can range from sedation to sleep, anesthesia, and finally coma. These agents are not selective in their actions and their antianxiety effects are not separable from their other depressant effects. The barbiturates will reduce slow wave and REM sleep. Respiratory depression produced by the barbiturates, often in combination with other CNS depressants, may be a major contributory factor to death in cases of barbiturate overdoses.

Adverse effects of the barbiturates include sedation and disruption of motor coordination. In some patients, for example, in elderly individuals, the administration of a barbiturate may lead to the appearance of paradoxical excitement. Allergic reactions may occur in some patients receiving barbiturates and exfoliative dermatitis may sometimes be caused by phenobarbital administration.

Chronic barbiturate intoxication may produce somnolence, confusion, ataxia, nystagmus, coarse tremor, and emotional instability. Severe barbiturate toxicity may lead to coma and respiratory depression. Respiratory depression can cause respiratory acidosis and cerebral hypoxia. Fatal complication of barbiturate toxicity may include pulmonary complications such as pulmonary edema and renal failure.

Pharmacology

With respect to their actions at the GABA_A receptor complex, low concentrations of barbiturates act as positive allosteric modulators of GABA action at the receptor. At higher concentrations the barbiturates may directly activate the GABA_A receptor. Millimolar concentrations of barbiturates appear to block the GABA_A receptor. The extent of activation of the GABA_A receptor system by barbiturates is dependent on the subunit composition of the receptor. The type α subunit contained in the GABA_A receptor may be a major determinant of the degree of receptor activation by barbiturates. For example, pentobarbital produces greater potentiation of the effects of GABA in receptors containing the α_6 as compared to the α_1 subunit (35). The maximum direct effect of this drug on GABA_A receptors was greatest in those receptors with α_6 as compared with those containing α_2 or α_5 subunits. In contrast to the benzodiazepines, pentobarbital also strongly activates GABA_A receptors containing the α_4 subunit.

Actions of the barbiturates may not be limited to their effects on GABA_A receptors. Ionotropic glutamate receptors may be subject to inhibition produced by barbiturate administration. Thiopental may decrease the activity of NMDA excitatory glutamate receptors, while phenobarbital appears to be ineffective in blocking the effects of NMDA (36,37). Thiopental and pentobarbital when administered may have inhibitory actions on AMPA receptors (38). In vitro, the sensitivity of AMPA receptors to pentobarbital is increased when these receptors contain the AMPA GluR2 subunit (38). Genetic deletion of the GluR2 subunit, however, results, paradoxically, in enhanced sensitivity of mice to the anesthetic effects of pentobarbital (39).

Barbiturates have inhibitory effects on voltage-gated calcium ion channels (40). This effect may lead to the inhibition of the stimulated release of noradrenaline and dopamine produced by thiopental, pentobarbital, and phenobarbital (41). Pentobarbital may also block calcium-dependent release of other neurotransmitters including GABA, glutamate, and acetylcholine (42,43).

The barbiturates are inactivated by hepatic metabolism, with oxidation being an important step in the biotransfor-

mation of most of these drugs. Approximately 25% of a dose of phenobarbital is excreted in the urine in unchanged form. Phenobarbital and other barbiturates induce cytochrome P450 enzymes in the liver. Cytochrome enzymes induced by phenobarbital exposure include CYP2B6, CYP2C9, and CYP3A4. Consequently, the chronic administration of phenobarbital has the potential to reduce the plasma concentrations of a large number of drugs.

Determinants of Abuse

While barbiturates may present a high risk for the development of dependence in many patient populations, this may not always be the case. The risk of developing dependence in seizure patients being treated with barbiturates may be low, but a small percentage of these patients do report feelings of craving and may use higher than prescribed doses of their medication (44).

In the laboratory setting the positive effects of pentobarbital have been shown to be greater than those of benzodiazepines (45). Healthy subjects rated a 100-mg dose of pentobarbital as producing greater “high” and “good effects” than placebo (46). This occurred in conjunction with larger pentobarbital-induced increases in ratings of drowsiness, sleepiness, and performance impairment.

Long-term use of the barbiturates can result in physical dependence characterized by a severe, sometimes life-threatening withdrawal syndrome. Delirium and seizures may appear during withdrawal. Withdrawal can be a problem for seizure patients who have discontinued treatment with phenobarbital. Migraine patients receiving butalbital containing combination drugs for extended periods of time are also at risk of developing withdrawal symptoms, which can include the onset of generalized seizures.

Tolerance to the barbiturates may result from both pharmacokinetic and pharmacodynamic factors. The ability of barbiturates such as phenobarbital to induce hepatic metabolic enzymes may lead to an increase in the rate of their own elimination, thus producing “pharmacokinetic” tolerance. Chronic exposure to pentobarbital can lead to the decrease in the interaction between the barbiturate and GABA recognition sites producing pharmacodynamic tolerance (7).

Prolonged exposure to pentobarbital results in the up-regulation of cerebellar δ GABA_A receptor subunit mRNA in tolerant rats, and downregulation of this subunit mRNA occurs during withdrawal from this agent (47). Pentobarbital tolerant rats show an increase in mRNA for α_6 subunit. The subunit composition of NMDA receptors, which mediate the excitatory effects of glutamate, may also change in response to chronic barbiturate exposure. NMDA receptor subunits also may be altered by chronic pentobarbital treatment. NMDA NR2B subunit mRNA is decreased in the parietal cortex and hippocampus, in animals made tolerant to pentobarbital and in animals withdrawn from this drug, while the opposite result was seen for cortical NR2A subunit (48).

γ-HYDROXYBUTYRATE (OXYBATE)

GHB is a short-chain fatty acid that is found in both the brain and peripheral tissues (49). Endogenous GHB may act as either a neurotransmitter or a neuromodulator. Synthetic GHB is used as a therapeutic agent and as a drug of abuse, but at doses that produce concentrations that are several orders of magnitude greater than those produced endogenously.

GHB is approved in the United States for the treatment of cataplexy and excessive daytime sleepiness in narcolepsy patients (49). This drug is used in Europe in the management of alcohol dependence and withdrawal. GHB has been abused, often in nightclub settings, sometimes in combination with other “club” drugs such as 3,4-methylenedioxymethamphetamine (MDMA) and ketamine. It also has been administered to women prior to sexual assault as a so-called “date-rape” drug.

GHB was available in the 1980s and early 1990s as a natural supplement, but is now classified as a controlled substance in the United States (50). Other designations for GHB include γ-hydroxybutyric acid, 4-hydroxybutanoic acid, and oxybate. The sodium salt of oxybate is marketed under the trade name Xyrem. GHB is called a variety of street names including “G,” GHB, Georgia Home Boy, Grievous Bodily Harm, “liquid ecstasy,” and “liquid X.” Precursors of GHB, γ-butyrolactone and 1,4-butanediol may be used as substitutes for GHB, because they can produce the same range of effects. This may sometimes occur when products sold as GHB contain precursors of this drug.

Exogenously administered GHB undergoes rapid absorption from the gastrointestinal tract and then readily crosses the blood–brain barrier. This agent can cause sedation and induce sleep, and at higher doses produce anesthesia. Subjects who abuse GHB report that this drug can cause euphoria, disinhibition, and increased libido. Other pharmacologic effects of this agent include impairment of motor coordination.

GHB has a low therapeutic index (49). Toxic doses of GHB can produce coma, respiratory depression, myoclonus, seizures, bradycardia, and death. Respiratory depression, pulmonary edema, and positional asphyxia may be contributory factors to death resulting from GHB. Intoxication with GHB frequently occurs while other abused substances are being used, such as ethanol, that act synergistically to enhance the toxicity of GHB.

Pharmacology

In the brain, GHB is the product of the transformation of succinic semialdehyde, a GABA metabolite with the conversion reaction being mediated by the enzyme semialdehyde reductase (49,50). GABA is converted into succinic semialdehyde by the enzyme GABA transaminase. This reaction is reversible and succinic semialdehyde can then undergo biotransformation into GABA. Semialdehyde reductase is found in GABA-containing neurons. GABA and GHB may colocalize in inhibitory nerve terminals.

The precise physiologic role of endogenous GHB remains unclear. Specific high-affinity binding sites have been found in the brain for this substance including in hippocampus, cortex, and thalamus. Selective GHB receptors have been isolated and

cloned. They appear to be orphan G-protein-coupled receptors. The behavioral effects of activation of selective GHB receptors remain to be elucidated. GHB-induced excitation of neurons in the prefrontal cortex is blocked by the administration of the selective GHB receptor antagonist NCS-382 (50).

GHB acts as a partial agonist at GABA_B receptors. Millimolar concentrations of GHB are required to activate these receptors (50). Consequently, the activity of GHB at the GABA_B receptor is of most relevance to the actions of this compound when it is exogenously administered. Behavioral manifestations of GHB-induced sedation include decreased locomotor activity, catalepsy, and loss of righting reflex. The administration of GABA_B antagonists can block these effects (50). Reductions in locomotor activity produced by treatment with either GHB or γ-butyrolactone are not observed in mice who do not express the GABA_B receptor (51).

The administration of GHB has an overall effect of producing a mild stimulatory effect on the firing of dopamine neurons in the ventral tegmental area (52). The activity of neurons in the nucleus accumbens is decreased by the administration of GHB. The activation of VTA dopamine neurons and the inhibition of nucleus accumbens neurons are characteristic changes in the mesolimbic system produced by a variety of abused substances.

GHB is readily absorbed when administered orally. Peak concentrations of this drug are attained in less than an hour following oral ingestion. The primary route of metabolism of GHB is oxidation to succinic semialdehyde by succinic semialdehyde dehydrogenase. GHB is rapidly eliminated with its half-life being in the range of 20 to 40 minutes. The rapid elimination of this compound makes it difficult to detect its use by utilizing chemical assays. Also, as a consequence of its short half-life, rapid reversal of the effects of GHB may occur, with rapid transitions from a state of unconsciousness to being alert in users being seen following ingestion of a large dose of this compound.

γ-Butyrolactone and 1,4-butanediol are biotransformed in humans into GHB. Both of these agents have been abused (49). Circulating lactonases mediate the conversion of γ-butyrolactone into GHB. Alcohol dehydrogenase and aldehyde dehydrogenase catalyze the conversion of 1,4-butanediol into GHB (49). Concurrent use of ethanol with 1,4-butanediol may result in competition between these compounds for alcohol dehydrogenase.

Determinants of Abuse

GHB is self-administered by rodents, but has not been consistently self-administered by monkeys. Clearer evidence of the high likelihood of GHB being abused is provided by human laboratory studies. In the human laboratory setting, GHB administration leads to responses in both abusers of sedative–hypnotics and GHB club users that include elevated ratings of drug-liking and good effects (45). Club users of this drug show elevations in ARCI-MBG scores and stimulation following GHB administration. The positive effects of GHB were at least comparable to those of ethanol and flunitrazepam in club users. In contrast to these two other agents,

GHB also produced bad effects including dizziness, confusion, and dysphoria as measured by the ARCI-LSD subscale. Sedative–hypnotic users also indicated experiencing nausea and other symptoms of gastrointestinal distress after the ingestion of GHB. GHB also produced impairments in memory function and psychomotor performance. At high doses GHB had a sedative effect in sedative–hypnotic users.

Tolerance to the sedative effects of GHB and signs of dependence during discontinuation of this agent were not observed in subjects receiving therapeutic doses of this drug (53). Case reports indicate that daily administration of high doses of either GHB (in the range of 20 g/day) or γ -butyrolactone may produce physical dependence (54). Experimental studies in baboons support the idea that the prolonged administration of high doses of either GHB or γ -butyrolactone can result in physical dependence (55).

CONCLUSION

Barbiturates have been used to treat a variety of disorders but possess the highest abuse liability of the sedative–hypnotics presently in common medical use. Their low therapeutic index poses high risks of toxicity, including lethal overdoses and severe withdrawal syndromes on drug discontinuation. In contrast, benzodiazepines are characterized by large margins of safety. Benzodiazepines are associated with moderate levels of risk for abuse and dependence, particularly in certain substance-using populations. Toxicity and rates of abuse for benzodiazepines are dramatically less than the barbiturates.

The Z-drugs appear to be an incremental advance over the benzodiazepines with regard to the safety of their use in the treatment of insomnia. There seems to be some, but comparatively lower risk of the development of problems related to abuse and dependence with these agents than the benzodiazepines, but more extensive prescribing experience is required to establish if these are clinically relevant differences.

GHB produces subjective effects that are similar to those produced by other sedative–hypnotic agents. It is interesting that in contrast to the other sedative–hypnotic agents, the effects of GHB appear not be mediated by the GABA_A receptor complex. With respect to its abuse liability, there is clear reason for concern regarding misuse because it produces positive stimulus effects that are at least equal to those of flunitrazepam and ethanol.

INTRODUCTION

This chapter focuses on the major current and past hallucinogens: the prototype ergot hallucinogen lysergic acid diethylamide (LSD); other indolealkylamines such as psilocybin, psilocin, and dimethyltryptamine (DMT); and the phenethylamines, including mescaline and dimethoxymethylamphetamine (DOM). Cannabis, phencyclidine (PCP), and designer drugs such as methylenedioxymethylamphetamine (MDMA or ecstasy), which are sometimes classified as hallucinogens, are covered in other chapters in this volume (see Chapters 15 and 19).

The term *hallucinogen* means “producer of hallucinations.” A hallucination is defined as a profound distortion in the perception of reality, frequently described as a sensory experience of something that is not there. Many drugs, when taken in sufficient quantity, can cause auditory and/or visual hallucinations. Such hallucinations can be present as part of a delirium, accompanied by disturbances in judgment, orientation, intellect, memory, emotion, and level of consciousness (e.g., organic brain syndrome). Delirium also can result from drug withdrawal (e.g., sedative–hypnotic withdrawal or delirium tremens in alcohol). However, hallucinogen generally refers to compounds that alter consciousness without producing delirium, sedation, excessive stimulation, or intellectual or memory impairment as prominent effects. This label actually is inaccurate because true LSD-induced “hallucinations” are rare; what are commonly seen are illusory phenomena. An illusion is a perceptual distortion of an actual stimulus in the environment: to see someone’s face seeming to be melting is an illusion; whereas, to see a melting face when no face is present is a hallucination. There are a variety of widely accepted synonyms for the hallucinogens, including the term *psychedelic* (1). The term *psychotomimetic*, meaning “a producer of psychosis,” also has been widely used. For a review of the original terminology and a classification system for the hallucinogenic drugs, see Shulgin (2).

Over the last 2 decades, a number of features regarding the study and use of hallucinogens have changed. First, the Internet has become a widely used source of information on hallucinogens (3). Second, during the 1980s little clinical research was carried out, but beginning in 1990s there was a resurgence of clinical studies carried out under highly controlled conditions (4–13). The results obtained from these clinical studies provided important and unbiased information, in contrast to much of the earlier anecdotal information that came from

limited first-person accounts (14), “street pharmacologists,” and from hospital emergency room reports. Third, this resurgence in clinical research has taken place at the same time that there have been major advances regarding mechanisms of action of the hallucinogens. For example, much more is now known about the effects of hallucinogens on the synthesis, release, and metabolism of indoleamines and catecholamines, and their interactions with specific pre- and postsynaptic receptor subtypes; we now might be reaching a point where we can begin to develop a unified conceptual framework regarding the fundamental mechanisms underlying their pharmacologic effects in humans.

HISTORY

To a large degree, the attention to drug abuse that began in the United States in the mid-1960s and continues today initially came from concern over the use of hallucinogens, particularly LSD. In the early 1960s, Timothy Leary, then a young psychology instructor at Harvard, began experimenting with hallucinogens, particularly LSD. He claimed that LSD provided instant happiness, enhanced creativity in art and music, facilitated problem-solving ability in school and at work, increased self-awareness, and might be useful as an adjunct to psychotherapy. Leary popularized this on college campuses, coining the phrase “turn on, tune in, drop out.” When he was not reappointed to the faculty at Harvard, he became a highly publicized, self-proclaimed martyr to his cause, and his followers began to proselytize for LSD. Leary’s advocates organized their lifestyle around LSD and developed a subculture of fellow LSD users who shared this common interest. Furthermore, they would not use other classes of drugs; they would not smoke tobacco, use amphetamine or amphetamine-like psychostimulants or barbiturates, or even drink alcohol. Thus, very little polydrug abuse occurred among these LSD users.

The lay press repeatedly “discovered” LSD and, in effect, advertised the LSD experience. As publicity increased, subcultures experimenting with LSD began to emerge in many east and west coast cities. Other hallucinogenic compounds, such as mescaline and psilocybin, began to be taken as well, although LSD remained the most widely used hallucinogen due to its ready availability on the street. Musicians, rock music, the hippie lifestyle, and “flower children” were loosely joined with Leary’s philosophy. There were highly publicized festivals celebrating LSD, such as “The Summer of Love” in the Haight-Ashbury district of San Francisco. Later, its use

began to increase in all socioeconomic groups, particularly among middle-class and affluent youth. Moreover, many of these individuals also became active in various “protest” movements, speaking out against such government policies as the war in Vietnam, and about other national issues, such as civil rights and “free speech.” About this time, various adverse reactions to LSD (and other hallucinogens) began to be reported from medical centers around the country. The whole phenomenon continued to be widely publicized, and in many cases sensationalized (15), by the press. The populace reacted with anxiety and fear, worrying that many of the young would soon become “acidheads.”

Many of the LSD users eventually became involved in polydrug abuse, using other drugs besides hallucinogens. This included the extensive use of marijuana, hashish, and, in some cases, methamphetamine or even heroin. Various “street” substances, whose identity was frequently unknown, as well as combinations of drugs were consumed. In addition, in the search for new drugs with different and improved characteristics, such as more or less euphoria, hallucinogenic activity or stimulant properties, longer or shorter duration of action, literally hundreds of so-called designer drugs were synthesized (e.g., DOM, MDMA, DMT). Concern about drug abuse rose to the point of becoming perceived as one of the nation’s most pressing problems, along with the economy and the war in Vietnam. The nation geared up to declare the “war on drugs,” and the national drug abuse effort expanded from a relatively small research-oriented program under the National Institute of Mental Health (NIMH) to the then newly created National Institute on Drug Abuse (NIDA) and the National Institute on Alcohol Abuse and Alcoholism (NIAAA). Eventually, a new “superagency,” the Alcohol, Drug Abuse, and Mental Health Administration (ADAMHA) was established to oversee NIDA, NIAAA, and NIMH. ADAMHA subsequently merged into the National Institutes of Health (NIH), only to be desolved in later years. Yet, these NIH institutes, the Drug Enforcement Agency (DEA), the Bureau of Alcohol, Tobacco, and Firearms (BATF), the Office of the National Drug Control Policy (ONDCP), and local law enforcement agencies continue to be involved in the “war on drugs.”

By the mid-1960s, more than a 1000 articles on LSD had appeared in the medical literature. Sandoz Laboratories stopped distributing the drug in late 1966 because of the reported adverse reactions and the resulting public outcry. At that time, all of the existing supplies of LSD were turned over to the government, which was to make the drug available for legitimate and highly controlled research; however, research on humans essentially was discontinued. Although some of the hallucinogens originally were developed and studied for use in chemical warfare, the results of these experiments remain classified. Today, LSD, along with heroin, marijuana, and other psychoactive drugs, remains classified as a Schedule I drug according to the Comprehensive Drug Abuse Prevention and Control Act of 1970. Legally, LSD is regarded as having no currently accepted medical use in the United States, a high potential for abuse, and to be unsafe even when

administered by a physician. Nevertheless, “black market” LSD remains widely available on the street. The therapeutic potential of LSD as an adjunct to psychotherapy, in the management of the dying patient, and in the treatment of alcoholism and neuropsychiatric illness such as obsessive-compulsive disorder remains unresolved (16–18), but there has been a resurgence in interest in carrying out hallucinogen research in humans (19–22).

EPIDEMIOLOGY

The available epidemiologic data on the use of hallucinogens center on the use of LSD and primarily come from the Monitoring The Future studies (23,24). Many studies have lumped hallucinogens and “club drugs” (e.g., MDMA) together, making the data very difficult to interpret. The use of LSD peaked in 1995 among college students and young adults and in 1996 among 8th, 10th, and 12th graders, after which it gradually declined, then dropped sharply in 2002 (23). This might have been due to, at least in part, the closing of a major LSD lab by the DEA. In 2008, 4% of 12th graders reported lifetime use of LSD, whereas approximately 20% of adults aged 29 to 30 reported lifetime use (24). A survey among club-going young adults indicated that 25% had used LSD (25). Among White, African American, and Hispanic 12th graders, Whites have the highest rate of LSD use (23). In 2008, approximately 28% of 12th graders indicated that LSD was fairly easy or very easy to get (23). More than 85% of 12th graders disapproved of trying LSD once or twice but only 34% felt trying LSD presented a risk (23).

PHENOMENOLOGY

In the 1960s, LSD was used primarily by those interested in its ability to alter perceptual experiences (sight, sound, taste, and feeling states). Much attention was paid to *set*, the expectation of what the drug experience would be like, and *setting*, the environment in which the drug was used. The early drug missionaries promulgated the erroneous notion that only good LSD “trips” would result if the prospective user established a number of preconditions before his or her drug experience. The preconditions relating to *set* included: being relaxed and largely stress/anxiety free; having no major resentment or anger and no recent arguments at home, school, or work; and freeing up several days, often an entire weekend, for the drug experience and its aftermath. The preconditions relating to *setting* included: having a close friend present as a sitter or guide for the experience; being in quiet, comfortable surroundings, particularly outdoors, or sitting on soft, thick carpeting; listening to pleasant sounds or music (originally, the sitar music of Ravi Shankar); and reading reassuring passages (originally, from the *Tibetan Book of the Dead*). In more recent years, users often attend concerts, dances (“raves”), or films (particularly psychedelic or brightly colored ones) during the drug experience. Use is rarely more than once weekly because tolerance to LSD and other hallucinogens occurs so rapidly (see below).

CHEMICAL CLASSIFICATION

The commonly abused hallucinogenic substances can be classified according to their chemical structure. Figure 18.1 shows the structures of these hallucinogens. Note that all of these drugs are organic compounds and some occur naturally.

NOREPINEPHRINE
(neurotransmitter)

AMPHETAMINE
(psychostimulant)

PHENETHYLAMINE HALLUCINOGENS

MESCALINE

DOM

MDA

MDMA

Indolealkylamines

All of the indole-type hallucinogens have structural similarities to the neurotransmitter serotonin (5-hydroxytryptamine [5-HT]), suggesting that their mechanism of action could involve the alteration of serotonergic neurotransmission.

SEROTONIN
(neurotransmitter)

INDOLEALKYLAMINE HALLUCINOGENS

LSD

DMT

PSILOCYBIN

PSILOCIN

Figure 18.1. Structures of phenethylamine- and indolealkylamine-type hallucinogens.

Lysergic Acid Derivatives

Lysergic acid is one of the constituents of the ergot fungus that grows on rye. Inadvertently baked into bread, ergot intake has been associated with profound mental changes (26). Because the presence of the diethylamide group is a prerequisite for hallucinogenic activity, it is not clear whether these reported epidemics actually were caused by ergot in the bread, or by some other related substances or (psychological) phenomena. LSD was first synthesized by Hofmann in 1938; as the 25th compound made in this series of experiments on ergot derivatives, the drug was designated as “LSD-25.” In 1943, Hofmann accidentally ingested some of the compound and soon had the first LSD “trip” on a famous bicycle ride home from his laboratory. The seeds of the morning glory (*Ipomoea*) contain lysergic acid derivatives, particularly lysergic acid amide. Although they are packaged commercially, many varieties have been treated with insecticides, fungicides, and other toxic chemicals.

Substituted Tryptamines

Psilocybin and psilocin occur naturally in a variety of mushrooms that have hallucinogenic properties. The most publicized is the Mexican or “magic” mushroom, *Psilocybe mexicana*, which contains both psilocybin and psilocin, as do some of the other *Psilocybe* and *Conocybe* species. DMT, although found in the psychoactive ayahuasca (13), is usually produced synthetically.

Substituted Phenethylamines

The substituted phenethylamine-type hallucinogens are structurally related to the catecholamine neurotransmitters dopamine, norepinephrine, and epinephrine.

Mescaline

Mescaline is a naturally occurring hallucinogen present in the peyote cactus (*Lophophora williamsii* or *Anhalonium lewinii*), which is found in the southwestern United States and northern Mexico. Peyote has been used by the Indians in these areas in highly structured tribal religious rituals for hundreds of years.

Phenylisopropylamines

The phenylisopropylamine hallucinogens DOM (or STP, from “serenity, tranquility, and peace”), MDA (methylenedioxyamphetamine or “Eve”), and MDMA (or ecstasy) are synthetic compounds and are structurally similar to mescaline as well as the psychostimulant amphetamine. They have inaccurately been called “psychotomimetic amphetamines,” and sometimes are referred to as “stimulant hallucinogens.” It should be pointed out that literally hundreds of analogues of the aforementioned compounds have been synthesized (14) and sometimes are found on the street, the so-called designer drugs (see Chapter 19).

ACUTE EFFECTS

The overall psychological effects of many of the hallucinogens are quite similar; however, the rate of onset, duration of action, and absolute intensity of the effects differ among the drugs. Moreover, the various hallucinogens vary widely in potency and the slope of the dose–response curve. Thus, some of the apparent qualitative differences among hallucinogens may be partly a result of the amount of drug ingested relative to its specific dose–response characteristics. LSD is one of the most potent hallucinogens known, with behavioral effects occurring in some individuals after doses as low as 20 μg . In the past, typical street doses ranged from 50 to 300 μg ; however, some anecdotal evidence indicates that today’s street LSD contains only 20 to 80 μg . However, doses reported on the street are often highly inaccurate. Because of its high potency, LSD can be applied to paper blotters or the backs of postage stamps. The absorption of LSD from the gastrointestinal tract occurs rapidly, with drug diffusion to all tissues, including the brain. The onset of psychological and behavioral effects occurs approximately 60 minutes after oral administration and peaks 2 to 4 hours after administration, with a gradual return to the predrug state in 10 to 12 hours. Both Hofmann (27) and Hollister (28) have described the effects of LSD in great detail.

The first 4 hours are sometimes called a “trip.” The subjective effects of LSD are dramatic (28) and can be divided into somatic (dizziness, paresthesias, weakness, and tremor), perceptual (altered visual sense and changes in hearing), and psychic (changes in mood, dream-like feelings, altered time sense, and depersonalization). The somatic symptoms usually occur first. Later, visual alterations are marked and sounds are intensified. Visual distortions and illusory phenomena occur, but true hallucinations are rare. Dream-like imagery may develop when the eyes are closed, and afterimages are prolonged. Sensory input becomes mixed together, and synesthesia (“seeing” smells, “hearing” colors) is commonly reported. Touch is magnified and time is markedly distorted. Feelings of attainment of true insight are common, as is the experience of delusional ideation. Separating one object from another and self from environment becomes difficult, and depersonalization can develop. Emotions become intensified, and extreme lability may be observed, with rapid and extreme changes in affect. Several emotional feelings may occur at the same time. Performance on tests involving attention, concentration, and motivation is impaired. Several hours later, subjects sometimes feel that the drug is no longer active, but later they recognize that at that time they had paranoid thoughts and ideas of reference. This is a regular, but little publicized, aftereffect that finally dissipates 10 to 12 hours after the dose. From 12 to 24 hours after the trip, there may be some slight let down or a feeling of fatigue. There is no immediate craving to take more drug to relieve this boredom; one trip usually produces “satiety” for some time. Memory for the events that occurred during the trip is quite clear.

Effects produced by DMT are similar to those produced by LSD, but DMT is inactive after oral administration and must be injected, sniffed, or smoked. It has a rapid onset, al-

most immediately after intravenous administration, and a short duration of action, about 30 minutes (8). Because of its short duration of action, DMT was once known as the “businessman’s LSD” (i.e., one could have a psychedelic experience during the lunch hour and be back at work in the afternoon). However, the sudden and rapid onset of a period of altered perceptions that soon terminates is disconcerting to some. DMT has never been a widely, steadily available or popular drug on the streets. The effects of ayahuasca, a psychoactive beverage that contains DMT, last about 4 hours (13). In contrast to DMT, a very slow onset and a long duration (longer than 24 hours) of effects are reported for DOM. Mescaline is approximately two to three orders of magnitude less potent than LSD, and its effects last about 6 to 10 hours, whereas the effects of psilocybin last about 2 hours (11).

The hallucinogens also possess significant autonomic activity. LSD produces marked pupillary dilation, hyperreflexia, increases in blood pressure and body temperature, tremor, piloerection, and tachycardia. Some of these autonomic effects of the hallucinogens are variable and might be partly a result of the anxiety state of the user. DMT and ayahuasca also increase heart rate, pupil diameter, and body temperature (7,13). LSD can cause nausea, and nausea and vomiting are especially noteworthy after the ingestion of mescaline or peyote. The hallucinogens also alter neuroendocrine function. For example, in humans, DMT elevates plasma levels of adrenocorticotrophic hormone (ACTH), cortisol, and prolactin (7). Similarly, the hallucinogen 1-(2,5-dimethoxy-4-iodophenyl)-2-aminopropane (DOI) (29) increases plasma glucocorticoids in the rat.

EFFECTS OF CHRONIC USE

A high degree of tolerance develops to the behavioral effects of LSD after repeated administration. Such behavioral tolerance develops very rapidly, after only several days of daily administration, and tolerance is also lost rapidly after the individual user stops taking the drug for several days. Because of this rapid development of tolerance, LSD users typically self-usually limit themselves the use of taking the drug to once or twice weekly (30). Cross-tolerance develops between LSD and other hallucinogens, such as mescaline and psilocybin, suggesting a similar mechanism of action. However, cross-tolerance does not develop to other classes of psychotropic agents that are thought to have different underlying mechanisms of action, such as amphetamine, PCP, and marijuana. It should be pointed out that little tolerance develops to the various autonomic effects produced by the hallucinogens. There is no withdrawal syndrome after the cessation of the chronic administration of the hallucinogens.

MECHANISMS OF ACTION

Hallucinogenic drugs interact with multiple neurotransmitter systems (31) and the mechanisms of action to evoke their physiologic and psychological effects are complex. However, the ability of LSD and other hallucinogens to alter serotonin

neurotransmission is of critical importance (32). Many hallucinogens, including LSD, were identified to be structurally similar to serotonin (see Fig. 18.1) and, in 1961, Freedman (33) was the first to provide direct evidence that LSD acted upon serotonergic systems within the central nervous system. He found that LSD increased the levels of serotonin in rat brain, but decreased the levels of serotonin metabolites, whereas the nonhallucinogenic analogue bromo-LSD failed to have the same effects. But, bromo-LSD does not produce hallucinatory phenomena, suggesting that the hallucinogenic effects of LSD might be caused by LSD-induced decreases in serotonin turnover (synthesis and release) in the brain. Other evidence supporting the interaction of hallucinogens with serotonergic systems: (a) the chronic administration of monoamine oxidase inhibitors decreased the density of serotonin receptors and reduced the behavioral effects of LSD (34) and (b) treatments that decreased brain levels of serotonin (e.g., lesions, reserpine, parachloroamphetamine, or other neurotoxins), upregulated postsynaptic serotonin receptors, and increased the behavioral effects of LSD (32).

Serotonin released from nerve terminals is available to interact with multiple receptors that transduce serotonin actions in the brain and periphery. Early studies demonstrated that LSD blocked the contractile effects of serotonin in isolated smooth muscle preparations, suggesting that LSD might produce its psychic effects by having similar antagonist activity at central serotonergic synapses. However, the LSD analogue bromo-LSD was identified as a potent peripheral serotonin antagonist that did not evoke an LSD-like psychopharmacologic profile. Thus, the mechanism of the hallucinogenic activity of LSD could not be explained solely by its direct serotonergic antagonist activity. Rather, evidence accumulated rapidly to support an agonist-like action for LSD and other hallucinogens at serotonin receptors in the brain. It is important to note that serotonin acts at multiple receptor subtypes (5-HT₁XR) found in the brain and periphery. These receptors have been identified and grouped into seven families (5-HT₁R to 5-HT₇R) according to their structural and functional characteristics, including 13 distinct G-protein coupled receptors, coupled to various effector systems, and two subtypes of the 5-HT₃R which is a pentameric ligand-gated ion channel (35). Our understanding of the serotonin system emerged rapidly as new receptor subtypes were cloned during the 1980s to 1990s, and several receptors were renamed and/or reclassified as functional information became available; thus, caution must be used in comparing results and conclusions drawn from older studies with the nomenclature currently used.

LSD binds to most serotonin receptor subtypes, except the 5-HT₃R and 5-HT₄R; however, its affinity for most of these receptors is too low to predict receptor activation at the brain levels achieved after ingestion of psychoactive doses. The receptors thought to contribute predominantly to its effects include the 5-HT_{1A}R, 5-HT_{2A}R, 5-HT_{2C}R, 5-HT_{5A}R, and 5-HT₆R. Aghajanian and coworkers found that LSD inhibits the firing of serotonergic neurons in the dorsal raphe nucleus, most likely by interacting with presynaptic autoreceptors (36), termed the

5-HT_{1A}R. Other indole-type hallucinogens, such as psilocin and DMT, also produce this effect (36). However, strong evidence refutes a direct linkage between the presynaptic effects of LSD and its hallucinogenic activity: (a) phenethylamine hallucinogens, such as mescaline, do not have the same inhibitory effects on the firing of serotonergic neurons (37); (b) there is no correlation between the activity of drugs at the presynaptic 5-HT_{1A}R and their hallucinogenic activity (38); and (c) tolerance does not develop to the effects of the hallucinogens on neuronal firing, but behavioral tolerance rapidly develops after the repeated administration of hallucinogens (37). These findings suggest that interactions with the presynaptic 5-HT_{1A}R cannot be the sole mechanism of action of the hallucinogens, and other factors must be involved.

Both indole- and phenethylamine-type hallucinogens bind with varying affinities to the three members of the serotonin 5-HT₂R which is composed of the 5-HT_{2A}R, 5-HT_{2B}R, and 5-HT_{2C}R; its actions at these receptors are characterized as either full or partial agonists (39). There is compelling evidence that an agonist action at the 5-HT_{2A}R is a key component underlying the mechanisms of action of the hallucinogens. For example: (a) there are very high correlations between the binding affinities of both indolealkylamine- and phenethylamine-type hallucinogens for the 5-HT_{2A}R and their hallucinogenic activity in humans and their potency in behavioral studies in laboratory animals (39); (b) the chronic administration of LSD, but not the nonhallucinogenic analogue bromo-LSD, decreases the density of 5-HT_{2A}R, an effect associated with the development of tolerance to the behavioral effects of LSD (40); and (c) preclinical studies found that many of the effects of hallucinogens are blocked by 5-HT_{2A}R antagonists (39).

Even though the interaction of hallucinogens with the 5-HT_{2A}R appears to be critical, other serotonergic receptor subtypes also might be involved. For example, interactions with the closely related 5-HT_{2C}R (formerly called 5-HT_{1C}R) might contribute to the psychoactive effects of hallucinogens (41). Although apparently not critical for hallucinogenic activity, interactions with presynaptic 5-HT_{1A}R might contribute to the effects of some hallucinogens. LSD has recently been reported to act as an agonist at the 5-HT₅R (5-HT_{5A}R and 5-HT_{5B}R) and 5-HT₆R; however, a full appreciation of how these receptors contribute to the myriad of effects of hallucinogens awaits a full characterization of the receptors. The differential interactions of the various hallucinogens with numerous sites and systems might underlie the qualitative differences between the subjective experiences of the class of hallucinogenic drugs. However, the commonality of interactions with 5-HT_{2A}R suggests that drugs that possess 5-HT_{2A}R antagonist activity might be useful in blocking the behavioral effects of the hallucinogens in humans.

ADVERSE REACTIONS

Strassman (42) has characterized adverse reactions according to the temporal relationship between drug exposure and symptomatology, with acute and chronic reactions at the end of the continuum, and delayed (subsequent panic attacks)

and intermittent (flashback phenomena) between the ends of the continuum. Although the existence of some of the acute adverse reactions is clear-cut and not subject to debate, some of the purported long-term adverse effects remain controversial. One of the problems is that many of the studies reporting long-term adverse reactions lack adequate knowledge concerning baseline levels of state prior to self-administration of the hallucinogen.

Acute Adverse Reactions

Social factors, media presentations, and public fear have all shaped perceptions of the effects of LSD and other hallucinogens. A person's reaction to the effects of a drug may be felt to be either a pleasant or an unpleasant experience; a perceptual distortion or illusion may cause intense anxiety in one user and be a pleasant and amusing interlude for another user. Individuals who place a premium on self-control, advance planning, and impulse restriction may do particularly poorly on LSD. Traumatic and stressful external events can precipitate an adverse reaction (e.g., being arrested and read one's rights in the middle of a pleasant experience may precipitate an anxiety reaction). Predictions of who will have an acute (or other) adverse reaction are unreliable (43), and the occurrence of multiple previous pleasurable LSD experiences renders no immunity from an adverse reaction. Adverse reactions have occurred after doses of LSD as low as 40 µg, and no adverse effects have been observed in some individuals after ingesting 2000 µg, although in general the hallucinogenic effects are dose dependent. Thus, acute adverse behavioral reactions generally are not dose related, but a function of personal predisposition, setting, and circumstance. Because of the perceptual distortions (and subsequent deficits in judgment), there is always the risk of self-destructive behavior. Some of the adverse reactions that occur after ingesting hallucinogens can be caused by other contaminants in the product, such as strychnine, PCP, or amphetamine. Once commonly reported by medical facilities, acute adverse LSD reactions are rarely seen today, yet the drug remains in use. Moreover, the paucity of users seeking emergency medical treatment may reflect increased knowledge of how to deal with such situations on the part of the "drug-using community," a decrease in the doses of LSD currently used compared to those used in the past, and the availability of drugs to reduce the adverse effects (e.g., benzodiazepines for anxiety reactions).

Acute anxiety or panic reactions, the so-called "bad trip," are the most commonly reported acute adverse reactions. They usually wear off before medical intervention is sought; most LSD is metabolized and excreted within 24 hours, and acute panic reactions usually subside within this time frame. Depression with suicidal ideation can occur several days after LSD use. Paranoid ideation, "hallucinations," and a confusional state (organic brain syndrome) are other commonly reported acute adverse reactions (44). Initially, it was thought that LSD could replicate the signs and symptoms of schizophrenia in some subjects, and the induction of such a model psychosis could be used to study and potentially find a cure for this major psychiatric illness. These hopes did not

materialize, as major differences have been found between hallucinogen-induced psychosis and the schizophrenic state (45). Using single-photon emission computed tomography (SPECT), it has been found that the administration of mescaline to controls produced a “hyperfrontal” pattern, whereas “hypofrontality” has been observed in schizophrenics (6). However, using positron emission tomography, Gouzoulis-Mayfrank et al. (10) found that psilocybin produced changes in glucose metabolism similar to those in acute schizophrenic patients.

The differential diagnosis between LSD psychosis and paranoid schizophrenia is an important distinction to be made clinically, particularly because patients, who in fact are paranoid, now often complain of being poisoned with LSD. A history of prior mental illness, a psychiatric examination that reveals the absence of an intact or observing ego, and auditory (rather than visual) hallucinations all suggest schizophrenia. Other drug-induced psychoses, including those from psychostimulants or PCP, must be ruled out. An organic brain syndrome in general speaks against LSD, especially when obtunded consciousness is present. Toxicologic analysis of body fluids can be helpful in making the ultimate diagnosis, but supportive treatment must not be withheld. Atropine poisoning can be differentiated by the presence of prominent anticholinergic effects such as dry mouth and blurred vision. Patients with amphetamine psychosis often fail to differentiate their perceptual distortions from reality, whereas LSD users are aware of the difference.

In terms of adverse physiologic effects, LSD has a very high therapeutic index. An elephant was killed after the experimental administration of a massive dose relative to brain weight, 0.15 mg/kg, or approximately 300,000 μ g of LSD (46). The lethal dose in humans has not been determined, and fatalities that have been reported usually are secondary to perceptual distortions with resultant accidental death (e.g., “flying” off a roof, merging with an oncoming automobile on the freeway) (47). Posterior reversible encephalopathy syndrome with accompanying seizures occurred after ingesting LSD (48). A fibrotic inflammatory mass located in the mesentery was reported in a chronic LSD user (49), and multifocal cerebral demyelination was reported after the use of “magic mushrooms” (50). Although LSD has prominent effects on the serotonin system, there is no evidence of association of its use with the serotonin syndrome, a potentially life-threatening reaction to some serotonergic drugs (51). DMT and ayahuasca have been reported to be relatively safe (52). Although mescaline is often viewed as posing a minimal health risk (53), a case of fatal peyote ingestion associated with Mallory–Weiss lacerations, probably as a result of peyote-induced vomiting, has been reported (54).

Treatment of Acute Adverse Reactions

Treatment of the acute adverse reactions to hallucinogens first must be directed toward preventing the patient from physically harming self or others. Anxiety can be handled by means of interpersonal support and reassurance. Psychotherapeutic

intervention consists of reassurance, placing the patient in a quiet room, and avoidance of physical intrusion until the patient begins to calm down. The use of a benzodiazepine, such as lorazepam, also can be effective. The oral route can be used for administering such medication in mildly agitated patients; however, it can be difficult to convince severely agitated and/or paranoid patients to swallow a pill, in which case parenteral administration might be necessary. Severely agitated patients who fail to respond to a benzodiazepine may be given a neuroleptic agent. Caution must be used in administering neuroleptics because they can lower the seizure threshold and elicit seizures, especially if the hallucinogen has been cut with an agent that has convulsant activity, such as strychnine. Phenothiazine-type antipsychotics, such as chlorpromazine given orally or intramuscularly can end an LSD trip and are effective in treating LSD-induced psychosis. Because anticholinergic crises can develop with chlorpromazine in combination with other drugs with anticholinergic activity (PCP and DOM), haloperidol is a safer therapeutic choice when the true nature of the drug ingested is unknown. It has been suggested that a combination of intramuscular haloperidol and lorazepam is particularly effective in treating acute adverse reactions (55). Theoretically, selective 5-HT_{2A}R antagonists should block the effects of hallucinogens; however, other drugs with significant 5-HT_{2A}R antagonist activity such as atypical antipsychotics (e.g., olanzapine and risperidone) also might be effective. Vollenweider et al. (11) found that the psychotomimetic effects of psilocybin are blocked by the 5-HT_{2A}R antagonists ketanserin and risperidone; however, haloperidol *increased* the psychotomimetic effects. It should be noted that there is some indication that risperidone might exacerbate flashbacks (56).

Long-Term Adverse Effects

There is no generally accepted evidence of brain cell damage, chromosomal abnormalities, or teratogenic effects after the use of the indole-type hallucinogens and mescaline (42). Chronic adverse reactions include psychoses, depressive reactions, acting out, paranoid states, and flashbacks. The use of LSD has been found to coincide with the onset of depression, suggesting its possible role in the etiology of some depression in the young (57). Flashbacks are a well-publicized adverse reaction that can occur after taking hallucinogens. They now have been renamed “hallucinogen persisting perception disorder” (58), and have specific diagnostic criteria (59). In the past, the use of variable definitions of what constitutes a flashback was a major problem; hopefully, the establishment of specific diagnostic criteria will facilitate the study and understanding of this problem. Only a small proportion of LSD and other hallucinogenic users experiences flashbacks. They can occur spontaneously a number of weeks or months after the original drug experience, appear not to be dose related, and can develop after a single exposure to the drug (60). During a flashback, the original drug experience is recreated complete with perceptual and reality distortion. Even a previously pleasant drug experience may be accompanied by anxiety

when the person realizes that he or she has no control over its recurrence. In time, flashbacks decrease in intensity, frequency, and duration (although initially they usually last only a few seconds), whether treated or not. Flashbacks may or may not be precipitated by stressors or the subsequent use of other psychoactive drugs, such as psilocybin or marijuana. The administration of selective serotonin reuptake inhibitor antidepressants (61) and risperidone (56) is reported to initiate or exacerbate flashbacks in individuals with a history of LSD use. Flashbacks usually can be handled with psychotherapy. An anxiolytic or neuroleptic may be indicated but probably is as much for the reassurance of the therapist as for the patient. Various pharmacologic agents, such as clonidine or clonazepam (62), or drug combinations (e.g., fluoxetine and olanzapine) (63), have been found to be useful in the treatment of flashbacks. The exact mechanism underlying this phenomenon remains obscure. Individuals with flashbacks have a high lifetime incidence of affective disorder when compared to non-LSD-abusing substance abusers (64). LSD users have long-term changes in visual function (65). For example, a visual disturbance consisting of prolonged afterimages (palinopsia) has been found in individuals several years after the last reported use of LSD (66). Such changes in visual function might underlie flashbacks.

Psychosis can develop and persist after hallucinogen use, but it remains unclear whether hallucinogen use can “cause” long-term psychosis, or if it has a role in precipitating the onset of illness. For example, hallucinogens may have a variety of effects in a person who is genetically predisposed to schizophrenia: they may cause the psychosis to manifest at an earlier age; they may produce a psychosis that would have remained dormant if drugs had not been used; or they may cause relapse in a person who has previously suffered a psychotic disorder (45). Although there is some evidence that prolonged psychotic reactions tend to occur in individuals with poor premorbid adjustment, a history of psychiatric illness and/or repeated use of hallucinogens, severe and prolonged illness has been reported in individuals without such a history (42).

There are few, if any, long-term neuropsychological deficits attributable to hallucinogen use (67). Chronic personality changes with a shift in attitudes and evidence of magical thinking can occur after the use of hallucinogens. There is always the risk that such thinking can lead to destructive behavior, in acute as well as chronic reactions. The effects of the chronic use of LSD must be differentiated from the effects of personality disorders, particularly in those who use a variety of drugs in polydrug abuse patterns. In some individuals with well-integrated personalities and with no previous psychiatric history, chronic personality changes have resulted from repeated LSD use. Personality changes that result from LSD use can occur after a single experience, unlike other classes of drugs (except PCP, perhaps). In addition, the hallucinogenic drugs interact in a variety of nonspecific ways with the personality, which may particularly impair the developing adolescent. The suggestibility that may come from many experiences with LSD may be reinforced by the social values of a particular subcul-

ture in which the drug is used. For example, if some of these subcultures embrace withdrawal from society, that is to say, a noncompetitive approach toward life, the person who “withdraws” after the LSD experience may be suffering from a side effect that represents more of a change in social values than a true drug effect. Treatment of chronic hallucinogen abuse can include psychotherapy on a long-term basis to determine what needs are being fulfilled by the use of the drug for this particular person. Twelve-step meetings also might be useful for reinforcement of the decision to remain abstinent.

Drug Interactions

Drug interactions involving the hallucinogens do not appear to be an important source of adverse reactions. There are reports that the effects of LSD are reduced after the chronic administration of monoamine oxidase inhibitors or selective serotonin reuptake inhibitor antidepressants such as fluoxetine (68,69), whereas the effects of LSD are increased after the chronic administration of lithium or tricyclic antidepressants (69).

Una D. McCann

Certain drugs of abuse do not fall under any readily categorized drug class. Among these are phencyclidine (phenylcyclohexylpiperidine, PCP) and 3,4-methylenedioxymethamphetamine (MDMA), which are both sometimes referred to as “designer drugs” because they are manufactured in a chemical laboratory, rather than being derived from natural substances. This chapter reviews the history, psychopharmacology, epidemiology, and neurotoxicity of PCP and MDMA, and briefly discusses several of the other more common “designer drugs” that continue to be used and abused on an international basis.

PCP

History

The original chemistry that led to the development of PCP took place in 1926 (1,2). However, it took approximately an additional 30 years for PCP’s anesthetic properties to be noted, initially in animals (3). In 1953, it was patented by Parke-Davis under the trade name of Sernyl in a research program targeting general anesthetics. Initial studies were promising and described the development of complete analgesia without respiratory or cardiovascular depression within a few minutes following intravenous administration of a relatively low dose (4). However, at higher doses that were necessary to achieve full surgical levels of anesthesia, undesirable adverse reactions were noted, including the requirement of pentobarbital for control of an “excited state” (4).

Other early experiments involving the use of PCP for general anesthesia in humans also reported untoward side effects, including the development of apparent trance-like ecstatic states during anesthesia, and hallucinations, visual distortions, dizziness, slurred speech, and manic behavior upon emergence from anesthesia (5,6). According to some reports, nearly half of the patients who received PCP for anesthesia went on to develop psychotic reactions, some of which persisted for more than a week after surgery (5,4,7). Qualitatively similar, but less severe adverse effects were seen following administration of lower doses of PCP (7). The trance-like states that occurred in patients undergoing anesthesia with PCP, without full loss of consciousness, led to its classification as a “dissociative” anesthetic, along with the related compounds, cyclohexamine and ketamine.

Despite early promise and potential advantages over traditional general anesthetics, PCP’s adverse effects and long half-life in the human body made it unsuitable for medical

applications and it was removed from the market in 1965. In 1967, it was given the trade name *Sernylan* and marketed as a veterinary anesthetic, but was again discontinued. Ironically, the ability of PCP to produce hallucinations and an altered sense of consciousness appeared to fuel, rather than deter, the first PCP epidemic in the 1970s (2).

Psychopharmacology

The existence of PCP receptors in the brain of rats was first demonstrated in 1979 (8,9). Subsequent research in the 1980s demonstrated that PCP’s primary mechanism of action was as a potent inhibitor of neurotransmission mediated by *N*-methyl-D-aspartate (NMDA) receptors, one of several receptor sites for the excitatory amino acid, glutamate (10). At 10-fold higher dosages, PCP also blocks presynaptic monoamine reuptake, resulting in increased synaptic levels of dopamine (DA), norepinephrine, and serotonin. Although activity at NMDA receptors occurs at much lower dosages of NMDA than required to influence monoaminergic activity, monoaminergic inhibition may be achieved at doses abused recreationally that lead to intoxication (10). At levels of extreme intoxication, PCP blocks sodium and potassium channels and can interact with cholinergic, opiate, and γ -aminobutyric acid (GABA)/benzodiazepine receptors. These interactions are minor and not likely to occur at doses typically used in recreational settings (10).

PCP is highly lipid soluble and is primarily metabolized through hepatic pathways. It is stored in fatty body tissues (11), and it is believed that mobilization of fat stores of PCP is responsible for waxing and waning states of intoxication that can last for weeks, “flashbacks,” and persistent “positive drug tests” that persist days to weeks after PCP ingestion (12). Hepatic recirculation of PCP may also explain fluctuating levels of intoxication seen following PCP use.

The behavioral effects of PCP are dose related but highly variable among individuals. In a classic National Institute on Drug Abuse research monograph published during the peak of the first PCP epidemic in the United States, Domino (13) described the major central nervous system effects of the drug as follows:

1. Small doses lead to a “drunken” state with numbness of the extremities and in some species, excitation.
2. In moderate doses, analgesia and anesthesia is observed.
3. A psychic state somewhat resembling sensory isolation is produced. Sensory impulses in grossly distorted form do reach the neocortex.

4. Cataleptiform motor responses occur.
5. Large doses may produce convulsions.

These early observations have largely borne out. Lower doses of PCP typically lead to a giddy euphoria that resembles alcohol intoxication, although anxiety, paranoia, and emotional outbursts can be seen (14,15). Higher dosages can lead to dysarthria, ataxia, increased deep tendon reflexes, decreased pain sensation, tachycardia, hypertension, and, as previously mentioned, altered perception (16). Malignant hyperthermia after PCP intoxication has been reported, and PCP intoxication can progress to stupor and coma (17). PCP is one of only a few drugs that can cause vertical nystagmus (horizontal nystagmus can also occur), the combination of nystagmus and hypertension in an otherwise healthy young adult should alert the physician to the possibility of PCP intoxication.

PCP-induced psychosis has been put forth as a model for schizophrenia (18,19), and a number of authors have hypothesized, based on clinical experience and available epidemiologic evidence, that individuals with previous psychiatric problems who use PCP are at the highest risk for developing persistent psychotic symptoms following PCP use (16,10).

Epidemiology

PCP is sold as tablets, capsules, or as white or colored powder. It is odorless and water soluble. It is often misrepresented as being more expensive substances (e.g., lysergic acid diethylamide, tetrahydrocannabinol, mescaline, and cocaine) and is often used to lace inferior batches of other drugs (e.g., marijuana). There are literally hundreds of street names for PCP (20), but commonly used names include angel dust, killer weed, PeaCe Pill, ozone, wack, and power fuel. Because of the large number of names for PCP and the fact that it is often used as an adulterant of other illicit substances, many people are unaware that they have used PCP. Epidemiologic data, therefore, are obtained using a variety of methods, including reports from emergency room visits, deaths, drug abuse treatment facilities, and national surveys.

Using these sources for data, it has been suggested that there was an epidemic of phencyclidine use between 1973 and 1979 and again, perhaps, between 1981 and 1984 (10). Although there are regional differences in the mode of ingestion, in more than 85% of the cases PCP is smoked (21), followed by inhalation or oral ingestion. Less than 2% of individuals use PCP intravenously. Usually, smoked PCP is in conjunction with marijuana, tobacco, or parsley (10). Individuals report developing a tolerance to PCP, with experienced users needing higher dosages of PCP to achieve the same effect.

Current Trends in PCP Use

According to the most recent data from the National Survey on Drug Use and Health (22), 53,000 individuals in the United States over the age of 12 initiated use of PCP during

2008. This is significantly lower than the numbers in 2002, 2003, and 2004, when the number of new users of PCP were estimated to be 123,000, 105,000, and 106,000, respectively. To put this number in perspective, the number of new users of marijuana in 2008 was estimated at 2.2 million, and new users of MDMA were estimated at 894,000. An estimated 6,631,000 individuals reported that they had used PCP at some point during their life in 2008, with approximately 99,000 individuals having used PCP within the past year (22). These numbers are not significantly different from those reported in 2007.

Neurotoxicity

In 1989, Olney and colleagues (23) reported that single doses of PCP and related compounds (MK-801 and ketamine) led to neuronal damage of cortical neurons in rats. In particular, neurons located in layers III and IV of the posterior cingulate and retrosplenial cortices were observed to have abnormal cytoplasmic vacuolization that was directly correlated with the potency of noncompetitive NMDA blockade. More recent studies (24) indicate that PCP induces neuronal degeneration in a variety of cerebrocortical and limbic regions, although the mechanism of degeneration is not well understood. It is also not known whether PCP-induced neuronal injury is related to lasting psychiatric and cognitive changes that have been reported in some PCP users.

MDMA

History

MDMA (sometimes also known as “ecstasy”) was synthesized and patented by Merck in 1914 but was never used for commercial purposes (25). Although it is an amphetamine analog, it is also structurally related to mescaline, the classic hallucinogen. MDMA received little attention from the pharmaceutical or scientific communities until the 1970s when, as part of a larger study of mescaline analogs, Hardman and colleagues (26) evaluated MDMA’s behavioral effects (and determined lethal dosages) in several animal species. A report by Shulgin and Nichols (27) indicated that MDMA produced “an easily controlled altered state of consciousness with emotional and sensual overtones” and further suggested that MDMA may have potential as psychotherapeutic adjunct. Little was written about MDMA following this report until 1985, when the Drug Enforcement Administration (DEA) in the United States moved to severely restrict MDMA use by placing it on Schedule I of controlled substances (28). The DEA indicated that their decision was based on reports that recreational use of MDMA was on the rise, as well as concerns that MDMA might pose a public health threat, since a closely related congener of MDMA, 3,4-methylenedioxyamphetamine (MDA), had recently been found to produce toxic effects on brain serotonin neurons in rodents (29). The DEA also argued that MDMA had no medical utility, a statement that

was disputed by a number of mental health specialists who asserted that it had utility in psychotherapeutic settings (30–32).

At roughly the same time that the DEA placed MDMA on Schedule I, MDMA's popularity was increasing on college campuses (33). Interestingly, this increase in popularity took place despite growing preclinical evidence that MDMA, like MDA, had the potential to damage brain serotonin neurons (34–36).

Psychopharmacology

The most prominent acute pharmacologic effect of MDMA is calcium-independent release of brain serotonin (5-HT) from brain serotonin neurons (37,38) via vesicular and plasma membrane monoamine transporters (39). To a lesser degree, MDMA also induces release of DA (40–42). Like other amphetamines, the most prominent effects of MDMA are mediated indirectly, via release of monoamines, rather than by directly interacting with monoaminergic receptors (43). This primary indirect action of MDMA is in contrast with hallucinogenic amphetamines that act primarily by activating serotonergic receptors (43).

Although MDMA's primary effects are indirect, it does bind to a several postsynaptic receptor sites (44,45). These include, in order of affinity, the 5-HT_{2A} receptor, the α -2 adrenergic receptor, the 5-HT₂ receptor, the histamine H₁ receptor, and the muscarinic M₁ receptor. Binding at other 5-HT and adrenergic receptors, DA receptors, opioid receptors, and benzodiazepine receptors only occurs at very high concentrations (44).

As might be predicted by its acute pharmacologic effects, in animals MDMA administration leads to typical signs of sympathomimetic stimulation (26,46,47). However, some behavioral studies suggest that MDMA can be distinguished from typical stimulants (48,49). In drug discrimination studies, MDMA substitutes for D-amphetamine in rats (50), pigeons (51), and monkeys trained to discriminate D-amphetamine from saline (52). Results from testing with hallucinogens are less clear-cut. In particular, MDMA does not substitute for the hallucinogen, DOB (53,54), but does substitute with the alpha-ethyl derivative of the hallucinogen, DOM, as well as the alpha-ethyl derivative alpha-methyltryptamine (55). Several animal models suggest that MDMA has abuse liability. In particular, both baboons and monkeys self-administer MDMA (56,57). Further, in intracranial self-stimulation models, MDMA consistently lowers the threshold for rewarding electrical stimulation delivered via electrodes stereotaxically implanted in the medial forebrain bundle region (58).

Knowledge regarding the behavioral effects of MDMA in humans has been derived from both retrospective clinical reports (59,60) and reports from research subjects who receive MDMA in controlled research settings (61–69). As might be anticipated by MDMA's acute pharmacology and behavioral effects in animals, both sources indicate that, as in animals, MDMA has prominent acute stimulant effects. In addition, human MDMA users also report effects that are commonly associated with hallucinogens. Shortly after drug ingestion,

stimulant effects of MDMA that have been reported include increased heart rate and blood pressure, increased core body temperature, dry mouth, decreased appetite, increased alertness, decreased speech fluency, jaw clenching, increased sleep latency, and altered sleep architecture. Associated with these physiologic effects of MDMA is an increased sense of well-being and, occasionally, euphoria. Most MDMA users do not report hallucinations, but often report increased emotional sensitiveness, a feeling of “oneness,” depersonalization or sense that certain body parts are “other,” derealization, and altered time perception.

There continues to be interest by some mental health practitioners in the utility of MDMA as a potential psychotherapeutic adjunct. In particular, in 2002, a plan to investigate the utility of MDMA in the treatment of posttraumatic stress disorder (PTSD) in the United States was announced (70). No results have yet been reported. A brief report describing a pilot study that was stopped prematurely “because of political pressures” was published, but insufficient subjects took part to determine the safety or efficacy of MDMA for the treatment of PTSD (71).

Epidemiology

The best epidemiologic data on MDMA use in the United States is derived from the Monitoring the Future (MTF) Survey, which has measured trends in drug use among 8th, 10th, and 12th graders since 1975 (72), and the National Survey on Drug Use and Health (22), which measures trends in drug use among individuals who are 12 years and older. According to MTF data, MDMA use peaked among adolescents in 2001 and has been relatively stable since 2006. Although use of MDMA is not currently rising, the perceived risk associated with MDMA use has been in decline for the past 6 years, which is considered a concern. In 2009, 4.3% of high school seniors reported having used MDMA in the past year, with 3.7% and 1.3% of 10th and 8th graders reporting past-year use.

The most recent National Survey on Drug Use and Health data indicate that in 2008, an estimated 555,000 individuals (0.2% of the population) in the United States over the age of 12 had used MDMA in the month prior to the survey. Lifetime use in this same demographic group was significantly increased from 4.3% (10.2 million individuals) in 2002 to 5.2% (12.9 million) in 2008; however, past-year use of MDMA decreased from 1.3% to 0.9% during the same period. Approximately 894,000 Americans used MDMA for the first time in 2008, which is a significant increase from the 615,000 first-time users reported in 2005 (22).

Toxicity

Toxic effects of MDMA are, in large part, an exaggeration of acute pharmacologic actions and can include anxiety, agitation, confusion, insomnia, nausea, and palpitations (73). More serious adverse effects include potentially fatal malignant hypertension, severe hyperthermia, cardiac arrhythmias, myocardial infarction, strokes (both ischemic and hemorrhagic),

cerebral edema, and seizures. Less well understood adverse effects of MDMA that have been reported are the development of a syndrome of inappropriate antidiuretic hormone secretion, marked elevation in serum creatine kinase in the absence of muscle injury, and persistent neuropsychiatric complications (73,74).

Neurotoxicity

In addition to its use as a recreational drug, MDMA is also a well-documented brain serotonin (5-HT) neurotoxin in animals (75). In particular, MDMA causes dose-related reductions of brain serotonin (5-HT) and 5-hydroxyindoleacetic acid (5-HIAA) concentrations (34–36,76), the density of 5-HT uptake sites (36,77,78), and the activity of tryptophan hydroxylase activity (35,79,80). Neurochemical deficits, which have been documented up to 7 years after drug administration in nonhuman primates, are associated with a loss of 5-HT axon terminals, as measured using immunocytochemical methods (81–83), indicating that they are related to a distal axotomy. Although MDMA-induced 5-HT neurotoxicity is dose related, even single oral dosages that produce plasma levels on the order of those seen following human recreational use (84) have been shown to produce neurotoxic injury (85).

There are also significant data indicating that some humans who use MDMA, like animals with documented MDMA-induced 5-HT lesions, develop a persistent reduction in brain 5-HT axonal markers (86–93). The duration of these lesions and their functional consequences are still a matter of debate, but it has been hypothesized that the MDMA-induced 5-HT neurotoxicity may underlie cognitive and sleep abnormalities that have been documented in abstinent MDMA users (94,95).

Miscellaneous Designer Drugs

As noted previously, designer drugs are drugs that are synthesized making minor modifications to the chemical structure of an existing drug. The goal of this enterprise is to circumvent laws (e.g., create a substance that is not illegal or scheduled) or to save money (create more potent or cheaper analogs of an existing, expensive product). In an effort to prevent the legal distribution and sale of “look alike” designer drugs, the U.S. government amended the Controlled Substances Act in 1986 to include the Controlled Substances Analogues Enforcement Act. This law states that a substance is classified as illegal if it is “substantially similar” to the chemical structure of an already controlled substance in Schedule I or II. Despite this action, there is sufficient ambiguity in the definition of “substantially similar” that some argue that the law is imprecise and essentially useless (96).

As might be concluded by the definition of designer drugs, the possibilities for such compounds are virtually endless. Indeed, in a classic book about “designer” phenethylamine analogs (97), Alexander Shulgin and Ann Shulgin describe the synthesis and subjective effects of 179 designer drugs, including MDMA.

In addition to MDMA and related compounds, the most important designer compounds in terms of public health and substance abuse have been drugs that have been used as substitutes for opiates. Alpha-methylfentanyl, also known as China White, was first manufactured in clandestine laboratories in Orange County, California in 1979, and was the first synthetically produced fentanyl; it resulted in at least 15 overdose deaths. Over the next 5 years, at least three other analogs were identified in street drug samples and in the bodily fluids of overdose victims: α -methylacetylfentanyl, 3-methylfentanyl, and parafluorofentanyl (98,99). In 1988, 3-methylfentanyl was identified in 16 unintentional overdose deaths in Allegheny County, Pennsylvania.

Designer analogs of meperidine (marketed as Demerol) have also appeared periodically in the illicit drug market. Two meperidine analogs that have appeared on the streets include MPPP (1-methyl-4-phenyl-4-propionoxypiperidine) and PEPAP (1-[2-phenylethyl]-4-acetyloxypiperidine). In 1983, there was an unusual outbreak of parkinsonism among young intravenous heroin abusers in California (100). These cases were reminiscent of an earlier similar case that had been identified at the National Institute of Health campus in Bethesda, Maryland (101). It was subsequently determined that the illicitly manufactured MPPP was tainted with 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP), a potent neurotoxin that destroys DA-containing cells in the pars compacta of the substantia nigra, the chief site of pathology in Parkinson disease (101–103). These cases underscore the potential disastrous results from even minor modifications to the chemical structure of drugs with known safety and efficacy profiles.

CONCLUSION

MDMA and PCP are illicit drugs that have the potential to damage brain cells, in addition to their risks as drugs of abuse. The functional consequences of MDMA- and PCP-induced neurotoxicity are not fully understood but may include lasting cognitive disturbance. Although other “designer drugs” are not used by large percentages of the population, they periodically appear in the drug market, particularly during periods when the parent drug is scarce or expensive. In the case of designer opioids, deaths from unintentional overdose related to increased drug potency, and the development of parkinsonism related to drug contamination, underscore the fact that even minor chemical modifications to a drug structure can lead to profound pharmacologic and toxicologic changes.

Volatile substances are ubiquitous and varied. Thus, *Inhalant Abuse* includes a variety of drug-using behaviors that cannot be easily classified by their pharmacology or toxicology but are grouped based on their primary mode of administration. Other substances can be inhaled (e.g., tobacco, marijuana, and even heroin or crack). Natural vaporization of these latter substances is not the primary mode of administration; therefore, they do not fall into the “inhalant” classification of abused “drugs.” The available products containing volatile solvent mixtures, gaseous products, and aerosols that are “inhalable” are variable from one region to another within the United States and throughout the world and over time. These products include a variety of chemical mixtures that can be found everywhere, in industry, in the workplace, and in the home. Thus, it is not surprising that anyone can find a favorite intoxicating vapor to be used to “get high.” These substances are a bargain when one compares the going price of a “toke” or a “hit” of marijuana or cocaine. This chapter reviews the use and the resulting toxicities of many of those substances now known to be commonly abused through inhalation of “unheated” vapors by various groups, many youth, those with psychoses, and various professional groups (dry cleaners, painters, medical personnel, everyday workers, and novices from all walks of life). The chemical mixtures present in the products inhaled (Table 20.1) present a pharmacologic challenge to understand, both from a toxicologic view and more importantly from an understanding of preference and dependence for any one substance. Both these issues will be addressed in this chapter. Categorization or grouping of any products using any specific chemical can only be accomplished through an understanding of physiologic actions of specific compounds. Where possible, the clinical toxicologic findings of different products are correlated with the “key” substance, contained in the product predominately being inhaled, through studies on animals. Those results have recently provided more valuable data to help interpret clinical findings and are discussed herein. These “disease states” will then be partially explained through the knowledge gained by these laboratory studies on small animals and primates. The DSM criteria of “inhalants,” still in flux, and limited treatment approaches of this condition are also discussed.

HISTORICAL EVENTS

Substances

Inhalation to produce euphoria can be traced to the ancient Greeks (1). Faraday was the first to report the effects of inhaling ether in 1818 (2). With the advent of the use of anesthetics in the mid-1800s, chloroform and ether parties occurred; these substances are still abused (3–5). The term “laughing gas” accurately describes one of the recreational uses of another anesthetic, nitrous oxide, which also originated in the late 1800s. It is stated that the use of ether and nitrous oxide at parties initiated the use of these compounds as anesthetics (2). With the increased use of gasoline at the turn of the 20th century, many more volatile substances became available through the process of petroleum “cracking” and distillation.

Little attention was given to the deliberate inhalation of these substances until the 1950s, when reporters (6) and judicial action focused on what was then called “glue sniffing.” One of the first reports on the inhalation of vapors (gasoline) to get high came in 1951 (7). Glue sniffing is still widely used today to describe a myriad of substances that now include special polishes, glue, gasoline, thinners, other solvents, aerosols (paint spray, cooking lubricant spray, deodorant and hair sprays, and others), cleaning fluids, refrigerant gases (e.g., fluorocarbons and the newer partially hydrogenated–halogenated replacements (8)), anesthetics, primarily nitrous oxide (commercially available in whipped cream aerosols as the propellant and often referred to as “whippets”), organic nitrites (often called room “odorizers”), cooking or lighter gases, and in recent years, head cleaners/electronic “dusters” (9). There are also clinical reports of other substances (e.g., mothballs Ref. (10)). For many years it has been common for Mexican street children to sell “toluene-type” solvents on the street. This practice of selling fairly pure toluene from commercial drums in coke bottles is practiced even in the United States.

Nitrous oxide also has a more unique history. In the late 1970s, head shops sold a device for releasing the gas from little cylinders of nitrous oxide to facilitate its use. Since then, the selling of nitrous oxide from tanks dispersed in balloons has become a profitable venture before it became illegal in some locales. Also, more ambitious vendors took a tank to outdoor

TABLE 20.1 Chemicals commonly found in inhalants

Inhalant	Chemicals
Adhesives	
Airplane glue	Toluene, ethylacetate
Other glues	Hexane, toluene, methyl chloride, acetone, methyl ethyl ketone, methyl butyl ketone
Special cements	Trichloroethylene, tetrachloroethylene
Aerosols	
Paint sprays	Butane, propane, hydrochlorofluorocarbons, toluene,
Hair sprays	Butane, propane, hydrogenated chlorofluorocarbons, vinyl Cl
Deodorants, air fresheners	Butane, propane, hydrogenated chlorofluorocarbons
Analgesic spray	Hydrogenated chlorofluorocarbons
Asthma spray	Hydrogenated chlorofluorocarbons
Fabric spray	Butane, trichloroethane
Personal computer cleaners	Fluorohydrocarbons (fluoroethane), Dimethyl ether
Anesthetics	
Gaseous	Nitrous oxide
Liquid	Halothane, enflurane
Local	Ethyl chloride
Cleaning agents	
Dry cleaners	Tetrachloroethylene, trichloroethane
Spot removers	Xylene, petroleum distillates, chlorohydrocarbons
Degreasers	Tetrachloroethylene, trichloroethane, trichloroethylene
Solvents and gases	
Nail polish remover	Acetone, ethyl acetate, (toluene)
Paint remover	Methylene chloride, methanol, acetone, ethyl acetate
Paint thinners	Petroleum distillates, esters, acetone
Magic markers, permanent markers	Isopropanol, other alcohols
Correction fluids (fast drying)	Trichloroethylene, trichloroethane
Fuel gas	Butane, isobutane, isopropane
Cigar-type gas	Butanes
Lighter fluid (cigarette)	Petroleum distillates, liquid hydrocarbons
Fire extinguisher propellant	Bromochlorodifluoromethane
Carburetor cleaner	Volatile hydrocarbons (mineral spirits)
Food products	
Whipped cream aerosols	Nitrous oxide
Whippets	Nitrous oxide
Room odorizers	
Poppers, fluids (Rush, Locker Room)	Isoamyl, isobutyl, isopropyl, or butylnitrite (now illegal) or cyclohexyl

music festivals of young people and sold balloons-full from a tank. Still today, vendors distribute information on the Internet about grades of nitrous oxide and “crackers,” a term used to describe implements that release “nitrous” from the “whip-pet” cartridges.

It is important to keep in mind that there are many different chemicals in most of the different products being abused. All have different dependence/reinforcing properties as well as different toxicities and are present in many different concentrations. Sometimes, the “desired” substances are listed on the container with or without the proportion of each; many times these substances come under the label of “nontoxic” substances, especially the propellants. It is important to focus on these propellants used in “aerosols,” as they are most often the undefined substance that is the most desired chemical in these products. *Freons* were one of the most popular propellants until the early 1980s when they became illegal to use due to atmospheric environmental concerns. Then butane/propane combinations became the propellant of choice. Although some thought this would no longer make aerosols a reinforcing product, it became apparent very early that these “new” aerosols, even without another dependence-producing substance in the product, were highly abused. “Glue sniffing” was the term early identified with inhalant abuse in the 1950s, but it is now most often referred to as “inhalant” or “volatile solvent” abuse. Along with glue, fluorocarbons and gasoline were prominently noted as abused substances (11); then cleaning/correction-type fluids became popular, then bottled-type nonhalogenated gases in propane tanks or butane cigar lighters, and most recently, other types of halogenated chemicals present in electronic head cleaners are abused. These are often referred to as “AIR” (Table 20.1). Because of the diversity and complex composition of many of the products, the primary substance(s) are often not readily recognized (e.g., aerosol spray paints often contain toluene as a solvent and butane/propane as the propellant). Hydrogenated fluorocarbons may now become more commonly used as the propellant.

Toluene is often quoted as the substance involved, when other substances are also present, that may contribute to or be the primary substance being studied. This can be put in perspective by the following example: Transmission fluid was reportedly abused in Florida and stated to contain toluene. However, there is no toluene in transmission fluid. There is toluene in “Transgo,” a wax stripper, which is a substance of abuse in the Florida area where transmission fluid is reportedly abused. When users are asked what substances they are abusing, it is easy to see how the above misnomer could easily occur, and a reporting error result. Also, one of the more toxic agents, hexane, a peripheral nervous system toxicant, was identified, after the fact, in products that did not list it on the product’s label. Only through careful analysis of the product, and verification by the formulator, was the characterized syndrome in those subjects abusing the product correlated with hexane exposure, instead of toluene. The best corroboration of the causative

substance is a measure, when possible, of the substance present in body fluids. Only through an analysis of the products used (e.g., by quantitative gas chromatography) is it possible to determine most of the volatile solvents and their proportion in a product (if the product can be readily obtained). Even then, the identification of all chemicals in one product used by the inhalant abuser may be very difficult due to the myriad of products included in the abuser’s repertoire that should be considered in the diagnosis of the health problem, or the dependence of the abuser on the product.

These substances are widely available, readily accessible, cheap, and legally obtained. The intoxicating effects of the toluene in airplane glue were accidentally discovered by a number of adolescents while working on their model airplane kits (12). In a specific case nearly 40 years ago, Knox and Nelson (13) described a man who felt euphoric while working with paint thinner at an aircraft-manufacturing company. His initial and insistent requests to continue working in the capacity that employed the paint thinner went unnoticed. Eventually, he developed a habit that escalated to deep inhalations of concentrated vapors from a small container more than 10 times per hour throughout the day, including meal times. This behavior persisted for over 14 years. In other places during those early years, articles appeared in the lay and scientific press about model airplane glue sniffing. These substances provide a quick high, with a rapid dissipation of the high. Subjects who use inhalants heavily over short periods often complain of headaches. The practice of “sniffing,” “snorting,” “huffing,” “bagging,” or inhaling to get high describes various forms of inhalation. If the substance is glue or some other form of dissolved solid, the users will empty the can’s contents (or a gas) into a plastic bag and then hold the bag to the nose/mouth and inhale (bagging). Another method is to soak a rag with the mixture and then stick the rag in the mouth and inhale the fumes (huffing). A simple but more toxic approach is to spray the substance directly into the oral orifices. These modes of administration allow abusers to be identified by various telltale clues; for example, *chemical* odors on the breath or clothes, stains on the clothes or around the mouth, empty spray paint or solvent containers, and other unusual paraphernalia. These clues may enable one to identify inhalant users before they suffer serious health problems or death.

Toxicities/Deaths

Historically, arrhythmia, cardiac arrest, and anoxia are the most serious consequences of inhalant abuse. *Death* is often the result of either anoxia or arrhythmia and can occur on the *first use or after many inhalation episodes*. Youth of the *very affluent, often well-educated as well as of the impoverished/indigent and troubled families fall victim* to the toxic actions of these substances. It has always been difficult to gather quantitative data on the number of deaths associated with inhalant use. In 1970, Bass studied

110 cases of “sudden sniffing deaths” resulting from intentionally inhaling fluorocarbons, gasoline, and other substances (14,15). There were noted “preponderance (of deaths) in the suburban middle-income white” families (14). Although there were no “bag-related” suffocations noted, hyperactivity was, and this preceded death in 18 of the youth. In many cases, the causes of several deaths were withheld and only in conversations with family or friends was a solvent identified as the cause of death. Since then, reports of deaths caused by different products (often identifying the primary chemical substance) have been an alarm for more critical intervention in “inhalant abuse” cases. Many of these deaths were reported (in the mid-1990s, more than 100 cases were reported in the U.S. newspapers as counted by different groups) and included detailed case histories. Many deaths are also noted in the yearly Annual Report of the American Association of Poison Control Centers (as reviewed in Ref. (15)). In these reports, deaths include accidental deaths brought to the attention of these centers, as well as those caused by the subject using the product to get high, or to commit suicide. It lists many deaths caused by many household products; the route of administration is also noted in the list of reported deaths. The number of tabulations of deaths noted in this report guides the field in understanding this issue.

Progression/Timing of These Events

In the years following Bass’s investigation of medical examiners’ records, many articles and medical reports have noted other types of inhalants (chemicals and/or products) as the major contributor to lethality. By following reports of death of different substances one can see some order of popularity of products shift from one substance to another. Thus, another halocarbon, trichloroethylene (TCE), present in typewriter correction fluid became popular and reports of deaths emerged in 1985 in Britain (16) and in the United States (17). The correction fluids, containing chlorocarbons, were often inhaled in the period of the 1970s till the 1990s and often resulted in death (18). The products have had formula changes and are, also, much less commonly available today in the desirable formulation needed for getting “high.”

Soon after that, butane gas inhalation was identified, in 1990 in the Cincinnati region by Siegel and Wason (19), as a serious and deadly practice. About that time, butane/propane mixtures replaced fluorocarbons as the main aerosol propellant in the early 1980s and may have contributed to many more deaths. England began tabulating butane deaths in the late 1970s and included butane and other aliphatic hydrocarbons. Many reports are still documenting deaths due to inhalant abuse of “butane/propane” on a regular basis (19–23). It is indeed unusual that these very dangerous substances are still inhaled, and it is often hard to tell whether some deaths are a result of intentional or accidental “overexposure.” Fire is an additional problem associated with butane when used as an inhalant (21). To reduce these serious outcomes

resulting from any undesired exposure to cooking gases, it is now mandatory in the United States to add thiols to some portable gas containers, such as propane tanks, and it has been suggested that thiols (a substance that is added to our natural gas supplied for cooking) be added to even smaller gas containers (e.g., cigar lighter gases).

The restriction of the use of fluorocarbons in aerosols in 1980 has not abolished fluorocarbon-type abuse (24). Current use of “partially hydrogenated fluorocarbons” (25) instead of the fully halogenated hydrocarbons still “entices” abuse. Early abuse of fluorocarbons was noted by the theft of the refrigerant (fluorocarbon) gases from air conditioning units to be used for inhalation purposes. The addictive nature of fluorocarbons is also exemplified by cases of asthma inhalers, when the “inhaler” uses these products at levels exceeding the level of medication (26). This specific problem was also studied in antisocial youth where high inhalant abuse prevalence occurs (27). This use of a “freon” as the propellant is being changed, but its replacement may still be a substance that would produce dependence. This is one of the few marketable forms of fluorocarbons present in substances used medicinally by the public.

The use of nitrous oxide became more prominent in the 1980s when whipped cream dispensers, nonclinical grade cylinder tanks (dispensing the gas by the balloon), and medical-grade tanks of nitrous oxide (most common in dentist’s offices) were used. Although some deaths were reported for nitrous oxide by 1978 (28), most reports started appearing a decade later and still are being published (29,30).

As often said, history repeats itself. With less “freon” available, electronic cleaner sprays, (containing simple fluoro- or chloro-carbons (often dihalo-ethane) and often referred to as “AIR”) have been discovered and abused (15), with numerous reports of death (31,32). Other problems occur with the abuse of “AIR Dusters.” One reports an occurrence of burns (33); others correlate different toxicities with the abuse of these products (34). Calling these products AIR misleads the user into believing these materials are nontoxic and do not contain any “chemical” other than nitrogen. Additional case reports of death continue to be printed and include toluene-type products (35–37), gasoline (38), and halocarbons (18,26, 39,40).

Tracking

Drug-related deaths are always of concern. Inhalants produce additional problems in the identification of those deaths that may be attributable to these substances compared to other drugs. First, due to rapid elimination, they are not easily identifiable in tissues or excrements. Although hippuric acid is readily measured in urine, it is also a natural product of body elimination. Thus, the level in urine must be very high to associate its presence with solvent abuse. Even the frequently occurring acetone breath may be the result of diabetes and may mislead emergency personnel. Deaths, occurring after inhalant exposure, leave even fewer clues. Because of this, medical examiner death

certificates are many times not associated with “inhalants,” especially as only relatives/friends know them as an inhalant abuser. Those death certificates identifying anoxia or cardiac arrest/arrhythmia as the cause of death often need to be followed up to identify if “inhalant abuse” was involved. In three local/statewide studies, they examined death certificates to measure the impact of “inhalant abuse,” one in Virginia (41) and others in Texas (42). The identified abused substances include butane/propane gases (Virginia), as well as halogenated (fluoro- or chloro-hydrocarbons) propellants/solvents (both states), as the causes of death. However, there is no indication that deaths with “no cause noted” were even accounted for in the number of possible deaths that could be linked to inhalant use. Thus, many deaths related to inhalants are missed.

One country, Great Britain, thoroughly tracks the cause of death by following up each case to identify and record the most likely cause for every death. In the continuing reporting of these causes of deaths in Great Britain, Field-Smith et al. annually record the number of deaths caused by butane/propane gases, aerosols, and other volatile solvents (16). This group in England has been accumulating data on deaths related to inhalant abuse for three decades (for solvents and gases, but excluding nitrous oxide deaths). The English are much more thorough in delineating almost all causes of death. They diligently pursue every case to determine this; very few are listed “cause unknown.” The number of these deaths increased from 50 in 1981 to 152 in 1990 (the highest number), and then dropped to a current value around 50 in 2006. Gas fuels generally accounted for approximately 50% of the inhalant abuse deaths throughout. Aerosols were over 20% at the peak level of cases, but their use has dropped; the use of glues has dropped most dramatically, possibly related to the pursuit of a strong prevention program in Great Britain over the last decade (16). Also, adoption of legislation banning the sale of butane lighter refills to minors was considered a major deterrent (16). Most deaths are attributed to direct toxic effects, which include the cardiotoxic actions of butane, fluorocarbons, and other solvents/gases, inhalation of gastric contents, trauma, and suffocation.

There are also other causes of death related to intoxication resulting from the inhalation of these substances (e.g., running in front of a car during or after intoxication). Garriott et al. documented such occurrences in their compilation of similar data for the Dallas and San Antonio areas (43). There is also an Australian report on numerous “inhalant deaths” attributed to or derived from inhalant gas exposure (44). They identified only “solvents” as the cause of death. The size of the population in the United States is five times that of Great Britain. If the United States pursued the cause of death more diligently, as do the Britons, the death rate in the United States related to inhalant abuse could well be well over a hundred per year and most of these are children. Hopefully, as there are some indications that fewer deaths per year occur now than a decade ago, due to efforts to educate the public, these tragic events may have

diminished. Although the United States has an annual reporting system of deaths identified by medical examiners related to abused substances, the Drug Abuse Warning Network (DAWN), the system is not set up to clearly identify many “inhalant-related” deaths. For example, in the past year only Massachusetts, of eight states listed, noted any deaths due to inhalants (45).

EPIDEMIOLOGY

Surveys

The prevalence of inhalant use continues to be a relatively underresearched drug abuse issue, especially among adults. The United States, England (16), and many other countries are systematically evaluating the abuse of solvents. Studies in Spain, Japan, Brazil, Canada, Australia, New Zealand, South Africa, Tunisia, and other nations underscore the global significance of inhalant use as a problem of serious proportions (46–48). Medina-Mora and Real recently reviewed studies relevant to the international epidemiology of inhalant use and inhalant use disorders (IUDs) (46). In the United States, the pattern of inhalant use is exemplified by national studies, including the National Institute on Drug Abuse: Monitoring the Future (MTF) (49) survey, which includes interviews of secondary school and college students, the Substance Abuse and Mental Health Services Administration: National Survey on Drug Use and Health (NSDUH) (50), and the Centers for Disease Control and Prevention’s Youth Risk Behavior Survey (YRBS) (51), a survey of 9th- to 12th-grade students. These surveys approach a national representation of youth; however, the MTF and YRBS are school based and do not include youth who are absent during survey administration due to truancy, expulsion, having dropped out, incarceration, or institutionalization. The NSDUH involves interviews of persons 12 and older that are conducted in households but does not include institutionalized or homeless populations. The failure of these large studies to survey incarcerated, institutionalized, or homeless populations is a particularly important limitation, because prior reports suggest that these groups may have disproportionately high levels of inhalant abuse (52). Other concerns with these surveys have to do with the validity of self-reported inhalant use, cross-sectional nature of the data (which does not allow causal inferences to be drawn regarding reported associations between inhalant use and other factors), and use of a single omnibus inhalant assessment item to assess use of chemically distinct classes of agents (e.g., nitrites, toluene, butane, and nitrous oxide).

Although one often looks at large state or national surveys, these surveys do not clearly delineate many regions where there is a higher proportion of inhalant use, such as in some inner cities that include impoverished or ethnic minorities or other isolated communities, especially those of Native Americans (53) or Latinos. In some surveys, there appears to be an underrepresentation of African Americans in the solvent-abusing populations, but inhalants *are* abused by African Americans (54). Although Hispanic

groups are often considered to be overrepresented in the solvent-abusing population, the large surveys generally do not find a much greater proportion of Hispanics than of the larger “Anglo-American” population using inhalants. The extent of use in these groups is difficult to evaluate properly, because many of the inhalant-using individuals are not accessed by survey systems. To look at the regional problems of solvent abuse, Beauvais and Oetting extensively studied many Native American groups (53). Howard et al. (55) studied urban Native Americans; others have studied Hispanic communities (56). Another study observed a lifetime prevalence of inhalants by the household population in the state of New York to be 2% to 4%, whereas the lifetime rate of use by the homeless was 15% to 18% (54). Poly-inhalant use appears to be the norm for many inhalant users. More than one third of adults with a history of inhalant use participated in the NSDUH reported lifetime use of two or more inhalants. Poly-inhalant use was even more prevalent among 12- to 17-year-old NSDUH inhalant users, with nearly one third reporting use of three or more inhalants and over one half reporting lifetime use of two or more inhalants (50). Studies of delinquent inhalant users have identified even higher rates of poly-inhalant use than those identified in the general population (52). The U.S. national government began to evaluate the extent of the problem of inhalant use in the mid-1970s. Annual or semi-annual surveys of the problem are now available online (<http://www.monitoringthefuture.org/>; <http://www.oas.samhsa.gov/nsduh.htm>). Inhalant abuse has also been recently studied in the U.S. military, as it had become identified as an unrecognized threat (57).

Abuse Patterns

The extent of use of inhalants can be compared to that of other drugs. In the national surveys, it is interesting to note that the prevalence of inhalant lifetime (ever use) use is highest in junior high students, but below that of marijuana, cigarettes, and alcohol. Although this measure of lifetime use of inhalants is often higher for youths younger than age 16, the drop in lifetime use beyond this age raises several questions. Are some “heavy” users lost to the survey? Are the questions misinterpreted by young respondents (at either the 8th- or 12th-grade levels)? For example, could very young children think that “liking the smell” is the equivalent of “getting high”? Is there a “forgetfulness” about this type of behavior or a downgrading of this event in the conscious thinking as they mature? Some assign this change to a diminished “remembrance” of this event as “getting high” for a number of reasons.

For that reason, the discontinuance of use of substances is now being studied. The so-called desistance or noncontinuation rates for inhalant use were the highest reported among 23 drug classes assessed in the MTF survey (49). MTF investigators defined noncontinuation rates as the proportion of people who “ever used a drug (once or more) and who did not use it in the twelve months preceding the survey.”

Of those drugs measured, lifetime (ever) use of inhalants shows the largest percentage of subjects reporting discontinuance of use, especially in the 12th graders. Inhalant discontinuation rates for 8th, 10th, and 12th graders were 47%, 52%, and 65% in 2007, respectively. For comparison purposes, discontinuation rates for alcohol use (the least discontinued drug) for 8th, 10th, and 12th graders were 18%, 9%, and 8%, respectively (Table 20.2). Factors that increase the risk for continuation of inhalant use, at least in high-risk antisocial youth, include younger age, prior problems with inhalants, greater psychiatric distress, more severe personal substance abuse problems, and friends/siblings who use inhalants (58).

A very recent study measured “the recantation” of inhalant use (59). The investigators compared self-reported responses of seventh graders and their responses again in the eighth grade. They also queried the use of cigarettes and alcohol. The observed validation of a positive response to inhalant lifetime use dropped to about half, whereas tobacco use diminished by only 5%. They noted denial of ever reporting this use as well as erroneous reporting as the bases of this “recanting.” From this study, they believe that 67% of those who reported earlier use was the likely *true* value. This further indicates a high overreported “ever use” of inhalants and, especially in very young children, may indicate they first report more of a curiosity “sniff” than actual use of the product to “get high.”

This lifetime use issue can be examined by comparing the use of inhalants and alcohol; two substances abused early by young people. These substances, plus cigarettes and marijuana, are the earliest and most frequently used drugs of addiction. This comparison of drug-use patterns is enhanced by examining the incidence/frequency of the use of these drugs; few surveys have examined the multiple or “chronic” use of most drugs. It is now becoming more common to ask about the frequency of drug use, especially in relation to use in the past month. The use of inhalants can be compared to that of alcohol; these two substances are seldom compared by prevalence but are both known to be depressants (Table 20.2). The lifetime inhalant use (especially when “corrected” for “recantation”) is about one fourth that of alcohol use. A comparison of use in “past year” or “past month” of inhalants by the 12- to 17-year-old group is about one tenth that of alcohol. Also, the number of subjects who repeatedly use each of these substances shows a 20- to 30-fold preference for alcohol (looking at number of respondents). These findings accentuate the difference in the “real” addictive nature of inhalants, as compared to alcohol, even at a young age, is not very high. One must additionally consider that the pharmacologic effects of inhalants are of much shorter duration (rapidly eliminated) than is alcohol, making these substances even weaker reinforcing agents than most other drugs.

SAMHSA has provided yearly data on the lifetime prevalence of various groups of inhalants for mind-altering purposes for several years. In 2007, inhalation of aerosol sprays, nitrous oxide, and toluene- or butane/propane-containing products were the most prevalent forms of

Number of respondents (in thousands): all groups = 22,676. Percentage responding to all categories is 9.2%.

“lifetime use” of inhalants for 12- to 17-year-olds. In younger children, use of spray paint, glue/toluene, gas/lighter fluid, and correction fluid was highest (Table 20.3). By age 14, these agents plus other sprays, lighter gas, nitrites, and thinner were becoming more prevalent. By age 16, nitrous oxide was nearly as popular. There is a great concern about the inhalation of gases/solvents by younger age groups (e.g., seventh and eighth graders) because of their lack of understanding of the problem, both what is meant by “getting high” and the resulting consequences of this use. This emphasizes the need for increased education for children, especially their parents, about the nature and dangers of this problem.

No study to date answers the perplexing question: What attracts young people to certain specific substances/products? Although some may consider the odor, color, or type of product to be important, the reinforcement and feeling one gets after inhalation is most important for continuing use of any inhalant. Even then, it is difficult to say what products/substances are preferred. Howard et al. (52) were among the first to assess preference for specific inhalants in a group of subjects. They asked 723 adolescents in residential care for behavior problems about their use of 65 inhalants, including 55 volatile solvents/gases, and 10 additional inhalants. The prevalence of use, numbers of those getting high, and frequency of use are presented in Table 20.4. Of the 55 volatile products used, gasoline, permanent markers, computer duster spray and other fluorocarbons, spray paint (and other products containing toluene); nitrous oxide, paint thinner, air freshener, correction fluid, butane, permanent markers, and Freon rated high in all these categories. Each youth reporting use of an inhalant was also asked if they “got high” when they inhaled the substance. Between 80% and 90% of users of gasoline, computer duster spray, paint thinner, “Freon,” ether and carburetor cleaner reported they became intoxicated when they used these products. Comparatively large percentages of butane (14%), computer duster spray (13%), gasoline (12%), liquid paint (11%), air freshener (10%), paint thinner or nitrous oxide (10%), and spray paint (8.4%) users reported 100 or more lifetime days of use of those substances. Conversely, most users of gun cleaning products, waxes, mothballs, cooking gases, other cleaning agents, plaster and gum remover, insecticide spray, shoe shine/polish, other glues/cements, and balsa wood cement reported less than 5 lifetime days of use of these inhalants, respectively. The high percentage who “got high” on nail polish is perplexing as many “like it’s smell,” but it is not very volatile. Garland, Howard, and Perron (60) reported that 16% of the 723 adolescents had used nitrous oxide, most of who reported intoxication following use of the agent. Thus, findings indicated that the most prevalently and frequently used volatile solvents were those that were perceived as generally producing intoxication; these results suggest that many adolescent inhalant users are purposively seeking out inhalants that reliably produce intoxication/reinforcement and were repeatedly searched for and used. A very recent analysis of

cases reported to the National Poison Data System (16) is unique in identifying the products (including primary substances present) that were abused.

Modalities

In terms of modalities of use, more than half of all inhalants were usually sniffed from a container such as a jar or bottle. Sniffing from a container was particularly common among nail polish, correction fluid, gasoline, and paint pen users. Spraying the inhalant into the nose or mouth was uncommon and associated with use of computer duster spray and butane. Inhaling from a cloth saturated with a substance was prevalent among users of paint thinner, air freshener, hair spray, paint remover, deodorant spray, ether, and carburetor cleaner. Mixed modes of administration were common across inhalants. Another inhalant-specific study was published using the sample described above. Hall and Howard (61) found that only 1.7%, of the 723 youth they studied, reported lifetime use of nitrites; however, most (83%) nitrite users reportedly became intoxicated when they used nitrites. A similarly low rate of nitrite use was recently reported in a nationally representative sample of adolescents (62).

SOCIALCULTURAL ISSUES

Many solvent abusers, more than other drug users, are poor, come from broken homes, have lower self-esteem, and do poorly in school (63,64). They have difficulty with acculturation and strong peer influence that enhances their entrance into inhalant use, as well as other drug use (64), although findings are not wholly supportive of an acculturation stress–inhalant use relationship (65). The family atmosphere is often disruptive for the abusers and has been identified as less adjusted or more conflictual than for controls (66). Relatively few rationally based or empirically derived typologies of inhalant users have been developed. Schemes proposed include McSherry’s (67) description of experimental abusers (14- to 17-year-olds with less than 2 years’ experience with inhalants and only sporadic use), acute abusers (17- to 21-year-old youth with 2 to 4 years of inhalant use at least three times weekly), and chronic abusers (ages 20 to 28 who have used inhalants for 5 to 15 years and who are dependent on them). Oetting et al. (68) distinguished between inhalant-dependent adults, polydrug abusers, and young adult users. Inhalant-dependent adults have the most serious health problems, because they have used heavily for a long time; the young inhalant users are those for whom treatment is most desirable to keep them from progressing to the other groups and for whom there may be hope for successful intervention. Although all inhalant abusers use other drugs (both illegal drugs, tobacco and alcohol), the first group predominately uses inhalants, even though other drugs are available. The second group infrequently uses inhalants primarily because they cannot get their drug of choice; their problems arise more from the use of other drugs and are less related to

TABLE 20.4

Inhalant use in a sample of 723 antisocial youth in residential care in Missouri: The lifetime prevalence of use and proportions of users who got high, reported 100 or more lifetime occasions of use, and who reported weekly or more frequent inhalant use in the prior year are presented for specific inhalants including volatile solvents, gases, nitrites, and nitrous oxide

Inhalant ⁵	¹ Prevalence N (%)	Got high ² N (%)	³ 100+ occasions of use	⁴ Past-year weekly use
Gasoline ^g	159 (22.0)	130 (81.8)	19 (11.9)	21 (13.2)
Computer duster spray ^f	106 (14.7)	96 (90.6)	14 (13.2)	22 (21.0)

Nitrous oxide ⁿ	65–80	55+	10+	9+
Butane ^b	50 (6.9)	29 (58.0)	7 (14.0)	9 (18.0)
Propane ^b	21 (2.9)	15 (71.4)	1 (4.5)	2 (9.5)
Permanent markers ^a	106 (14.7)	45 (42.5)	11 (10.4)	15 (14.2)
Airplane/model glue ^t	39 (5.4)	22 (56.4)	0 (0.0)	0 (0.0)
Rubber cement ^{a,c}	35 (4.8)	17 (48.6)	2 (5.7)	2 (5.7)
Other glues/cements ^{g,h}	29 (4.0)	17 (58.6)	2 (6.9)	2 (6.9)
Nail polish remover ^g	63 (8.7)	30 (47.6)	3 (4.8)	3 (4.8)
Paint remover/stripper ^{t,g}	25 (3.5)	19 (76.0)	1 (4.0)	0 (0.0)
Amyl, butyl nitrites	7 (1.0)?	5 (100)	1	0
Ether	20 (2.8)	18 (90.0)	1 (5.0)	2 (10.0)
Any other cleaner	18 (2.5)	9 (50.0)	0 (0.0)	1 (5.6)
Nail polish	61 (8.4)	25 (41.0)	3 (4.9)	4 (6.6)
Correction fluid ^c	52 (7.2)	18 (34.6)	1 (1.9)	0 (0.0)
PAM	7 (1.0)	3 (42.9)	0 (0.0)	1 (14.3)

Only reason for different “liking” of amyl versus butyl is availability; differences are less than for sucrose and glucose.

¹Lifetime prevalence of inhalant use; all figures in table are N's followed by percentages in parentheses.

²Number and percentage of users of each inhalant who reported having “gotten high” while using that inhalant.

³Number of inhalant users who reported 100 or more lifetime occasions of use of that inhalant.

⁴Weekly or more frequent use of that inhalant over the year prior to assessment.

⁵The Products in which the most likely primary reinforcing chemicals are noted by type of chemical likely present in high concentrations: a is for isopropanol or other alcohols, b is for low-molecular-weight gaseous hydrocarbons, pure butane/propane alone or if used as a propellant; c is for chlorinated hydrocarbons; f is for products with fluorocarbons; g is for gasoline and other liquid fuels with medium to high molecular weight hydrocarbons; h is for hexane, a very specific neurotoxin; n is for all forms of products containing only nitrous oxide gas; t is for products containing toluene. See Table 20.1.

those discussed in this chapter. The young inhalant users, however, are in the experimentation period with inhalants, having started with tobacco, alcohol, or possibly even marijuana, as well as inhalants. Before any of this group matures into the first group, inventing behavioral modifications are very important. May and Del Vecchio (69) also developed a tripartite classification scheme, identifying young inhalant users involved in experimental use of inhalants, adolescent polydrug users who use inhalants frequently, and adult chronic users of inhalants.

Vaughn et al. (70) identified one class of inhalant users with high levels of inhalant use in response to social contextual influences. This class evidenced significantly greater psychiatric distress and substance use problems than two other classes of adolescent inhalant users differing in frequency of social contextual inhalant use. Additional taxonomic studies are needed that empirically identify types of inhalant users. Recent findings in adolescents (71) and adults (72) suggest that inhalant users, particularly girls, women, and persons with *DSM-IV* IUDs, are at substantial risk for suicidal ideation and perhaps suicide itself. Studies have associated inhalant use early in life with later injection drug use (73). Additional findings in samples of inhalant users include significant academic problems such as high rates of dropout, suspension, and expulsion, parental alcoholism and criminality, histories of physical or sexual abuse, deviant peers including inhalant users, impulsive, sensation seeking and fearless temperaments, and involvement in criminal and antisocial conduct (52,71–73).

One trait that is often associated with “sniffers” is disruptive behavior. Some report them to be more violent. In one carefully controlled study, the only aggressive feature that stood out was self-directed aggression (63). Another recent study of a national sample of adult inhalant users identified significantly elevated rates of interpersonal violence in inhalant users compared to inhalant nonusers, with especially high rates of such violence observed among persons with lifetime inhalant abuse or dependence (74). Early aggressiveness, antisocial attitudes, and involvement in criminal behavior (52,55,64) were also found to be characteristic of inhalant users in longitudinal and cross-sectional studies. Two recent reports identified significant associations between serious behavior problems and inhalant use (75).

Cognitive measures support the antisocial and self-destructive nature of inhalant abusers. At least two major studies found these groups to have lower Wechsler verbal scores; it remains unanswered as to whether these groups self-selected inhalant abuse because of these predilections or whether the deficiencies came about as the result of inhalant abuse (66). In some instances, school records indicate that cognitive deficits probably occurred before inhalant use began. Although it is uncertain how they became dysfunctional, it is very likely that inhalants prevent their continued growth and development (64,68). For further reading on the nature of the problem, especially the social-cultural conditions, we refer the reader to other reviews of this area (64,68).

TOXICOLOGY OF INHALANT ABUSE

Criteria for Defining Inhalant Toxicity

High-level exposure occurs in the inhalant abuse setting at levels several thousandfold higher than the usual occupational setting. Also, most abusers inhale several distinctly different solvents as well as use other illicit “drugs.” These are hardly ever noted by “history” profiles on entry into hospital, doctor’s office, or in coroner’s reports, except when an “incident” identifies this as an issue. The majority of either “novices” or “very experienced” inhalant abusers never reach a hospital or an outpatient facility with inhalant abuse identified as a “health problem.” Basically the solvent abuser may appear as a “drunk or in an intoxicated state,” as many of the symptoms resemble alcohol intoxication. An initial excitation turns to drowsiness, disinhibition, lightheadedness, and agitation. With increasing intoxication, individuals may develop ataxia, dizziness, and disorientation. In extreme intoxications, they may show signs of sleeplessness, general muscle weakness, dysarthria, nystagmus, and, occasionally, hallucinations or disruptive behavior. Several hours after, especially if they have slept, they are likely to be lethargic, or hung over with mild to severe headaches. At lower levels (just over 200 parts per million [ppm]), fatigue, headache, paresthesia, and slowed reflexes appear (76). Exposure at levels approaching 1000 ppm causes confusion or delirium, and euphoric effects appear at or above that level. Physical symptoms include weight loss, muscle weakness, general disorientation, inattentiveness, and lack of coordination. Too many times, death can occur during the course of primary intoxication. When it does occur, it is usually the result of asphyxia, ventricular fibrillation, or induced cardiac arrhythmia following high exposures to various solvents. The concentration of toluene in the body that causes death has been estimated based on data from the deaths of painters by Hobara et al. (77).

Although most cases of inhalant abuse occur in the general population, anesthetics are an abuse problem of medical personnel (3,78,79), especially nitrous oxide (30) as well as other anesthetics. It is well known that oxygen should be administered using specific devices. However, in some instances (e.g., homes, food services, or the ophthalmologist’s office where it may be used as a cryogen), there are usually no masks available for those receiving nitrous oxide, and death may occur. Also, these and other expand from the “condensed” state causing the lips to freeze.

Neurotoxic disorders have a nonfocal presentation and may be confused with metabolic, degenerative, nutritional, or demyelinating diseases (80). Thus, chronic toluene abuse may clinically resemble the multifocal demyelinating disease, multiple sclerosis (MS), in the findings on neurologic examination (81). Mild cases of intoxication may be very difficult to diagnose. The most reliable information comes from documented cases of long-term heavy exposure; details of low-level exposure and presymptomatic diagnoses are vague at best. In general, inhalant-related neurotoxic

injuries rarely have specific identifying features on diagnostic tests such as computed tomography (CT), magnetic resonance imaging (MRI), or nerve conduction studies (80). Because many neurotoxic effects are reversible and some chronic neurotoxic injuries of the brain may not be associated with structural damage sufficiently large to be detected within the spatial resolution of current MRI scanners and imaging sequences, brain imaging studies are primarily used to rule out other disorders. However, recent studies of chronic solvent inhalant abusers suggests that MRI may be the most sensitive and specific method of detecting the brain injury associated with the high dose setting of the inhalant abuser. Chronic neurotoxic injury related to solvent abuse is slowly and incompletely reversible, and usually does not progress after cessation of exposure (81). In addition, acute neurotoxicities and clinical manifestations of a substance may *not* be attributable to the parent compound, but may be associated with a metabolite of this compound. In addition, in several known cases, a solvent was reported to either diminish or potentiate the neurotoxic potency of a second solvent (82). Some acute incidents that are irreversible probably act by producing secondary systemic effects such as cerebral hypoxia or a metabolic acidosis (83). Table 20.5 lists those syndromes associated with organic solvent exposure. Major neurotoxic syndromes occurring in individuals chronically exposed to select organic solvents include a peripheral neuropathy, ototoxicity, and an encephalopathy. Less commonly, a cerebellar ataxic syndrome or a myopathy may occur alone or in combination with any of these clinical syndromes.

This section reviews several important issues: (a) the different physiologic and psychologic medical effects, as demonstrated by case reports and by the use of toluene or nitrous-oxide-containing products in contrast to products that contain other substances such as butane, fluorocarbons, or acetone; (b) the use of PET studies of radiolabeled solvents locating

different sites of action in the brain; and (c) the toxic manifestations of several different inhalants as reflected in the cognitive and neuropsychologic consequences measured in animals.

CLINICAL NEUROTOXICOLOGY

Encephalopathy

In 1961, Grabski (84) reported the first patient with persistent neurologic consequences of chronic toluene self-maintained inhalation. Many of these case studies reporting persistent central CNS effects involved adults whose initial experience with the euphoric effects of abused solvents occurred in the occupational setting, unrecognizable by these exposed workers as being associated with the chemical effects of the solvent. Since then, many reports of neurotoxicity, often of a severe nature, have appeared in the literature (13,83,85–95). The neurologic pattern is very clearly delineated, with effects primarily on the CNS. Syndromes of persistent and often severe neurotoxicity include cognitive dysfunction (13,81,87,90,94,95), cerebellar ataxia (81,84–88,94,96), optic neuropathy (86,94,97–99), sensorineural hearing loss (86), and an equilibrium disorder (92). The encephalopathy has been characterized using CT (100) and, more extensively, using MRI (91,94,95,101–105). Most commonly, toluene neurotoxicity includes several of the above syndromes and with multifocal CNS involvement (81,89–91). There are many instances of “persistent” neurologic deficits. However, the enduring nature of these deficits has been difficult to capture and it is possible that brain structural changes measured with MRI or CT persist despite a return in cognitive function. For example, abstinence has been documented prior to clinical evaluation and appears to relate to the degree of structural damage (81,105). Although longitudinal experiments where several brain scans are obtained over

time with abstinence are lacking, most chronic solvent abusers represent the severe end of the spectrum, and the issue is further complicated by equivocal evidence concerning impairment of cognitive function in solvent abusers: reports have provided evidence both for (85,106) and against (85) recovery of cognitive impairment with prolonged abstinence.

Also, microencephalopathy has emerged as a possible embryopathic syndrome in infants of women exposed during pregnancy to solvents containing toluene (107). Recently, encephalopathies have been observed following inhalation of butane-type products (a fluorocarbon-152A was also present in one case) and low-molecular-weight chlorohydrocarbons. One study of butane exposure showed increasing cerebral atrophy by MRI after 3 weeks (95); another was unremarkable as measured by MRI 3 days after admission (96). Chloro-methane/ethane-type products (often from head cleaner aerosols) are also possibly encephalitic.

Twenty chronic abusers of spray paint, containing toluene, and with documented abstinence for at least 1 month prior to evaluation (81) were some of the early studies. In those chronic solvent abusers, 65% showed neurologic impairment. This was a small and unselected sample, so the findings probably do not reflect the true prevalence of neurologic damage. However, there was a fairly consistent pattern of neurologic abnormality. As has been suggested, the CNS is selectively vulnerable. In fact, no peripheral neuropathy has been correlated with toluene exposure. Intoxication with some aliphatic hydrocarbons, for example, *n*-hexane, in humans has been associated with diminished vision and memory (108).

Neurologic abnormalities varied from mild cognitive impairment to severe dementia, associated with elemental neurologic signs such as cerebellar ataxia, corticospinal tract dysfunction, oculomotor abnormalities, tremor, deafness, and hyposmia. Cognitive dysfunction was the most disabling and frequent feature of chronic toluene toxicity and may be the earliest sign of damage. Dementia, when present, was typically associated with cerebellar ataxia and other signs (81). One patient had pyramidal and cerebellar signs without cognitive impairment. Oculomotor dysfunction, deafness, and tremor were seen only in severely affected individuals. Cranial nerve abnormalities were confirmed for olfactory and auditory dysfunction. Toluene-induced optic neuropathy was not substantiated by larger studies (81,91). However, visual-evoked potential abnormalities were found in chronic toluene abusers. Studies from Japan and Turkey have identified visual-evoked latencies/amplitudes resulting from toluene exposure due to inhalation abuse and from occupational exposure (109). Abstinence from exposure commonly brought restoration of function. This type of toxicity also occurs following hexane exposure (see below), which is expressed more extensively in peripheral neuropathic conditions. Other investigators have found a similar syndrome after chronic exposure to toluene (85,88). Although some investigators

emphasized the cerebellar disorder, they noted that most cases also showed impairment in a variety of cerebral functions.

The clinical data suggest that the cognitive, cerebellar, corticospinal, and brainstem signs are caused primarily by diffuse effects of toluene on the CNS. In one prior report of an autopsy of a chronic solvent abuser, there was prominent degeneration and gliosis of ascending and descending long tracts with cerebral and cerebellar atrophy (110). Unfortunately, as in most reports of toluene neurotoxicity, this patient was abusing many solvents contained in several different product mixtures, so the effects of individual solvents could not be determined.

Clinical Neuropathology

The first report of neuropathologic changes was in an individual who was primarily an abuser of paint thinner containing toluene (84). In the late 1980s, the first reports were published that began to look more closely at the pathophysiology of toluene inhalation (87,90). These studies used MRI and demonstrated for the first time that chronic abuse of toluene-containing substances caused diffuse CNS white matter changes (87,90). This has been thoroughly reviewed by Filley (113). The first published report was based on the MRI findings of the brain in six individuals and the neuropathologic changes in one abuser not studied by MRI (90). All individuals abused the same toluene-containing mixture, which contained primarily toluene (61%) and methylene chloride (10%). MRI of the six individuals revealed the following abnormalities: (a) diffuse cerebral, cerebellar, and brainstem atrophy; (b) loss of differentiation in the gray and white matter throughout the CNS; and (c) increased periventricular white matter signal intensity on T2-weighted images. These findings were supported in a more recent neuropathologic study (103). In this latter report, the neuropathologic and biochemical changes seen in the brains of chronic toluene abusers were identical with those seen in adrenoleukodystrophy (ALD). ALD is a rare X-linked disorder associated with accumulation of very-long-chain fatty acids in certain tissues, including brain (111). More recent MRI studies support these original observations (86,87,93,95,101,102).

These latter studies come from the United States (104), Japan (112), and Turkey (102). In adults, toluene precipitates an organic mental syndrome characterized by personality change and intellectual decline with mild dysfunction of the peripheral nervous system (113). Acute toluene intoxication produces a reversible neurologic syndrome characterized by encephalopathy and cerebellar ataxia (81). Chronic inhalation abuse induces a more severe white matter leukoencephalopathy characterized by a profound reduction in brain white matter regions along with cerebellar, brainstem, and pyramidal tract dysfunction (113). White matter changes have been reported as an increased signal in white matter areas such as corpus callosum, internal capsule, centrum semiovale, brainstem, and

cerebellar peduncles in T2-weighted images along with many reports of enlarged ventricles (90,98,114). These changes most likely arise from a relative increase in the water content of white matter caused by demyelination (90,93,94). Specifically, MRI results (93) suggest a possible mechanism for the abnormalities in the basal ganglia and thalamus.

An important clinical feature of white matter disorders is that the potential for recovery may be greater than in gray matter disorders (115). Recent reports indicate a full recovery of cognitive function in adult abusers of petrol (106). Cerebral white matter pathology may not be as complete or permanent as is usually the case with primary neuronal disorders. For example, white matter may be damaged without neuronal loss, and recovery of function appears more likely. Spontaneous remission is well known in MS, a disease similar in loss of neuronal function and possibly related to remyelination (116). Remyelination also may restore axonal conduction after traumatic and compressive lesions (117).

Recent MRI studies of these and other cortical areas (102,105) confirmed the above as well as observed changes in the ratios of choline/creatine in the basal ganglia in “toluene” abusers. Only the U.S. study had a comparison group of other drug abusers (primarily chronic cocaine abusers), which also exhibited significant neuropsychological abnormalities but fewer MRI abnormalities. Of interest in the U.S. study, there was a dose–response relationship between the degree of inhalant abuse and the MRI changes, but no relationship was observed with neuropsychological measures. Additional studies using state-of-the-art MRI techniques may help to further delineate the pathophysiology of the neurologic effects of toluene abuse, and the degree of recovery of these pathophysiological effects with abstinence.

While MRI has been very useful in attempting to understand the central nervous system effects of toluene abuse, an additional study using the imaging technique of brain SPECT (single-photon emission CT) to measure brain perfusion (or blood flow) in boys aged 16 to 18 was recently published (100). Multifocal abnormalities were seen in all 10 patients studied, but no distinct pattern of abnormalities emerged among the subjects. This may be due to the wide range of abstinence observed within the relatively small cohort (from 1 to 11 months abstinent). In a single case study, brain glucose metabolism (a measure of brain function) was measured using positron emission tomography (PET) after high-dose exposure to tetrabromo-ethane. Compared to a large control group, this case study documented reduced glucose uptake in frontal and temporal cortical areas and subcortically in the hippocampus, basal ganglia, amygdala, thalamus, and putamen (118). These deficits were consistent with decrements in neuropsychological function, underscoring the notion that even relatively brief exposures can cause significant functional impairments reflected in both brain function and neuropsychological measures. Recovery of metabolic

or cognitive function was not studied in this patient. Clearly, more controlled studies of brain function using these types of functional biologic measures are necessary, due to the many equivocal findings regarding cognitive deficits associated with inhalant abuse described above.

Although an exact dose–effect relationship cannot be drawn yet for chronic toluene exposure, it is clear that all severely affected individuals have had heavy and prolonged exposure. The lack of correlation between the type or duration of exposure and neurologic impairment may be a result of unreliable histories or other factors, such as genetic predisposition (unlikely) or hypoxemia resulting from “huffing” or “bagging.” Nutritional factors and other concomitantly used substances may also be involved. Gradual resolution of acute toxicity and absence of withdrawal symptoms were probably due to slow elimination of “significant amounts” of toluene from the CNS.

Myelopathy (Nitrous Oxide)

This type of inhalation abuse can be evaluated prospectively and not rely on retrospective evaluation (119). This is only possible because nitrous oxide is an approved anesthetic, as is sevoflurane. In human laboratory studies, Zacny and colleagues have evaluated over several years the pleasurable inhalation of nitrous oxide by humans, exposed to various concentrations of oxygen and nitrous oxide (119,120). The investigators measured moods over time at different doses resembling those of the “recreational” user. They noted that the effects lasted only a couple of minutes, and word tests demonstrated that memory retention within 5 minutes of the event was reduced. Some users liked the effect, whereas others did not. Subjects preferred different levels of exposure to obtain the preferred dose of nitrous oxide to satisfy them. This group has also compared this anesthetic, although not at the same time, to another, sevoflurane (120) and in combination with alcohol self-administration (121). Moderate drinkers preferred nitrous oxide (at levels 20–40% nitrous oxide) more than light drinkers, showing an enhanced desire for nitrous oxide in the presence of significant levels of alcohol. Other studies have measured the neuropsychological effects of nitrous oxide on humans after lower 1-hour doses (122) or after anesthesia (123). Other reports discuss the use of nitrous oxide for anxiety reduction, especially for children in dental treatment (124); another report even suggests use of nitrous oxide for treatment of alcoholism, an untested and unapproved treatment.

Nitrous oxide is not an organic solvent but has been noted to cause some unusual toxicities. A neuropathy was first observed in medical personnel (125). Recently, three other cases of myelopathy were reported (125). In the early studies, both central and peripheral nerve damage resulted following high levels of N₂O exposure, which occurred even in the presence of adequate oxygen and even after short-term use when nitrous oxide was used as an anesthetic

(126). This is consistent with recent case reports documenting numbness and weakness in the limbs, loss of dexterity, sensory loss, and loss of balance with the clinical use of nitrous oxide (127). The neurologic examination indicates sensorimotor polyneuropathy. Patients with vitamin B₁₂ deficiencies are especially sensitive (128), and a combined degeneration of the posterior and lateral columns of the cord has been observed that resembles vitamin B₁₂ deficiency. Studies focusing on the mechanism of action indicate that cobalamins (vitamin B₁₂) are inactivated by N₂O; more recent studies show an inactivation of the methionine synthase, an enzyme that needs vitamin B₁₂ to function (129). There was no recovery using vitamin B₁₂ (or folinic acid) in some patients (129); however, recovery was documented in others (130). In this regard, a report of a neuropathy in an undiagnosed “cobalamin-deficient” infant exposed to nitrous oxide (131) is of interest. Another treatment approach, the use of dietary methionine, might be helpful as indicated by studies in rats (132). Rehabilitation proceeds with abstinence from nitrous oxide exposure and is relative to the extent of neurologic damage. Recent reviews cover the medical aspects of the pros and cons of using nitrous oxide (129), most recently by Sanders, Weimann and Maze (133). Despite the widespread distribution of this information to the medical community (134) and the reduced availability of pressurized cylinders, cases are still being observed (30). A recent report even identifies inflammation as a result of nitrous oxide exposure (135).

Laboratory Studies

There are new important imaging techniques increasingly used to elucidate human toxicology through use of animal studies. PET and other imaging approaches, such as MRI, combined with behavioral measures evaluates/identifies those volatile solvents/gases with mild to strong abuse potential. The physiologic consequences of inhalant abuse and the capacity of neural systems to rebound upon cessation of inhalant exposure are also being studied. Also reviewed are electrophysiologic and behavioral studies used to elucidate functional and morphological changes in the brain associated with inhalant exposure, especially as they relate to inhalant abusing subjects.

It is especially important to understand the complexities of human toxicology of inhalants in the developing brain. Primates begin myelination at birth; then, there is a period of increased myelination in adolescence and periadolescence as the brain remodels to ensure efficient communication between cortical and subcortical brain regions (136). Similarly, rodents begin myelination around postnatal day (PND) 15, with a surge in the number of myelinated axons between 25 and 60 days (137). In view of the potent toxicity of volatile solvents, the impact of inhalant abuse in this age group on the structural genesis of the brain and on brain function could be severe and lasting. Neuropsychological deficits observed in adult inhalant abusers have been directly related to the degree of

white matter pathology (90,91). However, it is not known how this is manifested, especially in adolescent brains.

The reinforcing properties and CNS effects of inhalants are related chemically and pharmacologically. For years, studies of animals have explored the relative abuse potential of different organic solvents using models describing the stimulus properties of these chemicals. Nonhuman primates, for example, will self-administer vapors of toluene (138), mice will intravenously self-administer toluene (139), and develop a preference for environments in which they previously inhaled toluene (140,141). In addition, nonhuman primate PET studies were established to measure the uptake and distribution of several potentially abused inhalants (142).

Case reports (13,84) of occupational overexposure were the basis for animal models of inhalant abuse. Conditioned place preference (CPP) paradigms utilize a drug-free animal that has previously received pairings of an inhaled solvent in a particular environment and subsequently become conditioned to favor a drug environment over a neutral environment. In fact, it has been observed that adults at risk for solvent abuse include those whose work brings them into contact with these substances, such as shoemakers, painters, people working with gas and jet fuel, in addition to aircraft manufacturing (143). These case reports are a guide not only for establishing the CPP technique but also to the ubiquity of addictive and surprisingly toxic substances that are generally considered “safe” by the average user.

Traditional radioligand competition assays have facilitated the identification and comparison of widely abused drugs, for example, cocaine and heroin, with few common chemical features. However, inhalant pharmacology has been clouded by the absence of a potently bound initial protein target in the brain. The net effect of most abused compounds is to increase brain dopamine concentrations, whether through direct mechanisms (e.g., binding to dopamine receptors or stimulating dopamine synthesis in the mesolimbic reward system) or indirect pathways (inhibition of inhibitory GABA tone and subsequent disinhibition of dopamine). Yet the impact of inhalants on mesolimbic dopamine has yet to be unequivocally demonstrated (144–146). Different strengths of reinforcement of different inhalants related to site-directed actions had to be approached differently (147). An understanding of the protein-specific nature of inhalant effects has been indirectly inferred based on the lipophilicity hypothesis (144): (a) the ability of specific compounds (e.g., benzodiazepines and barbiturates) (148) to block or substitute for behavioral aspects of inhalant reinforcement (148,149) and (b) specific protein mutations that affect inhalant action on cell membranes and ion channels (150).

The uptake and distribution of inhalants can be attributed to factors including tissue lipid content and blood perfusion rates (142). The identification of the “target systems” is enhanced by the ability of specific compounds to block or substitute for behavioral aspects of inhalant reinforcement

(148,149) and specific protein mutations that affect inhalant action on cell membranes and ion channels (150). Also, the reversal of toluene-induced place preference by prior treatment with a drug that increases brain GABA (149) indicates another route.

Toluene

The measure of radioactive binding in PET studies, using radiotracers of toluene, most likely reflects both specific and non-specific binding. However, these measures indicate high uptake and rapid clearance of [^{11}C]toluene from the brains of anesthetized baboons (151), consistent with clinical observations that toluene intoxication lasts approximately 5 minutes and takes 30 minutes to subside (35). Primate studies are more relevant to human toxicology than are rodents. Toluene metabolites are formed quickly and include benzoic and hippuric acids, which are excreted in urine, and benzaldehyde. There is also a clear redistribution of the labeled compound to brain regions of high white matter content (149,151), such as the corpus callosum and central semiovale (Fig. 20.1), in agreement with molecular resonance (MR) measures of pathology observed in human abusers. Thus, the enduring effects of toluene and other abused inhalants as measured by MRI techniques need further exploration in suitable animal models to understand these “white matter” manifestations. In this respect, toluene and other inhalants resemble alcohol, focusing on metabolic parameters instead of a “drug-binding” site.

As in primate studies, toluene uptake was greatest in pons, colliculi, and the internal capsule of the rodent brain (see Fig. 20.2; 152). At 20 minutes, histologic examination of coronal slices of the striatum (a), internal capsule (b), mammillary bodies (c), and cerebellar white matter (d and e) of rat brain shows very little uptake of toluene in gray matter (i.e., cortical regions). MTR scans revealed enlarged ventricles in these animals. White matter changes and thalamic hypointensity were observed, as well as a strong decrease in MTR signal in the pons, medulla, corpus callosum, and midbrain. On the other hand, hyperintensity was present in the frontal, sensory/motor cortex, and the amygdala. These studies of rats (152) demonstrate that brain regions where toluene accumulates are also the most vulnerable to structural damage, as measured by MRI. There is a strong correlation between toluene uptake and regional decline in the MTR MRI signal. Therefore, PET may be a useful tool to predict which areas of the brain are vulnerable to insult with the abuse of different inhalants.

FDG PET Studies of Toluene-Induced Changes in Brain Glucose Metabolism

Toluene alters brain metabolic function in adolescent animals, and these alterations are reproducible, regionally specific, and to some extent, reversible with abstinence. Analysis of region-specific effects indicates that the thalamus and hippocampus are particularly sensitive to toluene-induced changes in FDG uptake and that the temporal cortex is particularly resistant to recovery (Fig. 20.3). However, light microscopic analysis of myelin integrity showed no gross morphological differences between toluene and air-exposed animals.

The highest decreases in FDG uptake in rats were in cortical regions, including the temporal and somatosensory cortices (153). The white matter appears more predominantly in areas such as the pons, where neural tracts are bundled together. The gray matter more predominantly

Figure 20.2. Distribution of ^{11}C -toluene in the rat brain. The brain has been separated into coronal slices showing uptake in the septum at the level of the striatum (a), internal capsule (b), mammillary bodies (c), and cerebellar white matter (d and e).

Figure 20.3. Impact of CPP to 5000 ppm toluene on 18FDG uptake. Serial data obtained from the same animal in adolescence prior to, throughout, and following a course of conditioning in which this animal expressed a significant preference (CPP) for toluene.

occupies regions such as cortex and thalamus and consists mainly of neuronal cell bodies and unmyelinated fibers. Because white matter regions are responsible for transmission of neural signals between gray matter regions, it is feasible that the impact of toluene on white matter could be reflected by alterations in gray matter as well as white matter function. This is evident in the high uptake of toluene itself in lipophilic, typically white matter-rich regions, while the functional consequences of toluene exposure are largely in gray matter regions such as the cortex. Thus, solvent or toxin-induced changes in morphology and metabolism ultimately raise the question of whether changes in morphology lead to functional decline or whether functional (i.e., metabolic) deterioration produces morphological damage. Taken together with clinical findings, it is possible that initially reinforcing doses of toluene produce functional changes resulting from metabolic disturbances which after years of abuse, alter brain structure and contribute to the well-established leukoencephalopathy described by Filley and colleagues (113). In addition, affected areas with less lipid content, such as the frontal and temporal cortices, reflect alterations in neurochemical transmission after repeated toluene exposure. The degree to which the regional distribution and mechanism of action of toluene and other abused inhalants are mediated by a receptor- or enzyme-driven mechanism is an area of active investigation (144). Early studies observed toluene-produced changes on brain dopamine concentrations, with more of an effect in the frontal cortex than in the striatum (152). More recently, studies of frontal areas appear more susceptible to the consequences of toluene exposure than striatal regions.

Butane/Propane

Very little is known about the mechanism of action through which these gases affect brain function. For example, butane is the prototypical aliphatic hydrocarbon abused and

even high concentrations of butane or cyclopropane fail to alter the function of GABA_A receptors (156). Unlike toluene, butane and cyclopropane do not act directly through GABA-mediated mechanisms (150,154–156,158). Instead, psychoactive concentrations of these gases appear to inhibit *N*-methyl-D-aspartate (NMDA)–sensitive glutamate channels and neuronal nicotinic acetylcholine receptors, a mechanism also shared by toluene and TCE (150,156,157).

Clinical reports and preclinical behavioral studies support the observed differences in the mechanism of action between toluene and butane. A butane-induced “high” is known to be extremely short-lasting (of the order of minutes) and of different quality (more pronounced visual hallucinations and distorted perception of body form) than the “high” experienced after toluene inhalation, where users report that thoughts are slowed, time appears to pass more quickly, and tactile hallucinations are experienced (35,155). Toluene is much more soluble in tissues, and butane is excreted rapidly through the lungs. Furthermore, the aliphatic hydrocarbon with the shortest chain length, methane, is rarely abused because it does not induce the desired pharmacologic effects (35). Evidence such as this supports the notion that the pharmacokinetics and pharmacodynamics of individual inhaled solvents greatly impact their rewarding or reinforcing properties. The link between pharmacokinetics and behavioral features of these inhalants related to their abuse liability remains to be established.

Acetone

Acetone is present in nail polish removers and some paint thinners. Acetone is not metabolized (158). It is a less potent CNS depressant than toluene or butane and less toxic. Radiolabeled metabolic PET studies support this conclusion (Fig. 20.4) (142). Acetone diffuses more slowly into the CNS than toluene (159,160). The acetone brain/blood ratio is 0.82; the

Figure 20.4. Radioactivity distribution of abused or potentially abused compounds in the primate brain. The distribution of two compounds with established abuse liability, ^{11}C -cocaine (a) and ^{11}C -methamphetamine (b), can be compared to compounds with lower abuse liability such as ^{11}C -butane (c), ^{11}C -toluene (d), ^{11}C -acetone (e), control (f).

toluene brain/blood ratio is 2.7, indicating that toluene passes from the blood into the brain much faster and at much lower concentrations. It is possible that, unlike toluene, which distributes to specific regions of the brain and other lipid-rich regions of the body, acetone prefers more aqueous regions. In fact, DiVincenzo (161) observed that the slow rate of disappearance of acetone from the blood of humans and animals followed zero-order kinetics, a characteristic of water-soluble anesthetics. The initial distribution of acetone in the primate brain resembles that of water, whereas toluene and butane distribute immediately from the blood into lipid-rich regions of the brain (142).

The abuse potential of acetone is low, since it is highly soluble in blood and solute areas and will poorly diffuse into the brain (160). These authors determined the LD_{50} for acetone to be 55,700 ppm while that for toluene was only 8600 ppm. In sum, it seems unlikely that solvent abusers would select acetone because of its slow onset and prolonged duration of action. Although early behavioral studies (161,162) suggest that acetone is reinforcing, more recently no effect at all was observed (162). Other studies of a wide range of inhaled acetone concentrations failed to produce a place preference in rodents (141). Inasmuch as toluene is the prototypical abused solvent, acetone should be at the other end of the spectrum—that of the prototypical nonabused solvent. Nevertheless, acetone is ubiquitous in commercial products in combination with other solvents and likely plays a role in the overall effect experienced by the person who abuses these toxicants.

Chlorohydrocarbons

Trichloroethane and TCE (common in dry cleaning fluids) share a profile of acute behavioral effects similar to those of CNS depressants and reproducibly substitute for benzodiazepines in drug discrimination studies (148,163). Other similarities include the development of sensitization (148,163) and tolerance (164), and biphasic effects on locomotor activity (165) and operant responding (166).

Limited *ex vivo* studies of these chlorohydrocarbons in rats provide evidence for a unique regional brain distribution (167). They also observed a decrease in cGMP (cyclic glucose monophosphate) production after administration of these chemicals. cGMP is a second messenger for excitatory (glutamatergic) transmission and reflects the general functional state of the nervous system (168). Changes in cGMP were noted to be regionally specific after inhalation of trichloroethane (169). While other compounds were not studied in these experiments, several neurochemical consequences of trichloro-ethane/ethylene exposure are thought to distinguish these inhaled solvents from other volatile chemicals such as toluene or halothane. Differences/similarities between toluene, styrene, and trichloro-ethane/ethylene actions on the cerebellar-vestibular circuit (170) are discussed below. Also, trichloroethane, but not florothyl, inhibits NMDA receptor function (157).

Nitrous Oxide

Nitrous oxide (N_2O) is an abused inhalant as well as an anesthetic, used primarily in dentistry for analgesia. This inhalant differs from most small hydrocarbons; it has a well-defined site(s) of action. Recent reports discuss the mechanisms of actions of nitrous oxide (125,171,172). Opioids have been known to alter the antinociceptive effect by the release of an opioid peptide in the brain stem, activating the descending noradrenergic inhibitory neurons and thereby modulating pain processing in the spinal cord. These authors studied the involvement of the brain stem opioidergic and γ -aminobutyric acid-mediated (GABAergic) neurons in the N_2O -induced antinociceptive effect. These results support the hypothesis that both opioidergic and GABAergic neurons mediate the antinociceptive effect of N_2O at the periaqueductal gray area and A7 in the brain stem. The authors postulate that N_2O -induced opioid peptide release leads to the inhibition of GABAergic neurons via opioid receptors. The descending noradrenergic inhibitory pathways, which are tonically inhibited by these γ -aminobutyric acid neurons, are thereby activated (disinhibited) and modulate pain processing in the spinal cord.

Other groups have focused on the action of nitrous oxide through the NMDA system (171,172). One group observed a reversible neurotoxic reaction in neurons of the posterior cingulate/retrosplenial cortex exposure of adult rats exposed to nitrous oxide (N_2O) and resembles that caused by low doses of NMDA antagonists (172). They consider N_2O to also be an NMDA antagonist. Prolonged

exposure to other NMDA antagonists can cause neurons to die. They also noted that prolonged N₂O exposure also causes neuronal cell death in adult rats. After termination of N₂O exposure and following concurrently administered GABAergic agents (e.g., diazepam or isoflurane) prevented this cell death. Also, an increased binding of MK801, an NMDA antagonist, occurred with nitrous oxide administration (172).

Ketamine is another anesthetic acting on the NMDA glutamate receptors, and clinically, induces a psychotomimetic reaction in humans and pathomorphological changes in the rat brain. They found a combination of ketamine and N₂O caused an apparent neurotoxic reaction in young adult rat brain. In another study, they compared the neurotoxicity of ketamine and/or N₂O in 18- and 24-month-old rats to 6-month-old rats. Here, they observed a greater neurotoxic reaction in the older rats induced by either ketamine alone or the ketamine plus N₂O combination, but an equal neurotoxicity in either age group induced by N₂O alone (172).

With regard to the dependency of nitrous oxide, animal studies on selectively bred mice for alcohol dependence showed a cross-dependency on nitrous oxide (173). They also observed handling-induced convulsions shortly after cessation of nitrous oxide, which could be prevented by either alcohol or nitrous oxide. This might indicate a physical dependence on nitrous oxide that needs to be dealt with in the treatment of patients in this drug abuse state. Almost all solvents produce anesthesia if sufficient amounts are inhaled; some of them are described in a detailed study (174). Although this is an important property of the agent, the ability to produce anesthesia has not been correlated with the extent of abuse of any given substance. Eger and colleagues have measured different anesthetic neuronal responses for years, especially nitrous oxide (175).

PERIPHERAL NEUROPATHIES

Ototoxicity

Clinical

The clinical nature of ototoxicity was evaluated in 11 chronic toluene abusers by measures of brainstem auditory-evoked responses (BAERs) and MRI (90). Neurologic abnormalities, including cognitive, pyramidal, cerebellar, and brainstem findings, were seen in 4 of 11 individuals. MRI of the brain was abnormal in 3 of 11 individuals, and all 3 also had abnormalities on neurologic examination. Abnormalities on MRI were the same as those reported previously (91). BAERs were found to be abnormal in 5 of 11 individuals and were similar to those previously reported in toluene abusers (89). In this study (90), all three individuals with abnormal MRI scans and neurologic examinations also had abnormal BAERs. Of the five individuals with abnormal BAERs; however, two had normal neurologic examinations and MRI

scans. This study suggests that BAERs may detect early CNS injury from toluene inhalation even at a time when neurologic examination and MRI scans are normal. These results suggested that BAERs could be a screening test to monitor individuals at risk from toluene exposure for early evidence of CNS injury.

Laboratory Studies

Laboratory-based studies have clarified some of the “toluene-type” neurotoxicities (176). Early studies of Pryor et al. (176) were the first to demonstrate persistent irreversible mid-frequency hearing loss by cued behavioral responses, BAERs, and pathology. Other studies (170,177) extended these findings. Hearing deficits are produced after as little as 2 weeks of exposure to 1200 ppm or 1400 ppm of toluene. This is attributed to cochlear dysfunction rather than the central conduction pathology found in the human studies noted above. After the initial studies on toluene were observed, Pryor et al. conducted a broad ranged structure–activity study on other related solvents. This group was also the first to identify a mid-frequency hearing loss in rats after exposure to TCE similar to that observed for toluene exposure (178). Others have since corroborated these studies (179). Pryor has published a list (Table 20.6) of several solvents that produce this hearing loss, including TCE, ethylbenzene (but not benzene), and styrene (180). Recently, ethylbenzene has been recommended to be defined as “ototoxic” in occupational settings (181). The exposure of rats to TCE produces a loss of spinal ganglion cells in the middle turn of hair cells (182). Other than ototoxicity, studies on rats have identified a toluene-induced motor syndrome that is characterized by a widened landing foot splay and a short and widened gait that may relate to the cerebellar syndrome in humans (183).

The common chemical structure feature of the most hazardous compounds is the presence of a vinyl-type unsaturation, not dissimilar to that occurring in some fatty acids. Further work needs to be done to clarify the chemical and molecular basis of this toxicity. Niklasson and colleagues (170) also analyzed the effects of some of these compounds on the vestibular function and correlated the changes with nystagmus. In a related area, Mergler and Beauvais (184) studied olfactory responses to toluene.

Hexane augments toluene toxicities, presumably through a reduction in the metabolism of toluene. Toluene causes age-related hearing loss in various inbred mice populations (185). This may result from different rates of metabolism in C57, but not CBA mice. In addition, noise has been thought to contribute to ototoxicity in the presence of toluene. A recent study of rats demonstrated that only “impulse” noise augmented auditory toxicity, not “low-level” noise (186). Also, toxicities in workers exposed to solvents were measured (187). They did not observe any changes in the amplitude of the auditory P300-evoked potential but did observe abnormal latencies in these subjects. A recent report discusses the difference between toluene

TABLE

20.6

Hearing loss produced (or not) by different solvents

Solvent	Hearing loss
Benzene	No
Toluene	Yes
Ethylbenzene	Yes
<i>n</i> -Propylbenzene	Yes
Isopropylbenzene (cumene)	No
Methoxybenzene	Yes
1,4-Dimethylbenzene (<i>p</i> -xylene)	Yes
1,2-Dimethylbenzene (<i>o</i> -xylene)	No
1,3-Dimethylbenzene (<i>m</i> -xylene)	No
Styrene	Yes
Monochlorobenzene	Yes
Carbon disulfide	Yes
Dichloromethane	No
Trichloroethane	No
Trichloroethylene	Yes
Tetrachloroethylene	No
Acetone	No
Methyl ethyl ketone	No
Ethyl alcohol	No
<i>n</i> -Hexane	No

type and excessive noise impairment of auditory function (188). As hearing loss has been identified in humans exposed to high levels of toluene, inhalant abusers of these types of chemicals should be provided good auditory evaluations.

n-Hexane and Methyl Butyl Ketone

These two organic solvents are classified together because both *n*-hexane and methyl butyl ketone (MBK) are metabolized to the same neurotoxin, 2,5-hexanedione (2,5-HD), and produce an identical clinical syndrome characterized by a peripheral neuropathy. MBK had limited industrial use until the 1970s when it became more widely used as a paint thinner, clearing agent, and a solvent for dye printing. Soon afterward, numerous outbreaks of polyneuropathy associated with chronic exposure to MBK were reported (189). Originally, methyl isobutyl ketone had been used. When methyl isobutyl ketone was replaced by MBK, reports of polyneuropathy began to appear in the literature.

The clinical syndrome is characterized by the insidious onset of an initially painless sensorimotor polyneuropathy, which begins several months after continued chronic exposure.

Even following cessation of exposure, the neuropathy may develop or may continue to progress for up to 3 months. In severe cases, an unexplained weight loss may be an early symptom. Sensory and motor disturbance begins initially in the hands and feet, and sensory loss is primarily a small fiber (i.e., light touch, pinprick, and temperature) with relative sparing of large-fiber sensation (i.e., position and vibration). Electrophysiologic studies reveal axonal polyneuropathy, pathologically multifocal axonal degeneration and multiple axonal swellings, and neurofilamentous accumulation at paranodal areas (190). Overlying the axonal swellings, thinning of the myelin sheath occurs. These findings are typical of a distal axonopathy or “dying-back” neuropathy described in other toxic and metabolic causes of peripheral neuropathy. Prognosis for recovery correlates directly with the intensity of the neurologic deficit before removal from toxic exposure, with mild to moderate residual neuropathy seen in the most severely affected individuals up to 3 years after exposure.

In related incidents in the 1970s, peripheral neurotoxicities were correlated with *n*-hexane, a solvent used in printing, in the extraction of vegetable oils, as a diluent in the manufacture of plastics and rubber, in cabinet finishing, and as a solvent for glues and adhesives. Cases of *n*-hexane polyneuropathy have been reported both after occupational exposure (191) and after deliberate inhalation of vapors from products containing *n*-hexane, such as glues (108,192). When glues have been analyzed in some reports of a polyneuropathy occurring after glue sniffing, *n*-hexane has been a major component of the products' composition. Another major component of glues has been toluene. However, polyneuropathy does not occur from inhalation of glues containing only toluene without the presence of *n*-hexane. In contrast to toluene, *n*-hexane does not usually induce significant signs of CNS dysfunction, except with high-level exposures where an acute encephalopathy may occur. Many cases of peripheral neuropathies still occur in industry (191). Both sensory and sensory-motor peripheral neuropathies have resulted in a shoe factory using glues with up to 50% hexane (191). Altered subclinical visual-evoked responses were also reported for some of these workers. In this study, 18 patients had sustained altered motor and sensory responses; 83% did have complete recovery 12 months later. Although the United States limits the use of hexane in many products, glues and other products (including some non-U.S. products) still contain this chemical in sufficient amounts to cause neuropathies in “glue sniffers.”

2,5-HD is responsible for most, if not all, of the neurotoxic effects that follow exposure to *n*-hexane or MBK (193,194). Chemical structure may predict, but not invariably, the neurotoxic effects. This is exemplified by studies of two closely related compounds: 2,5-HD (the toxic metabolite of *n*-hexane) and 2,4-HD. A fixed dose of 2,5-HD produces axonal degeneration in a particular species that is very similar to that produced by hexane, whereas 2,4-HD never produces these changes. Thus, a small but

important change in the compound's structure elicits a change from a positive to a nonpharmacologic action. Methyl ethyl ketone (MEK) alone produces neither clinical nor pathologic evidence of a peripheral neuropathy in experimental animals (193). The importance of MEK is related to a synergistic effect between MEK and MBK and between MEK and *n*-hexane detected in experimental animals and probably in humans (82). This potentiation of toxicity of one compound (MBK or *n*-hexane) by an otherwise nontoxic compound (MEK) underscores the difficulty with sorting out toxic effects of individual solvents contained within a mixture and suggests that any human exposure to solvent mixtures should be carefully monitored and kept to extremely low levels.

Both clinical and experimental animal studies provide some evidence of CNS effects from *n*-hexane. Experimental animal studies show *n*-hexane to cause axonal degeneration in the CNS (195). Clinically, cranial neuropathy, spasticity, and autonomic dysfunction occasionally occur (193). Abnormalities on electrophysiologic tests of CNS function, including electroencephalography, visual-evoked responses, color vision testing, and somatosensory-evoked responses, are also seen (196). In spite of these findings, clinically chronic low-level exposure to *n*-hexane primarily affects the peripheral nervous system.

Methylene Chloride (Dichloromethane)

Methylene chloride is widely used for paint stripping, as solvent for degreasing, in rapidly drying paints, and in aerosol propellants. As with other solvents, methylene chloride is a CNS depressant at high levels of exposure and may lead rapidly to unconsciousness and death (197,198). This has been reported both in industrial settings (197) and as a result of solvent inhalation abuse (198). A similar problem has also resulted from deliberate inhalation of the higher homologue dichloroethane. Methylene chloride is metabolized to carbon monoxide (199); consequently, both its hypoxic effect and its narcotic actions must be considered together with regard to its CNS-depressant effects. Carbon monoxide, at high levels, and other forms of cerebral hypoxia are known to cause permanent neurologic sequelae.

The effects of methylene chloride exposure on three tests of cognitive function (reaction time, short-term memory, calculation ability) were tested in 14 normal subjects (200). Three different exposures of methylene chloride showed no statistically significant impairment in performance. Methylene chloride may not be a choice inhalant if it is the only chemical present. However, inhalant abusers do inhale large quantities of methylene chloride from paint stripper solutions (90). In this regard, a recent report on the oral ingestion of this material identifies the problems that may occur after deliberate excess inhalation of methylene chloride (201). These include CNS depression, tachypnea, gastrointestinal injury, and high carboxyhemoglobin. In summary, the evidence suggests that methylene

chloride does not produce permanent neurologic sequelae except with massive acute exposures that are associated with hypoxic encephalopathy. No evidence exists that chronic low-level exposure causes any serious long-term CNS injury.

1,1,1-Trichloroethane

1,1,1-Trichloroethane is widely used as an industrial degreasing solvent and, compared with other solvents, is less toxic. However, several reports of severe toxicity and deaths exist in the literature (202). Its acute toxicity has made it unsuitable as a volatile anesthetic, and its use as a carrier in aerosols was abandoned in the United States in 1973. In those cases where postmortem examination of the brain was undertaken, the pathologic changes suggested cerebral hypoxia occurred either primary to CNS depressant effect (202) or secondary to cardiac or respiratory arrest (202). 1,1,1-Trichloroethane is postulated to act on the autonomic nervous system and to cause sleep apnea (203). Cardiac toxicity is also a possible toxicity related to chronic 1,1,1-trichloroethane exposure (204). It appears that 1,1,1-trichloroethane is not associated with either acute or chronic neurotoxicity at levels below 1000 ppm and that the only permanent neurologic sequelae are related to cerebral hypoxia after massive exposure. In contrast to TCE, equivalent doses of trichloroethane do not produce hearing loss when administered to rats (180).

Gasoline

Gasoline is a complex mixture of organic solvents and other chemicals and metals. The inhalation of gasoline is common among various solvent abusers, especially on some remote Native American reservations. Leaded gasoline is not now readily available in the United States but still may present a problem in some areas. Although some CNS or peripheral neuropathies may occur as a result of the solvents in gasoline, there have been toxicities that resulted from tetraethyllead (or its metabolite triethyllead) (106). In cases where high lead levels were observed, various disorders occurred, including hallucinations and disorientation, dysarthria, chorea, and convulsions. The symptoms include moderate to severe ataxia, insomnia, anorexia, slowed peripheral nerve conduction, limb tremors, dysmetria, and sometimes limb paralysis. In most cases, the electroencephalogram (EEG) is normal, but in severe states, an abnormal to severely depressed cortical EEG is observed. In only one lethal case was any kidney damage noted; electrolytes are usually in the normal range. Because many of these symptoms in the early stages of the disease can be reversed by parenteral chelation therapy with ethylenediaminetetraacetic acid (EDTA), British anti-Lewisite (BAL) (dimercaprol), and/or penicillamine. It is important to check the serum lead levels in any chronic inhalant abuser to see whether this treatment should be prescribed. This type of therapy has recently been reviewed

(205). It was considered generally effective and the complications surrounding the treatment of these individuals were discussed (206).

Alcohol Alone or with Other Solvents

Methanol neurotoxicity is well known and exemplified by one case (207), where necrosis of the putamen region of the brain was noted. Recent studies of rats exposed to methanol have described the damage done to the retina and optic nerve (208). Methanol intoxication was identified in an individual intoxicated on a spray can of carburetor cleaner containing toluene (42%), methanol (23%), and methylene chloride (20%) (209). Although mild acidosis did occur, the main concern was the high blood level of methanol. Ethanol therapy was used to prevent formation of high levels of formic acid from methanol. The above mixture is abused and is very similar in composition to paint thinner; yet the repercussions of prolonged use are unclear.

One interesting phenomenon has been observed following the exposure to two or more solvents. Degreaser's flush was ascribed to a flushing of the face when occupational workers left their degreasing vats and drank alcohol after leaving work (210). Heavy drinking has been associated with toluene exposure (211). More recently, both humans and rats have been noted to be thirsty when exposed to toluene and alcohol (212,213). Also, animal studies have shown that solvents alter the metabolism of alcohol and prolong its action (214). This might explain the "flushing phenomenon" but may or may not relate to the psychological dependence of solvents or to the development of thirst. An attempt to study the acute effects of alcohol and toluene, at low exposures in human volunteers, failed to produce any interaction as measured by their behavior. This may be indicative that the interaction takes some time and/or high levels of exposure to develop. Another alcohol–drug interaction was recently reported. Campo et al. (215) showed an enhanced hearing loss in rats when ethanol was combined with toluene exposure. Again, both solvents given together are more hazardous following dual administration rather than with only one solvent.

NONNERVOUS SYSTEM TOXICITY OF INHALANT ABUSE

Most of the known adverse clinical effects of inhalant abuse involve the nervous system. There are, however, other adverse effects on other organ systems.

Renal Toxicity

Currently, spray paints are widely abused substances, at least in the United States. The abuse of these substances occurs not only among polydrug users but also by painters. Metallic spray paints contain large quantities of toluene; also, thinner and glue contain high levels of toluene noted in a study of street children in Turkey (216). The exposure

to these and similar substances has resulted in the hospitalization of inhalant abusers for various kidney disorders (217–234). A recent report of diminished electrolytes occurred in a worker overexposed to paint thinner in a poorly ventilated room. He died after several days of corrective treatment for these low electrolytes and for hyposmia (219). A 32-year-old woman, identified as having renal distal acidosis after sniffing spray paint (220), presented to the hospital with severe quadriplegia. These subjects often have associated gastrointestinal involvement, including nausea, vomiting, and severe abdominal cramps. Lauwerys et al. (221) reviewed the early reports on nephrotoxicity in humans.

In one of the early reports, Streicher et al. (217) examined several cases and described them in detail, eliciting the nature of distal renal acidosis in groups of paint and/or glue sniffers from the southwestern United States and Hawaii. Streicher et al. and others have noted the recurrence of renal dysfunction associated with solvent abuse: the disease state reappears in many individuals who return to their habit after release from the hospital. Their symptoms include hyperchloremic metabolic acidosis, hypokalemia, hypocalcemia, and other electrolyte imbalances. A recent case included quadriplegia and respiratory failure (218). Solvents usually cause a unique distal-type tubular acidosis, but proximal tubules are also affected. Although the distal tubule is responsible for the known electrolyte and metabolic imbalance, the proximal type is responsible for the wasting of amino acids and other proteins. In spite of this tubular damage being reversible, other organs, particularly brain, are the target of repetitive acidosis, plus a depletion of important amino acids. A slightly different kidney dysfunction, glomerulonephritis, has also been identified in workers using solvents, especially painters, and reviewed by Daniell et al. (222). In addition, an interstitial nephritis leading to renal failure has been reported by Taverner et al. (223). Rhabdomyolysis is also observed after exposure to solvents (224). All of these reports indicate that kidney dysfunction is a common toxicity noted for solvent abusers. Even of greater concern might be the diabetic patient who presents after an overdose of solvents. Solvent odors might cover up the "acetone breath" of the diabetic patients and prevent the identification of the condition and/or the basis of that acidosis if the patient is unconscious (225). In a recent study of renal function in street children in Turkey, pyuria, hematuria, and proteinuria were common (216), and glomerulopathy and tubulopathy were apparent. No acute or chronic renal failure indicators were evident. Glomerular filtration rate was in the lower range of normal, but urinary output of protein was higher, including urinary NAG (*N*-acetyl-glucosaminidase). These could be early indicators of renal toxicity and failure in these children. Toluene content of the thinner and glue that were abused was reported and appears to be the predominant solvent present.

There are also reports that haloalkanes—chloroform and others (226), methylene chloride (227), TCE (228),

methoxyflurane (229), and dichloropropane (230)—may contribute to, if not cause, renal damage. The nephrotic pathologic changes reported include tubular necrosis and calcification. Studies of humans occupationally exposed to high levels of TCE, compared to nonexposed individuals, had elevated levels of alpha-microglobulin excretion. This relates to an increased reported incidence of renal cell cancer incidence in these TCE-exposed individuals (231), reviewed by Lock et al. (226). Others (232) observed signs of Goodpasture syndrome; also, bladder changes are correlated to toluene exposure (233).

Although toluene is often proposed as the toxic agent and is present in most of the substances abused by these subjects, there has been no animal data to verify that toluene is a causative agent for renal dysfunction. Recently, Battle et al. (234) exposed the turtle bladder to high concentrations of toluene and observed a diminished hydrogen ion transport that had no effect on the sodium transport. Also, toluene did not reduce the pH gradient across the bladder. Efforts to reproduce these nephrotic changes in rodents have met with limited success. Acute solvent exposure of liver cells determined an induced activation of cytochrome P4502E1 as the cause of proximal tubular cell necrosis by oxidative stress (235). Animal studies have also shown mild nephrotic changes following exposure to hydrocarbons (236). In most cases, more than one substance is present; this may indicate that the most severe nephrotic changes occur in the presence of two or more of these solvent compounds.

Thus several kinds of solvent mixtures are associated with glomerulonephritis, distal renal tubular acidosis, or other nephrotic changes. Usually, these different kidney disorders do not occur in the same individual and may be related to individual and/or other environmental factors. Although metallic spray paints are frequently used by these subjects, they also use paint thinners, glue vapors, and other solvents. It would appear reasonable to conclude that toluene may account for some but not all of these renal abnormalities. Renal toxicity may also be due to the metals contained in the spray paint, such as cadmium and lead, which are known to be nephrotoxic (237), or concurrent alcohol use and/or infections (238,239). As cases of renal toxicity continue to be reported, it is important that individuals exposed to high doses of solvents be checked for renal changes and metabolic imbalance. Correction of salt and electrolyte imbalance, including potassium, calcium, magnesium, and chloride, should be considered in the treatment of solvent abusers for muscle fatigue, even in the absence of more severe kidney disorders. However, one has cautioned the use of bicarbonate early for the treatment of these subjects.

Renal Toxicity in Pregnancy

One must especially be alert for nephrotoxicity in pregnant women who abuse solvents (also see the “Neonatal Syndrome”

section). Pregnant women have presented with renal tubular acidosis. In one report (240), three of the five infants showed growth retardation. A similar case was reported where no known causative agent was identified (241). These women often, but not always, respond to treatment for their metabolic imbalance after 72 hours of treatment and abstinence of solvent abuse.

Hepatotoxicity

Chlorohydrocarbons (e.g., TCE, chloroform, halothane) have been known for years to produce hepatotoxicities. Several reports describe solvent-related toxicities (3,229, 239,242–244). Any individual who is chronically exposed to these compounds would expect hepatorenal insults, depending on the dose and length of exposure (242). Buring et al. (245) evaluated the effects of low levels of exposure measured retrospectively by several investigators. They concluded an increased risk exists for operating room personnel using chlorohydrocarbon anesthetics; however, Brown and Gandolfi (229) questioned whether liver toxicity occurs very often after use of halothane as an anesthetic.

The inhalation of correction fluids for “pleasure,” which did, and may still, contain TCE, and trichloroethanes or tetrachloroethanes (246), did lead to toxicities in inhalant abusers (247). Even during occupational use, exposure to chlorohydrocarbons in poorly ventilated areas is considered to lead to hepatotoxicity. A recent paper describes an occurrence of hepatitis for a shoemaker working with a glue containing TCE in his basement for several years (244). He presented with anorexia, fatigue and upper abdominal discomfort. Marked elevation of liver enzyme and bilirubin levels could only be related to the TCE exposure. Although there was no knowledge that this excessive exposure occurred due to self-directed inhalation, this type exposure of these halohydrocarbons by inhalant abusers does occur and may have resulted in hepatic damage in some unreported individuals.

A refrigerant gas, HCFC-123, was identified as hepatotoxic in a hospital worker (248). This is more readily metabolized than the previously used fully halogenated fluorocarbons and has been compared in toxicity to an analogue, halothane, which is used for anesthesia (249,250). Hepatocellular and other carcinomas are observed at high doses of TCE (228) and halothane (251). Anesthetic chlorinated hydrocarbons (halothane, TCE, and chloroform) are also considered to be carcinogenic (252). Increased availability of TCE for dry-cleaning purposes could present more cases of nephrotic and hepatotoxic diseases, including cancer (253).

Pulmonary Toxicity

The trachea and lungs are the primary organs affected by inhalants; yet, there are few cases noted where the pulmonary system is severely compromised. As mentioned earlier, asthmatics excessively administer the very medication

that they need (27). These products have been reported to cause pulmonary hypertension, acute respiratory distress, increased airway resistance, and residual volume and restricted ventilation. One “outbreak of respiratory illness” was associated with changes in solvents/propellants of a leather conditioner (254). This product produced tachypnea, pulmonary edema, and hemorrhage in rats. Respiratory problems would therefore be expected in inhalant abusers using these or similar products. In addition, increased airway resistance or residual volume may be more clearly noted following an exercise challenge (255). Additionally, response to an aerosolized bronchodilator is suggestive of an airway involvement perhaps induced by habitual inhalation of hydrocarbons. Smoking may have been a contributory factor in one study (256) and was not ruled out in the others. In studies of workers using waterproofing aerosols containing trichloroethane (257) or using a paint stripper (258), acute respiratory distress has been correlated with the chlorinated hydrocarbon exposure. Although solvents irritate the pulmonary system, it is not at all clear from the limited case studies reported, to date, how extensive or what types of pulmonary damage occur that can be primarily caused by solvent exposure and not to other inspired substances that are dissolved in the solvents. For example, a report of a homicidal case (a spray paint “sniffer”) noted metallic deposition along with hemorrhagic alveolitis (259). It is uncertain how to generalize the impact of dual exposure of solvent and infection, but an animal study showed decreased pulmonary bacteriocidal activity after exposure to dichloroethylene (260). Injury of trachea mucosa was recently observed following spray paint exposure (261). This case, however, was not associated with self-abuse.

Cardiotoxicity

It is not as evident, but the results of several cases link fibrillation and other cardiac insufficiencies to the use of halocarbons (4,18,202–204) and numerous others. These types of products range from anesthetics (halothane) used by hospital and other medical personnel to the more common solvents/propellants and fluorocarbons (dichloroethanes, trichloroethanes, tetrachloroethanes, and TCE) contained in cleaning fluids and other products. Most interestingly, the resuscitation of inhalant abusers following cardiopulmonary arrest does not usually occur; yet, a successful resuscitation from fluorocarbon cardiac arrhythmia has been reported (262); also, another patient who suffered nonfatal respiratory arrest (twice) after “sniffing glue” was resuscitated (263). In another report, cardiopulmonary complications resulted from paint thinner (containing toluene and benzene derivatives) overexposure for several hours (219). Cardiac arrest occurred on day 2, he was resuscitated, but remained unconscious till death 9 days later.

Many solvent abusers may die from direct or indirect cardiotoxic actions of solvents without note in any public or private record. Several cases of the abuse of different products

have been reported (204,262). Some of the subjects had inhaled TCE- (264) or trichloroethane-containing solvents (204) and some subjects were additionally compromised by anesthesia (e.g., halothane) (204). Fluorocarbons cause arrhythmias in animals (265). Chenoweth and colleagues showed that butane, hexane, heptane, gasoline, some anesthetics, and toluene also produce these arrhythmias (266). Reports have linked glue sniffing to arrhythmias, myocarditis, and cardiac arrest. Glues usually do not contain halocarbons but do contain toluene and other hydrocarbons. A very recent report identifies a cardiomyopathy following paint thinner and glue (containing toluene) inhalation (267). Recent studies, conducted on oocytes (268), measured sodium or potassium channel currents to partially explain the cardiotoxic actions of toluene. Therefore, where heavy solvent exposure is suspected, strenuous exercise or anesthesia should be avoided.

Hematologic Toxicity

There are three areas of concern with regard to solvent inhalation and the hematopoietic system. First, methylene chloride exposure can increase the carboxyhemoglobin levels (198), a change that also occurs with cigarette smoking. The levels of carboxyhemoglobin may become sufficiently high to cause brain damage (269) or death (270). In one case, inhalation of methylene chloride prompted a sustained (at 24 hours postexposure) elevation of carboxyhemoglobin (199). A second substance, benzene, causes aplastic anemia, acute myelocytic leukemia, and other hematopoietic cancers (221,271). Benzene is present in thinners, varnish removers, and other solvents, and in varying proportions in gasoline, sometimes at high concentrations that will produce “toxic” levels following episodes of inhalant abuse. A third group of substances, the organic nitrites, produce methemoglobinemia and hemolytic anemia (272).

The latter group, the volatile liquid isoamyl (amyl), isobutyl or butyl nitrites, propyl nitrites, cyclohexyl nitrites, and maybe other organic nitrites deserve a special discussion. During the late 19th and early 20th centuries, amyl nitrite was used in clinical practice as a vasodilator to treat angina pectoris. Although this use of the drug is uncommon today, it is sometimes used for diagnostic purposes in echocardiogram examinations (273) and for cyanide poisoning (274). These abused drugs do *not* produce the typical solvents/gases neurologic actions described above; however, they are often included in the “inhalant abuse” category. Different adult individuals (predominately homosexuals) are the primary abusers of these organic nitrites. Subjects may use them for sphincter dilation and penile engorgement. Use by others for nonsexual purposes is unclear. One study could not correlate changes in regional blood flow with any psychological measures or somatic changes (275); also, isoamyl nitrite did not substitute for barbiturates, as do toluene and other solvents (276). These studies do not offer any explanation for why individuals become

dependent on nitrites. However, the finding by Mathew et al. (275) that nitrites reduce anger, fatigue, and depression may offer a clue.

The nitrites are usually not considered acutely toxic during inhalation because of syncope (fainting). However, Guss et al. (277) noted a dangerously high 37% methemoglobin level in a normal subject who had used isobutyl nitrite. This methemoglobinemia is the major identified toxicity and is the cause of several deaths. There is a specific treatment for nitrite overdose. The high and slowly reversible reduction of methemoglobin can be aided by the use of methylene blue (278).

Heavy organic nitrite has been considered a risk factor for the development of acquired immune deficiency syndrome (AIDS) (279) and of Kaposi sarcoma (KS) (280). Thus, the use of organic nitrites became an issue when KS (now considered to be caused by the virus HHV-8 (281)) was linked with nitrite use in homosexual populations (282). A recent study (283) of HIV-negative men showed that abuse of nitrite inhalants was an independent risk factor for infection with HHV-8, the etiologic agent of KS. The potential use of nitrites has also been studied in the U.S. military (57).

To understand the actions of these nitrites, animal studies were conducted to evaluate their actions on the immune system (284). Soderberg reviews the potential for nitrites to impair the immune system (285). Earlier studies reported that exposure to isobutyl nitrite inhibited several acquired immune responses, including the induction of T-dependent antibodies (285). B cells and isolated T cells, however, had normal functions. In their studies, after inhalation exposure of mice for 14 days to isobutyl nitrite, there is a reduced capacity for the concanavalin A (but not lipopolysaccharide) stimulation of T-cell functions, an induction of cytotoxic T cells, a reduced tumoricidal activity, and an increased tumor incidence (285). Recent data suggest that at least some innate immune mechanisms were also impaired by inhalant exposure, that is, a reduction in important AIDS factors, the chemokines. IL-1 has been reported to inhibit HIV replication through the induction of chemokines, MIP-1 α , MIP-1 β , and RANTES (286). Abusers of nitrite inhalants could be more susceptible to HIV infection and to KS tumor growth in multiple ways if the inhalants impair both acquired and innate immune responses. In this manner, the factors leading to or augmenting KS, including the organic nitrites, are discussed in Refs. (281,285). In other reports from Fung's laboratory, isobutyl nitrite stimulated the hepatic mRNA and protein expression of vascular endothelial growth factor (VEGF) (287). Isobutyl nitrite reduces several hepatic enzymes, including cytochrome-mediated deethylation (288). They discussed the issue of KS related to some of these findings.

Neonatal Syndrome

There is evidence that solvent inhalation during pregnancy produces a "fetal solvent syndrome." There are numerous

cases of infants of mothers who chronically abuse solvents (107,240,241,289–292) diagnosed with this syndrome. The mothers inhaled paint reducer, solvent mixtures from paint sprays, and drank various quantities of alcohol. Whether toluene alone (often noted as the major solvent), other solvent components, and/or these components in combination with alcohol or other environmental factors are responsible is still unsubstantiated by laboratory studies. Toluene still appears to be a major contributor. This toluene embryopathy has been compared to the better recognized fetal alcohol syndrome (107). The infants present with growth retardation, some dysmorphic features, including microcephaly, as well as distal renal acidosis, aminoaciduria (290), ataxia, tremors, and slurred speech (291). Toluene has been considered a human teratogen (292). This inhalant "fetal syndrome" has recently been evaluated in a study of pregnant women who used toluene-based solvents and/or alcohol (293). In this study, only the babies of mothers who abused alcohol were observed to have a "fetal alcohol syndrome." However, some of the newborns of solvent abusers presented with renal acidosis.

Some of these abnormalities related to toluene and other solvents were also observed in rodents exposed to toluene (294); however, the extent and severity of the effects are unclear. It is difficult to produce these abnormalities in rodents (295). Growth retardation occurs in rats with doses of toluene that produce fetal mortality without producing malformations (296). Weight loss, altered motor activity, renal abnormalities, and some neurologic insults were also recently reported (297–299).

Nitrous oxide has been reported to produce some "major visceral and minor skeletal (fetal) abnormalities" (300). Surprisingly, these abnormalities are reportedly protected against by 0.27% halothane, but not by folic acid. Also, animal fetal liver toxicities occur after administration of carbon tetrachloride (301) or malformations following chloroform (302). With so little knowledge and yet with all the potential dangers, it is very important that pregnant women not be exposed to very high concentrations of solvents/gases.

DSM EVALUATIONS OF INHALANT ABUSE

DSM-IV and Inhalant Use Disorders

Inhalant use and IUDs are defined by the *Diagnostic and Statistical Manual of Mental Disorders*, 4th Edition (*DSM-IV-TR*, American Psychiatric Association [APA], 2000). *DSM-IV* inhalant abuse and dependence criteria parallel the generic *DSM-IV* substance abuse and dependence diagnostic criteria, except that the withdrawal criterion included in the generic substance dependence criteria set is not included in the inhalant dependence criteria set. One of four criteria must be met to receive a *DSM-IV* inhalant abuse diagnosis (e.g., legal trouble due to inhalant use) and at least three of six criteria

(e.g., tolerance to inhalants) must be met to receive a diagnosis of inhalant dependence, the most serious of the inhalant disorders. Inhalant-induced disorders include inhalant use-precipitated delirium and dementia, among other clinically important conditions, but specifically exclude use of nitrite vasodilators such as amyl or isobutyl nitrite and the anesthetic gas nitrous oxide.

The estimated prevalence of IUDs depends to some extent on the nosology employed to assign diagnoses and the characteristics of the sample under investigation. For example, Howard, Cottler, Compton, and Ben-Abdallah (303) found a substantially smaller proportion of lifetime inhalant users, who participated in the *DSM-IV* Field Trial for Substance Use Disorders, met *DSM-IV* IUD criteria than met comparable *DSM-III-R* or ICD-10 criteria. Rates of formal IUDs are also often higher in samples of antisocial or delinquent youth and in other high-risk populations than in the general population.

Few studies of the natural history of IUDs have been conducted. Perron, Howard, Maitra, and Vaughn (304) recently reported that 19%, who initiated inhalant use in the NESARC (National Survey on Alcohol and Related Conditions) study, developed a *DSM-IV* IUD. Most of these transitions were to inhalant abuse rather than inhalant dependence and that risk for transition was substantially greater in the first year following initiation of inhalant use and low thereafter. The presence of a mood or anxiety disorder or alcohol use disorder antedating initiation of inhalant use predicted significantly elevated risk for IUD, whereas being married lowered risk for onset of IUDs. Nationally representative data from the NESARC survey also reveal high rates of *DSM-IV* mood, anxiety, and personality disorders (305) and prevalent noninhalant substance use disorders (306) among adult inhalant users.

Adolescents

Relatively few studies have examined the prevalence of IUDs in national samples of adolescents. Wu, Pilowsky, and Schlenger (307) examined the prevalence of IUDs in 36,850 12- to 17-year-olds who participated in the 2000–2001 National Household Survey on Drug Abuse. Overall, 0.4% of adolescents aged 12 to 17 years met past-year inhalant abuse or dependence criteria. Alternatively, 10.6% of past-year inhalant users met past-year inhalant abuse or dependence criteria. Similar figures were reported for 15- to 24-year-olds participating in the National Comorbidity Survey (NESARC); 8% of participants reported inhalant use, the proportion of overall respondents ($N = 8,098$) with a history of inhalant dependence was 0.6%, and the proportion of inhalant users with a lifetime history of dependence was 8% (308).

Ridenour, Bray, and Cottler (309)¹ reported much higher rates of *DSM-IV* IUDs in a community sample of 162 adolescents/young adult inhalant users (medium age = 20; SD = 2.4)

who were recruited via community flyers or referral. Approximately, 28% of respondents met criteria for inhalant abuse, whereas 12% met inhalant dependence criteria. Overall, use of inhalants in hazardous situations (29%) was the most prevalent inhalant abuse criterion, whereas inhalant-related legal problems (1.9%) was the least prevalent inhalant abuse criterion. The most prevalent dependent criteria were inhalant use despite a known physical or psychological problem related to such use (59%) and using inhalants in a greater quantity over a longer time than was planned (30%). Sakai et al. (310) examined IUDs in 847 youth aged 13 to 19 who were treated at a university-based program for behavior or substance misuse problems. Although approximately 19% of youth had used inhalants, only 3.3% met criteria for lifetime inhalant abuse or dependence. In another study, high rates of inhalant abuse (19%) and dependence (28%) were observed among 279 inhalant users who were in residential care for antisocial behavior in Missouri (311). Overall, 18.1% of youth in the Missouri Division of Youth Services residential treatment system met criteria for Inhalant Use Disorders and 5 of 10 *DSM-IV* IUD criteria were met by <10% of the total sample of 723 current residents.

Adults

Drawing upon data from the 2002–2003 administrations of the NSDHU, Wu and Ringwalt (312) estimated that approximately 10% of U.S. adults had used inhalants and that 4.8% of this group had used inhalants within the prior year. Among past-year inhalant users, approximately 8% met criteria for past-year IUDs. Among participants aged 15 to 54 in the NESARC, the proportion of overall respondents with a history of inhalant dependence was 0.3%, and 3.7% of inhalant users developed inhalant dependence (62). Only 2% of adult respondents in the NESARC reported lifetime inhalant use, but of this proportion nearly one in five (19%) met criteria for a lifetime IUD (305). Taken together, surveys of adolescents and adults suggest that inhalant use is far more prevalent than IUDs in the general population. However, signs and symptoms of IUDs and associated criteria may be prevalent among some high-risk groups such as antisocial youth, which are commonly excluded from large surveys of noninstitutionalized populations.

TREATMENT

There is no accepted treatment approach for inhalant abusers. There are a variety of treatment programs for inhalant abusers used by educators, drug treatment clinics, and physicians, but there are a relatively few drug abuse treatment “professionals,” who focus primarily on inhalant “abusers.” The available programs range from basic and limited behavioral modification to medical pharmacologic clinics (which do not usually segregate inhalant abusers from other drug abusers), but little is evidence-based treatment.

¹ The subdividing of various “inhalant abusers” in this paper into different groups uses overlapping chemical/physical criteria that place some of the abused compounds in more than one “class.”

Many drug treatment facilities refuse treatment of the inhalant abuser, as some believe that inhalant abusers are resistant to treatment. Some programs use models that range from short-term to longer periods of treatment. Longer periods of treatment are needed to be able to address the complex psychosocial, economic, and biophysical issues of the “heavy” inhalant user. Many environmental stimuli are associated with these “drug” effects and include family problems, poverty, environment, and associations. When brain injury in a very limited number of subjects occurs, mostly in the form of cognitive dysfunction, the rate of progression in recovery is even slower.

The diagnostic criteria, which measure signs of compulsive drug seeking, are the same for all drug categories, even though the mechanisms for activating the reward system are quite different (313). Also, when psychiatric disorders co-occur with addiction, these disorders must be treated concomitantly and preferably by the same treatment team. Use of many addictive drugs may be diminished by pharmacologic action, and thus, treatment may benefit by medication. No specific, well-documented pharmacologic agent has been reported, although case studies of the use of different drugs have been sporadically reported noting limited success. The primary addictive disorder may also benefit through combination of counseling with medication (313). However, no pharmacologic treatment is known for “inhalants.” The “serious” inhalant abuser typically does not respond to any usual drug rehabilitation treatment modality. Several factors may be involved, particularly in situations of the chronic or “heavy” abuser, where significant psychosocial problems may coexist. Treatment becomes slower and progressively more difficult when the severity of brain injury worsens as abuse progresses from transient social use (experimenting in groups) to chronic use in isolation. Specific drug treatment may also be difficult to evaluate largely due to the weak tolerance or physiologic dependence that occurs with inhalants.

Sakai et al. (310) have published studies on the clinical treatment of inhalant abuse. This is one of few studies of patients, which measures various disorders associated with inhalant abuse. In this program, few are “chronic inhalant users.” They describe an association between inhalant use and antisocial behavior, which has long been noted in cross-sectional studies (310). Also, some adolescents in this study had been in a jail, detention center, prison, hospital, or treatment program prior to follow-up assessment. It was stated that inhalant intoxication in this sample of drug abusers accounted for the high severity of relapse at follow-up. It may be that inhalant use serves as a marker for severity of impulsivity, risk taking propensity, and poor decision-making ability. Interestingly, only one adolescent in this group reported using inhalants in the previous 30 days at the 2-year follow-up. This is characteristic of most “inhalant abusers” in these treatment programs; they are not current chronic users of inhalants and may never have been. As a corollary, the physicians did not observe neuropsychological impairment associated with inhalant use (310).

Beauvais queried several associated treatment groups they worked with (314). This study assessed the attitudes

and success of drug user treatment program directors toward the problem of inhalant “abuse.” Areas covered included treatment success and prognosis for inhalant users, level of neurologic damage incurred by users, availability of treatment resources, their program’s policies toward admission of users, and staff training needs for inhalant use including their assessment of barriers to treatment and subjective feelings about the topic of inhalant use. Five hundred and fifty responses were received. The responses were general in nature with limited details. Reidel, Herbert and Byrd (315) have published a more substantive report regarding the effects of and approaches to treatment of some of these inhalant users. These authors are associated with one of the few treatment programs in the country dedicated to “primary” inhalant users. They detected significant improvement in neuropsychological functioning among patients at the end of treatment (using Halstead–Reitan scores).

Dinwiddie et al. (316) studied treatment of eleven “primary” inhalant users, who were mostly in their twenties. The data came from subject records of those admitted for treatment and which were reviewed for medical and psychiatric illness and other substance abuse. Antisocial personality disorder and narcotics abuse were commonly associated factors; also symptoms suggesting neurologic or gastrointestinal dysfunction were noted. The patients’ response to treatment was poor. Those patients, using solvents chronically, had associated behavioral patterns that contribute to poor social adjustment. Ten entered treatment, but only half finished, and all relapsed within 6 months.

Drug screening may be useful in monitoring inhalant abusers (317). Routine urine screens for hippuric acid, the major metabolite of toluene (219), performed two to three times weekly, will detect the high level of exposure to toluene usually seen in “chronic” inhalant abusers. However, analysis must always take into account the average background level of hippuric acid resulting from general metabolism. It should be noted that the metabolism of any one compound may be modified by the presence of another, either increased (following inducement by drugs, e.g., barbiturates) or decreased (benzene metabolism reduced in the presence of toluene) (219).

Neuroleptics and other forms of pharmacotherapy are usually not useful in the treatment of inhalant abusers. However, as alcohol is a common secondary drug of abuse among inhalant abusers, a monitored program for alcohol abuse may be necessary in any treatment. Other medication has been used but seldom evaluated, especially in any large population samples. Also, “oil of mustard” has been considered and sometimes used to prevent abuse. Its presence in “correction fluids” often irritated secretaries and others who use the product correctly, but it does not appear to stop those who really want to “sniff.” Risk perception is a frequent question on national surveys (NUSDUH and MTF). However, it has seldom been evaluated. See discussion in the “Epidemiology” section.

Neuroimaging studies in inhalant-exposed animals could reveal the role of a number of molecular targets in solvent-induced white matter degeneration, narrowing possible treatment options for stimulating remyelination in animal models of treatment (318). For example, if toluene's rewarding effects are mediated by dopamine, then this dopamine site becomes a therapeutic target for its addictive liability. Similarly, if toluene selectively damages white matter, then remyelinating agents that have been successful in the treatment of relapse-remitting MS might facilitate recovery. Some examples are interferon beta 1b (319), copolymer 1 (320), and interferon beta 1a (321).

ACKNOWLEDGMENTS

The authors acknowledge the support of the National Institute on Drug Abuse, NIH, DHHS. The authors also acknowledge the excellent assistance of Dr. James Colliver (SAMHSA), the excellent technical support of Betty Sharp, without whom this chapter would not have been completed, and the excellent previous contributions of Dr. Neil Rosenberg, who passed away suddenly in 2003. His contribution is still part of this chapter. Dr. Rosenberg, as an active neurologist, was concerned about young people's drug habits causing dementia prematurely. He focused not only on excessive voluntary exposure to solvents but also on the use of other neurotoxic substances such as methamphetamine. He was a pioneer in the field of defining the neurologic manifestations of solvent abuse. To assist those in need, he and his wife, Cathy, founded the International Institute on Inhalant Abuse. He also devoted his energies through academic groups, including NIH and the American Academy of Neurology. He traveled throughout the United States and Central and South America educating people about the dangers of inhaling chemicals and did extensive humanitarian work with poor people in Peru and other countries in Latin America, as well as with Native Americans in the northern hemisphere, always with the prime goal of diminishing solvent and other drug use. He is sorely missed.

INTRODUCTION

Nicotine causes tobacco addiction, which in turn causes serious health problems, including heart disease, lung disease, and cancer, and increased susceptibility to a variety of infectious diseases. Most of the nearly 45 million adults in the United States who smoke indicate an interest in quitting, but rates of successful cessation remain disappointingly low. The chronicity and relapsing characteristics of nicotine can be largely explained by the actions of nicotine on the brain. This chapter provides a review of the clinical neuropharmacology of nicotine, with a focus on new discoveries since the previous edition of the textbook. Topics include the latest findings on individual differences in vulnerability to nicotine addiction, mechanisms associated with nicotine dependence, evaluation and treatment considerations, and current efforts to regulate nicotine delivery products.

HISTORY

Nicotine is named after *Nicotiana tabacum*, the tobacco plant, which is named after Jean Nicot de Villemain, a French ambassador who sent tobacco and seeds from Brazil to Paris in 1560 and promoted their medicinal use. Nicotine was first isolated from tobacco by German chemists Posselt and Reimann in 1828, who thought it was a poison (1). Thus, nicotine has long been considered a toxic chemical and has even been used previously as an insecticide (2). It is one of the most toxic chemicals in tobacco, significantly contributing to tobacco-related disease. Not until 1964, however, did the landmark 1964 Surgeon General's Report on Smoking and Health definitively indicate nicotine use via smoking to be extremely harmful, causing lung cancer and other diseases.

EPIDEMIOLOGY

Prevalence

There are about 1.2 billion smokers in the world, with the prevalence varying greatly by country from less than 5% (e.g., women in China and India) to more than 55% (e.g., men in Indonesia and Russia) (3). It is estimated that smoking causes 5 million deaths per year worldwide, and if present trends continue 10 million smokers are projected to die per year by 2025 (3). In the United States, recent data from the January–June 2009 National Health Interview Survey

conducted by Centers for Disease Control and Prevention (CDC) indicate that 20.4% of adults aged 18 years and older were current smokers (4). Prevalence varies by gender and race and thus needs to be evaluated separately for a more accurate picture.

Recent Trends and Patterns

The percentage of adult smokers has not changed significantly over the past 5 years, hovering around 20%. However, these rates are substantially decreased from the late 1960s, at which time about 40% of adults reportedly were current smokers (see Fig. 21.1).

Prevalence rates vary greatly between men and women. Currently, in the United States the percentage of smokers is higher for men (23.3%) than for women (17.7%). Smoking rates also vary by age. For both sexes combined, the percentage of adults who report being current smokers is lower among adults aged 65 years and older (9.5%) compared to adults aged 18 to 44 years (22.9%) and 45 to 64 years (22.1%). For the age groups 18 to 44 and 45 to 64 years, men were more likely than women to be current smokers. With regard to race and ethnicity, the January–June 2009 CDC National Health Interview Survey indicates, adjusting for age and sex difference, that approximately 13.2% of Hispanic persons, 22.4% of non-Hispanic white persons, and 22.0% of non-Hispanic black persons are current smokers.

Public Health Impact

To assess the economic and public health burden from smoking, the CDC calculates smoking-attributable mortality (SAM), years of potential life lost (YPLL), and productivity losses in the United States from smoking. The most recent data from 2000 to 2004 indicate that cigarette smoking and exposure to tobacco smoke resulted in at least 443,000 premature deaths, approximately 5.1 million YPLL, and \$96.8 billion in productivity losses annually. The premature death rate is higher than the average annual estimate of approximately 438,000 deaths during 1997–2001. Further, although smoking prevalence has declined dramatically since its peak in the 1960s, the number of smoking-attributable deaths has remained unchanged, primarily because of increases in population size (particularly among older age groups). Cohorts of smokers with the highest peak prevalence have now reached the ages with the highest incidence of smoking-attributable diseases.

Figure 21.1. Estimated percentage of persons aged >18 years who were current smokers, by sex—National Health Interview Survey, United States, 1965–2006. During 1965–1991, current smokers were defined as persons who reported smoking at least 100 cigarettes during their lifetimes and who, at the time of interview, reported smoking (“Have you smoked at least 100 cigarettes in your entire life?” and “Do you smoke cigarettes now?”). In 1992, the definition changed to more accurately assess intermittent smoking (i.e., smoking on some days) and included persons who reported they smoked either every day or some days (“Do you now smoke cigarettes every day, some days, or not at all?”). Centers for Disease Control and Prevention. Cigarette Smoking Among Adults—United States, 2006. *MMWR* 2007; 56(44):1161.

NICOTINE DEPENDENCE AND TOBACCO ADDICTION

It is primarily the pharmacologic effects of nicotine that produce dependence and tobacco addiction. Indeed, non-nicotine-containing cigarettes do not sustain addiction. *DSM-IV* criteria for nicotine dependence include evidence of the following: (1) tolerance, (2) withdrawal or smoking to avoid or reduce withdrawal, (3) smoking in larger amounts or longer than intended, (4) persistent desire or unsuccessful efforts to cut down, (5) great deal of time spent to obtain, use or recover from smoking, (6) activities given up or reduced because of smoking, and (7) smoking despite physical or psychological problems caused or exacerbated by smoking. An individual is classified as dependent if he or she reports experiencing at least three of these criteria associated with their smoking behavior. Research findings from the SAMHSA 2006 National Survey on Drug Use and Health (NSDUH) show that among cigarette smokers aged 12 or older, 57% met criteria for nicotine dependence. Those who were nicotine dependent were more likely to engage in alcohol use and to experience serious psychological distress in the past year than those who were not nicotine dependent (5).

The likelihood of dependence does not correspond directly with the duration and quantity of nicotine use. Nicotine dependence can occur in smokers who report low (nondaily) levels of use (6). Conversely, some heavy daily cigarette smokers do not meet criteria for nicotine dependence (7). Thus, factors in addition to cigarette consumption are critical in the development of nicotine dependence.

Predictors of Nicotine Dependence

Smoking onset takes place in adolescence with most smokers trying their first cigarette before age 18. Following initial tobacco use, progression to daily smoking and development of nicotine dependence is very rapid. In one recent study, 25% of young tobacco users progressed to full dependence syndrome within 23 months following onset of smoking (8). Of note, however, is the fact that most adolescents who experiment with tobacco do not become dependent on nicotine (9). Factors associated with increased risk of transitioning to nicotine dependence are listed in Table 21.1, along with recent supporting evidence.

Racial and gender differences in risk of nicotine dependence have been identified. Rates of nicotine dependence are higher among whites than minorities and among females than males. Rates of nicotine dependence are inversely related to level of education and income (14). Age of onset has been identified as a risk factor. Animal studies have shown that early exposure to nicotine, including in utero exposure, predicts greater neurochemical changes, higher nicotine self-administration as adults, and more severe levels of dependence (24). Vulnerability to development of nicotine dependence is higher in people with psychiatric disease and/or substance abuse disorders. Some studies (14,20), but not all (15), have found that offspring of parents who smoke have an increased risk of becoming regular smokers or nicotine dependent. Association with peers who smoke has been shown to increase risk of dependence (14,15,21). Another risk factor is prenatal maternal smoking, which predicts offspring nicotine dependence (20,25). There is also evidence that sensitivity to the initial smoking experience predicts continued smoking and perhaps nicotine dependence. The most sensitive individuals, that is, those who initially experience more positive or both more positive and negative effects, may be most likely to become dependent (14,15,18).

Determining which adolescents are more susceptible to the addictive nature of nicotine has been a major area of research. A number of environmental and individual factors play a role in the development of nicotine dependence. Many of these factors may result from preexisting genetic vulnerabilities, as described in the following section.

Genetic Influences on Nicotine Dependence

Approximately 50% of the variance in risk for nicotine dependence is attributable to genetic factors (26,27). Attempts to identify specific genes are complicated by the fact that nicotine dependence is complex and polygenic, involving several chromosomes that are functionally overlapping and interactive (28). A variety of plausible candidate genes have been examined, primarily in two main areas: genes involved in the neurotransmitter pathways for the brain reward system and genes altering nicotine metabolism.

Nicotine’s addictive properties are a result of the activation of nicotinic acetylcholine receptors (nAChRs) in the

TABLE 21.1 Predictors of nicotine dependence

Factors associated with higher rates of nicotine dependence in adolescents	Supporting evidence
White race/ethnicity; female gender	Andreski and Breslau, 1993 (10); Breslau et al., 2001 (7); DiFranza et al., 2002 (11); Kandel and Chen, 2000 (12); O'Loughlin et al., 2002 (13)
Lower education level; lower income level	Hu et al., 2006 (14)
Earlier age of smoking onset	Audrain-McGovern et al., 2007 (15); Breslau et al., 1994 (16)
Shorter latency between onset and daily smoking	Hu et al., 2006 (14)
Use of other substances	Audrain-McGovern et al., 2007 (15); Timberlake et al., 2007 (17)
Comorbidity with psychiatric disorders (e.g., depressive mood, anxiety, personality disorders)	DiFranza et al., 2004 (18); Isensee et al., 2003 (19)
Parental smoking	Hu et al., 2006 (14); Lieb et al., 2003 (20)
Peer smoking	Audrain-McGovern et al., 2007 (15); Baker et al., 2004 (21); Ellickson et al., 2004 (22); Hu et al., 2006 (14)
Prenatal maternal smoking	Abreu-Villaca et al., 2004 (23); Lieb et al., 2003 (20)
Greater sensitivity to the reinforcing effects of nicotine	Audrain-McGovern et al., 2007 (15); DiFranza et al., 2004 (18); Hu et al., 2006 (14)

brain and the impact this has on certain neurotransmitter systems (e.g., dopamine, serotonin, and GABA). Thus, genes that encode nAChR proteins have been investigated as likely candidate genes (29). Several nAChR subunit genes have been identified (e.g., CHRNA3–CHRNA6 and CHRNB2–CHRNB4 gene clusters) and shown to be associated with smoking-related phenotypes (30,31), including linkage for nicotine dependence (20). Gene association studies have also identified variation in dopamine receptor subtypes (D_1 – D_5). In particular, the A1 allele of the *DRD2* gene (TaqI A) polymorphisms has been associated with smoking initiation (32), cigarette consumption (33), and craving (34). One interpretation is that individuals with DRD2 A1 genotypes exhibit lower dopamine D2 receptor density and, therefore, may have lower levels of neuronal dopamine-dependent activity compared to individuals with DRD2 A2 genotypes (35). In an effort to compensate for deficiencies in the dopaminergic system, carriers of the DRD A1 allele use more nicotine to increase brain dopamine levels.

Allele frequencies have also been examined in studies of the *CYP2A6* gene. Nicotine is almost wholly metabolized by the CYP2A6 enzyme. Dependent smokers regulate the amount they smoke to maintain plasma and brain nicotine levels, thus smoking behavior is increased when renal nicotine clearance (metabolism) is high. The hypothesis that genetically poor metabolizers (i.e., people with variant *CYP2A6* genes associated with substantially reduced enzyme activity) smoke fewer cigarettes and are less dependent on nicotine has been supported in some (36), but not all (37), studies.

Although considered a relatively new field of study, pharmacogenetics research in smoking has shown promise, with evidence that genetic variation is related to differential outcome to nicotine cessation pharmacotherapies. In studies of the U.S. Food and Drug Administration (FDA)-approved medications, including nicotine replacement and bupropion, candidate alleles at the D2 dopamine receptor gene and μ -opioid receptor gene have been shown to predict therapeutic response (38–40). Response to bupropion has also been studied in a preliminary manner, with evidence of an association with the CYP2B6 genotype and the dopamine DRD2 gene (41).

In summary, there is convincing evidence that smoking behavior and nicotine dependence are strongly influenced by genetic and environmental factors. Research has been productive in identifying genes that alter sensitivity to nicotine and potentially predict response to specific pharmacotherapies. Further development of genetics-based methods and models is underway.

DETERMINANTS OF USE

Nicotine Pharmacology

Nicotine is the main psychoactive ingredient in cigarettes, readily crossing the blood–brain barrier and targeting the nAChRs (42). The nAChR complex is diverse, consisting of five subunits. It is the α -4 and β -2 subunit receptors that account for 90% of high-affinity binding in the brain. The β -2 subunit is critical for dopamine release and for the behavioral

effects of nicotine, while the α -4 subunit is an important determinant of nicotine sensitivity (43).

Activation of presynaptic nAChRs facilitates release of neurotransmitters. Dopamine release in particular is critical to the reinforcing effects of nicotine and other drugs of abuse. Other neurotransmitters are released and mediate various behaviors in smokers, including norepinephrine (arousal, appetite suppression), acetylcholine (arousal, cognitive enhancement), serotonin (mood modulation, appetite suppression), GABA (reduction of anxiety and tension), glutamate (learning, memory enhancement), and endorphins (reduction of anxiety and tension) (43). It is primarily through its effects on dopamine release that acute nicotine administration increases brain reward function.

Chronic nicotine exposure results in neuroadaptation or the development of tolerance to some of the effects of nicotine (44). Neuroadaptation is characterized by an increase in the number of nAChR binding sites in the brain, which in turn leads to upregulation in response to nicotine-mediated desensitization of receptors (45). This process has been linked to key aspects of nicotine dependence, including nicotine withdrawal (46). Symptoms of nicotine withdrawal due to deficient dopamine responses include craving and inability to experience pleasure. These neural plasticity changes appear to be long lasting and responsible for persistent craving and risk of relapse long after stopping smoking.

Nicotine Pharmacokinetics and Pharmacodynamics

Smoking is a highly efficient form of drug administration. Compared to absorption through mucous membranes (e.g., chewing tobacco, snuff, or nicotine gum), inhaled nicotine enters the circulation rapidly through the lungs and moves into the brain within seconds. This increased speed of absorption and entry of the drug into the brain corresponds with greater concentrations and reinforcing effects of the drug. The smoking process allows for precise dose titration. Smokers have fingertip control of the dose, on a puff-by-puff basis, so that topographic features of smoking, such as number, volume, duration, and depth of inhalation, can predict the exact level of nicotine intake. Regular smokers become very consistent in self-administering nicotine to a level that produces desired effects.

Nicotine is metabolized to cotinine, primarily by the liver enzyme CYP2A6 (47). Cotinine is subsequently metabolized to *trans*-3-hydroxycotinine (3HC) by CYP2A6 (43). It is the ratio of 3HC to cotinine that has been used as a phenotypic marker for defining rate of nicotine metabolism (i.e., CYP2A6 activity). As mentioned above, recent findings show that slower metabolizers are at lower risk to develop nicotine dependence and may have lower risk for certain cancers (48,49). In general, Asians and African Americans metabolize nicotine more slowly than do Caucasians or Hispanics (50). In addition, the rate of nicotine metabolism is faster in women than men (51,52).

At low doses, nicotine acts like a stimulant, producing arousal, increased heart rate, and blood pressure. In contrast, high doses of nicotine produce ganglionic blockade, leading to bradycardia, hypotension, and depressed mental state (43). Tolerance to many of the acute subjective effects and physiologic effects of nicotine develops within a day for most smokers. That means that for a daily smoker the positive rewards of smoking diminish throughout the day, and smoking becomes driven primarily by efforts to maintain a threshold level of nicotine to keep withdrawal symptoms at bay.

Environmental Factors

Cigarette smoking is maintained, in part, by conditioning. The behavior of smoking is paired, repeatedly, with specific situations (e.g., with coffee and after a meal), settings (e.g., bar), or mood states (e.g., stress and frustration). Over time, these associations cause environmental situations to become strong cues for smoking or the urge to smoke. In similar fashion, other aspects of the smoking behavior (handling the cigarette, the taste and smell of smoking) become associated with the pleasurable effects of nicotine and further strengthen the conditioning process. Functioning imaging studies have shown that just the exposure of smoking-related cues can activate cortical regions of the brain (53).

Conditioning develops from pairing the pharmacologic actions of nicotine with associated behaviors and environmental situations. At the same time, however, conditioning factors appear to maintain nicotine use during periods of receptor desensitization, that is, when there is a loss or decrease in the biologic response to nicotine due to prior exposure to nicotine. Thus, environmental conditioning plays a critically important role in the reinstatement or relapse to smoking in abstinent smokers. To be effective, therapies for nicotine dependence need to address the role of conditioned stimuli and conditioned reinforcers in maintaining smoking behavior.

EVALUATION AND TREATMENT

Screening and Identification

According to the *Clinical Practice Guideline on Treating Tobacco Use and Dependence* (hereafter referred to as the *Guideline*) at least 70% of smokers see a physician each year, and almost one third see a dentist (54). Other smokers are likely to come in contact with physicians, nurse practitioners, pharmacists, counselors, and other clinicians. These various clinicians are in prime position to intervene with patients on their tobacco use. Many smokers report wanting to quit smoking and cite that physician's advice to quit smoking is an important motivator for attempting to stop smoking. Unfortunately, clinicians and health care systems do not capitalize on this opportunity consistently. According to the National Committee for Quality Assurance's "State of Health Care Quality Report," improvements have been made in increasing tobacco use interventions

for patients with some form of private insurance, including Medicare; 71% to 75% of these patients received cessation advice. By contrast, however, only 25% of Medicaid patients reported any assistance with their smoking habits. In addition, only about one third of adolescents who visited a physician or dentist reported receiving counseling regarding the dangers of using tobacco, according to the 2000 National Youth Tobacco Survey. Another study indicated that while 71% of 4207 patients reported that they had been advised to quit smoking at least once over the past year, 56% were assessed for nicotine dependence, 49% received some form of assistance, only 38% were offered pharmacotherapy, and only 9% received a recommendation for follow-up (55). Clearly, improvements are needed in screening and intervention with tobacco users in health care settings.

The *Guideline* put forth compelling reasons why members of a busy clinical team should make the screening and treatment of tobacco use a priority: (1) clinicians can make a difference with even a minimal (less than 3 minutes) intervention; (2) a relation exists between the intensity of intervention and tobacco cessation outcome (higher intensity = better outcomes); (3) even when patients are not willing to make a quit attempt, clinician-delivered brief interventions enhance motivation and increase the likelihood of future quit attempts; (4) tobacco users are being primed to consider quitting by a wide range of societal and environmental factors (e.g., public health messages, policy changes, cessation marketing messages, and family members); (5) there is growing evidence that smokers who receive clinician advice and assistance with quitting report greater satisfaction with their health care than those who do not; (6) tobacco use interventions are highly cost effective; and (7) tobacco use has a high case fatality rate (up to 50% of long-term smokers die of a smoking-related disease).

Identifying tobacco users is, of course, the first step in this process. Formal screening instruments exist that can be used to identify smokers and their nicotine dependence severity. The most well-known is the Fagerström Test for Nicotine Dependence (FTND) (56). The FTND is a standardized questionnaire for assessing level of physical dependence on nicotine. FTND scores may assist in tailoring treatment, for example higher scores suggest more intensive treatment versus lower scores, and can be used to track progress over time. Many clinicians are not accustomed to using standardized instruments, however, and therefore may be reluctant to incorporate this measure. An alternative is to simply ASK the patient about tobacco use at each clinical encounter. Repeated tobacco-use screening and brief intervention is one of the top three most important and cost-effective preventive services that can be provided in medical practice (57,58).

Treatment

There are many treatment options to promote smoking cessation, both pharmacologic and behavioral. Pharmacologic therapies fall into two main categories: (1) nicotine replacement therapies (NRTs) and (2) non-nicotine medications.

A brief summary of these treatments is provided in Table 21.2 and the following section. The reader is referred to Chapter 6 of this textbook for a more comprehensive review.

Nicotine Replacement Therapies

The primary aim of NRT is to reduce the physiologic and psychomotor withdrawal symptoms often experienced during smoking cessation attempts, which theoretically should increase the likelihood of abstinence. Nicotine replacement products are formulated for absorption through oral mucosa (chewing gum, lozenges, sublingual tablets, inhaler) or skin (transdermal patches). Across multiple studies, the various forms of NRT in general are associated with a 50% to 70% increase in the rate of long-term abstinence when compared to placebo treatment (59). Evidence that NRT helps people to stop smoking is now well accepted, and many clinical guidelines recommend NRT as the first-line treatment for people amenable to pharmacologic assistance with quitting smoking (e.g., Ref. 54).

The choice of which form of NRT depends upon the patients' preferences, needs, tolerability, and cost considerations. The nicotine patch is distinct from the other forms of NRT in that nicotine is delivered slowly and passively throughout the day, with some brands designed for 24-hour use and some for 16-hour use; wearing the patch during daytime only has been found to be as effective as wearing it for 24 hours/day (59). With the patch, plasma levels tend to be similar to the trough levels seen in heavy smokers (59). Patches are likely to be easier to use than gum, nasal spray, or inhaler, but patches cannot be used for relief of acute cravings, nor do they replace the behavioral activities of smoking. There is evidence of benefit from combining the nicotine patch with an acute dosing NRT (e.g., gum) compared to use of a single form (59).

Non-nicotine Medications

Bupropion Bupropion sustained release (SR) (Zyban) is the first non-nicotine FDA-approved medication for smoking cessation. Its mechanism of action is presumed to relate to its ability to block the reuptake of dopamine and norepinephrine, with no clinically significant effects on serotonin (60). Thirty-one studies with almost 10,000 participants comparing bupropion SR to placebo confirm the benefit of this medication, indicating that it approximately doubles long-term (>5 months) abstinence rates compared to placebo (54,61). Other studies also support its efficacy. Gonzales et al. (62) evaluated smokers ($n = 450$) who had previously used bupropion in a smoking cessation attempt. Subjects received either bupropion SR 300 mg per day or placebo for 12 weeks. The bupropion group exhibited significantly higher continuous abstinence rates at 6 months postquit (12%) than did the placebo group (2%). While the recommended dose is 300 mg daily, at least two studies have documented no evidence of a significant difference in the odds of being quit at 12 months for 150 mg daily compared to 300 mg.

With regard to relapse prevention, Hays and colleagues (63) examined 429 smokers who had recently quit smoking.

TABLE 21.2 Mayo clinic NDC tobacco dependence treatment medication

Description & examples	Pros & cons	Comments	Dosing recommendations
Combination nicotine replacement therapy (NRT)	<p>Pros</p> <ul style="list-style-type: none"> ■ Permits sustained levels of nicotine with rapid adjustment for acute needs ■ More efficacious than monotherapy <p>Cons</p> <ul style="list-style-type: none"> ■ May increase risk of nicotine toxicity ■ Cost 	<p>Comments/limitations</p> <p>Providing two types of delivery system, one passive and one active, appears to be more efficacious. Should be considered for those who have failed single therapy in the past and those considered highly tobacco dependant.</p> <p>Not an FDA approved strategy.</p>	<p>Dosing**</p> <p>Dose the patch as described. Prescribe 2 mg gum, 2 mg lozenge, nicotine inhaler or nicotine nasal spray on an as needed basis when acute withdrawal symptoms and urges to use tobacco occur. Adjust dose of patch if frequent use of other NRTs: goal is to minimize need for short-acting NRT dosing.</p>
Nicotine patch (OTC) 24 hour delivery systems 21, 14, 7 mg/24 hr 16 hour delivery systems 15 mg/16 hr (Generic available)	<p>Pros</p> <ul style="list-style-type: none"> ■ Achieve high levels of replacement ■ Easy to use ■ Only needs to be applied once a day ■ Few side effects <p>Cons</p> <ul style="list-style-type: none"> ■ Less flexible dosing ■ Slow onset of delivery ■ Mild skin rashes and irritation 	<p>Comments/limitations</p> <p>Patches vary in strengths and the length of time over which nicotine is delivered.</p> <p>Depending on the brand of patch used, may be left on for anywhere from 16 to 24 hours. Patches may be placed anywhere on the upper body—including arms and back. Rotate the patch site each time a new patch is applied.</p> <p>May purchase without a prescription</p>	<p>Dosing** (24 hour patch)</p> <ul style="list-style-type: none"> ■ ≥ 40 cpd = 42 mg/day ■ 21–39 cpd = 28–35 mg/day ■ 10–20 cpd = 14–21 mg/day ■ < 10 cpd = 14 mg/day <ul style="list-style-type: none"> ■ If a dose > 42 mg/day may be indicated, contact the patient's prescriber. ■ Adjust based on withdrawal symptoms, urges, and comfort. After 4–6 weeks of abstinence, taper every 2–4 weeks in 7–14 mg steps as tolerated.
Nicotine lozenge (OTC) Delivers nicotine through the lining of the mouth while the lozenge dissolves. 2 mg, 4 mg	<p>Pros</p> <ul style="list-style-type: none"> ■ Easy to use ■ Delivers doses of nicotine approximately 25% higher than nicotine gum <p>Cons</p> <ul style="list-style-type: none"> ■ Should not eat or drink 15 minutes before use or during use ■ Should not be chewed or swallowed ■ Nausea frequent (12–15%) 	<p>Comments/limitations</p> <p>Use at least 8–9 lozenges/day initially.</p> <p>Efficacy and frequency of side-effects related to amount used.</p> <p>May purchase without a prescription</p>	<p>Dosing as monotherapy</p> <p>Based on time to first cigarette of the day:</p> <ul style="list-style-type: none"> ■ < 30 minutes = 4 mg ■ ≥ 30 minutes = 2 mg <p>Based on cigarettes/day (cpd)</p> <ul style="list-style-type: none"> ■ > 20 cpd: 4 mg ■ 20 cpd: 2 mg <p>Initial dosing is 1–2 lozenges every 1–2 hours (minimum of 9/day).</p> <p>Taper as tolerated</p>

<p>Nicotine gum (OTC) 2mg, 4mg Flavors: Orange, Mint, Regular The term “gum” is misleading. It is not chewed like regular gum but rather is chewed briefly and then “parked” between cheek and gum. The nicotine is absorbed through the lining of the mouth (Generic Available)</p>	<p>Pros</p> <ul style="list-style-type: none"> Convenient/flexible dosing Faster delivery of nicotine than the patches <p>Cons</p> <ul style="list-style-type: none"> May be inappropriate for people with dental problems and those with temporomandibular joint (TMJ) syndrome Should not eat or drink 15 minutes before use or during use Frequent use during the day required to obtain adequate nicotine levels 	<p>Comments/limitations</p> <p>Many people use this medication incorrectly. Review package directions carefully to maximize benefit of product</p> <p>May purchase without a prescription</p>	<p>Dosing as monotherapy** Based on cigarettes/day (cpd) >20 cpd: 4 mg gum 20 cpd: 2 mg gum Based on time to first cigarette of the day: <30 minutes = 4 mg >30 minutes = 2 mg Initial dosing is 1–2 pieces every 1–2 hrs (10–12 pieces/day). Taper as tolerated.</p>
<p>Nicotine nasal spray Delivers nicotine through the lining of the nose when sprayed directly into each nostril.</p>	<p>Pros</p> <ul style="list-style-type: none"> Flexible dosing Can be used in response to stress or urges to smoke Fastest delivery of nicotine of currently available products but not as fast as cigarettes <p>Cons</p> <ul style="list-style-type: none"> Nose and eye irritation is common, but usually disappears within 1 week. Frequent use during the day required to obtain adequate nicotine levels 	<p>Comments/limitations</p> <p>Unlike nasal sprays used to relieve allergy symptoms, the nicotine spray is not meant to be sniffed. Rather, it is sprayed against the lining of each nostril once or twice an hour (maximum of five times in one hour). Prescription required for purchase</p>	<p>Dosing as monotherapy 1 spray in each nostril 1–2 times/hr (up to 5 times/hr or 40 times/day) Most average 14–15 doses/day initially Taper as tolerated</p>
<p>Nicotine inhaler A plastic cylinder containing a cartridge that delivers nicotine when puffed. The inhaler delivers nicotine to the oral mucosa, not the lung, and enters the body much more slowly than the nicotine in cigarettes.</p>	<p>Pros</p> <ul style="list-style-type: none"> Flexible dosing Mimics the hand-to-mouth behavior of smoking Few side effects <p>Cons</p> <ul style="list-style-type: none"> Frequent use during the day required to obtain adequate nicotine levels May cause mouth or throat irritation 	<p>Comments/limitations</p> <p>Puffing must be done frequently, far more often than with a cigarette. Each cartridge designed for 80 puffs over 20 minutes of use. Patient does not need to inhale deeply to achieve an effect. Prescription required for purchase</p>	<p>Dosing as monotherapy Minimum of 6 cartridges/day, up to 16/day Taper as tolerated</p>

TABLE 21.2 Mayo clinic NDC tobacco dependence treatment medication (Continued)

Description & examples	Pros & cons	Comments	Dosing recommendations
Non-nicotine medication Bupropion SR (Generic available)	Pros <ul style="list-style-type: none"> ■ Easy to use ■ Pill form ■ Few side effects ■ May be used in combination with NRT (nicotine patches, spray, gum and inhaler)** Cons <ul style="list-style-type: none"> ■ Contraindicated with certain medical conditions and medications 	Comments/limitations A slight risk of seizure (1:1000) is associated with use of this medication. Seizure risk should be assessed. Risk of seizure is increased if: <ul style="list-style-type: none"> ■ Personal history of seizures ■ Significant head trauma/brain injury ■ Anorexia nervosa or bulimia ■ Concurrent use of medications that lower the seizure threshold Prescription required for purchase	Dosing: Take doses at least 8 hours apart Start medication 1 week prior to the Target Quit Date (TQD) 150 mg once daily for 3 days, then 150 mg twice daily for 4 days, then On TQD STOP SMOKING Continue at 150 mg BID 12 weeks, or longer if necessary. May stop abruptly; no need to taper.
Non-nicotine medication Varenicline	Pros <ul style="list-style-type: none"> ■ Easy to use ■ Pill form ■ Generally well tolerated ■ No known drug interactions Cons <ul style="list-style-type: none"> ■ Nausea is common 	Comments/limitations <ul style="list-style-type: none"> ■ Nausea is common. Taking the medication with food and titrating the dose as directed will help ■ It appears that varenicline can be safely used in combination with bupropion and/or NRT. However, efficacy of these combinations has not been shown ■ Dose must be adjusted if kidney function is impaired Prescription required for purchase	Dosing: TAKE WITH FOOD Start medication 1 week prior to the Target Quit Date (TQD) 0.5 mg once daily X3 days, then 0.5 mg twice daily X4 days, then ON TQD STOP SMOKING AND Take 1.0 mg twice daily X11 weeks If not smoking at the end of 12 weeks, may continue at 1.0 mg twice daily for an additional 12 weeks May stop abruptly. No need to taper.

SMOKELESS TOBACCO (ST)	24 hour nicotine patch:	Other NRTs:	Non-nicotine pharmacotherapy
Treatment recommendations	<p>>3 cans or pouches/week = 42 mg/day</p> <p>2–3 cans or pouches/week = 21 mg/day</p> <p><2 cans or pouches/week = 14 mg/day</p> <p>Adjust based on withdrawal symptoms, urges, and comfort. After 4–6 weeks of abstinence, taper every 2–4 weeks in 7–14 mg steps as tolerated</p>	<p>Nicotine lozenge: 4 mg if >3 tins/week</p> <p>2 mg if 3 tins/week</p> <p>Nicotine gum or nicotine lozenge may be combined with nicotine patch as described for cigarette smokers.</p> <p>Nicotine inhaler and nicotine nasal spray are <i>not</i> recommended for use in ST users.</p>	<p>Empiric evidence suggests that bupropion and varenicline may be of benefit in this population of tobacco users, using the dosing guidelines recommended for cigarette smokers.</p>

The table is a summary of recommendations for use of medication in the treatment of tobacco dependence. The most effective dose varies by individual. Costs will vary depending on retailer. (Adapted from Ebbert JO, et al. *J Thorac Oncol*. 2007;2: 249–256; Fiore, et al. U.S. Public Health Service Guide line, June 2000; Shiffman et al., *Arch Intern Med*. 2002; 162: 1267–1276. Varenicline Product Information profile (May 2006). Revised November 2007.)

All participants received bupropion SR 300 mg per day for the initial 7 weeks of the trial, then the same dosage or placebo for the next 38 weeks. Although there was an initial benefit from continued therapy at 1 year from the quit date, no significant differences were found at 2 years. Other studies have also noted bupropion's lack of effect for preventing relapse (64,65).

Nortriptyline Typically used as an antidepressant (tricyclic), nortriptyline does not have FDA approval for smoking cessation. It remains a second-line medication because of potential side effects and limited evidence to support its efficacy. Several studies have demonstrated benefit for nortriptyline over placebo for smoking cessation, while several have not (66,67). Comparisons of bupropion and nortriptyline have favored bupropion, but no significant differences between the two have been found (66–68).

Varenicline In 2006 a new medication, Varenicline (Chantix), was approved by the FDA for smoking cessation. Varenicline is a highly selective partial agonist that also displays antagonist properties, that is, it prevents full stimulation of the nicotine receptor that ensues when nicotine is coadministered. Thus, varenicline has the potential to provide relief from withdrawal (agonist effect) and block the rewarding effects of nicotine (antagonist effect) (69). It is well tolerated in most patients, although there have been recent reports of increased psychiatric symptoms associated with varenicline administration. In February 2008, the FDA added a warning indicating that depressed mood, agitation, changes in behavior, suicidal ideation, and suicide have been reported in patients attempting to quit smoking while using varenicline.

A randomized, double-blind clinical trial comparing varenicline (2 mg), bupropion (300 mg), and placebo showed overall continuous abstinence rates through 1 year posttreatment of 23%, 14.6%, and 10.3% (70). Further, varenicline nearly tripled the odds of quitting over placebo during the last 4 weeks of treatment (70). A recent review of nicotine receptor partial agonists for smoking cessation concluded that varenicline increased odds of quitting over Bupropion SR with a minimal to moderate side effect profile (71). In a separate study, an additional 12 weeks of varenicline (24 total weeks) was shown to reduce the risk of relapse among smokers who were abstinent at the end of the first 12 weeks, suggesting a relapse prevention benefit as well (72). Smokers taking varenicline have reported significantly less craving and withdrawal symptoms.

The FDA-approved dosing of varenicline is 2 mg/day (1 mg twice daily), however there is evidence that 1 mg daily is also effective. A meta-analysis of four studies with five study arms was conducted to evaluate the effects of the dose (73). Results indicated that compared to placebo, the 1 mg daily dose approximately doubles a smoker's likelihood of long-term abstinence from tobacco, while the 2 mg daily dose approximately tripled the likelihood of abstinence. Thus, the 1 mg dose is an acceptable alternative for smokers who experience intolerable, dose-related side effects.

Combination Smoking Treatments

Clinical practice guidelines for tobacco treatment state that some combinations of first-line medications have been found

effective for smoking cessation. Only the nicotine patch + bupropion combination has been approved by the FDA for smoking cessation; however, other combinations have been tested. A 2008 meta-analysis revealed that the nicotine patch + bupropion SR, nicotine patch + inhaler, and long-term nicotine patch + ad libitum NRT have all been shown effective relative to placebo, and are recommended for use as first-line treatments (54,74). At least one study is underway to evaluate combination therapy with bupropion and varenicline (by PI [P. Cinciripini]). The presumed differences in mechanisms of action may afford a broader range of biologic targets identified as important in smoking cessation.

Behavioral Therapies

The characteristics of behavioral interventions for smoking cessation vary widely. The *Guideline* examined four of these characteristics: advice to quit, intensity, treatment format, and type of clinician, as well as specific elements of various types of counseling and therapy.

Overall results revealed a strong dose–response relationship between treatment intensity (i.e., session length, total contact time, and number of sessions) and treatment effectiveness. However, evidence also indicated that physician advice to quit smoking significantly increases long-term abstinence rates, even with a modal intervention length of 3 minutes or less. Analysis of different treatment formats demonstrated that telephone and group and individual counseling all improve smoking abstinence rates compared to no intervention; further, using multiple treatment formats increases abstinence rates as compared to use of a single format. A comparison of the effectiveness of different clinician types (e.g., physician, psychologist, nurse, and dentist) revealed no significant differences in abstinence rates based on this factor. Also studied was the effectiveness of including multiple clinicians from different disciplines. Although nonsignificant statistically, findings suggest that the involvement of a variety of clinicians in treatment may be more effective than that of a single clinician.

Brief Clinician Interventions There are five main components of a brief intervention for smoking cessation that are often referred to as “the 5 A’s” and are particularly useful in a health care setting (see Table 21.3). As mentioned earlier in this chapter, the first step is to ASK the patient at each visit if he or she uses tobacco. This can be done in either written or oral fashion with the primary goal of systematically identifying all tobacco users at every visit. Second, once a smoker has been identified, the health care provider should ADVISE the patient to quit. The provider should present the advice clearly and strongly. For example, “As your clinician, I need you to know that quitting smoking is the most important thing you can do to protect your health now and in the future.” The advice should also be personalized. Tobacco use should be tied to current symptoms and health concerns, and/or social and economic costs, and/or the impact of tobacco use on children or others in the household. For example, “Continuing to smoke will make your asthma worse, while quitting smoking would make it better.”

The next step is to ASSESS the patient's willingness to make a quit attempt. If the patient is willing to try to quit, the

TABLE 21.3 The “5 A’s” for brief intervention

Ask about tobacco use	Identify and document tobacco use status for every patient at every visit
Advise to quit	In a clear, strong, and personalized manner urge every tobacco user to quit
Assess willingness to make a quit attempt	Is the tobacco user willing to make a quit attempt at this time?
Assist in quit attempt	For the patient willing to make a quit attempt, use counseling and pharmacotherapy to help him or her quit
Arrange follow-up	Schedule follow-up contact, preferably within the first week after quit date

From Fiore MC, Jaen CR, Baker TB, et al. *Treating Tobacco Use and Dependence: 2008 Update*. Clinical Practice Guidelines. Rockville, MD: U.S. Department of Health and Human Services, Public Health Service; 2008:40.

physician should ASSIST the patient with a plan. This plan should include first-line medications such as NRTs, bupropion or varenicline, and smoking cessation counseling. Free telephone counseling is available through various federal agencies or organizations such as the American Cancer Society. For the patient who is not interested in quitting, strategies are available to increase motivation and the likelihood of future quit attempts. Finally, the physician should ARRANGE follow-up. For patients willing to set a quit date, arrange a subsequent appointment for 1 week after that date. Multiple contacts are encouraged. For patients unwilling to make a quit attempt, be sure to repeat the 5 A’s at their next clinic visit.

For patients who are unwilling to attempt to quit smoking, motivational strategies can be employed that may increase the likelihood of later quitting. These strategies have been adopted from motivational interviewing (MI) (75), a directive yet patient-centered counseling method. There is evidence that MI is effective in increasing future quit attempts (76,77), although positive abstinence outcomes have been elusive, particularly for those already motivated to quit (78). As summarized in the *Guideline*, the general strategies involve exploring feelings, beliefs, ideas, and values that result in abstinence about using tobacco. The clinician selectively elicits, supports, and strengthens the patient’s “change talk” (e.g., reasons, ideas, and needs for eliminating tobacco use) and commitment language (e.g., intentions to take action to change smoking behavior). Eliciting ideas about change from patients is more effective than lectures or arguments for change presented by the physician (79).

Based on a meta-analysis of 64 studies, more intensive counseling and behavioral interventions with demonstrated effectiveness include: (1) providing smokers with practical problem-solving skills, (2) providing support and encouragement during a smoker’s direct contact with a clinician, (3) intervening to increase social support in the smoker’s environment, and (4) using aversive smoking procedures (rapid smoking, rapid puffing, other smoking exposure). However, the authors of the *Guideline* in reviewing multiple studies decided not to recommend extra-treatment social support as

well as aversive smoking based on questionable effectiveness and side effects from the latter.

In summary, there is a myriad of smoking cessation treatments available, both pharmacologic and behavioral, with proven effectiveness. Thus, health care providers have the luxury of tailoring their treatment to patients’ needs and preferences. If one method fails, there are many more, including combination pharmacotherapy, that can be utilized. Establishing clinic-wide policies among multiple health care providers to promote smoking cessation with every patient at every visit has the potential for major impact on smoking rates.

SPECIAL CONSIDERATIONS

Nicotine and Psychiatric Comorbidities

Tobacco smoking is highly prevalent and more intense in psychiatric patients. Comorbidity rates are particularly high for schizophrenia and depression, where smoking rates of 70% to 90% have been reported (80) compared to <25% in the general population. Those who have a psychiatric diagnosis and are nicotine dependent (7%) consume 34% of all cigarettes. Early onset of tobacco use has been associated with greater risk of later psychiatric problems (81).

It is commonly assumed that psychiatric patients use tobacco for self-medication. For example, the actions of nicotine on nAChRs improve attention in schizophrenia by normalizing several deficits in sensory processing. Moreover, a genetic link between the α -7 nAChR subunit and schizophrenia has been found (82). Nicotine improves attention in ADHD patients likely through its effects on dopamine release (similar to stimulant ADHD medications).

Increased smoking and nicotine dependence in schizophrenics may represent an attempt to overcome the potentially dysphoric and unwanted side effects of traditional neuroleptic medications caused by dopamine blockade (83). A related hypothesis is that neuroleptic medications may block the aversive properties of nicotine, thereby increasing sensitivity to the dependence producing rewarding properties of nicotine (84).

Some clinical evidence suggests that smoking may be associated with reduced symptoms of parkinsonism (85) but increased tardive dyskinesia (86). Studies of patients with schizophrenia who are treated with atypical (e.g., clozapine, olanzapine) rather than conventional antipsychotics have reported lower frequency of smoking and higher cessation rates (87,88).

Smokers with depression are less likely to quit and more likely to experience severe withdrawal symptoms, including depressed mood. Depressed smokers themselves often perceive smoking as a self-medicating strategy, reporting an increased likelihood of smoking during negative emotional situations than nondepressed smokers. In terms of antidepressant effects, nicotine has been shown to improve psychomotor retardation, sleep, and overall depressive symptomatology (89,90). The release of serotonin and norepinephrine in the brain by nicotine is similar to the neurochemical effects of certain antidepressant medications. Additionally, cigarette smoking inhibits MAOA and MAOB, similar to the antidepressant effect of MAO inhibitors (91).

Tobacco smoke activates the cytochrome P450 1A2 (CYP1A2) enzyme that is responsible for the metabolism of many commonly used psychiatric drugs. This increased CYP1A2 activity by tobacco smoke can result in substantially lower serum concentrations of psychiatric drugs in smokers compared with nonsmokers. Cigarette smoking has been shown to be associated with increased clearance of fluphenazine, haloperidol, olanzapine, and tiotixene, as well as some benzodiazepines (92). Faster metabolism of these drugs can result in need for higher dosages, which can increase side effects, cost, adherence, and efficacy. It is important that plasma levels of psychiatric drugs be carefully monitored in patients who are attempting to stop smoking.

In summary, understanding how psychiatric comorbidities contribute to smoking and vice versa is increasingly important, especially as this represents a growing subpopulation of difficult-to-treat smokers (93). The literature to date highlights key mechanisms explaining this comorbidity. The reader is referred to Chapter 6 of this textbook and Ziedonis et al. (94) for a more complete review of tobacco cessation strategies in psychiatric disorders.

Nicotine and Other Drug Dependence

The prevalence of tobacco use among individuals who use alcohol and/or other illicit drugs is high (~75%). Compared with nonsubstance abusing populations, substance abusers tend to smoke more heavily, report more symptoms of nicotine dependence, experience more severe withdrawal symptoms, and have greater difficulty quitting smoking. Substance abusers who smoke are at higher risk of health consequences due to the synergistic effects of smoking and alcohol/drugs on the development of cardiovascular disease and cancers.

The comorbidity of nicotine with other substance use disorders may be due to a common genetic vulnerability. Support for this idea comes from classic genetic studies showing that polygenic genetic variants influence risk of addiction to substances in general, rather than to specific substances (95,96). One approach has been to identify genetic variants as-

sociated with personality-related phenotypes. Impulsivity, for example, defined as a predisposition toward rapid, unplanned reactions to internal or external stimuli without regard to the negative consequences of these reactions to themselves or others (97), is highly associated with addictive disorders. Not surprisingly, candidate genes with variants for impulsivity have been associated with alcoholism and other addictions (98). Other studies have identified genetic variants associated with risk-taking traits and addiction (99). Genetic linkage studies have also identified genetic variants of stress responsivity, that is, HPA axis function, with addiction risk (100,101). Thus, multiple genetic variants that influence vulnerability to addiction in general might explain the high rates of nicotine dependence in people with other drug dependence disorders.

Pharmacologic mechanisms may explain the strong comorbidity. Combined drug effects may be additive, that is, producing enhanced rewarding effects, or modulatory. Both nicotine and alcohol, for example, have anxiolytic and antidepressant effects, which appear to be additive when the drugs are used together (102). At the same time, alcoholic individuals may use nicotine to offset or delay the sedative and cognition-impairing effects of alcohol (103). Nicotine effects have been shown to modulate alcohol withdrawal symptoms and mitigate some of alcohol's neurotoxic effects (104,105). Finally, the direct actions of nicotine on cholinergic systems, that is, nAChRs, appear to be involved in the development and maintenance of psychostimulant-rewarded behaviors. From this, it has been proposed that exposure to nicotine may facilitate dependence on cocaine and other stimulants (106).

From a behavioral perspective, environmental cues present during combined drug use acquire strong motivating and controlling properties. Models of young adult peer influence also offer possible explanations for the concurrent use of cigarettes and other drugs. In a recent study of young adults aged 19 to 25, both concurrent and prospective analyses found that peer use predicted young adult cigarette use and other substance use (107). The "gateway" theory of substance use predicts that use of a less dangerous drug (e.g., nicotine) increases the risk of starting to consume other more harmful drugs, in a so-called "staircase" fashion. In general, research on patterns of onset of substance use among adolescents show typical progression through initiation of tobacco, alcohol, and marijuana before use of other illicit drugs (108,109). Substance use progression appears to be influenced not only by causal biologic mechanisms, but also by variables such as drug availability and attitudes (109).

In summary, co-occurring use of nicotine and other substances is highly prevalent and associated with harmful consequences. Most patients seek treatment for a single drug problem, despite their codependence. A better understanding of the genetic, neurochemical, and behavioral factors that underlie comorbid addictions will improve prevention and treatment efforts.

Nicotine Regulation

It is fitting to close this chapter with a brief discussion of current events regarding nicotine and tobacco regulation efforts. As a result of an unequivocal evidence regarding the

TABLE 21.4 The Family Smoking Prevention and Tobacco Control Act, H.R. 1256

The Family Smoking Prevention and Tobacco Control Act	
■	Grants the Food and Drug Administration (FDA) power to regulate tobacco products.
■	Requires tobacco product manufacturers to disclose all ingredients in its products, the form and delivery method of nicotine, and any research into the health, toxicologic, behavioral, or physiologic effects of tobacco products to the FDA and notify the FDA of any future changes to any of the above.
■	Requires tobacco manufacturers to release all marketing research documents to the FDA.
■	Requires tobacco manufacturers to notify the FDA of any future changes to the ingredients of their products.
■	Requires all owners and operators of companies manufacturing or processing tobacco products to register with the Secretary of Health and Human Services and to be inspected once every 2 years.
■	Prohibits the FDA from banning existing tobacco products or requiring that they eliminate nicotine.
■	Requires FDA review of new tobacco products before they can go to market unless they are similar to products marketed before February 15, 2007.
■	Bans companies from promoting products as lower-risk alternatives to traditional tobacco unless the FDA certifies that its sale is likely to improve public health.
■	Establishes a mechanism to assess fees on tobacco companies and traders to finance FDA oversight of the industry.
■	Orders a study on the public health implications of raising the minimum age to purchase tobacco products.
■	Requires the Secretary of Health and Human Services to create a plan relating to enforce restrictions on the advertising and promotion of menthol and other cigarettes to minors.
■	Mandates larger more varied and more prominent warning labels on tobacco products.

addictiveness and harmfulness of cigarette smoking, a truly historic event occurred on June 22, 2009 when President Obama signed into law the Family Smoking Prevention and Tobacco Control Act, H.R. 1256, giving the FDA the authority to effectively regulate the manufacturing, marketing, labeling, distribution, and sale of tobacco products. In essence, this law ends the special protections enjoyed by the tobacco industry and instead begins to protect the nation's health (Table 21.4). Thus, this legislation represents the strongest action that the federal government has ever taken to reduce tobacco use, the leading preventable cause of death in the United States.

The new law will take several steps toward restricting tobacco marketing and sales to youths. In addition, it will empower the FDA authority to require changes in tobacco products, such as the removal or reduction of harmful ingredients. The reader is reminded that modern cigarettes are uniquely designed to enable relatively easy inhalation of nicotine and other substances deep into the lung. New tobacco products that offer reduced exposure or risk are currently being marketed to smokers as alternatives to conventional cigarettes. “Quest” (Vector Tobacco Inc., Durham, NC; <http://www.questcigs.com>) cigarettes, for example, use genetically modified tobacco with substantially lower nicotine levels compared to regular brands. Whether such products produce meaningful health benefit or, as some have argued, actually increase tobacco use (amount and frequency) because of their perceived “safer” profile remains to be determined and has become an important topic of study (110,111).

CONCLUSIONS

The intent of this chapter is to review the latest research on nicotine, including how the pharmacologic effects of nicotine influence smoking behavior and promote development of dependence. Approximately 20% of American adults are cigarette smokers, with rates of smoking two- to fourfold higher in patients with comorbid psychiatric and other substance use disorders. Prevalence rates vary by gender, with men smoking more than women. Rates differ by race as well. Hispanic persons are less likely to smoke than non-Hispanic white or non-Hispanic black persons.

Research has shown that nicotine dependence produces numerous changes to behavioral and neural functioning, and these changes can be modulated by environmental and genetic factors. Certain individuals appear to be more vulnerable to nicotine dependence, with new evidence that genetic factors contribute significantly to this vulnerability. As researchers continue to identify specific genes involved in nicotine dependence, the findings are likely to have important implications for improving existing smoking cessation treatments.

The first step in treatment is identifying tobacco users and characterizing the degree to which the patient is physically dependent on nicotine, either formally using the FTND or informally during a clinical interview. All smokers should be provided with a recommendation to quit and offered behavioral and/or pharmacologic treatment. Various NRT products, bupropion SR, varenicline, and combination therapy are all effective first-line tobacco treatments. Brief clinician

interventions for smoking should also be implemented by all health care providers to every patient at every visit. More intensive behavioral treatments are also available if warranted.

New federal regulation of nicotine products offers the promise of a nicotine-reducing strategy to make cigarettes less addictive. Studies on the feasibility of nicotine reduction will need to address the concern that smokers will smoke more cigarettes to compensate for lower nicotine levels. Current knowledge about the clinical pharmacology of nicotine will be critical in future decisions about harm reduction and federal regulatory strategies.

Caffeine (1,3,7-trimethylxanthine) is the most widely used mood-altering drug in the world. Caffeine is found in more than 60 species of plants and is the best-known member of the methylxanthine class of alkaloids. The dimethylxanthines, which include theophylline and theobromine, are structurally related compounds that are also found in various plants.

Caffeine is a nonselective A_1 and A_{2A} adenosine receptor antagonist and mild central nervous system (CNS) stimulant that produces various physiologic and psychological effects. It has long been recognized for its mild stimulating effects and has been consumed in one form or another for thousands of years despite repeated attempts throughout history to ban its use on moral, medical, economic, or political grounds. Today caffeine use remains ubiquitous. In fact, caffeine ingestion is so intricately tied to social customs and daily rituals that it is often not perceived as a drug, despite its well-documented pharmacologic effects. Moreover, common foods and other products often contain significant amounts of caffeine, although they may not be labeled as such. Thus, it is possible to significantly underestimate caffeine consumption and the role that it may play in one's daily experiences.

Behaviorally active doses of caffeine are consumed daily by a majority of adults in the United States. Caffeine is generally considered to be safe relative to classic drugs of dependence, and research suggests that it may even offer protective effects against certain diseases (e.g., Parkinson disease). However, caffeine is not a completely innocuous drug. Although there is a lack of agreement on whether caffeine should be formally considered a drug of clinical dependence, some behavioral features of caffeine use closely resemble those associated with classic drugs of dependence. Caffeine can produce tolerance and a characteristic withdrawal syndrome, and heavy use (>400 mg/day) is associated with increased risk for various health problems. Caffeine functions as a reinforcer and many habitual caffeine consumers report an inability to quit or reduce caffeine use despite a desire to do so. Caffeine can cause discrete psychopathology (e.g., caffeine intoxication, caffeine-induced anxiety disorder), exacerbate existing psychopathology (e.g., anxiety, insomnia), and interfere with the efficacy of some medications (e.g., benzodiazepines). There is also evidence that caffeine may interact with classic drugs of dependence. This chapter will review empirical data on the pharmacologic, behavioral, and clinical effects of caffeine. The review will conclude with a discussion of the clinical implications of caffeine use and practical guidelines for modifying caffeine use.

HISTORY

Caffeine was first isolated from coffee in 1820 and tea in 1827, and its chemical structure was first characterized in 1875. Caffeine has been ingested in one form or another throughout various parts of the world for thousands of years. Tea was first cultivated in China; coffee in Ethiopia; guarana, cocoa, and maté in South America; and kola nut in West Africa. The word coffee is believed to have been derived from the Arabic word “qahwa,” which historically referred to wine. According to legend, coffee was discovered after an Arabian goatherd observed his goats eating berries and subsequently behaving in an energetic manner. The technique of roasting and grinding coffee beans for beverage preparation was developed in Arabia by the 14th century. With the development of worldwide trade routes during the 17th and 18th centuries, caffeinated products spread rapidly from their indigenous environments to other parts of the world. The introduction of caffeine into societies, not unlike the introduction of other drugs such as tobacco, has sometimes provoked moral outrage and attempts to ban use. Failed efforts to suppress the use of caffeine-containing foods, usually in the form of coffee or tea, have been documented worldwide (including Arabia, Turkey, Egypt, England, France, and Prussia). In the late 1700s America protested a British tax on tea resulting in the “Boston Tea Party” in which shipments of tea were thrown into the Boston Harbor. The Continental Congress subsequently passed a resolution against tea consumption, and over the course of a few years coffee became the caffeinated beverage of choice in America. Today coffee is second only to oil as the largest import in the United States.

In the late 1800s, entrepreneurs began selling flavored carbonated beverages with added caffeine. Soft drink consumption has increased steadily over the last century and has become a significant source of caffeine use among individuals of all ages. Over the past decade energy drinks, which typically contain significantly higher concentrations of caffeine than soft drinks, have been growing in popularity in the United States and elsewhere. Some countries presently ban the sale of energy drinks or require health warnings on them due to concerns about negative health effects.

SOURCES OF CAFFEINE

Caffeine occurs naturally in a variety of plant-based products including coffee, tea, cocoa, kola nut, guarana, and maté. In addition to beverages made from these plants, significant

TABLE 22.1 Caffeine content of common foods and medications

Product	Serving size (volume or weight)	Typical caffeine content (mg)	Range (mg)
Coffee			
Brewed/drip	6 oz	100	54–210
Starbucks hot brewed coffee	16 oz	330	
Espresso	1 oz	70	60–95
Starbucks espresso (solo)	1 oz	75	
Instant	6 oz	70	20–130
Decaffeinated	6 oz	4	0–10
Tea			
Brewed	6 oz	40	30–90
Instant	6 oz	30	10–35
Canned or bottled	12 oz	20	8–32
Soft drinks			
Typical caffeinated soft drink	12 oz	40	22–69
Mountain Dew/Diet Mountain Dew	12 oz	55	
Pepsi One	12 oz	55	
Mellow Yellow/Diet Mello Yellow	12 oz	51	
Diet Coke	12 oz	47	
RC Cola	12 oz	43.2	
Diet Sunkist	12 oz	42	
Sunkist	12 oz	41	
Dr. Pepper/Diet Dr. Pepper	12 oz	41	
Mr. Pibb/Diet Mr. Pibb	12 oz	40	
Pepsi-Cola	12 oz	38	
Diet Pepsi	12 oz	36	
Coke Classic	12 oz	35	
Coke Zero	12 oz	35	
Cherry Coke	12 oz	34	
A&W Cream Soda	12 oz	29	
Barq's Root Beer	12 oz	23	
A&W Diet Cream Soda	12 oz	22	
Cocoa/hot chocolate	6 oz	7	2–10
Chocolate milk	6 oz	4	2–7
Chocolate			
Hershey's Chocolate Bar	1.55 oz	9	
Hershey's Special Dark	1.45 oz	18	
Hershey's Baking Chocolate	1.0 oz	30	
Caffeinated water			
Typical amount	16.9 oz	60	60–200
Water Joe	16.9 oz	60	
Buzzwater	16.9 oz	100 or 200	
Energy drinks			
Typical amount	varies	varies	50–505
Wired-X-505	23.5 oz	505	
FIXX	20 oz	500	
Cocaine	8.2 oz	280	
Rockstar	16 oz	160	
Full Throttle	16 oz	144	

Product	Serving size (volume or weight)	Typical caffeine content (mg)	Range (mg)
Red Bull	8.3 oz	80	
Coffee ice cream or yogurt	8 oz (one cup)	50	8–85
Dannon Coffee Yogurt	6 oz	30	
Starbucks Coffee Ice Cream	8 oz	60	
Miscellaneous foods and beverages			
Stay Alert Caffeinated Gum	1 stick	100	
Starbucks bottled Frappuccino	9.5 oz	85	
Extreme Sport Beans Jelly Beans	1 oz	50	
Powerbar Tangerine Powergel	41 g	50	
Jolt Caffeinated Gum	1 stick	33	
Penguin Peppermints	1 mint	7	
Stimulants			
Typical	1 tablet	100 or 200	100–200
Vivarin	1 tablet	200	
NoDoz	1 tablet	100 or 200	
Analgesics (OTC and prescription)			
Typical	2 tablets	64 or 130	64–130
Anacin Advanced Headache	2 tablets	130	
Excedrin Extra Strength	2 tablets	130	
Goody's Headache Powder	1 powder packet	32.5	
Fiorinal	2 tablets	80	
Darvon	1 tablet	32.4	
Weight-loss products/sports nutrition			
Typical	1 or 2 tablets	Varies	50–300
Metabolife Ultra	2 caplets	150	
Dexatrim Max	1 caplet	50	
Leptopril	2 capsules	220	
Stacker 3	1 caplet	254	
Swarm Extreme Energizer	1 capsule	300	

1 fluid oz = 30 mL; 1 oz weight = 28 g; serving sizes are based on commonly consumed portions, typical container sizes, or pharmaceutical instructions. Caffeine values for brand name products were obtained from product labels, or the manufacturer's Web site or customer service department.

amounts of caffeine are found in foods such as coffee ice cream, coffee yogurt, and dark chocolate. Caffeine is added to cola and noncola soft drinks as well as to other common food items such as energy drinks, water, candy bars, mints, and gum. Caffeine is also added to hundreds of prescription and over-the-counter (OTC) medications including stimulants, analgesics, weight-loss supplements, and nutritional supplements. Table 22.1 lists the caffeine content of many common foods and medications.

In the United States, coffee and soft drinks are the major dietary sources of caffeine. The Food and Drug Administration limits the amount of caffeine that can be added to soft drinks to 0.2 mg/ml or 71.5 mg for a 12-oz serving. It is noteworthy that energy drinks often contain significantly higher levels of caffeine than those permitted in soft drinks with levels ranging from 50 to over 500 mg per can or bottle (1).

Also, manufacturers are not required to list caffeine as an ingredient in products made with naturally occurring sources of caffeine (e.g., coffee, guarana, kola nut, maté). Products made from some of the less well-recognized sources of caffeine can be a significant hidden source of caffeine. Manufacturers are also not required to provide the amount of caffeine added to beverages and other food products; however, some of the larger soft drink manufacturers have begun to label the amount of caffeine in their products in recent years.

EPIDEMIOLOGY

Estimating actual caffeine exposure in the population is challenging because caffeine is present in a vast number of products, and many consumers are completely unaware of

Figure 22.1. Annual per capita consumption of the three major dietary sources of caffeine in the United States. Data from the USDA/Economic Research Service 2009. U.S. Food Supply Data (1970–2007).

whether or not a given product contains caffeine. Furthermore, for many types of caffeinated products both the caffeine concentration and the serving sizes can vary over a wide range. For example, the amount of caffeine in a serving of coffee can range from 17 mg for a small 5-oz cup of instant coffee to 500 mg for a large 20-oz cup of drip coffee.

The most recent large-scale published epidemiologic data on caffeine consumption in the United States was collected more than 10 years ago. Based on the Continuing Survey of Food Intakes by Individuals in 1994 to 1996 and in 1998, it is estimated that 87% of the population in the United States 2 years and older regularly consume caffeine with an average daily consumption of about 193 mg (2). Caffeine use tends to increase with age with the highest consumption observed among adults aged 35 to 64 years (2). Caffeine consumption among adult consumers in the United States is estimated to be about 280 mg with higher daily intakes estimated for some European countries (3). Subgroups that have been identified as being heavy caffeine consumers include psychiatric patients, prisoners, smokers, alcoholics, and individuals with eating disorders. Coffee is the major source of caffeine for adults, followed by soft drinks and tea, whereas soft drinks are the major source of caffeine among children and adolescents (2). More than 50% of adults consume coffee every day, and drink just over three cups per day. Caffeinated soft drinks account for the vast majority of soft drink sales.

Figure 22.1 displays trends in annual per capita consumption of coffee, tea, and soft drinks, the three major sources of caffeine consumption in the United States. Over the nearly four decades shown, use of carbonated soft drinks has more than doubled, while coffee consumption has decreased by about 25%. Tea consumption has increased only slightly over this time period. Since the introduction of Red

Bull in the United States in 1997, the energy drink market has grown exponentially, with hundreds of different brands of energy drinks now available to consumers. Sales of energy drinks have increased an average of 55% each year and sales are expected to continue on this trajectory in the coming years (1).

GENETICS

There is evidence that genetic factors account for some of the variability in the use and effects of caffeine (for citations see (4)). Large-scale twin studies have shown that relative to dizygotic twins, monozygotic twins have higher concordance rates for total caffeine consumption, heavy caffeine consumption, coffee and tea intake, caffeine tolerance, caffeine withdrawal, caffeine intoxication, and caffeine-related sleep disturbances with heritabilities ranging between 34% and 77% (5). Findings from twin studies have also suggested that there may be common genetic factors that underlie the use of caffeine, cigarette smoking, and alcohol. One large-scale twin study found that caffeine and nicotine dependence were substantially influenced by genetic factors that appeared to be unique to these licit drugs and distinct from genetic factors found to be common among illicit drugs (6).

Association studies have also been conducted to evaluate how specific gene variations are related to individual differences in the use and effects of caffeine. Because caffeine's primary mechanism of action is adenosine receptor antagonism, one particular gene that has been the focus of attention is the A_{2A} receptor gene (ADORA2A). Another gene of interest is the CYP1A2 gene, which is linked to enzymes responsible for caffeine metabolism. It has been posited that understanding variability in the CYP1A2 gene across individuals could explain variability in caffeine consumption. It has also been pro-

posed as a method of elucidating dose-response associations between actual caffeine consumption and various effects, and health and pregnancy outcomes, by taking differences in caffeine metabolism into account. For example, recent studies have indicated that individuals who carry the CYP1A2 genotype associated with slow caffeine metabolism are at greater risk for coffee-associated hypertension and myocardial infarction (7,8). In another large-scale study, genetic variability in the ADORA2A receptor gene, but not the CYP1A2 gene, was associated with caffeine consumption (9). Variability in the ADORA2A gene has also predicted differential effects of a specific caffeine dose on anxiety (10) and sleep (11).

PHARMACOKINETICS

After oral consumption, caffeine is rapidly and completely absorbed. Caffeine rapidly passes through the blood–brain barrier and enters the brain, which accounts for the quick onset of mood-altering effects (12). Peak caffeine blood concentration (C_{max}) is generally reached in 30 to 45 minutes (13). Caffeine is highly lipid soluble and is rapidly and widely distributed throughout all body tissues and fluids including breast milk and semen. There is no placental barrier to caffeine, and thus the levels of caffeine in the fetus approach the levels of the mother (14). Saliva caffeine concentrations are highly correlated with plasma caffeine concentrations and are often used as a noninvasive alternative to measuring serum levels.

Caffeine metabolism is complex, and more than 25 caffeine metabolites have been identified in humans (15). The primary metabolic pathways involve the cytochrome P-450 liver enzyme system (primarily the CYP1A2 isoenzyme), which carries out the demethylation of caffeine to three pharmacologically active dimethylxanthines: paraxanthine, theophylline, and theobromine (16). These active metabolites need to be considered in understanding the pharmacologic actions of caffeine, especially the primary metabolite paraxanthine. The half-life of caffeine is typically 4 to 6 hours; however, the rate of caffeine metabolism is quite variable across healthy adults and can range from 2 to 12 hours (12). Due to impaired enzyme functioning, caffeine metabolism is significantly slowed among individuals with liver disease (17) as well as women in the second and third trimesters of pregnancy, who show about a threefold increase in the half-life of caffeine (18). Fetuses and newborns lack the liver enzymes needed to metabolize caffeine. Thus, caffeine metabolism in infants prior to 6 months of age is very slow, with a half-life of 80 to 100 hours (18). Tobacco smoking increases the rate of metabolism of caffeine due to stimulation of the CYP1A2 enzyme, with smokers metabolizing caffeine about twice as fast as nonsmokers.

An implication of the central role of cytochrome P-450 liver enzymes in metabolizing caffeine is that other therapeutic drugs may pharmacokinetically interact with caffeine. Inhibition of caffeine metabolism via competition for liver enzymes could lead to caffeine intoxication symptoms that could be misattributed to the effects of the drug. Further-

more, caffeine can impair the metabolism of other drugs, thus interfering with their safety and therapeutic effectiveness. Because the large majority of the population consumes caffeine, knowledge of potential caffeine–drug interactions is desirable when treating various types of psychological and physical conditions. Numerous compounds have been shown to significantly inhibit the metabolism of caffeine including but not limited to oral contraceptives, quinolone antibiotics (e.g., Enoxacin), and some selective serotonin reuptake inhibitors (SSRIs) (e.g., Luvox), reducing the clearance of caffeine by 40% to 80% (15). Some medications used to treat gastroesophageal reflux disease (GERD; e.g., cimetidine) and heart arrhythmias (e.g., propafenone) also interfere with the metabolism of caffeine (15). Caffeine has been shown to interfere with the metabolism of the sleep medication zolpidem, the antipsychotic clozapine, and bronchodilator theophylline (15).

NEUROPHARMACOLOGY

Adenosine

The primary mechanism of action of caffeine is nonselective antagonism at adenosine receptors. Adenosine is an endogenous nucleoside that plays a role in a number of central and peripheral nervous system functions. Although four adenosine receptor subtypes have been identified, A_1 and A_{2A} receptors are the major targets of caffeine (19). A_1 and A_{2A} receptors are both g-protein coupled receptors that produce a variety of downstream cellular effects via multiple mechanisms including inhibition and activation of adenylyl cyclase, respectively, and inhibition and activation of various ion channels (e.g., Ca^{2+}) (14). A_1 receptors are widely expressed in the brain with the highest densities in the hippocampus, cerebellum, cerebral cortex, and areas of the thalamus. A_{2A} receptors tend to be concentrated in dopamine-rich areas of the brain including the striatum, nucleus accumbens, and the olfactory tubercle (14). Adenosine receptors are also colocalized and functionally interact with each other as well as with dopamine receptors and glutamate receptors in various brain regions (19). A detailed analysis of the respective functions of adenosine receptors and their heteromers in physiologic and behavioral processes is presented elsewhere (14,19).

In general, adenosine has inhibitory effects on the CNS. Adenosine inhibits the release of excitatory neurotransmitters, reduces the spontaneous rate of neuron firing, and has anticonvulsant effects (14). There is also evidence that the accumulation of adenosine, triggered by energy depletion, functions as a sleep-promoting factor (20). Adenosine also suppresses motor activity and operant response rates. In the periphery, adenosine causes cerebral vasodilation, constricts bronchial smooth muscle, produces negative inotropic/chronotropic effects on the heart, and inhibits gastric secretions, lipolysis, and renin release (21).

Caffeine, which is structurally similar to adenosine, binds with adenosine receptors and produces effects that are consistent with reversal of the inhibiting effects of adenosine on

the aforementioned systems. For example, in the CNS, caffeine increases spontaneous neuronal firing, increases the turnover or levels of various neurotransmitters (e.g., acetylcholine, norepinephrine, dopamine, serotonin, glutamate, and GABA), has convulsant activity, increased motor activity, and inhibits sleep (20,21). Some of the peripheral nervous system effects of caffeine include cerebral vasoconstriction, relaxation of bronchial smooth muscle, and increased gastric secretions.

Dopamine

Similar to classic stimulants such as amphetamine and cocaine, there is evidence that some of the motor and reinforcing effects of caffeine are mediated by dopaminergic mechanisms. Caffeine antagonizes adenosine at receptors that are colocalized and that functionally interact with dopamine receptors (i.e., adenosine–dopamine heteromers). Functionally, caffeine produces its motor and reinforcing effects in part by releasing the pre- and postsynaptic brakes imposed by antagonistic adenosine–dopamine interactions (19). In animal studies, caffeine produces behavioral effects similar to classic dopaminergically mediated stimulants such as increased locomotor activity, increased rotational behavior, stimulant-like discriminative stimulus effects, and self-injection. Caffeine potentiates the behavioral effects of dopaminergically mediated stimulants on these same behaviors, effects that can be diminished or abolished by the blockade or depletion of dopamine receptors (14,22).

Dopamine release in the shell of the nucleus accumbens appears to be a neuropharmacologic mechanism underlying the abuse potential of many drugs (23). In vivo microdialysis studies demonstrate that caffeine increases dopamine release in the dorsal shell of the nucleus accumbens (24,25).

Other Mechanisms

Caffeine can also inhibit phosphodiesterase activity and mobilize intracellular calcium release (21). However, these effects are generally observed at levels much higher than typical dietary doses. Nevertheless, it remains possible that these non-adenosine mechanisms may mediate some of the effects produced by high doses of caffeine such as those associated with caffeine intoxication. For example, there are preclinical data that suggest that some of the cardiac and respiratory effects of caffeine may be mediated via inhibition of phosphodiesterase activity (21).

PHYSIOLOGIC EFFECTS

Caffeine produces effects on a variety of organ systems as has been reviewed elsewhere (4,12). At moderate dietary doses, caffeine increases blood pressure and tends to have no effect or to reduce heart rate. Caffeine constricts cerebral blood vessels and reduces cerebral blood flow. Caffeine dilates bronchial pathways, although not as effectively as theophylline (12), and increases the rate of respiration. Caffeine

stimulates gastric acid secretion (12) and colonic activity. Caffeine produces dose-related thermogenic effects, lipolysis (12), and has been shown to be ergogenic during exercise (26,27). Caffeine increases plasma epinephrine, norepinephrine, rennin, and free fatty acids. Caffeine increases diuresis and the urinary excretion of calcium, magnesium, potassium, sodium, and chlorides. Caffeine also increases adrenocorticotrophic hormone (ACTH) and cortisol levels. Caffeine increases insulin levels and reduces insulin sensitivity in healthy individuals, and increases postprandial glucose and insulin responses among patients with type 2 diabetes who are habitual coffee drinkers (28). Not all of the observed physiologic effects of caffeine necessarily have clinical significance (see the section “Caffeine and Health” in this chapter), and the development of tolerance needs to be considered in understanding the physiologic effects of caffeine consumption.

THERAPEUTIC USES

As a mild central nervous stimulant, caffeine is commonly used to increase energy and alertness and ward off fatigue. A number of OTC caffeine preparations are marketed as energy aids (e.g., Vivarin, NoDoz). Studies demonstrate that caffeine can enhance cognitive and motor performance, especially under conditions of fatigue, sleep deprivation, or caffeine withdrawal. Caffeine is also used to enhance athletic performance due to its ergogenic effects (26,27), and has been restricted by some major athletic governing bodies. Caffeine can enhance the analgesic effects of certain medications, and it is currently added to a variety of OTC and prescription analgesics (e.g., Excedrin, Cafergot) used to treat various types of pain including headache. Not surprisingly, caffeine is the most effective treatment for caffeine withdrawal headaches, which are likely caused by rebound cerebral vasodilation in response to acute caffeine abstinence. Likewise, caffeine can prevent postsurgical caffeine withdrawal headaches when administered prophylactically to habitual caffeine consumers (29). As a respiratory stimulant, caffeine is one of the standard treatments for apnea of prematurity in neonates. Because of its lipolytic and thermogenic effects, caffeine is also used to promote weight loss and can be found in many weight-loss products. Caffeine has also been used to treat postprandial hypotension, although its therapeutic effectiveness for this indication is unclear.

CAFFEINE AND HEALTH

The possibility that caffeine may pose health risks is of great interest to the general public and scientific community, and has been the focus of numerous studies and scholarly reviews (30–32). Though associations between caffeine consumption and various health conditions have been found, there is no evidence for nonreversible pathologic consequences of caffeine use (e.g., cancer, congenital malformations). However, there are some groups of individuals who are considered to be at higher risk for caffeine-related problems including pregnant women, children, adolescents, and the elderly (31). Further-

more, individuals with medical problems such as hypertension, diabetes, cardiac problems, urinary incontinence, insomnia, and anxiety may be more vulnerable to the adverse effects of caffeine. As discussed in more detail throughout this chapter, caffeine use can also be associated with several distinct psychiatric syndromes: caffeine intoxication, caffeine withdrawal, caffeine dependence, caffeine-induced sleep disorder, and caffeine-induced anxiety disorder. Recent epidemiologic research also suggests that caffeine and/or coffee consumption may offer some protective effects against specific diseases (31). The associations between caffeine and specific health issues are briefly outlined below.

Negative Health Effects

Research has shown that caffeine can increase blood pressure by 5 to 15 mg Hg systolic and 5 to 10 Hg diastolic for several hours in healthy adults (32). It has been argued that, even after taking the effects of tolerance into account, the hypertensive effects of caffeine represent an important cardiovascular risk factor (33,34). A recent longitudinal genetic association study found that variability in the CYP1A2 gene predicted the later development of hypertension, with those carrying the allele associated with slow metabolism of caffeine having a much greater risk of developing coffee-associated hypertension (7). Caffeine can influence heart rate variability and increase arterial stiffness with peak effects about 60 minutes after ingestion, but the clinical significance of these findings is not clear (35). Both caffeinated and decaffeinated coffees contain lipids that significantly raise serum total and low-density lipoprotein (LDL) cholesterol (31). The highest levels of lipids are delivered from espresso (a component of many popular coffee drinks such as cappuccino and latte), French press, Turkish, and boiled coffee. Instant coffees and those prepared by paper filtration contain much lower levels of these lipids. Epidemiologic studies examining the relationship between coffee consumption and risk of myocardial infarction (MI) on the whole have been equivocal; however a recent analysis suggests that coffee-associated risk of MI is much greater among coffee drinkers who have the CYP1A2 genotype associated with slow caffeine metabolism (8). Some studies suggest that coffee can exacerbate gastroesophageal reflux (GERD); however, it is not clear if it is due specifically to caffeine or other coffee constituents.

Caffeine also increases detrusor instability (i.e., unstable bladder) in patients with complaints of urinary urgency and detrusor instability. Chronic caffeine consumption has been shown to contribute to urinary incontinence in psychogeriatric patients, and caffeine reduction can improve urinary incontinence symptoms (36). Caffeine increases the urinary excretion of calcium. Thus, it has been suggested that caffeine may negatively affect overall calcium balance; however, the amount of increased calcium loss due to caffeine is likely not clinically significant in individuals with adequate calcium intake (32). Associations between high caffeine consumption and bone fractures have been observed in some epidemiologic studies, particularly among women with low calcium intake

(37); however, a direct effect of caffeine on the increased likelihood of fractures has not been observed. Caffeine has also been shown to impair glucose metabolism and insulin sensitivity among individuals with type 2 diabetes (28) and among pregnant women with gestational diabetes (38).

The degree to which maternal caffeine consumption affects pregnancy outcomes has been given considerable research attention. Caffeine readily crosses the placental barrier and is distributed to all fetal tissues including the CNS. Fetuses lack the necessary enzyme systems to metabolize caffeine, and caffeine metabolism slows considerably in the later stages of pregnancy allowing for substantial fetal exposure (18). Research suggests that maternal caffeine use increases the likelihood of spontaneous abortion in a roughly dose-dependent fashion (39,40). Associations between high caffeine use and decreased fecundity and reduced fetal growth have also been observed (31,32), including a recent study that showed that reduced fetal growth was predicted by as little as one to two cups of coffee consumption per day (41). Comprehensive scientific reviews of research on caffeine and pregnancy have concluded that reproductive aged women should consume no more than 300 mg of caffeine per day (31,32).

There is no evidence that caffeine has negative effects on cancer risk, fibrocystic breast disease, peptic or duodenal ulcers, or risk of stroke.

Positive Health Effects

Case control and epidemiologic studies have suggested a relationship between caffeine consumption and reduced risk of Parkinson disease (42). Epidemiologic studies have also reported an association between coffee drinking and reduced incidence of chronic liver disease (43), although the potential mechanisms are unclear, and may be unrelated to caffeine. Additionally, epidemiologic studies have reported a protective effect of coffee drinking for risk of developing type 2 diabetes with the effects attributed to coffee constituents other than caffeine (44).

SUBJECTIVE AND DISCRIMINATIVE STIMULUS EFFECTS

Acute doses of caffeine in the typical dietary dose range (i.e., 20 to 200 mg), produce a number of positive subjective effects including increased well-being, happiness, energy, alertness, and sociability (4,45). These effects are qualitatively similar to those produced by other stimulants such as amphetamine and cocaine (46). In habitual caffeine consumers positive subjective effects are most reliably demonstrated when caffeine is administered after a period of caffeine abstinence and thus may in part represent a reversal of withdrawal (47,48). However, positive subjective effects of caffeine have also been demonstrated in caffeine consumers under conditions of minimal caffeine abstinence as well as among light nonhabitual caffeine consumers.

Negative subjective effects typically emerge at higher caffeine doses. Acute doses of caffeine greater than 200 mg are

more likely to produce increased reports of anxiety, jitteriness, tense negative mood, upset stomach, insomnia, and “bad effects.” Individual differences in caffeine sensitivity and tolerance seem to play an important role in the likelihood and severity of negative subjective effects. For example, individuals with panic disorder or generalized anxiety disorder tend to be particularly sensitive to the anxiogenic effects of caffeine.

The negative subjective effects of caffeine tend to be relatively mild and short-lived, consistent with its half-life of 4 to 6 hours. However, very high doses of caffeine have been associated with clinically significant distress and psychopathology (e.g., caffeine intoxication), as discussed in the section “Caffeine Intoxication.”

Several studies have demonstrated that most individuals can reliably discriminate caffeine (100 to 320 mg) from placebo (4). Some individuals are able to discriminate very low doses of caffeine (e.g., 10 mg) after training (45), which is consistent with findings that low doses of caffeine (e.g., 9 to 12.5 mg) can produce improvements in behavioral performance (49). Subjects in these studies generally report making the discrimination based on the subjective effects of caffeine, with positive subjective effects typically providing the basis for low caffeine dose discrimination and negative subjective effects providing the basis for high dose discrimination.

Drug discrimination studies have demonstrated both similarities and differences between caffeine and other stimulant drugs. For example, both caffeine and *d*-amphetamine produced cocaine-appropriate responding in a cocaine versus placebo discrimination study (50). Other studies showed that caffeine produced dose-related partial generalization to *d*-amphetamine in *d*-amphetamine-trained subjects (46) and that subjects can be trained to reliably discriminate between caffeine and *d*-amphetamine (51). In caffeine-trained subjects methylphenidate and theophylline produced caffeine-appropriate responding (4).

PERFORMANCE

Many studies have examined the effects of caffeine on human performance (for citations see (4)). In general, caffeine at normal dietary doses can restore performance that has been degraded by sleep deprivation, fatigue, prolonged vigilance, or caffeine withdrawal (52,53). Specifically, caffeine improves sustained attention (or vigilance), reaction time, and tapping speed relative to placebo, although results are variable across studies and the effects are often small. The effect of caffeine on memory has also been investigated, but there is little evidence for an association. A number of recent studies using military personnel have demonstrated that caffeine can improve performance relative to placebo on military-type cognitive (e.g., vigilance) and physical tasks (e.g., running times) after periods of prolonged wakefulness (53).

The great majority of studies claiming to demonstrate performance-enhancing effects of caffeine are difficult to interpret because they do not account for the effects of caffeine withdrawal. That is, many studies compare the effects of caf-

feine versus placebo in regular caffeine consumers who have abstained from caffeine, usually overnight. Under these conditions, improvements in performance after caffeine relative to placebo may reflect restoration of performance deficits caused by withdrawal, rather than a performance-enhancing effect of caffeine per se (47). However, some studies have shown caffeine-related performance enhancements among light nondependent caffeine consumers and nonconsumers. It seems likely that caffeine enhances human performance on some types of tasks (e.g., vigilance), especially among non-tolerant individuals. Performance enhancements beyond withdrawal reversal effects are likely to be modest among high-dose habitual caffeine consumers (47).

There is a growing body of research on the effects of caffeine on exercise performance. In general, controlled studies show that relative to placebo, caffeine can enhance performance during endurance exercise (e.g., 30 to 120 minutes) (26,54), can reduce ratings of perceived exhaustion or effort, and can improve speed and/or power output in simulated race conditions. Some studies have also demonstrated a beneficial effect of caffeine during short-term high-intensity exercise and anaerobic resistance training, but these effects are generally more difficult to demonstrate and smaller than effects observed during endurance activities (54). A number of nonindependent mechanisms have been proposed to explain caffeine’s ergogenic effects including increased fatty acid oxidation, increased availability of muscle glycogen, mobilization of intracellular calcium, increased muscle contractile force, and direct CNS effects via adenosine antagonism (26). There is also some evidence that caffeine may increase muscle contractile force during endurance exercise (27).

Studies have directly compared the effects of caffeine, modafinil, and *d*-amphetamine on vigilance performance after an extended period of sleep restriction (44 to 64 hours) and showed that the three stimulants were equally effective at restoring vigilance performance, with caffeine having the shortest duration of action and *d*-amphetamine having the longest (55).

CAFFEINE AND SLEEP

It is well documented that caffeine increases wakefulness and inhibits sleep onset. The mechanism of action is hypothesized to be antagonism of endogenous adenosine, which is believed to be a homeostatic sleep factor that mediates sleepiness following prolonged wakefulness (20). Perhaps the most widely accepted therapeutic use of caffeine is to increase wakefulness and alertness, and reverse performance decrements produced by sleep deprivation (56). There is also abundant evidence that caffeine has disruptive effects on planned sleep (i.e., insomnia). Caffeine ingested throughout the day or before bedtime has been shown to interfere with sleep onset, total time slept, sleep quality, and sleep stages (56). Because of caffeine’s ability to disrupt sleep, caffeine is used as a challenge agent to study insomnia in healthy volunteers. Caffeine’s effects on sleep appear to be determined by a number of factors including dose, the time between caffeine ingestion and attempted sleep, and in-

dividual differences in sensitivity and/or tolerance to caffeine. Caffeine's effects on sleep appear to be dose dependent, with greater amounts of caffeine causing greater sleep difficulties. The closer caffeine is taken to bedtime, the more likely it is to produce disruptive effects. However, 200 mg of caffeine taken early in the morning has been shown to produce small but significant effects on the following night's total sleep time, sleep efficiency, and EEG power spectra (57). Caffeine-induced sleep disturbance is greatest among nonconsumers of caffeine; however, it is not clear whether this difference is due to an absence of acquired tolerance or to a preexisting population difference in sensitivity to caffeine. Genetic factors appear to explain some of the individual differences in sensitivity to the sleep-disruptive effects of caffeine. For example, variation in the *ADORA2A* gene has been shown to be associated with individual differences in caffeine's effects on sleep, measured both subjectively and objectively (11). Although there is evidence for tolerance to the sleep-disrupting effects of caffeine, tolerance appears to be incomplete, and thus regular caffeine consumers may still be vulnerable to caffeine-related sleep problems. A recent study concluded that the sleep-disruptive effects of caffeine are more pronounced during daytime recovery sleep than nocturnal sleep, perhaps due to an interaction of caffeine pharmacology and circadian rhythms (58).

In addition to caffeine's ability to disrupt sleep, there have been case reports of caffeine causing hypersomnia. Furthermore, acute abstinence after chronic caffeine consumption has been shown to increase daytime sleepiness as well as to increase nighttime sleep duration and quality (59).

The *DSM-IV-TR* includes a diagnosis of caffeine-induced sleep disorder, which is characterized by a prominent sleep disturbance that is etiologically related to caffeine use (60). It is not necessary to meet full criteria for a *DSM-IV-TR* sleep disorder to qualify for a diagnosis of caffeine-induced sleep disorder. Caffeine is most often associated with insomnia; however, the *DSM-IV-TR* also recognizes hypersomnia due to caffeine withdrawal. Caffeine-induced sleep disorder is diagnosed when symptoms of a sleep disturbance (e.g., insomnia) are greater than would be expected during caffeine intoxication or caffeine withdrawal. There are no specific data on the prevalence or incidence of caffeine-induced sleep disorder.

REINFORCEMENT

A number of carefully controlled research studies over the past 20 years provide substantial evidence for the reinforcing effects of caffeine (for citations see (4)). Controlled laboratory studies demonstrate that subjects will choose caffeine over placebo in double-blind choice procedures, as well as perform work or forfeit money in exchange for caffeine. When multiple self-administration opportunities are available within a day, doses as low as 25 mg have been shown to be reinforcing (61). When self-administration is limited to once a day, then doses of 100 and 200 mg are reinforcing, while doses of 400 mg and greater tend to be avoided.

There is quite a bit of individual variability in the reinforcing effects of caffeine. Across studies, the overall incidence

of caffeine reinforcement in normal caffeine users is approximately 40%, with a higher incidence (i.e., 80% to 100%) of reinforcement under conditions of repeated caffeine exposure. In choice studies, subjects who choose caffeine tend to report positive subjective effects, whereas those who choose placebo are more likely to report negative subjective effects (e.g., jitteriness) at low to moderate caffeine doses (62).

Caffeine physical dependence potentiates the reinforcing effects of caffeine. For example, caffeine consumers were more than twice as likely to show caffeine reinforcement if they reported caffeine withdrawal symptoms after drinking decaffeinated coffee (63). In studies in which caffeine physical dependence has been experimentally manipulated, subjects are more than twice as likely to choose caffeine over placebo when they are physically dependent (64). There is also evidence that avoidance of caffeine withdrawal determines caffeine consumption to a greater extent than the positive effects of caffeine (64). Caffeine reinforcement also appears to be influenced by task requirements. That is, in a double-blind study subjects chose caffeine over placebo when required to perform a vigilance task, but chose placebo over caffeine when required to engage in relaxation (65).

A series of studies have used a conditioned flavor preference paradigm to provide indirect evidence of caffeine reinforcement (66). In these studies, subjects who were repeatedly exposed to a novel flavored drink paired with caffeine tended to show increased ratings of drink pleasantness, while subjects receiving placebo-paired drinks showed decreased ratings of drink pleasantness (67). Among habitual caffeine consumers, the ability of caffeine to produce increases in flavor liking appears to be primarily determined by the alleviation of withdrawal symptoms (i.e., negative reinforcement) (67). It seems plausible that such conditioned flavor preferences in the natural environment play an important role in the development of consumer preferences for different types of caffeine-containing beverages.

Caffeine reinforcement has also been observed in animals using self-administration, conditioned place preference, and conditioned taste aversion procedures. In contrast to classic abused stimulants such as amphetamine and cocaine, caffeine self-administration is observed in animals under a relatively narrow range of conditions (4).

TOLERANCE

The degree of caffeine tolerance depends on a number of factors including the challenge and maintenance doses, frequency of administration, and individual differences in caffeine elimination. High doses of caffeine (400 to 1200 mg/day) administered throughout the day have been shown to produce "complete" tolerance to some, but not all of the effects of caffeine. However, typical dietary doses of caffeine do not usually produce complete tolerance to caffeine's central and peripheral effects.

Controlled human laboratory studies have demonstrated tolerance to the subjective effects of caffeine. Complete tolerance (i.e., no difference between placebo and caffeine after

prolonged caffeine administration) to subjective effects (e.g., energetic) has been demonstrated after 300 mg t.i.d. for 18 days (62) and 200 mg b.i.d. for 14 days (68), but not after lower doses or shorter exposure periods (69). Substantial but incomplete tolerance has been shown to the sleep-disruptive effects of high doses of caffeine (e.g., 400 mg t.i.d. for 7 days) (4).

Some studies have shown complete tolerance to blood pressure and other physiologic effects (plasma norepinephrine and epinephrine and plasma rennin activity) after high doses of caffeine (e.g., 600 to 750 mg/day) (33). However, about half of the subjects fail to show complete tolerance to the hypertensive effects of caffeine even after maintenance dosing with 600 mg/day (70). Doses in the range of typical daily caffeine consumption (i.e., 300 to 400 mg/day) produce only incomplete tolerance to hypertensive and other physiologic effects of caffeine (e.g., cerebral blood flow velocity, EEG) (33,68,69).

PHYSICAL DEPENDENCE AND WITHDRAWAL

The caffeine withdrawal syndrome has been well-characterized. A 2004 comprehensive review of caffeine withdrawal evaluated 57 experimental studies and 9 survey studies to validate individual symptoms of caffeine withdrawal and identify other important parameters of the caffeine withdrawal syndrome (71). That review identified 13 caffeine withdrawal symptoms that were reliably observed across carefully controlled studies (Table 22.2). Headache is a hallmark feature of caffeine withdrawal with approximately 50% of regular caffeine users reporting headache by the end of the first day of abstinence. Such headaches have been described as diffuse, throbbing, gradual in development, and sensitive to move-

ment. Caffeine constricts cerebral blood vessels via antagonism of adenosine. Caffeine abstinence produces rebound cerebral vasodilatation and increased cerebral blood flow, and such vascular changes are a likely mechanism underlying caffeine withdrawal headache (68,72). Other commonly observed caffeine withdrawal symptoms include fatigue, decreased energy/activeness, decreased alertness, drowsiness, decreased contentedness, depressed mood, difficulty concentrating, irritability, and foggy/not clearheaded. In addition, flu-like symptoms, nausea/vomiting, and muscle pain/stiffness can be present (71). These symptoms can be conceptually clustered into five categories: (a) headache, (b) fatigue or drowsiness, (c) dysphoric mood, depressed mood or irritability, (d) difficulty concentrating, and (e) flu-like somatic symptoms of nausea, vomiting, and muscle pain/stiffness (71), but empirical studies are needed to statistically determine how symptoms cluster together. Changes in EEG, increased cerebral blood flow, and cognitive and behavioral performance deficits have also been observed during acute caffeine abstinence (68,71).

Withdrawal symptoms typically emerge 12 to 24 hours after the last dose of caffeine and tend to peak within the first 2 days. Symptoms usually persist anywhere from 2 to 9 days (71), although there are reports of caffeine withdrawal headache lasting for up to 3 weeks (71).

The severity of caffeine withdrawal can range from mild to incapacitating. There is variability in withdrawal severity both within and across individuals. The incidence of caffeine withdrawal-related impairment or distress to the point of significantly interfering with normal functioning is about 13%. For example, caffeine withdrawal can produce severe headaches that are described as the worst ever experienced (73). Some individuals experiencing caffeine withdrawal have reported that they cannot continue to perform their normal daily activities such as caring for children or going to work (74).

Although there is wide variability across individuals, in general the likelihood and severity of caffeine withdrawal increases as daily caffeine dose increases (75). The daily caffeine dose necessary to produce withdrawal is surprisingly low, with significant withdrawal symptoms observed in individuals consuming as little as 100 mg caffeine per day—the amount in a small cup of brewed coffee (75,76). Caffeine withdrawal can occur after relatively short-term exposure to daily caffeine. Significant withdrawal symptoms have been observed after just three consecutive days of 300 mg/day caffeine, with more severe withdrawal symptoms manifesting after 7 and 14 consecutive days of caffeine (75). In individuals who normally abstain from caffeine, withdrawal headache has been observed in individuals after just a week of prescribed heavy caffeine consumption (i.e., 600 to 750 mg) (73).

Caffeine withdrawal symptoms are usually alleviated quickly after caffeine re-exposure (i.e., 60 minutes or less). Caffeine withdrawal can be suppressed by caffeine doses well below the usual daily dose (e.g., 25 mg caffeine suppressed withdrawal after daily doses of 300 mg) (75). An implication of these findings is that a substantial decrease in caffeine consumption is necessary to manifest the full caffeine withdrawal syndrome.

TABLE 22.2 Empirically validated symptoms of caffeine withdrawal

Headache
Tiredness/fatigue
Drowsiness/sleepiness
Irritability
Depressed mood
Difficulty concentrating
Muzzy/foggy/not clearheaded
Flu-like symptoms
Nausea/vomiting
Muscle pain/stiffness
Decreased energy/activeness
Decreased alertness/attentiveness
Decreased contentedness/well-being

Source: Juliano LM, Griffiths RR. A critical review of caffeine withdrawal: empirical validation of symptoms and signs, incidence, severity, and associated features. *Psychopharmacology (Berl)*. 2004;176:1–29.

Retrospective survey studies have also been conducted to determine the frequency of caffeine withdrawal in the general population. In one population-based random digit dialing survey study, 44% of caffeine users reported having stopped or reduced caffeine use for at least 24 hours in the past year. Of those, over 40% reported experiencing one or more withdrawal symptoms. Interestingly, over 70% of those who stopped or reduced caffeine as part of a permanent quit attempt reported withdrawal symptoms, and 24% reported headache and other symptoms that interfered with performance (77). In another study, 11% of caffeine users who were making an inquiry about participation in a clinical research trial reported that they had “problems or symptoms on stopping caffeine in the past,” of which 25% reported that the problems were severe enough to interfere with normal activity (78). The number of individuals who actually experienced a period of caffeine abstinence was not ascertained.

Although most withdrawal research has been with adults, there is evidence that children and adolescents who use caffeine also experience caffeine withdrawal symptoms upon abstinence (79). It is possible that children may be even more susceptible to experiencing withdrawal episodes as they likely have less control over the regular availability of caffeine-containing products. Caffeine withdrawal has also been documented in neonates born to mothers who have had recent caffeine exposure.

The observations that caffeine withdrawal can cause clinically significant distress or functional impairment have resulted in the inclusion of caffeine withdrawal as an *ICD-10* diagnosis (80) and as a proposed diagnosis in *DSM-IV-TR* (60,81). The 1994 *DSM* Work Group included caffeine withdrawal as a proposed diagnosis rather than an official diagnosis to encourage further research on the range and specificity of caffeine withdrawal symptoms (81). Carefully controlled research on caffeine withdrawal has more than doubled since 1994, now providing a sound empirical basis for a diagnosis of caffeine withdrawal (71). The *DSM-IV-TR* criteria are conservative in that it excludes cases in which other withdrawal symptoms occur in the absence of headache. It also excludes symptoms that have been documented in recent studies including dysphoric mood, difficulty concentrating, and irritability, and includes a symptom for which there is little empirical support (i.e., anxiety). To date, only one study has evaluated the incidence of caffeine withdrawal using *DSM-IV-TR* criteria (77). This population-based survey found that 11% of those who had given up or reduced caffeine use in the past year met criteria for caffeine withdrawal. Among individuals who reported trying to stop caffeine use permanently, 24% met criteria for caffeine withdrawal.

Caffeine withdrawal symptoms overlap with various psychological and physical ailments. Caffeine withdrawal should be considered when patients present with headaches, fatigue, mood disturbances, impaired concentration, and flu-like symptoms. Patients are often asked to stop food and fluids before certain blood tests, surgery, or medical procedures (e.g., colonoscopies, fasting blood

sugar tests) and may experience adverse effects that could go unrecognized as caffeine withdrawal. Caffeine withdrawal has been identified as a significant cause of postoperative headaches, the risk of which can be reduced if habitual caffeine consumers are administered caffeine on the day of the surgical procedure (29).

A recent study directly compared periods of abstinence from either caffeine or nicotine among habitual users of both drugs and found no differences between the two in the psychosocial manifestations of withdrawal as measured by subjective well-being, social functioning, and drug craving (82).

CAFFEINE INTOXICATION

Caffeine intoxication is currently defined by the *DSM-IV-TR* by a number of symptoms and clinical features that emerge in response to excessive consumption of caffeine (Table 22.3) (60). The most common features of caffeine intoxication include nervousness, restlessness, insomnia, gastrointestinal upset, muscle twitching, tachycardia, and psychomotor agitation. Fever, irritability, tremors, sensory disturbances, tachypnea, and headaches have also been reported in response to excess caffeine use (4).

DSM-IV-TR diagnostic guidelines require that the diagnosis be dependent on recent consumption of at least 250 mg of caffeine, but much higher doses (>500 mg) are usually associated with the syndrome. High-dose intoxicating effects of caffeine are very unpleasant and are not usually sought out by users. Individual differences in sensitivity to caffeine and tolerance likely play a role in vulnerability to caffeine intoxication. Although caffeine intoxication can occur in the context of habitual chronic consumption of high doses of caffeine, it most often occurs after consumption of large doses in infrequent caffeine users, or in regular users who have substantially increased their intake. There are generally no long-lasting consequences of caffeine intoxication, although caffeine can be lethal at very high doses (e.g., 5 to 10 g), and there are documented cases of accidental death and suicide by caffeine overdose, usually in the form of pills (4).

Few studies have assessed the prevalence of caffeine intoxication, and most have evaluated selected populations (e.g., psychiatric inpatients) and used ambiguous criteria. One general population survey found that 7% of respondents met *DSM-IV* criteria for caffeine intoxication (77). The occurrence of individual symptoms of caffeine intoxication appears to be fairly common (e.g., nervousness). For example, a study involving more than 3600 twins found that 29% reported having felt ill or shaky or jittery after consuming caffeinated beverages (83). In a survey of college students, 19% reported experiencing heart palpitations after consuming energy drinks (1).

A recent study evaluated 265 cases of caffeine overuse that were reported to a local area poison center between 2001 and 2004 after ingestion of caffeinated products other than coffee or tea (1). They found that caffeine was in the

TABLE 22.3 Diagnostic criteria for caffeine intoxication (*DSM-IV-TR*)

A) Recent consumption of caffeine, usually in excess of 250 mg (e.g., more than two to three cups of brewed coffee)
B) Five (or more) of the following signs, developing during, or shortly after, caffeine use:
1) Restlessness
2) Nervousness
3) Excitement
4) Insomnia
5) Flushed face
6) Diuresis
7) Gastrointestinal disturbance
8) Muscle twitching
9) Rambling flow of thought and speech
10) Tachycardia or cardiac arrhythmia
11) Periods of inexhaustibility
12) Psychomotor agitation
C) The symptoms in Criterion B cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.
D) The symptoms are not due to a general medical condition and are not better accounted for by another mental disorder (e.g., an anxiety disorder).

From American Psychiatric Association. *The Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition Text Revision*. Washington, DC: American Psychiatric Association; 2000, with permission.

form of a medication in 77% of the cases, a caffeine-enhanced beverage in 16% of cases, and a dietary supplement in 14% of cases. Patients were typically young (21 years old on average), half were male, and 12% required hospitalization. Caffeine was implicated in 4656 reports to poison control centers in the United States in 2005, with half warranting treatment in a health care facility (1). Caffeinated gum and energy capsules have also been implicated in published case reports of caffeine intoxication in teenagers requiring medical attention.

It appears that reports of caffeine intoxication may be increasing with the growing popularity of highly caffeinated energy drinks (1). It has been postulated that the potential for caffeine intoxication to occur from consumption of energy drinks may be greater than other dietary sources of caffeine because of the absence of caffeine content labeling and appropriate health warnings, and their appeal and marketing to young and perhaps nontolerant individuals (1). For example, a recent series of case reports based on poison control center data found that a particular energy drink containing 250 mg of caffeine was implicated in a number of reports of caffeine intoxication. The most common symptoms were hypertension, jitteriness, agitation, tremors, nausea, vomiting, and dizziness (84). Consumption of about eight cans of energy drinks (or 640 mg caffeine) was implicated in the cardiac arrest suffered by a 28-year-old male motocross racer (1). There have also been numerous media reports of children becoming sick after consuming energy drinks (1).

CAFFEINE AND ANXIETY

The anxiogenic effects of caffeine are well established (for citations see (4)). Acute doses of caffeine generally greater than 200 mg have been shown to increase anxiety ratings in nonclinical populations, with higher doses sometimes inducing panic attacks (85). Individuals with anxiety disorders tend to be particularly sensitive to the effects of caffeine. Experimental studies have demonstrated that caffeine exacerbates anxiety symptoms in individuals with panic disorder and generalized anxiety disorder to a greater extent than healthy control subjects. Genetic factors can predict variability among individuals to the anxiolytic effects of caffeine. Genetic polymorphisms on the A_{2A} receptor gene (*ADORA2A*) were shown in two studies to be associated with anxiogenic responses to 150-mg dose of caffeine among low caffeine consumers (10). Furthermore, first-degree relatives of patients with panic disorder show a greater anxiogenic response to a high dose of caffeine (85). It has been suggested that individuals with anxiety disorders may find the stimulus effects of caffeine aversive and therefore may naturally limit their caffeine intake. Laboratory studies have demonstrated that lower baseline anxiety levels predict caffeine consumption using drug choice procedures under double-blind conditions (62). Some correlational studies have found that individuals with anxiety disorders, such as panic disorder, report consuming less caffeine than healthy controls. However, other studies have shown a positive relationship between anxiety disorders or

greater anxiety levels and caffeine use, or no relationship. In light of this mixed data, it seems reasonable to conclude that some but not all highly anxious individuals will limit caffeine, and it is possible that some may fail to recognize the role that caffeine plays in their anxiety.

Abstinence from caffeine has been shown to produce improvements in anxiety symptoms among individuals seeking treatment for an anxiety disorder. Interestingly, individuals with high caffeine consumption have been shown to have greater rates of minor tranquilizer use (e.g., benzodiazepines) relative to those with low to moderate caffeine consumption (86), although the mechanism underlying this association has not been established.
