1 The ovarian egg and ovulation **1**
A. Tsafriri, R. Reich and A. Abisogun

1.1 Introduction 3
1.2 The primordial cells 4
1.3 Oogonia 6
1.4 The oocyte 8
1.5 Ovarian differentiation and folliculogenesis 12
1.6 Follicular growth 13
1.7 Ovulatory changes 28
1.8 Concluding remarks 56
Acknowledgements 58
References 58

2 Pre-implantation development **93**
C.R. Austin

2.1 Introduction 94
2.2 The cleaving eutherian egg and the blastocyst 96
2.3 Development in monotremes and marsupials 111
2.4 Experimental manipulation 114
Acknowledgement 136
References 136

3 Implantation **157**
C.R. Finn

3.1 Introduction 159
3.2 Species variation 159
3.3 Preparation of the uterus for implantation 162
3.4 Implantation of the blastocyst 176

3.5 The decidual cell reaction 186
3.6 Evolution of the endometrial response to implantation 203
Acknowledgement 205
References 205

4 Placentation **233**
F.B.P. Wooding and A.P.F. Flint

4.1 Introduction 235
4.2 General characteristics and definitions 236
4.3 Development of embryonic membranes in the various vertebrate taxa 293
4.4 Placental endocrine function 407
4.5 Interspecific embryo transfer and hybrid pregnancies: role of the placenta 423
4.6 Viviparity 424
Acknowledgements 429
References 429

5 Hormones of the placenta: hCG and hPL **461**
W.R. Butt, T. Chard and R. Iles

5.1 Introduction 463
5.2 Human chorionic gonadotrophin 463
5.3 Chorionic gonadotrophin and the glycoprotein hormones 464
5.4 Human placental lactogen 490
References 505

6 Normal and abnormal embryo–fetal development in mammals **535**
J.P. Hearn, A.G. Hendrickx, G.E. Webley and P.E. Peterson

6.1 Introduction 537
6.2 Embryo-maternal interactions 538
6.3 Regulation of the corpus luteum 553
6.4 Rates of development 562
6.5 Prenatal mortality 573
6.6 Development of the reproductive tract 586
6.7 Abnormal development 615
6.8 Concluding comments 636
References 637

7 Endocrinology of pregnancy, parturition and lactation in marsupials **677**
Marilyn B. Renfree

7.1 Introduction 678
7.2 Patterns of reproduction 679
7.3 Early pregnancy: ovulation, cleavage and the early blastocyst 683
7.4 Embryonic diapause 688
7.5 Initiation and maintenance of diapause 691
7.6 Reactivation after diapause 693
7.7 Maintenance of pregnancy 704
7.8 Acquisition of endocrine organs during development 718

7.9 Control of parturition 729
7.10 Lactation: lactogenesis and galactopoiesis 737
7.11 Control of milk secretion and concurrent, asynchronous lactation 743
7.12 Adaptive significance of the marsupial mode of pregnancy and lactation 749

PREFACE

In 1910 F.H.A. Marshall established a landmark in the history of science when he published the first edition of *The Physiology of Reproduction*. A revised second edition was published by Marshall in 1927 and in this he was assisted by a young graduate, A.S. Parkes (later Sir Alan), who accepted an invitation to organize and edit the third edition, the preparation of which was planned in 1939 and then delayed by the advent of the Second World War. It was subsequently completed in three volumes, the first of which appeared in 1956 and the final volume in 1966.

For nearly a century succeeding editions of *Marshall's Physiology of Reproduction* have provided an advanced reference text for reproductive biologists. We hope the current volume will maintain this role.

Organizing and editing the work of the Fourth Edition has involved an extension of the scope of each succeeding text while retaining a comprehensive philosophical approach to the review of literature. The coverage demanded for such an advanced text has expanded exponentially during the last decade.

For the Fourth Edition, Volume 1 *The Reproductive Cycles of Vertebrates* published in 1984, provided a synopsis of the various reproductive patterns. It contains major contributions concerning fishes, reptiles, amphibia, birds, marsupials and eutherian mammals. The volume included special chapters on Non-human Primates and Humans.

Volume 2 on *Reproduction in the Male*, published in 1990, provided a detailed analysis of research on male reproductive physiology, male life cycles and seasonality, the physiology of the testis and accessory sexual organs, artificial insemination and the preservation of semen.

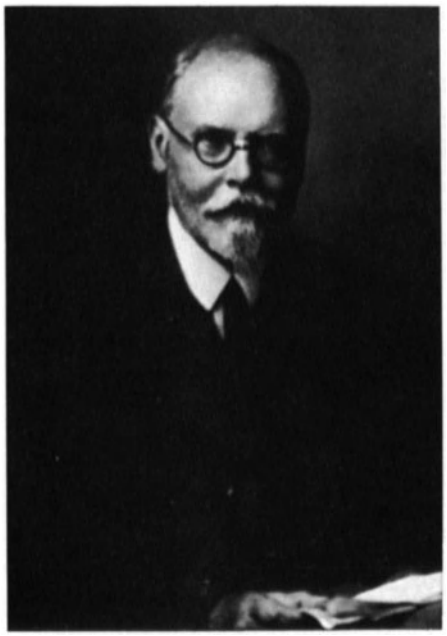
The current volume aims to maintain Marshall's traditional comparative approach with particular emphasis on reviewing research data derived from studies of farm and laboratory animal species, non-human primates and humans. A major effort has been made by contributors in the final revision of their texts to present the results of the most recent research. However, given the time required to receive and edit the manuscripts, check the proofs and index the volume, it is as fully up-to-date as possible. The increasing impact of new information on the reproductive physiology of humans is well reviewed and this aspect amplifies the valuable interrelationship which exists between those working experimentally with farm and laboratory species and those engaged in the control of reproduction and assisted conception in humans. The comparative aspects of placentation, embryo and fetal development, the initiation of parturition and lactation are extensively reviewed.

It is our established editorial policy to seek contributions from the most eminent international authorities. This I trust we have achieved in full measure. I acknowledge and welcome the contributions made by the authors from Australia, New Zealand, Israel, the United States of America, as well as those from the UK.

G.E. Lamming
University of Nottingham

A BIOGRAPHICAL NOTE PREPARED BY *SIR ALAN PARKES*

(for the Third Edition)



F. H. A. MARSHALL
CBE, MA, PhD, DSc, ScD, FRS.
11th July 1878–5th February 1949

Marshall's name is associated, mainly or even exclusively, with the study of the physiology of reproduction in its many branches. He was preceded in this field by another pioneer, Walter Heape, who was completing his classic studies of the primate uterus and collecting material for his analysis of the oestrous cycle at the time when Marshall was an undergraduate in Cambridge. The two men did not meet until later, but they corresponded freely, and Heape's morphological studies and extensive knowledge of living animals were of great value to Marshall in his early days. Heape, however, was not a physiologist – he seems, for instance, to have regarded the ovary merely as a producer of eggs – and it is to Marshall that we owe the foundations of our present knowledge of the role of internal secretions in the reproductive processes.

Marshall's debut was characteristic of an age in which research was a calling rather than a profession; a precarious calling to which young men were drawn by interest, not by ambition. In 1900, the late Lord Carmichael gave £200 to Prof. Cossar Ewart, Professor of Natural History in the University of Edinburgh, to enable a Research Student to assist with his long-term experiments on telegony, and to undertake work on reproduction in farm animals. Cossar Ewart's inquiries resulted in Marshall accepting an invitation to go to Edinburgh. The work on telegony, which involved a detailed study of the hair of the Equidae, was uninteresting and unproductive, and

Marshall turned his attention to research on the sexual cycle in the sheep, for which he was to make use of Ewart's farm at Penicuik. This work was the subject of his first important scientific publication, which appeared in the *Transactions of the Royal Society* in 1903. Similar studies followed with Schäfer on the oestrous cycle in the ferret (1904), and with Jolly on the oestrous cycle in the dog (1905). A communication on the ovary as an organ of internal secretion, written in collaboration with Jolly and published in the *Transactions of the Royal Society* in 1905, constituted the first serious attempt to correlate the changes in the uterus during the reproductive cycle with the cyclic production of different internal secretions by the ovary.

Marshall returned to Cambridge in 1908, and continued his work on the physiology of reproduction. During the war, 1914–18, he studied, on behalf of the Ministries of Food and Agriculture, such problems as the most economic age and condition at which to slaughter cattle. Subsequently, Marshall's researches have dealt mainly with the influence of exteroceptive factors – light, climate, etc. – on the reproductive processes, and in 1936 he made this the subject of his Croonian Lecture. He was also intensely interested in the courtship and breeding behaviour of birds, on which he was a considerable authority.

Marshall spent a great deal of time preparing the first edition of *The Physiology of Reproduction* in which he gathered together all relevant knowledge concerning the breeding season, cyclic changes in the reproductive organs, fertilization, fertility, lactation and so on. The book was published by Longmans, Green & Co. in 1910, and immediately achieved success. A second edition was called for after the 1914–18 war. This second edition, published in 1922, was necessarily much larger than the first, for since 1910 knowledge of the reproductive processes in mammals and lower vertebrates had increased considerably. A third edition, largely rewritten by Marshall's pupils and colleagues, and again much enlarged, is now in the course of publication.

Marshall's main contribution to biology has been twofold. In the first place, the stimulating synthesis of existing knowledge embodied in the first edition of *The Physiology of Reproduction* gave impetus and balance to a branch of biology sadly lacking in both. The fact that between the wars the physiology of reproduction became a subject of intensive study by scientists in all countries was due in no small measure to the stimulus given by Marshall's writings. In the second place, Marshall's remarkable prescience in deducing correctly the existence and respective roles of follicular and luteal hormones long before either was isolated, or even obtained in active extracts, had a profound influence on the development of the subject. During the early years of the century Ludwig Fraenkel in Breslau and P. Bouin in Strasbourg, working on the rabbit, concentrated attention on the corpus luteum; in the 1920s intensive study of the follicular hormone by Edgar Allen and his colleagues in the USA swung attention to the follicular apparatus. It fell to the English school of workers, under Marshall's influence, to hold the balance until the final demonstration and isolation of the corpus luteum hormone in G.W. Corner's Rochester laboratory completed the working out of his early predictions.

Scientists are of many kinds, but inspiration flows most fruitfully from those who are able, by some gift withheld from lesser men, to divine the richness of uncharted country and sense the vital landmarks. Thus do they avoid the barren places and the morasses of unimportant detail which engulf so many. To these, discovery is an art rather than a science, a matter of instinct rather than of intellectual machinery. Such was Marshall.

20 October, 1948 A.S.P.
Revised 10 February, 1949.

F.H.A. MARSHALL

CURRICULUM VITAE

Francis Hugh Adam Marshall was the younger son of the late Thomas Marshall, J.P., and was born at High Wycombe on 11 July, 1878. He was educated at St. Mark's School, Windsor, and privately. After a short time at University College, London, he went to Christ's College, Cambridge, in 1896, and took the Natural Science Tripos in 1899. During the latter part of the time in Edinburgh Marshall became Carnegie Fellow and Lecturer on the physiology of reproduction. After his return to Cambridge he was Lecturer and then Reader in Physiology, in the School of Agriculture, for more than 35 years, until 1943. For a short period, Marshall followed the late Prof. T.B. Wood in directing the Institute of Animal Nutrition. He became in succession, Fellow, Tutor, Dean, and finally, in 1940, Vice-Master of Christ's College. He was a Proctor in 1911–12 and afterwards served on the Council of the Senate. Marshall was an original member of the Council of Management of the *Journal of Endocrinology* and was one of the four honorary members of the Society for Endocrinology. For many years he was an editor of the *Journal of Agricultural Science*, and finally became principal editor. Marshall's scientific distinctions included D.Sc. (Edin.), Sc.D. (Cantab.), D.Sc. (Hon. Manch.), LL.D. (Hon. Edin.), F.R.S. (1920), C.B.E. (1933), Council of the Royal Society (1933–5), Baly Medal of the Royal College of Physicians (1935), Croonian Lecturer (Royal Society) 1936, and Royal Medal (Royal Society) 1940.

A BIOGRAPHICAL NOTE PREPARED BY *G. E. LAMMING*

(for the Fourth Edition)

PROFESSOR SIR ALAN PARKES
CBE, FRS.

Sir Alan Parkes' association with F.H.A. Marshall began when he enrolled as an undergraduate at Christ's College, Cambridge and Marshall became his tutor. Parkes describes this first association with Marshall as no more than formal since he preferred to avoid undue contact with those in authority, no doubt prompted by previous experience at school and in the army. Parkes read agriculture, obtaining a pass degree in 1921 and an MA in 1924. After graduating in 1921 he applied for a position at the Shirley Cotton Research Institute in Manchester which (fortunately for reproductive physiology) he failed to obtain. However, fortified by his father's encouragement and support he entered Manchester University as a PhD student in the Zoology Department to research on the mammalian sex ratio. During this period Parkes accepted a request from Marshall to help him with indexing the second edition of MPR which was published in 1922. No doubt Marshall had been impressed, not so much by Parkes' enthusiasm as an undergraduate, but by the initiative he had shown in carrying out a literature search for his first published paper on 'Sex heredity', which appeared in *Science Progress* in 1921.

At Manchester, Parkes completed his PhD in two years having A.V. Hill as an internal examiner and Marshall as the external. The inclusion of A.V. Hill was fortunate for it resulted in Parkes moving with Hill, now a Professor, to University College, London, where Parkes remained until 1931, holding a

series of three research fellowships. Here he co-operated in researches with a number of famous contemporaries including Jack (later Sir Jack) Drummond, Professors F.W.R. Brambell, Guy Marrion and Solly (later Lord) Zuckerman. From 1932 to 1961 Parkes was a member of the MRC's National Institute of Medical Research, first at Hampstead and later at Mill Hill. He was responsible, with others, for organizing a number of research programmes in reproductive endocrinology, many of which had major influences on developments in reproductive physiology as applied to agriculture. Detailed research on important topics included the induction and control of ovulation and lactation, and the cryo-preservation of animal tissues. In 1961 Parkes returned to Cambridge, fittingly as the first holder of the newly created Mary Marshall Chair in the Physiology of Reproduction, established under the terms of Marshall's will. Here the nature of his work changed, for the Marshall position was vastly different from his previous MRC post; it lacked the fabric for Parkes to continue his detailed researches. Nevertheless, the change produced benefits which history may well judge of equal merit, for Parkes continued to influence the course of reproductive physiology by virtue of major roles in organizing societies and scientific journals including the Society for the Study of Fertility, its associated *Journal of Reproduction and Fertility*, and also the *Journal of Biosocial Sciences*, acting for a number of years in addition as executive editor for both journals. The following is abstracted (by kind permission of the publishers, A & C Black (Publishers) Limited) from his entry in the 1990 edition of *Who's Who*.

PARKES, Sir Alan (Sterling), Kt 1968; CBE 1956; FRS 1933; MA, PhD, DSc, ScD; Fellow of Christ's College, Cambridge, 1961–69, Hon. Fellow 1970; Fellow of University College, London; Chairman, Galton Foundation, since 1969; *b* 1900; *y s* of E. T. Parkes, Purley; *m* 1933, Ruth *d* of Edward Deanesly, FRCS, Cheltenham; one *s* two *d*. *Educ*: Willaston School; Christ's College, Cambridge; BA Cantab, 1921, ScD 1931; PhD Manchester, 1923; Sharpey Scholar, University College, London, 1923–24; Beit Memorial Research Fellow, 1924–30; MA Cantab 1925; Schäfer Prize in Physiology, 1926; DSc London 1927; Julius Mickle Fellowship, University of London, 1929; Hon. Lecturer, University College, London, 1929–31; Member of the Staff of the National Institute for Medical Research, London, 1932–61; Mary Marshall Prof. of the Physiology of Reproduction, Univ. of Cambridge, 1961–67, Professor Emeritus 1968. Consultant, Cayman Turtle Farm Ltd, Grand Cayman, BW1, 1973–. Foulerton Student of the Royal Society, 1930–34. Mem., Biol. and Med. Cttee, Royal Commn on Population, 1944–46. Assoc. for the Advancement of Science, 1958; Eugenics Soc., 1968–70; Inst. of Biology, 1959–61; Assoc. of Scientific Workers, 1960–62. Chairman: Soc. for Endocrinology, 1944–51; Soc. for Study of Fertility, 1950–52, 1963–66; Nuffield Unit of Tropical Animal Ecology, 1966–69; Breeding Policy Cttee, Zool Soc. of London, 1960–67; Scientific Adv. Cttee, Brit. Egg Mkting Bd, 1961–70. Mem. Adv. Cttee on Med. Research of the WHO, 1968–71. Executive Editor, Jl Biosocial Science, 1969–; Sec., Jls of Reproduction & Fertility Ltd, 1970–76. Consultant, IPPF, 1969–79. Cameron Prize, 1962; Sir Henry Dale Medal, Soc. for Endocrinology, 1965; John Scott Award (jtly with Dr A. U. Smith and Dr C. Polge), City of Philadelphia, 1969; Marshall Medal, Soc. Stud. Fert., 1970; Oliver Bird medal, FPA, 1970. *Publications*: The Internal Secretions of the Ovary, 1929; Sex, Science and Society, 1966; Patterns of Sexuality and Reproduction, 1976; Off-beat Biologist, 1985; Biologist at Large, 1988; papers on the Physiology of Reproduction, on Endocrinology and on the behaviour of living cells at low temperatures in Jl of Physiology, Proc. Royal Society and other scientific jls. Ed. Marshall's Physiology of Reproduction, 3rd edn, 1952, consultant 4th edn, 1994. *Address*: 1 The Bramleys, Shepreth, Royston, Hertfordshire SG8 6PY.

Professor Parkes died on July 17th 1990.

ACKNOWLEDGEMENTS

Fortunately, few will have experienced the volume of work involved in commissioning, editing and preparing a text of this size. It can only be completed by competent teamwork. My main task has been to persuade the team members to participate and then organize their work.

My special thanks goes initially to the contributors but also to their secretaries. It is well known that the best authors are busy individuals heavily committed both to their research and to allied commitments, (including travel abroad). Thus, many of my queries concerning the texts are handled initially (and, in some cases, entirely) by secretaries. I applaud their tenacity and tact, and also their skill, especially in checking reference citations. I owe them a special vote of thanks.

Mrs Pamela Blythe completed the initial secretarial work prior to her move to a senior managerial post elsewhere. The main bulk of the editorial work was completed by Mrs Linda Faillace during her husband's (Dr L. Faillace) postdoctoral research work in this department. I acknowledge her skill in the preparation of texts for printing and thank her husband and family for their forebearance in tolerating the many hours of work she completed, both in the office and at home. I also thank Mrs Monica Bagshaw for providing additional secretarial help, and Dr Karen Shelton for her contribution to chapter 2.

I again thank collectively the advisers to the Fourth Edition. Professor Parkes assisted, prior to his death, in the initial plans. Several of the advisers were helpful not only in planning the volume, but also in the detailed discussions involving our move to publication by Chapman & Hall. I acknowledge the commitment, skill and speed of the Chapman & Hall staff (Miss Rachel Young, Mr Martin Tribe and Mr Jeremy Macdonald) in publishing this volume.

Finally, I reserve special praise for those who have completed the indexing of volume 3 with a total of about 10 000 reference citations. What a pleasure it is to have the continued help of Dr Barbara Weir as an adviser, and to take advantage of her skill in the preparation of the subject index. Her knowledge of world literature in reproductive physiology, gained from years of experience as Editor of the *Journal of Reproduction and Fertility*, is invaluable. I am sure many who use these texts, and who know Barbara personally, will support my expression of gratitude.

The author index was ably and generously completed by my young staff colleagues. (They may comment that they had little choice since I organize their work schedule). I am most fortunate to have young staff colleagues who cheerfully tackled these time-consuming chores, and I record my sincere appreciation to Misses Morag Batten, Sarah Machin, Jane Plowright and Alison Clarkson.

1.1 INTRODUCTION

The production of a fertilizable ovum is a protracted process spanning the embryonic, post-natal, prepubertal and sexually mature life of the mammalian female. In Figure 1.1 the life history of the rat ovum is depicted schematically on the background of ontogenetic development.

In brief, a short period of mitotic activity of oogonia is followed by their transformation into primary oocytes which embark on meiosis. The meiotic process is subject to multiple stop–go controls. The term 'oogenesis' has been used in the literature to describe (i) the transformation of oogonia into oocytes (Franchi *et al.*, 1962; Zuckerman and Baker, 1977; Peters and McNatty, 1980) and (ii) the entire process of the formation and maturation of the female germ cell (Baker, 1982). This wider definition is similar to the term spermatogenesis and is presently used more frequently and will be adopted here. We shall use the term 'oocytogenesis' (Kennelly and Foote, 1966; Siracusa *et al.*, 1985) to indicate the transformation of oogonia into oocytes and initiation of meiosis.

From early stages of germ cell life a close association with somatic cells of the ovary is established (Mitchell and Burghardt, 1986). Oocytes which do not become enclosed within granulosa cells, and thus incorporated into primordial follicles, usually degenerate (Ohno and Smith, 1964). Furthermore, the growth of the oocyte and of the follicle are closely coordinated and the ovulatory stimulus induces changes both in the oocyte and in the somatic compartment of the follicle. Therefore, normal development of the ovum, especially the later stages of its growth and maturation, can be properly discussed only within the framework of follicular physiology.

In most mammalian species meiotic maturation is initiated during prenatal life or shortly after birth, but the process is arrested (**first meiotic arrest**) at the diplotene stage. In rodents, the chromosomes become diffuse and the stage is referred to as the dictyate stage of the prophase of first meiotic division (Figure 1.2).

The meiotic arrest is maintained throughout oocyte and follicular development to the Graafian follicle stage. *In vivo* the meiotic process is resumed only in fully grown oocytes in follicles responding to the preovulatory surge of gonadotrophins (Ayalon *et al.*, 1972) or in follicles undergoing atresia (reviewed by Tsafriri and Braw, 1984). At ovulation, in most mammalian species, a secondary oocyte arrested at the metaphase of the second meiotic division (**second meiotic arrest**) is released. The second meiotic division is completed only after fertilization or a parthenogenetic stimulus and evidenced by abstriction of the second polar body.

The maintenance of first meiotic arrest throughout oocyte and follicular growth and its termination following the preovulatory surge of gonadotrophins has been the subject of many recent studies. While, within the follicle, resumption of meiosis is strictly dependent upon hormonal stimulation, explantation of ova from Graafian follicles results in their spontaneous maturation *in vitro* (Pincus and Enzmann, 1935). Subsequent studies demonstrated that the ability of oocytes to resume meiosis spontaneously, usually referred to as 'meiotic competence', is acquired only during later stages of oocyte growth and is related to follicular development (Szybek, 1972; Erickson and Sorensen, 1974; Bar-Ami and Tsafriri, 1981).

In this chapter we shall review the life history of the mammalian ovum throughout embryonic development to ovulation and relate it to follicular development. Attention will be given to the following subjects: (i) the development of meiotic competence; (ii) mechanisms involved in the maintenance of meiotic arrest; (iii) the ovulatory changes induced by the surge of gonadotrophins, in-

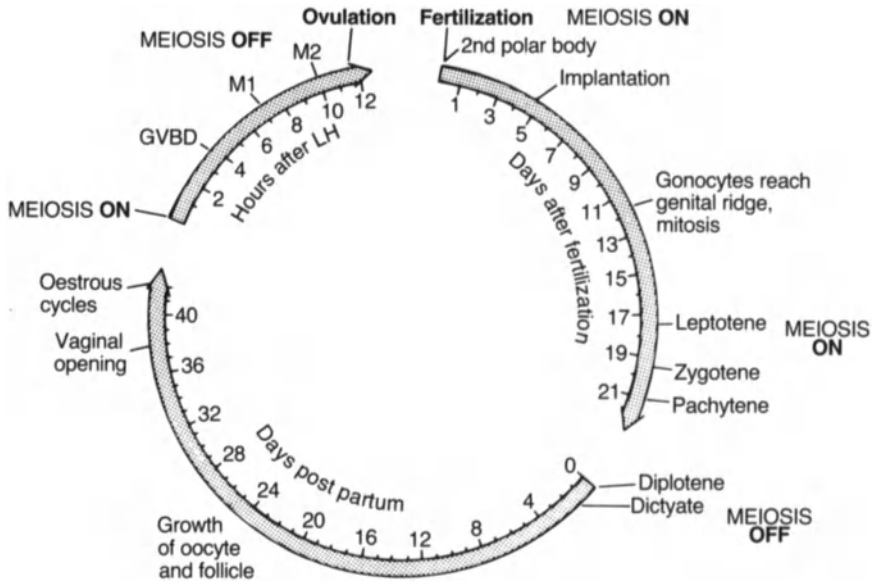

Figure 1.1 Schematic presentation of oogenesis and its multiple stop–go controls in the rat. (From Lindner *et al.*, 1980.)

cluding resumption of meiotic maturation and follicular rupture.

Most of the investigations to be reviewed have been performed using laboratory animals, such as mice, rats and rabbits. Studies carried out on other species will be referred to when pertinent.

1.2 THE PRIMORDIAL GERM CELLS

The origin and biology of mammalian primordial germ cells (PGCs) have been reviewed recently (Gondos, 1978; Hardisty, 1978; Heath 1978a; Eddy *et al.*, 1981; McLaren, 1981, 1983a; Siracusa *et al.*, 1985; Byskov, 1986).

Experimental evidence for the extragonadal origin of germ cells in mammals was obtained by Everett (1943). He demonstrated that transplantation of genital ridges from 10.5- to 14-day-old mouse embryos beneath the kidney capsule of adult mice resulted in normal differentiation of the transplanted gonads. By contrast, genital ridges explanted from younger mouse embryos, between 9.5 and 10 days, before germ cells could be discerned, did not develop germ cells.

The PGCs were first recognized at the base of the allantois of human embryos (Witschi, 1948). This early observation was later extended using PGCs' high alkaline phosphatase activity as a marker (McKay *et al.*, 1953). In the mouse PGCs were identified in the yolk sac endoderm and at the root of the allantois as early as the eighth day of gestation, around the time of the appearance of the first somite (Chiquoine, 1954; Mintz and Russell, 1957; Jost and Prepin, 1966; J.M. Clark and Eddy, 1975). The progenitors of PGCs in the mouse were traced 24 h earlier to a small cluster of alkaline phosphatase-positive cells just posterior to the primitive streak in the extraembryonic mesoderm (Ginsburg *et al.*, 1990). The germ cell lineage derives from the epiblast (embryonic ectoderm; McLaren, 1983a; Gardner *et al.*, 1985) and not from the yolk sac endoderm as previously believed. Blastomeres of a two-cell embryo (Tarkowski, 1959), or at least three blastomeres of a four-cell embryo (Kelly,

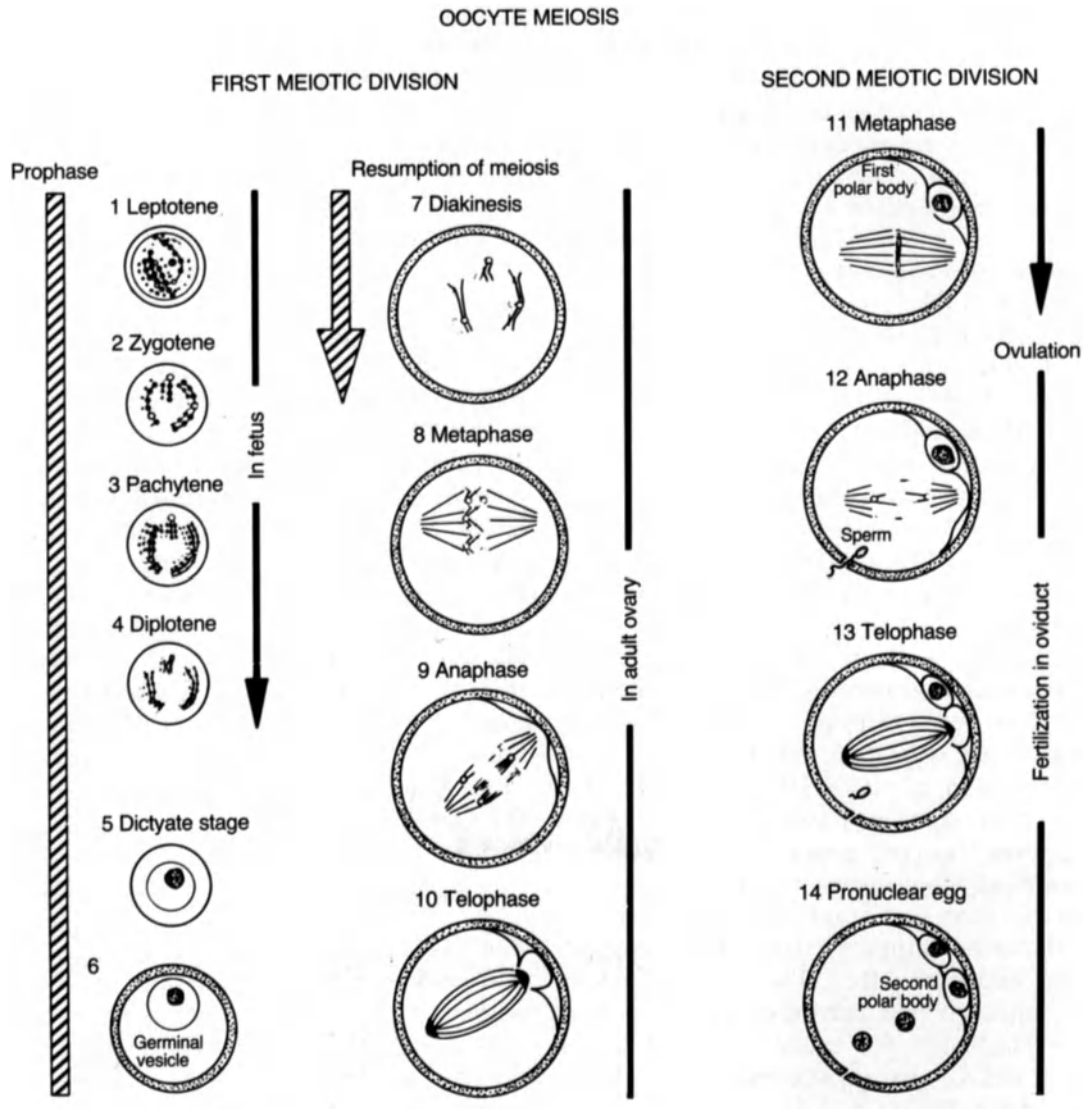

Figure 1.2 Oocyte meiosis. For simplicity, only three pairs of chromosomes are depicted. (1–4) Prophase stages of the first meiotic division that occur in most mammals during fetal life. At zygotene (2) the homologous maternal and paternal chromosomes begin to pair. At pachytene (3) they are paired along their entire length, thus forming bivalents. During pachytene, each homologue cleaves longitudinally to form two sister chromatids, so that each bivalent forms a tetrad. During this stage, interchange of genetic material between maternal and paternal chromatids may occur by crossing over. At diplotene (4), the chromosomes begin to separate, remaining united at the chiasmata. The meiotic process is arrested at this stage (first meiotic arrest), and the oocyte enters the dictyate stage. When meiosis is resumed, the first maturation division is completed (7–11). Ovulation usually occurs at the metaphase II stage (11) (second meiotic arrest), and the second meiotic division (12–14 is completed in the oviduct following sperm penetration. (From Tsafriri (1978) with kind permission of Plenum Publishing, New York.)

1977) or at least two cells in fifth day primitive ectoderm (Gardner *et al.*, 1985), can give rise to both somatic cells and functional germ cells when transplanted into host blastocysts. Thus, the segregation of the germ line occurs after day 5 of mouse embryonic development (Gardner *et al.*, 1985) and before day 7 (see discussion in Eddy *et al.*, 1981).

In the mouse the PGCs migrate from the yolk sac and allantois (8- to 9-day embryos), throughout the hindgut epithelium (9- to 10-day embryos) and dorsal gut mesentery (10- to 12-day embryos), into the developing gonads (beginning on day 10.5) (Chiquoine, 1954; Mintz, 1959; Ozdzenski, 1967). The migration route of PGCs is similar in other mammalian species examined.

The precise mechanism(s) involved in the migration of PGCs to the gonad are poorly understood. The identification of pseudopodia-like projections in mouse, rat and human PGCs (Jeon and Kennedy, 1973; Spiegelman and Bennet, 1973; Zamboni and Merchant, 1973; Chung, 1974; Eddy, 1974; Eddy and Clark, 1975; Fujimoto *et al.*, 1977; Miyayama *et al.*, 1977; Heath, 1978b; Lin *et al.*, 1982; Kuwana and Fujimoto, 1983) supports active amoeboid movement. Identification of microfilaments in the cytoplasmic processes of migrating mouse PGCs lends further support to this notion (Spiegelman and Bennet, 1973). Morphogenetic movement of the surrounding tissues was also suggested for translocation of PGCs (Jeon and Kennedy, 1973; Snow, 1981; Snow and Monk, 1983).

The direction of PGCs' movement is attributed to contact guidance or differential adhesion of the surrounding tissue. Chemotaxis, i.e. movement directed towards the developing gonads, which secrete a chemical attractant, was suggested by Witschi (1948). Transplantation of mouse hindguts into developing chick embryos resulted in invasion of mouse PGCs into the host gonad (Rogulska *et al.*, 1971), thus supporting the suggested chemotactic action of the gonad. PGCs from 12.5- to 15.5-day-old mouse embryos specifically adhered to somatic cells of mature gonads, but not other embryonal and adult cell types (De Felici and Siracusa, 1985).

During their migration and settling in the gonad the PGCs divide mitotically. When first recognized, the number of PGCs in mouse embryos is less than 100, it reaches 4000 on day 12 (Mintz and Russell, 1957), and 25 000 by day 13.5 when colonization of gonads is completed (Tam and Snow, 1981). A doubling time of 16 h was estimated for mouse PGCs during migration (Tam and Snow, 1981).

The number of PGCs may be influenced by genetic defects and experimental manipulation. Thus, in homozygous embryos for the mutant genes *Steel* (S1) or *White-spotting* (W), the number of PGCs reaching the gonad is markedly reduced (Bennet, 1956; Mintz and Russell, 1957). Administration of busulphan (Merchant-Larios, 1975; Merchant-Larios and Coello, 1979) or mitomycin C (Tam and Snow, 1981) to pregnant mice or α-irradiation of pregnant rats (Beaumont, 1966) decreased the number of PGCs.

1.3 OOGONIA

The PGCs colonizing the developing ovary and undergoing mitotic divisions are termed oogonia. When mitotic divisions cease and the cells enter meiosis they are termed oocytes. As already indicated, very often the transformation of oogonia into oocytes was referred to as 'oogenesis'. Here, we shall use the term 'oocytogenesis' instead.

Morphologically oogonia are similar to PGCs. They are somewhat more rounded when compared with PGCs, which are amoeboid in appearance (Gondos, 1978). In measurements using histological sections (probably underestimates due to dehydration), oogonia in dog and monkey ovaries had a diameter of 13 μm (Andersen and Simpson, 1973; Gulyas *et al.*, 1977). In ovaries

embedded for electronic microscopy in plastic, oogonial diameter of 22 μm was reported in cat ovaries (Amselgrüber, 1982) and 19 μm in the human ovary (Dvoràk and Tesàrik, 1980). The major distinction between PGCs and oogonia is in their location. Oogonia are located within more or less distinct germ cells cords or in clusters (Gondos, 1978; Byskov, 1986). In many species examined oogonia are connected by intercellular bridges (see Gondos, 1978, and Byskov, 1986, for references). They are formed by incomplete cytokinesis at telophase. The intercellular bridges are thought to serve for intercellular communication and transfer of metabolites and regulatory substances. Synchronization of mitoses within conjoined cells has been demonstrated in oogonia in the mouse (Ruby *et al.*, 1969), rabbit (Peters *et al.*, 1965), cow and sheep (Rüsse, 1982, 1983).

1.3.1 OOGONIAL PROLIFERATION AND DEGENERATION

The oogonial stage of development is characterized by mitotic activity. In some species the oogonial stage occurs entirely during the prenatal life (rat, mouse, guinea pig, cow, sheep, pig, rhesus monkey and human), while in others it extends into the neonatal life (cat, rabbit, ferret, mink, vole and hamster, see Table 1.1).

Analysis of oogonial divisions revealed resemblance with spermatogonial divisions in the sheep (Mauléon, 1967) and prespermatogonia in the rat (Hilscher and Hilscher, 1978). The relatively high mitotic index of oogonia results in marked increase in their number (rat, Beaumont and Mandl, 1962; mouse, Tam and Snow, 1981; guinea pig, Ioannou, 1964; rabbit, Chretien, 1966; pig, Black and Erickson, 1968; human, Baker and O, 1976).

The proliferation of oogonia is accompanied by degeneration of large numbers of oogonia. Oogonia degenerate at interphase or during mitosis. Some authors (Beaumont and Mandl, 1962; Ioannou, 1964), used the term 'atretic divisions' for the latter. Degeneration of oogonia does not include conspicuous changes in somatic cells of the ovary. We prefer to use the term 'atresia' only

Table 1.1 Time and duration of ooctytogenesis in different mannals. (From Peters and McNatty, 1980, by permission of Granada Publishing, London).

	Age of post-partum fetus (days)		
Species (ref [a])	*Onset of meiosis*	*Arrest of meiosis*	*Duration*
Rat[1]	17	18	2 days
Mouse[2]	13	16	4 days
Guinea pig[3]	30	50	3 weeks
Pig[4]	30	100	10 weeks

for elimination of antral follicles by other means rather than ovulation (Tsafriri and Braw, 1984). Oogonial degeneration, too, seems to appear in clusters of oogonia (Gondos and Zamboni, 1969; Gondos, 1973).

1.3.2 PREMEIOTIC DNA SYNTHESIS

In several mammalian species examined, the mitotic activity reaches its peak just before the start of meiosis (mouse, Hilscher and Hilscher, 1981; Peters and Crone, 1967; rat, Hilscher *et al.*, 1974; guinea pig, Ioannou, 1964; sheep and cattle, Rüsse, 1982; pig, Black and Erickson, 1968; monkey, Baker, 1966; human, Baker, 1963).

In all mitotically proliferating cells, DNA is synthesized during the S phase of the interphase of the cell cycle. Likewise, in mitotically dividing germ cells, PGCs or oogonia, DNA is synthesized during interphase preceding division. In addition, there is a phase of DNA synthesis during the interphase preceding the initiation of meiosis and transformation of oogonia to oocytes. This transition is probably initiated during the G_1 phase of the cell cycle, and the subsequent S phase is referred to as 'premeiotic S phase' or 'premeiotic DNA synthesis'. This premeiotic DNA synthesis may extend from interphase to leptotene stage of the prophase of the meiotic division as observed in rabbit oocytes by autoradiography (Peters *et al.*, 1965). The duration of this phase is similar (9–12 h) in mouse and rabbit oocytes (Lima-de-Faria and Borum, 1962; Crone *et al.*, 1965; Kennelly *et al.*, 1970) and it coincides with the transformation of oogonia to oocytes, or oocytogenesis. Thus, multiple injections of tritiated thymidine between days 13 and 15 in mouse embryos and during the neonatal period in rabbits result in labelling of almost all oocytes in the adult animal (Borum, 1966; Kennelly and Foote, 1966). These experiments provided the conclusive evidence for the continuity of the germ cell line from oogonium to the ovum and refuted the suggestion of neoformation of germ cells after this period of DNA synthesis. For further discussion of these two alternatives see the reviews by Franchi *et al.* (1962) and Zuckerman and Baker (1977).

Nevertheless, in some species of the Lemuroid family, groups of oogonia persist in the adult ovary. These oogonia can be labelled by tritiated thymidine and may transform into oocytes, suggesting oocytogenesis in the adult life (Herlant, 1961; Ioannou, 1967; Anand Kumar, 1968). It is doubted whether these oocytes enter the phase of follicular growth (David *et al.*, 1974).

1.4 THE OOCYTE

The first meiotic maturation is characterized by essentially universal and orderly sequenced changes in chromosome structure during the protracted prophase. These were described at the turn of the century in histological preparation of rabbit, human and cat ovaries (von Winiwarter, 1901; von Winiwarter and Sainmont, 1909). In later studies squash preparations or spreads (Ohno *et al.*, 1961, 1962; Luciani *et al.*, 1974; Bakken and McClanahan, 1978; Speed, 1982) and electron microscopy were employed (Franchi and Mandl, 1962; Tsuda, 1965; Baker and Franchi, 1967a, 1972; Comings and Okada, 1972; Holm and Rasmussen, 1977; Speed, 1982).

During leptotene, dispersed chromatin condenses progressively into regular threads containing a proteinaceous axial core. In zygotene, the pairing of homologous chromosomes starts. The synaptonemal complex forms with the appearance of its central element between closely opposed chromosomal axial cores, in effect zipping them up. Pairing is completed during early pachytene, when the chromosomes reach their most compact state and are short and thick. Electron microscopic studies revealed lateral projections of the chromatin fibres (Baker and Franchi, 1967a), and these become more pro-

nounced in early diplotene chromosomes. During diplotene the homologous chromosomes separate, their axes elongate and the chiasmata can be recognized. Thus, during the meiotic prophase exchange of paternal and maternal genes is made possible by crossing over.

In growing oocytes of many animal species producing large eggs, with notable examples in anuran and urodele amphibia, the pachytene–early diplotene chromosomes have large lateral loops with appearance of a test-tube brush or lampbrush and hence are referred to as 'lampbrush chromosomes'. These loops may reach several micrometres in length (Müller, 1974). These loops represent very active transcription units. The chromosomes of mammalian prophase oocytes cannot be considered as lampbrush chromosomes on the basis of their morphological and functional properties (see Bachvarova, 1985).

The duration of leptotene stage is between 3 and 6 h in the mouse and between 3 and 8 h in the rabbit. Zygotene is completed in the mouse within 12–14 h, and within 16–44 h in the rabbit. Pachytene takes more than 60 h in the mouse and lasts up to 10 days in the rabbit (mouse, Lima-de-Faria and Borum, 1962; Crone *et al.*, 1965; rabbit, Peters *et al.*, 1965; Kennelly *et al.*, 1970). At the diplotene stage the meiotic process is arrested, to be resumed only upon atresia or in preovulatory follicles after the surge of gonadotrophins. Hence, diplotene is by far the longest stage of meiotic prophase. In the human it may last about 50 years, i.e. from the initiation of diplotene in the fetus to the last ovulation in adult life. In many mammalian species, including the cat, cow, rabbit and human, the chromosomes retain their diplotene configuration throughout meiotic arrest (Ohno *et al.*, 1962; Baker and Franchi, 1967b; Zybina, 1975). Conversely, the diplotene chromosomes of rodents, such as the rat, mouse and hamster, become diffuse and assume the appearance of elongated fuzzy threads occupying most of the nuclear volume and are currently referred to as dictyate. This term is, therefore, equivalent to diffuse diplotene.

During the meiotic prophase the female germ cell undergoes morphological changes though maintaining spherical shape of the cell and the nucleus (see Gondos, 1978). The nuclear membrane is sustained throughout meiotic prophase. At the leptotene, the chromosomes attach to the inner nuclear membrane. These attachment sites seem to be crucial for the formation of synaptonemal complexes (Baker and Franchi, 1972; Rasmussen and Holm, 1980). The nucleolus remains compacted and relatively small until diplotene, when it enlarges and occasionally assumes complex reticular structure (Gondos *et al.*, 1971). In the human oocyte, multiple micronuclei associated with the heterochromatin appear during this period (Stahl *et al.*, 1973, 1975). The number and size of cytoplasmic organelles increases during meiotic prophase, but these changes differ among species (Gondos, 1978).

1.4.1 REGULATION OF MEIOSIS INITIATION

Meiosis is initiated much earlier in female germ cells than in male ones. Thus, in the female mouse, all germ cells enter the prophase of meiosis nearly a week before birth, while in the male the first meiotic germ cells do not appear in the testis until a week after birth. Two hypotheses were raised to account for the early onset of meiosis in female germ cells: local influence of the environment or a preprogrammed event. At the present it is impossible to decide between these two alternative hypotheses because of conflicting experimental observations and inadequacies of the available *in vitro* systems (see McLaren, 1984; Byskov, 1986).

The observation that meiosis starts in the central parts of the ovary, close to the mesonephric tissue (see Gondos, 1978; Byskov, 1986), gave rise to the hypothesis that cells of

mesonephric origin trigger the initiation of meiosis (Byskov, 1975). Transplantation experiments involving fetal mouse ovaries resulted in initiation of meiosis only when they were explanted with their attached mesonephric tissue (Byskov, 1975). Furthermore, meiosis could be induced in fetal undifferentiated mouse testes cultured in close proximity with ovaries containing the attached mesonephros (Byskov and Saxén, 1976). It was suggested that the mesonephric–ovarian complex, rete ovarii, secretes a meiosis-inducing substance (MIS) which is responsible for the initiation of meiosis (Byskov, 1978a). Similar results were obtained in fetal hamster ovaries transplanted *in vitro* (O and Baker, 1976; Fajer *et al.*, 1979).

The delay in the initiation of meiosis by male germ cells in the testis was ascribed to the action of a meiosis-preventing substance (MPS) and, conversely, the initiation of meiosis at puberty to either cessation of MPS secretion (Byskov and Saxén, 1976; Grinsted *et al.*, 1979) or to an increase in MIS secretion (Parvinen *et al.*, 1982).

In cultures of fetal rat ovaries initiation of meiosis was not dependent on the presence of mesonephric tissue (Stein and Anderson, 1979; Byskov, 1986) and no evidence for MIS activity was obtained in co-cultures of fetal mouse gonads (Evans *et al.*, 1982). Finally, in sheep and in the mouse, germ cells located in the adrenals were in meiotic prophase in both female and male fetuses (Upadhyay and Zamboni, 1982; Zamboni and Upadhyay, 1983). These findings were confirmed and extended in mouse ectopic germ cells. In female fetuses both ovarian and ectopic germ cells entered meiosis. Conversely, in male fetuses only testicular germ cells did not enter meiosis, but many germ cells in extratesticular stroma entered meiosis at days 18 and 19 of development (McLaren and Hogg, cited in McLaren, 1984; Francavilla and Zamboni, 1985). These latter findings seem to suggest that the autonomous differentiation potential of the mammalian germ cells is predominantly female and this is superseded by testicular influence.

The reactivation of the second X chromosome in female germ cells occurs prior to initiation of meiosis (Monk and McLaren, 1981). Nevertheless, reactivation of X chromosome occurs also in sex-reversed (Sxr) XX testes and the germ cells enter meiosis well after birth (McLaren and Monk, 1981). Reactivation of X chromosome, or chromosome constitution, therefore, does not seem to play a decisive role in the initiation of meiosis (see McLaren, 1983b).

In conclusion, experimental evidence for predetermined female-type early initiation of meiosis and for local MIS and MPS activity has been forwarded. Nevertheless, the precise interaction of any or all of these factors during ovarian development of various mammalian species remains obscure. Initial data seem to suggest that MIS is of steroid-like nature (Yding Andersen *et al.*, 1981). Work aimed at the chemical characterization and purification of MIS and MPS is especially needed. This would allow direct experimentation and determination of the mechanism(s) involved in regulation of initiation of meiosis.

1.4.2 DEGENERATION OF OOCYTES

Onset of meiosis is accompanied by further increase in germ cell degeneration. The proportion of germ cells surviving degeneration ranges from only 5% in the cow (Erickson, 1966) and human (Baker, 1963) to 50% in the pig (Black and Erickson, 1968). Thus, the maximal number of germ cells is reached upon oogonial mitoses, and from this fetal peak there is continuous depletion in their number throughout embryonic development, infancy and sexually mature life (Figure 1.3).

Germ cells degenerate at all stages of development, but quantitatively three major 'waves' of degeneration have been reported in the human fetal ovary. These 'waves'

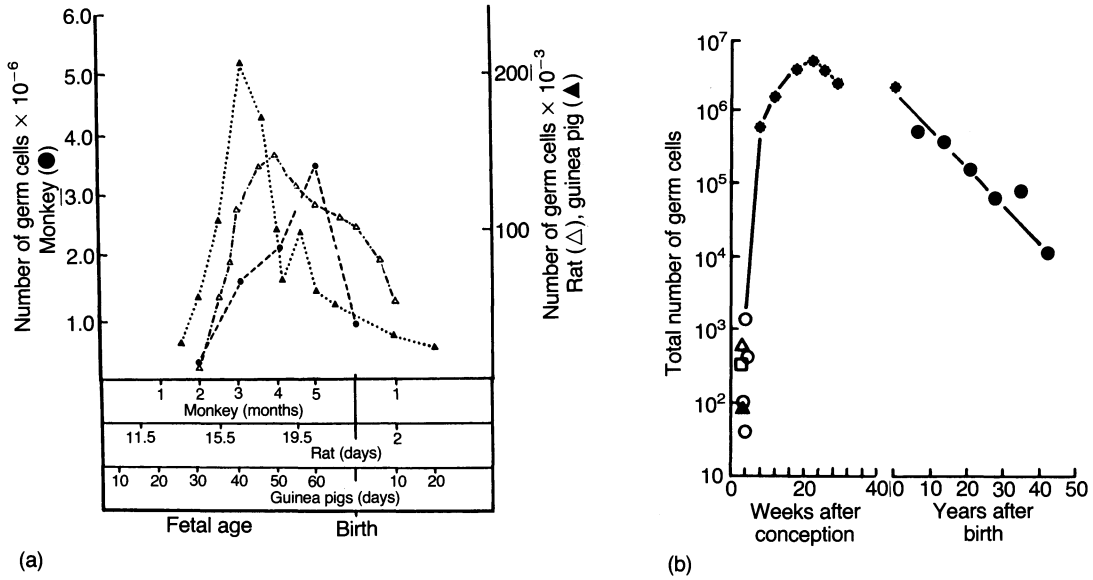

Figure 1.3 The number of germ cells in (a) the ovaries of fetuses and neonates in monkey, rat and guinea pig (from Baker, 1972) and (b) in the human female. (From Siracusa *et al.*, 1985.)

affect mitotically active oogonia, as well as oocytes in pachytene and diplotene stages of meiotic prophase (Baker, 1963). Degenerating zygotene and pachytene oocytes have been referred to as 'Z' cells (Beaumont and Mandl, 1962). Degenerating cells are characterized by conspicuous condensation of chromosomes and are phagocytosed by somatic ovarian cells (see details and references, Gondos, 1978).

Genetic factors play an important role in oocyte degeneration. Thus, X chromosome monosomy results in excessive degeneration of oocytes in early meiotic prophase in the human (Singh and Carr, 1966) and during fetal and neonatal development in the mouse (Burgoyne and Baker, 1981).

The role of extragonadal hormones in progression of meiosis and maintenance of primary oocytes is obscure. In fetal hypophysectomized rhesus monkeys germ cell degeneration was increased greatly. The poor development of the rete ovarii or their absence was suggested as a possible reason for germ cell degeneration, rather than direct dependence on fetal pituitary hormones (Gulyas *et al.*, 1977). Likewise, thymectomy of rhesus monkey fetuses resulted in reduction in the number of oogonia and meiotic oocytes in ovaries observed at term, in addition to increased degeneration of preantral and antral follicles (Healy *et al.*, 1985). The mechanisms involved remain obscure. As thymectomy raised fetal plasma gonadotrophin levels, it is possible that endocrine as well as immune mechanisms are involved in germ cell differentiation and maintenance. Recently, a marked increase in the progression of meiosis in rabbit fetal ovaries cultured *in vitro* with pituitaries was observed (Mazur and YoungLai, 1986). The higher FSH levels in female fetuses at the time of initiation of meiosis, as compared with male fetuses of the same age, in sheep (Mauléon and Reviers, 1969) and rabbits (YoungLai *et al.*, 1981) support the notion that hypophyseal secretions may be involved in the progression of meiosis and maintenance of meiotic germ cells. Nevertheless, it should be emphasized that meiosis proceeds, albeit in a smaller number of germ cells, even in the absence of pituitary. It is possible, therefore,

that pituitary secretions affect the number of germ cells indirectly through trophic action on somatic cells of the ovary.

1.5 OVARIAN DIFFERENTIATION AND FOLLICULOGENESIS

In the previous sections our discussion was focused on the ovarian germ cell compartment. Now the changes in the germ cells will be related with those occurring in the somatic compartment(s) of the ovary. Ovarian differentiation has been reviewed recently (Merchant-Larios, 1978; Peters, 1978; Pelliniemi and Dym, 1980; Peters and McNatty, 1980; Byskov, 1986; Byskov and Hoyer, 1987; Hirshfield, 1991), therefore, only a brief overview will be presented.

1.5.1 OVARIAN DIFFERENTIATION

In most mammalian species the most conspicuous early change associated with ovarian differentiation is the initiation of meiotic prophase (Peters, 1970). Nevertheless, in some species, such as the sheep, pig, cow and rabbit, initiation of meiosis is delayed (Mauléon, 1967, 1969) and, hence, a relatively long delay period separates the first manifestation of gonadal sex differentiation, i.e. recognizable testes in the male and the onset of meiosis in the female fetuses.

In species with delayed onset of meiosis, ovarian differentiation includes formation of well-defined sex cords containing germ cells (horse and cow, Y. Hashimoto and Eguchi, 1955a,b; Henricson and Rajakoski, 1959; cat, mink and ferret, Byskov, 1975; sheep, Zamboni *et al.*, 1979; pig, Pelliniemi and Lauteala, 1981) or formation of distinctive cortex and medulla (human and rabbit, Wartenberg, 1983; YoungLai and Byskov, 1983). By contrast, in species with early meiosis, like the mouse and the rat, there is no formation of distinct germ cell cords or organization of cortex–medulla (Byskov, 1978a). Further development of the ovary includes formation of follicles, folliculogenesis and the differentiation of steroid-producing cells.

1.5.2 FOLLICULOGENESIS

In the early stage of ovarian development, the nuclei of the oocytes lie closely together in nests with only partial separation by a plasma membrane. The nests of oocytes are usually surrounded by thin stromal cells (see Peters, 1978). As the oocytes reach diplotene stage, the plasma membrane is completed and the bridges between adjacent oocytes disappear. Thus, during ovarian differentiation the nests of oocytes are transformed from a cell syncytium into clusters of naked oocytes surrounded by somatic cells. The enclosure of diplotene oocytes with somatic cells is called folliculogenesis. The resulting small follicles consist of an oocyte, granulosa cells and a basement membrane. The time of follicle formation varies in different mammalian species (Table 1.2).

In most mammals folliculogenesis is limited to a well-defined period. Oocytes which do not become incorporated into follicles usually degenerate (Ohno and Smith, 1964).

Three tissues were suggested as the source of somatic cells of the follicle: (i) the coelomic or surface epithelium; (ii) the central blastema (or central stromal cells); (iii) the cells of the rete ovarii. The process of folliculogenesis starts at the innermost parts of the ovarian cortex. The granulosa cells of these follicles are initially continuous with rete ovarii, and only the formation of the basement membrane severs this continuity (mouse, Byskov and Lintern-Moore, 1973; Byskov and Rasmussen, 1973; rat, Stein and Anderson, 1979; dog, von Kölliker, 1898; rat, mink and ferret, Byskov, 1975). Furthermore, removal of the rete ovarii prior to the initiation of folliculogenesis prevents formation of follicles, while the removal of the surface epithelium has no effect on follicle formation in the mouse (Byskov, 1974; Byskov *et al.*, 1977).

Table 1.2 Ovarian differentiation and folliculogenesis in mammals

Species	*Gestation (days)*[a]	*Initiation of gonadal sex differentiation (days)*[a]	*Delay period (days)*[b]	*Follicular formation begins*	
				Post coitum (days)[c]	*Post partum (days)*[c]
Hamster	16	11–12	3		7
Mouse	19	12	0.5		2
Rat	21	13–14	3		1
Rabbit	31	15–16	15		14
Cat	65	30	12		11
Guinea pig	68	22–23	7	48	
Pig	114	26	18	64	
Sheep	150	35	20	65	
Cow	280	39	45	95	
Rhesus monkey	165	38	10	50	
Human	270	40–42	10[d]	56	

[a]From Gondos (1978).
[b]The period separating the time of gonadal sex differentiation, i.e. testicular differentiation which is observed earlier, and the beginning of meiosis in the ovary. From Byskov (1986).
[c]From Peters (1978). See the original publications for references.
[c]According to Gondos *et al.* (1986), oocytogenesis begins between 11 and 12 weeks of age, hence the delay period is > 35 days in the human.

Thus, a contribution of rete ovarii to follicle cells seems well established. The contribution of surface epithelium varies between species. In the human (van Wagenen and Simpson, 1965; Gondos, 1975), monkey (van Wagenen and Simpson, 1965), dog (Andersen and Simpson, 1973), cat (von Winiwarter and Sainmont, 1909), rabbit (Gondos, 1969) and guinea pig (Jeppesen, 1975) marked proliferation of the surface epithelium is observed at the time of follicle formation. Cords of epithelial cells extend from the surface and penetrate into the ovarian stroma. Some of these cords lose their connection to the surface, associate with oocytes and form small follicles. The ontogeny of thecal cells has been discussed recently by Hirshfield (1988).

Germ cells are required for folliculogenesis. Follicle formation is not observed in the absence of oocytes. The Turner's syndrome (XO constitution) in the human entails loss of germ cells and thus ovarian follicles are not formed. The resulting ovary, referred to as a 'streak' ovary, is devoid of follicles and normal endocrine activity (Singh and Carr, 1966; Morishima and Grumbach, 1968; Weiss, 1971; Reddoch *et al.*, 1986). Likewise, experimental destruction of germ cells during fetal development in the rat by busulphan abolishes folliculogenesis. The ovary is made up of a network of rete-like cords and tubules. Only when occasional oocytes survive do follicles form (Merchant-Larios, 1976). The small follicles form the pool from which follicles begin to grow throughout fetal, prepubertal and pubertal life.

1.6 FOLLICULAR GROWTH

1.6.1 CLASSIFICATION OF FOLLICLES

A classification of follicles first proposed for the mouse (T. Pedersen and Peters, 1968) and later adapted to the human (Peters *et al.*, 1978) has proved most useful for analysing follicular development (Figure 1.4).

Thus, four groups of follicles can be distinguished:

1. Small, non-growing follicles (also called **primordial** or **primary follicles**) consist of a small oocyte, a few flattened granulosa cells and a basement membrane. They lie in the outer cortex of the ovary and represent the pool of resting follicles.
2. The **preantral follicle** (also called **secondary**, **medium** or **growing** follicle) is the one that enters the growing phase. Its oocyte begins to grow and granulosa cells enlarge and multiple to form two or three layers around the oocyte. The zona pellucida forms and cells of the ovarian stroma organize into the theca layers.
3. The **antral follicle** contains a fully grown oocyte, several layers of granulosa cells, an antrum filled with fluid and, outside the basement membrane, well-differentiated theca layers.
4. The **large antral follicle** (also referred to as **Graafian follicle**), which reaches its maximum diameter and is fully responsible to the preovulatory surge of gonadotrophins.

1.6.2 FOLLICULAR GROWTH BEFORE PUBERTY

(a) Fetal life

In man and monkeys follicular growth starts during fetal life (van Wagenen and Simpson, 1965). The first small follicles appear during the fourth month of gestation and around the sixth month many preantral follicles can be located in the innermost part of ovarian cortex. Antral follicles often develop during the last 2 months of fetal life and the ovary of the newborn is often crowded with large antral follicles. However, these follicles show signs of degeneration or atresia and of irregular growth (Peters *et al.*, 1978).

Anencephalic human fetuses have a greatly reduced pituitary gland which contains only about 2% of the normal gonadotrophin content (Grumbach and Kaplan, 1973). Ovaries of such fetuses at term are

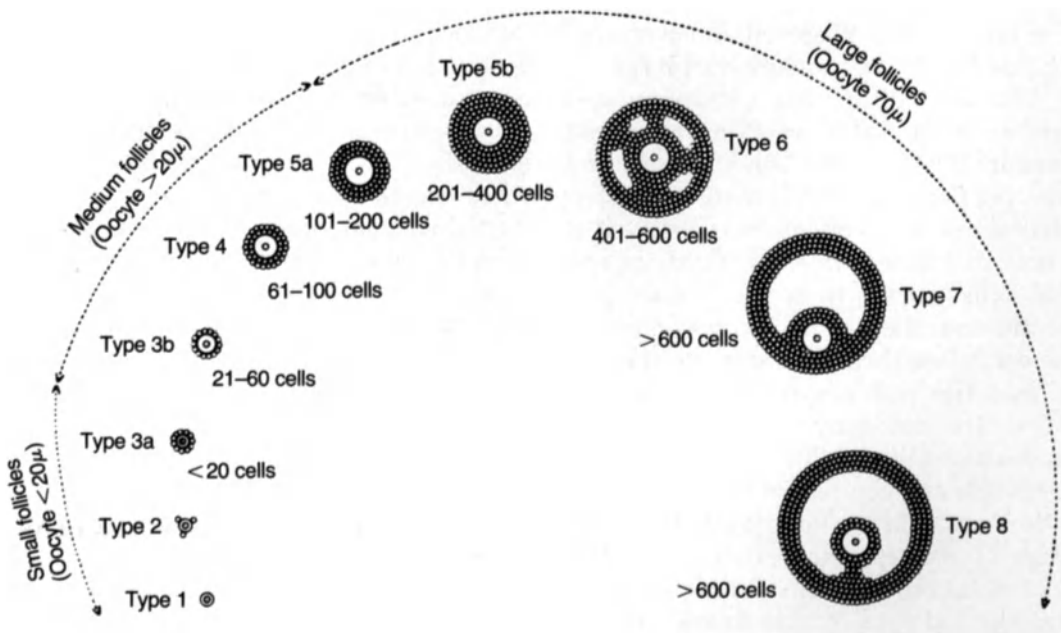

Figure 1.4 Classification of mouse follicles in the mouse ovary. (From Pedersen and Peters, 1968.)

small and contain very few preantral and no antral follicles (Baker and Scrimgeour, 1980). Also, hypophysectomy *in utero* of rhesus monkeys resulted in impaired growth of follicles (Gulyas *et al.*, 1977). These studies suggest that gonadotrophins of the fetal pituitary are involved in follicular growth during fetal life.

(b) Prepuberty

In primates, follicular growth, which has been begun during fetal life, continues throughout childhood (van Wagenen and Simpson, 1965; Peters *et al.*, 1976). All the follicles beginning to grow before puberty are doomed to degeneration. Follicles undergo atresia at any stage of their development, but the percentage of atretic follicles increases as follicular development advances (Vermande-van Eck, 1956; Koering, 1969; Himelstein-Braw *et al.*, 1976).

In other mammalian species follicular growth begins in prepubertal life. In fact, in rodents, the number of follicles starting to grow in the immature is much higher than their number in the mature animal. Follicles reach the antral stage and premature ovulation can be induced by exogenous gonadotrophins.

It seems that follicular development in prepubertal animals is related to the rise in basal levels of gonadotrophins in the blood. Administration of gonadotrophin antiserum to newborn mice did not prevent the initiation of follicular growth (Eshkol and Lunenfeld, 1972; Nakano *et al.*, 1975) but such treatment for 2 weeks resulted in poorly organized granulosa, ill-defined basal membrane and deficient development of the thecal layers and of follicular vasculature. Furthermore, normal follicular development could be restored by substitution with exogenous gonadotrophins. While follicle-stimulating hormone (FSH) restored normal preantral follicle formation, both FSH and luteinizing hormone (LH) were needed for the development of antral follicles (Eshkol *et al.*, 1970; Purandare *et al.*, 1976). These data seem to indicate that gonadotrophins affect the ovary even when the number of gonadotrophin receptors in granulosa cells is very low (Presl *et al.*, 1972, 1974) and before ovarian responsiveness to LH in terms of cAMP formation is established (Lamprecht *et al.*, 1973; Kolena, 1976).

1.6.3 DYNAMICS OF FOLLICULAR GROWTH IN MATURE MAMMALS

The dynamics of follicular growth in rodents has been examined by radiolabelling of granulosa cells (T. Pedersen, 1970; Chiras and Greenwald, 1977; Hage *et al.*, 1978). The kinetic aspects of follicular development in the rat have been discussed recently (Hirshfield and Schmidt, 1987). In the mature female, the growth-initiation rate is constant; in the mouse about 20 follicles begin to grow every day (T. Pedersen, 1972). Follicular growth is continuous and there is no evidence for arrest during growth (Peters and McNatty, 1980). Likewise, the rate of growth of human dominant follicles did not change under hormonal stimulation (Kerin *et al.*, 1981; Jacobs *et al.*, 1985; Templeton *et al.*, 1986; Baird, 1987). In the mouse it takes 19 days (i.e. four to five cycles) for a follicle that begins to grow to reach ovulation (T. Pedersen, 1972). In the sheep (Turnbull *et al.*, 1977; Dufour *et al.*, 1979; Cahill and Mauléon, 1980) and the human (Gougeon, 1982) about 6 months are needed for follicular growth. Most of this period is preantral development. It takes about 24 days for a sheep follicle to reach ovulation from the first appearance of the antrum (Turnbull *et al.*, 1977; Cahill and Mauléon, 1980) and about 60 days in the human (Gougeon, 1982, 1986).

1.6.4 GENERAL FEATURES OF FOLLICULAR GROWTH

The primordial follicle entering the growth phase undergoes two major changes: trans-

formation of the granulosa cells from flattened to cuboidal shape and increase in oocyte volume (Lintern-Moore and Moore, 1979). Further development includes mitotic proliferation of granulosa cells and their transformation into multilayered membrane granulosa. The earliest stages of thecal differentiation and their timing are obscure (Hirshfield, 1988).

In all species examined, follicular growth includes two phases. During the first phase there is a proportional increase in oocyte and follicular volume, while during the second one the oocyte increases only slightly, but the follicle continues marked growth, primarily due to accumulation of follicular fluid (Brambell, 1956). In most mammalian species, the final size of preovulatory follicles is related to body size (see Harrison and Weir, 1977).

The factors involved in initiation of follicular growth are obscure. Recruitment of follicles from the non-growing pool may be in a random fashion or orderly, i.e. oocytes entering the meiotic prophase first are recruited first into the pool of growing follicles and subsequently mature earlier. This latter view is referred to as the 'production line hypothesis' and was put forward by Henderson and Edwards (1968) on the basis of reduced chiasma frequency and parallel increase in chromosomal univalents in mouse oocytes. Data supporting the 'production line hypothesis' were obtained by labelling oocytes with tritiated thymidine *in vitro* and examination of the maturing oocytes after transplanting the ovaries *in vivo* (Polani and Crolla, 1981, 1989). However, the available data are not sufficient to prove any of these hypotheses. The rate of initiation of follicular growth is determined genetically and varies with the age of the female. Thus, it is highest in the young animal and is reduced with the approach of puberty. Once follicular growth is initiated, it continues until the follicle undergoes atresia or ovulates. Only a few of the follicles starting to grow reach ovulation and the vast majority degenerates. Follicular growth is associated with an increase in the proportion of atretic follicles (Pincus and Enzmann, 1937; Vermande-van Eck, 1956; Himelstein-Braw *et al.*, 1976). Various aspects of follicular atresia have been reviewed (Ingram, 1962; Weir and Rowlands, 1977; Byskov, 1978b; Peters and McNatty, 1980; Tsafriri and Braw, 1984; Hirshfield and Schmidt, 1987) and will not be dealt with.

Follicular growth entails a multitude of morphological and physiological changes in all follicular compartments. A brief account of some of these follows.

(a) The formation of zona pellucida

In growing follicles (type 3a, Figure 1.4) a homogeneous material forming pocket-like partitions between the oocyte and adjacent granulosa cells is deposited. These patches coalesce to form a microscopically continuous sheath around the oocyte, the zona pellucida. It is freely permeable to proteins of high molecular weight such as ferritin (Hastings *et al.*, 1972) and immunoglobulin M (Sellens and Jenkinson, 1975).

Scanning electron microscopy reveals that the surface of zona pellucida of the rat (Phillips *et al.*, 1978), the mouse and the hamster (Phillips and Shalgi, 1980) is characterized by numerous fenestrations rendering it of a sponge-like appearance. In transmission electron microscopy the zona appears as a homogeneous layer (Baca and Zamboni, 1967; Kang, 1974; Zamboni, 1974). Staining with ruthenium red (an electron-dense stain with high affinity for acidic mucopolysaccharides) differentiates between the outer and the inner layer of zona pellucida of mouse (Baranska *et al.*, 1975), pig (Hedrick and Fry, 1980) and rat (Wolgemuth and Gavin, 1981) oocytes.

The biology and biochemistry of the zona pellucida were recently reviewed by P.M. Wassarman *et al.* (1985) and Wassarman (1988). Studies in the mouse identified by electrophoresis three glycoproteins, desig-

nated ZP1 (≃ 120 kDa), ZP2 (≃ 120 kDa) and ZP3 (≃ 80 kDa). These account for virtually all the mass of the mouse zona pellucida (Bleil and Wassarman, 1980a). Competitive sperm binding assays demonstrated that ZP3, but not ZP1 and ZP2, possesses sperm receptor activity (Bleil and Wassarman, 1980b, 1983). Likewise, three major glycoproteins were identified in the zona pellucida of pig and rabbit oocytes (Dunbar *et al.*, 1981).

The cellular origin of the zona pellucida has been controversial (see Tsafriri, 1978). Recently, the synthesis of all three zona proteins by mouse denuded oocytes was demonstrated *in vitro* while ovectomized follicles (i.e. follicles from which the oocytes were removed) did not produce any zona proteins (Bleil and Wassarman, 1980c; Greve *et al.*, 1982; Shimzie *et al.*, 1983). By immunocytochemical procedures zona pellucida antigens were localized in cumulus cells of the hamster and the human (Bousquet *et al.*, 1981) and the rabbit (Wolgemuth *et al.*, 1984). It is not clear, however, whether this localization is indicative of cumulus cell synthesis of zona proteins or is a secondary result of endocytosis or phagocytosis of zona pellucida material. In fact, the immunocytochemical staining of cumulus cells was limited to the innermost layers of cumulus cells, appeared appreciably later than in the oocyte or the extracellular matrix and diminished once the oocyte was fully grown (Wolgemuth *et al.*, 1984). These findings are compatible with secondary distribution of zona proteins in cumulus cells, probably associated with formation of cumulus–oocyte channels. Thus, the available data clearly suggest the oocyte as the major source of the proteins of the zona pellucida.

(b) Intercellular communication within the follicle

The ovary, from its early stages of differentiation, is characterized by the close association of cells which allows functional coupling by intercellular communication. Groups of oogonia and oocytes are connected by intercellular bridges and the associated cells undergo developmental changes synchronously. These intercellular bridges disappear during enclosure of the diplotene oocytes by granulosa cells at folliculogenesis.

Throughout follicular development intercellular communication between homologous cells (i.e. granulosa or theca cells) and heterologous cells (i.e. granulosa–cumulus cells and the oocyte) is maintained through gap functions. Gap junctions are specialized intercellular channels allowing ionic coupling and transfer of low molecular weight metabolites between adjacent cells (Hertzberg *et al.*, 1981; Loewenstein, 1981; Macdonald, 1985). The physiological role of gap junctions, with special emphasis on the ovary, was reviewed by Schultz (1985).

The first observed gap junctions in the ovary appear between rete ovarii cells (presumptive progenitors of granulosa cells) in sex cords of 13-day-old mouse embryos (Mitchell and Burghardt, 1986). These gap junctions persist as the cells differentiate into granulosa cells. Furthermore, the number of junctional contacts increased during fetal development between days 15 and 19. The first heterocellular gap junctions were detected between oocytes and presumptive granulosa cells as early as fetal day 17 (Mitchell and Burghardt, 1986).

Gap junctions between conjoining granulosa cells of primordial follicles were observed in mouse embryos (Mitchell and Burghardt, 1986) and neonatal rats (Fletcher, 1979). However, they increase in number and size during follicular development (Albertini and Anderson, 1974) to form an extensive network of communication throughout the membrana granulosa compartment of antral and preovulatory follicles (Bjersing and Cajander, 1974a; Albertini *et al.*, 1975; Amsterdam *et al.*, 1976; Anderson and Albertini, 1976). Gap junctions were observed also in conjoining theca internal cells,

but they do not appear to reach the number and proportion of those of the granulosa cell compartment (Amsterdam *et al.*, 1976; Fletcher, 1979).

Formation of the zona pellucida brings about the separation of the oocyte and follicle cells. Simultaneously, both the oocyte and the surrounding follicle cells facing the oocyte develop cytoplasmic projections. Those of the follicle cells at first are short and bulky, and later on become longer and narrower. In the larger processes, cytoplasmic organelles can be seen frequently. The oolemma develops short microvilli, and the number of oocyte microvilli increases with follicular growth (Anderson and Beams, 1960; Hope, 1965; Baca and Zamboni, 1967; Hertig and Adams, 1967; Albertini and Anderson, 1974; Zamboni, 1974, 1976; Anderson and Albertini, 1976). Simultaneous appearance of micropapillae on the oolemma was described (H. Pedersen and Seidel, 1972; Zamboni, 1974, 1976). These appear as hemispherical, lens-shaped thickenings of oocyte membrane located mainly on the microvilli. It was suggested that the micropapillae enhance the adhesion of the oocyte microvilli to the follicle cell processes (Zamboni, 1974). The dilated, bulbous extremities of follicle cells terminate at the oocyte surface. In primates, very deep penetration of those processes into the oocyte was described (Hope, 1965; Baca and Zamboni, 1967; Zamboni, 1974, 1976).

The junctions between the oocyte and granulosa cells were identified as gap junctions (Amsterdam *et al.*, 1976; Anderson and Albertini, 1976). Unlike the gap junctions between granulosa cells (Merk *et al.*, 1973; Albertini and Anderson, 1974), those between the oocyte and the follicle cells are extremely small in size (Amsterdam *et al.*, 1976; Anderson and Albertini, 1976).

The extensive network of gap junctions between follicular granulosa cells and between the cumulus granulosa cells and the oocytes provides ionic coupling and transfer of regulatory molecules between all cells enclosed by the basement membrane (Schultz, 1985). Thus, in spite of the heterogeny among granulosa cells in terms of morphology (Zoller and Weisz, 1978), gonadotrophin binding (Amsterdam *et al.*, 1975), biosynthetic (Zoller and Weisz, 1979) and mitotic activity (Hirshfield, 1986), the gap junctions allow physiological integration of follicular responses. The suggested role of gap junctions and intercellular communication in oocyte growth and resumption of ovum maturation will be described below.

(c) Formation of theca layer

The formation of follicular theca layer is probably the least studied and understood (Harrison and Weir, 1977; Bjersing, 1978; Peters and McNatty, 1980; Hirshfield, 1988). Presumptive theca cells begin to appear in follicles with a single layer of cuboidal granulosa cells (Fletcher, 1979). The theca cells are first indistinguishable from fibroblasts and become aligned concentrically around the basement membrane. As the follicle grows, the theca layer thickens, the cells differentiate and develop smooth endoplasmic reticulum, large Golgi complexes and lipid droplets (Gillim *et al.*, 1969). Later, at the time of antrum formation, the theca differentiates into theca externa and interna (Brambell, 1928). The endocrine and physiological aspects of theca cells were discussed in Erickson *et al.* (1985) and Zlotkin *et al.* (1986).

(d) Hormonal correlates of follicular growth

The hormonal factors involved in follicular development, changes in follicle cell responsiveness to gonadotrophins and steroidogenic activity have been reviewed (Richards 1978, 1980; diZerega and Hodgen, 1981; Baird, 1983; Goodman and Hodgen, 1983; Baird, 1987; Greenwald and Terranova, 1988).

Initiation of follicle growth is apparently

not dependent upon gonadotrophic stimulation but is related to an as yet unknown signal, probably of ovarian origin. Thus, gonadotrophin deprivation by hypophysectomy or administration of antisera does not prevent growth of preantral follicles, whereas it does prevent the development of antral follicles (Mauléon, 1969; Eshkol *et al.*, 1970; Nakano *et al.*, 1975; Purandare *et al.*, 1976). Nevertheless, in the absence of gonadotrophins, the organization of the membrana granulosa and the theca layer is not normal (Eshkol *et al.*, 1970; Eshkol and Lunenfeld, 1972).

In vitro studies with 1- or 4-day-old rat ovaries seem to indicate that the ovary acquires some degree of steroidogenic activity independently of gonadotrophins (Funkenstein *et al.*, 1980; Funkenstein and Nimrod, 1981). Further development of growing follicles is influenced by the steroids produced in the ovary. In general, oestrogens enhance granulosa cell proliferation in rodents, whereas excessive levels of androgens are inhibitory and promote atresia (Payne and Runser, 1959; Goldenberg *et al.*, 1972). Follicular steroidogenesis was reviewed by Gore-Langton and Armstrong (1988).

Theca and ovarian interstitial cells are the major source of androgens (sheep, Seamark *et al.*, 1974; hamster, Makris and Ryan, 1980; rat, Fortune and Armstrong, 1977; rabbit, Erickson and Ryan, 1976a). The main enzymes necessary for the conversion of pregnenolone to androstenedione, C_{21} steroid 17α-hydroxylase and 17–20-desmolase, are located in microsomes (Ball and Kadis, 1965; Inano *et al.*, 1970). Androstenedione, a biologically weak androgen, is an important precursor of the more potent testosterone.

Oestradiol and oestrone are the major oestrogens synthesized by the follicle. The aromatizing enzymes converting C_{19} steroid (androgen) to C_{18} steroid (oestrogen) are located in the microsomes (Areco and Ryan, 1967). It is generally accepted that theca and granulosa cells act synergistically in oestrogen production. The so-called 'two-cell theory' was first proposed by Falck (1959), on the basis of his *in vivo* observations in the rat, and later modified and documented by *in vitro* studies in the hamster (Makris and Ryan, 1975, 1980), rabbit (Erickson and Ryan, 1975, 1976a), rat (Fortune and Armstrong, 1977) and sheep (Baird, 1977; Moor, 1977). This theory asserts that the theca interna cells, under the influence of LH, produce androgens that are transported to granulosa cells where they are converted to oestrogen by aromatizing enzymes induced by FSH. Thus, granulosa cells are the only source of follicular oestrogen in these species. However, in primate and porcine follicles the theca interna has been shown to provide an additional minor source of oestrogen (human, Channing, 1969; McNatty *et al.*, 1979a; monkey, Channing and Coudert, 1976; Channing, 1980; Marut *et al.*, 1983; Vernon *et al.*, 1983; sow, Haney and Schomberg, 1981; Stoklosowa *et al.*, 1982) and granulosa cells can produce androgens (human, Channing, 1969; McNatty *et al.*, 1979a,b; sow: Stoklosowa *et al.*, 1982), indicating that steroidogenesis is not rigidly compartmentalized in all species and throughout follicular differentiation (reviewed by Ryan, 1979; Hillensjö, 1981). An additional aspect of granulosa–theca cell synergism was suggested to include transfer of C_{21} steroids from the granulosa to the theca (Lischinsky and Armstrong, 1983; Fortune, 1986), thus involving the granulosa cells in thecal androgen synthesis.

It has been shown that theca cells of preantral and antral follicles have receptors for LH and that granulosa cells of most follicles, including small preantral ones, have receptors for FSH. Only in large preovulatory follicles do the granulosa cells also have receptors for LH (Eshkol and Lunenfeld, 1972; Presl *et al.*, 1972; Channing and Kammerman, 1973; Zeleznik *et al.*, 1974; Kammerman and Ross, 1975; Nimrod *et al.*, 1976; Richards *et al.*,

1976). Hence the development of receptors to LH in the granulosa cells seems to have a decisive role in follicle development and will be reviewed briefly.

The use of hypophysectomized immature rats has demonstrated the role of oestrogen and FSH in the proliferation of granulosa cells. Both hormones stimulated granulosa cell divisions and differential and their action was additive, suggesting action through different intracellular mechanism (Richards, 1975; Rao *et al.*, 1977). Further, oestrogen alone did not increase granulosa cell gonadotrophin receptors, but oestrogen priming enhanced FSH stimulation of the development of FSH and LH receptors on granulosa cells (Zeleznik *et al.*, 1974; Louvet and Vaitukaitis, 1976; Richards *et al.*, 1976; Ireland and Richards, 1978). As already mentioned, in addition to its effect on the increase of granulosa cell LH receptors, FSH enhances granulosa cell aromatization of androgen to oestrogen (Armstrong *et al.*, 1979).

LH also plays an important role in early follicular development. For example, human chorionic gonadotrophin (hCG) enhanced the effects of FSH in oestrogen-primed hypophysectomized rats (Ireland and Richards, 1978); in pregnant rats in the presence of elevated basal FSH sustained increases in serum LH (but not FSH) supported the development of preovulatory follicles (Richards, 1980; Bogovich *et al.*, 1981). In intact immature rats, small sustained increases in serum LH (hCG) stimulated the maturation of small antral follicles, and this effect of LH was enhanced by elevated concentrations of serum progesterone (Richards and Bogovich, 1982). This requirement for LH appears to be related to its stimulation of thecal cell differentiation and increase in thecal androgen biosynthesis. Thus, the development of ovulatory follicles is dependent upon the delicately balanced interactions of FSH, LH and steroid hormones. Any inappropriate change in the levels of gonadotrophins or steroids at critical stages of follicular development may lead to follicular atresia. Follicular growth is initiated continuously and, once follicles are recruited from the resting pool, they grow sequentially until they either become atretic or ovulate (Peters *et al.*, 1975). It seems, therefore, that from the continuum of growing follicles only those reaching a critical stage of their development coincident with the appropriate changes in serum gonadotrophin and steroid levels will be rescued and reach ovulation rather than atresia. Perhaps the most clearly demonstrated case of such selection is the rescue of early antral follicles (200–400 μm in diameter) by the pro-oestrous surge of FSH in the rat (Hirshfield and Midgley, 1978a,b). Similarly, rescue of follicles from atresia by PMSG was observed in mice (Peters *et al.*, 1975) and rats (Braw and Tsafriri, 1980). Accordingly, administration of an antiserum to FSH to pro-oestrous hamsters did not affect ovulation on the following night, but delayed ovulation at the next cycle (Sheela Rani and Moudgal, 1977).

Similar factors seem to be involved in the regulation of growth and selection of follicles in other species such as sheep, rhesus monkey and human (Ross and Lipsett, 1978; diZerega and Hodgen, 1981; McNatty, 1981; Hodgen, 1982; Baird, 1983; Goodman and Hodgen, 1983; Webb and Gauld, 1985; Baird, 1987). In sheep and in primates the preovulatory follicle becomes dominant a few days after the regression of the corpus luteum. The dominant follicles are characterized by increased secretion of oestrogen, a higher number of granulosa cells, measurable FSH and reduced androgen levels in follicular fluid (McNatty *et al.*, 1976, 1979c,d; McNatty and Baird, 1978; diZerega and Hodgen, 1981). It seems, therefore, that establishment of follicular dominance in the sheep and primates is due to an increase in the ability of granulosa cells to aromatize androgen precursor synthesized by the theca and thereby secreting large amounts of oestradiol. The dominant follicle, in turn, affects the development of follicles lower in hierarchy

towards atresia by suppressing FSH secretion by oestradiol (diZerega and Hodgen, 1981; Zeleznik, 1981; Zeleznik *et al.*, 1985) and inhibin (Schwartz and Channing, 1977; Channing *et al.*, 1982, 1985; Findlay and Risbridger, 1987) or by direct action of paracrine factor(s) (diZerega *et al.*, 1983a,b; Goodman and Hodgen, 1983; Cahill *et al.*, 1985a,b; Tonetta and diZerega, 1986). Nevertheless, the role of oestrogen in regulating follicular growth locally in primates and the human has been questioned recently. Thus, it has been shown that ovarian follicular development could be induced in a woman with 17α-hydroxylase deficiency in spite of extremely low ovarian concentrations of androgen and oestrogen (Rabinovici *et al.*, 1988). Furthermore, except for the ovarian germinal epithelium, oestrogen receptors were not detected in any other ovarian structure (Hild-Petito *et al.*, 1988; Stouffer *et al.*, 1993).

In the sheep, ovulation occurs within 3 days after natural or induced luteal regression, while in the rhesus monkey and the human the equivalent period is 14–19 days (Goodman *et al.*, 1977; Baird and McNeilly, 1981; Nilsson *et al.*, 1982; Goodman and Hodgen, 1983; Baird *et al.*, 1984). This difference may be attributed to the fact that in the sheep development of antral follicles (4–6 mm in diameter) continues throughout the luteal phase (Turnbull *et al.*, 1977; Cahill *et al.*, 1979). By contrast, in the human luteal phase, all follicles with a diameter above 4–6 mm are atretic (McNatty *et al.*, 1983). It was suggested that this difference in the pattern of follicular development is related to the pattern of steroid secretion by the corpora lutea (Baird *et al.*, 1975). Thus, in the ewe, the corpus luteum secretes only progesterone, whereas in the primates the corpus luteum secretes both progesterone and oestrogen, which suppresses release of gonadotrophins and hence further follicular development. Details on the hypothalamic–hypophyseal gonadal axis during oestrous and menstrual cycles can be found in chapters by Rowlands and Weir, Spies and Chappel and Yen and Lein in Volume 1 of this series.

Luteal regression in the sheep is followed by a rise in serum levels of LH and oestradiol, but not FSH (Baird *et al.*, 1981; Baird, 1983). This is accompanied by a marked decline in the percentage of healthy antral follicles, and by 36 h after luteolysis, except for the preovulatory follicle(s) all the antral follicles are atretic (McNatty *et al.*, 1982). It seems, therefore, that in the sheep the selection of the ovulatory follicle occurs early in the follicular phase. Both LH and FSH seem to be present during the luteal phase in minimal concentrations required for development of large antral follicles. FSH may be considered as having a permissive role and the rise in LH secretion seems to play an essential role in follicle selection in the sheep (Baird *et al.*, 1981).

Follicular rescue may be achieved during the luteal phase in the rhesus monkey by administration of exogenous gonadotrophin (diZerega and Hodgen, 1980). On the basis of experience with gonadotrophin induction of ovulation in hypogonadotrophic women, Brown (1978) suggested that follicles are selected by threshold levels of FSH, above which final stages of follicular development can proceed to ovulation. The difference between a threshold and subminimal dose may be as small as 20%. According to this concept, the modest rise in FSH concentration in the early follicular phase is sufficient to sustain follicular development beyond 4 mm size in spite of the later decrease in FSH levels. This hypothesis was recently supported in the macaque monkey (Zeleznik and Kubik, 1986). Endogenous gonadotrophins were blocked in these monkeys by a gonadotrophin-releasing hormone (GnRH) antagonist and increased amounts of FSH were infused until the threshold of follicular development, as monitored by serum oestradiol, was reached. Once follicle selection had occurred, reduction of FSH levels was accompanied by progressive rise in oestradiol

levels and preovulatory follicle growth. Thus, the selected follicle seems to continue its development in spite of falling FSH levels, insufficient to support the growth of smaller follicles. Following enucleation of corpora lutea in the human there was a fall in plasma levels of progesterone and oestradiol (Nilsson *et al.*, 1982; Baird *et al.*, 1984). The rise in gonadotrophin levels was delayed by 24 h following surgery and it preceded the rise in plasma oestradiol levels (Baird *et al.*, 1984). Luteectomy in the rhesus monkey resulted in a small rise in FSH concentrations, which was considered by the authors to be insignificant (Goodman *et al.*, 1979). It is possible that this is a result of infrequent blood sampling. Furthermore, the finding that only a small 20–30% rise in FSH for a limited period is required in the human (Baird *et al.*, 1984) and the macaque (Zeleznik and Kubik, 1986) for follicular rescue supports the notion that a rise in FSH is involved in follicle selection in primates.

1.6.5 OOCYTE GROWTH AND DEVELOPMENT OF MEIOTIC COMPETENCE

As already discussed, oocyte and follicular growth are interrelated. The increased rate of follicular growth initiation during neonatal development in rodents allows detailed studies on oocyte growth and biosynthetic activity. Most of these studies were performed using mouse oocytes (Bachvarova, 1985; Siracusa *et al.*, 1985; Van Blerkom, 1985; Schultz, 1986). Here we shall review some of the salient findings of these studies and relate them to the ability of the oocyte to resume the meiotic process.

The oocyte, during its growth, increases in size from 18–20 μm (Figure 1.5).

This is accompanied by marked changes in oocyte ultrastructure. Thus, early stages of oocyte growth are characterized by few and short microvilli, extensive network of smooth endoplasmic reticulum, elongated and dumbbell-shaped mitochondria with laminar mitochondrial crests which are associated with the endoplasmic reticulum. The ribosomes are in clusters, the Golgi apparatus consists of flattened stacks of parallel lamellae, and there is a rapidly enlarging fibrillogranular nucleolus. During growth, the number of microvilli increases and they become longer. The smooth endoplasmic reticulum becomes vesicular and less abundant. The number and size of mitochondria is reduced, they assume round or oval shape and their cristae are columnar and later on arched or arranged concentrically. The number of free ribosomes is reduced and ordered lattices appear and their number increases. The Golgi apparatus progressively becomes more vacuolated and granular, often associated with lipid droplets, the number of multivesicular bodies increases and also the nucleolus increases in its size and density (Zamboni, 1974; P.M. Wassarman and Josefowicz, 1978).

(a) Oocyte growth and intercellular communication

The junctional communication between cumulus–granulosa cells plays an important nutritional role in the dictyate oocyte (Schultz, 1985). Thus the cumulus–granulosa cells provide the major route of entry into the oocyte for most metabolites, such as energy sources, and precursors of RNA, protein and phospholipid biosynthesis (Cross and Brinster, 1974; P.M. Wassarman and Letourneau, 1976; Heller and Schultz, 1980; Moor *et al.*, 1980a; Heller *et al.*, 1981). This has been established by uptake and pulse chase experiments comparing intact cumulus cell–oocyte complexes and denuded oocytes. Treatments known to disrupt gap junctions in other cell types result in reversible breakdown of communication between cumulus cells and the oocyte (Heller *et al.*, 1981). Furthermore, the extent of communication between cumulus and the oocyte is directly

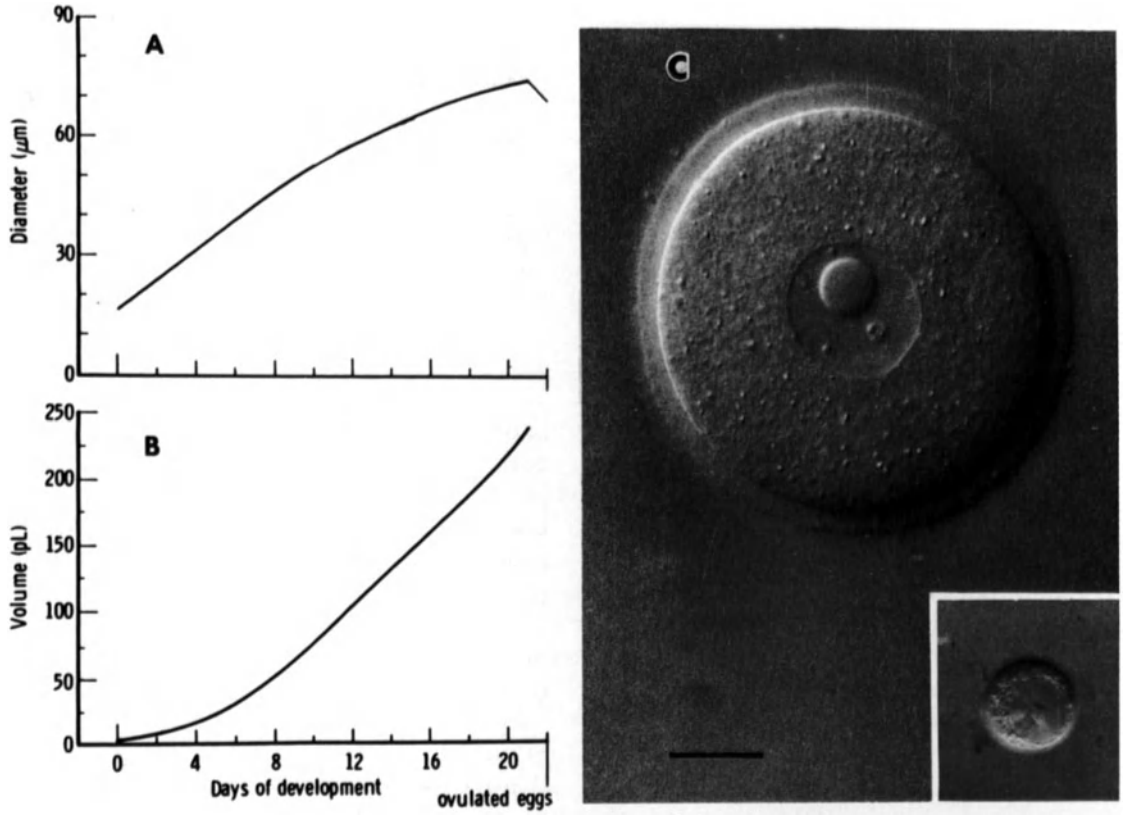

Figure 1.5 Growth of mouse oocytes. (A) The average diameter of freshly isolated oocytes from mice of increasing age. (B) Increase in oocyte volume with time, calculated from (A). (From Bachvarova, 1985.) (C) A fully grown and (inset) a quiescent mouse oocyte at the same magnification. The quiescent oocyte was isolated from 3-day-old mouse and the fully grown from an adult mouse. Differential interference contrast microscopy; bar=20 μm. (From Siracusa *et al.*, 1985.)

related to the number of attached cumulus cells (Brower and Schultz, 1982).

In explanted follicles, obtained by enzymatic digestion of ovaries, oocyte growth continues at a rate equal to that *in vivo*, in spite of the fact that many follicular cells migrate away and form a monolayer (Eppig, 1977, 1979). By contrast, denuded oocytes, free of attached cumulus cells, do not grow *in vitro*. Nevertheless, denuded oocytes cultured either directly on a monolayer of follicular cells or indirectly on ovarian cells covered by agar also grow *in vitro*, albeit at a considerably slower rate (Bachvarova *et al.*, 1980). Therefore, the presence of follicle cells is a prerequisite for oocyte growth, which can proceed at a lower rate even in the absence of junctional communication. The rate of oocyte growth is directly related to the extent of cumulus–oocyte communication (Brower and Schultz, 1982), and re-establishment of intercellular communication restores oocyte growth (Herlands and Schultz, 1984).

(b) Biosynthetic activity of growing oocytes

RNA synthesis

Early radioautographic studies demonstrated nuclear and nucleolar synthesis of RNA in

growing oocytes of the rat, mouse and monkey (Oakberg, 1968; Baker *et al.*, 1969). These were complemented later by assay of RNA polymerase activity in ovarian sections (Moore, 1978; Moore and Lintern-Moore, 1978) and *in vitro* incorporation studies into various RNA classes (Bachvarova, 1981; Brower *et al.*, 1981; Kaplan *et al.*, 1982; reviewed by Bachvarova, 1985; Schultz, 1986). The kinetics of RNA accumulation is biphasic: essentially all oocyte RNA is accumulated by the time they reach two-thirds of their final volume (Sternlicht and Schultz, 1981; Kaplan *et al.*, 1982).

The bulk of RNA synthesized by growing mouse oocytes is very stable, and about 80% of the radioactive RNA precursor detected 2 days after administration was retained in ovulated oocytes 10–20 days later (Bachvarova, 1974; Jahn *et al.*, 1976). Likewise, poly(A^-) RNA, predominantly rRNA and tRNA, has been estimated half-life of about 28 days and poly(A^+)RNA of about 10–14 days (Bachvarova, 1981; Brower *et al.*, 1981). Analysis of the distribution of newly synthesized cytoplasmic RNA revealed that about one-quarter of the newly synthesized mRNA and one-third of other rRNA appear in polysomes, thus suggesting that the bulk of ribosomal and messenger RNA is accumulated for later use (De Leon *et al.*, 1983). At the end of its growth period the mouse oocyte contains between 0.4 and 0.6 ng of total RNA (Olds *et al.*, 1973; Bachvarova, 1974; Sternlicht and Schultz, 1981; Kaplan *et al.*, 1982), i.e. about 200 times the amount of typical somatic cells. Of this, 10–15% is mRNA, 20–25% tRNA and 60–65% ribosomal RNA (P. Wassarman, 1983; Bachvarova, 1985). The transcription of several genes, the proto-oncogenes c-*mos* and c-*kit*, a transcription factor *oct-3*, two enzymes, t-PA and LDH (lactate dehydrogenase) and a sperm receptor *mZP3* during oogenesis has been recently reviewed (Eppig, 1991; P.M. Wassarman and Kinloch, 1992).

During oocyte growth in rodents, conspicuous fibrillar or lamellar structures accumulate in the cytoplasm (Weakley, 1967, 1968; Zamboni, 1970; Burkholder *et al.*, 1971; P.M. Wassarman and Josefowicz, 1978). Whether these structures, assuming lattice-like appearance in mouse oocytes, represent inactive ribosomes (Burkholder *et al.*, 1971) or yolk bodies (Szöllösi, 1972) remains to be determined (see Piko and Clegg, 1982; Bachvarova, 1985; Schultz, 1986).

Protein synthesis

During its growth phase the oocyte undergoes a 100-fold increase in its volume. Total protein content of the oocyte increases linearly with the increase in oocyte volume reaching 28–30 ng in the fully grown oocyte (Brinster, 1967; Schultz and Wassarman, 1977a). The absolute rate of protein synthesis during oocyte growth increases from 1.1 pg/h in non-growing oocytes to 45–48 pg/h in the fully grown oocyte (Canipari *et al.*, 1979; Shultz *et al.*, 1979a). Calculations based on this measured absolute rate of protein synthesis in denuded oocytes led Schultz *et al.* (1979b) to conclude that the oocyte could synthesize only half of its protein. However, these measurements may underestimate the rate of protein synthesis (Canipari *et al.*, 1979) and, furthermore, uptake of animo acids and protein synthesis in denuded oocytes is reduced as compared with follicle-enclosed oocytes (Crosby *et al.*, 1981; Salustri and Martinozzi, 1983). Bachvarova (1985), therefore proposed that the growing oocyte could synthesize all of its protein. In view of possible experimental errors, it is very difficult to conclude on the basis of these calculations whether part of oocyte proteins is produced elsewhere. In any case, uptake of serum proteins by the oocyte has been obtained *in vivo* (Glass, 1971) and evidence for active pinocytosis has been observed by electron microscopy (Zamboni, 1974).

The available information on synthesis of specific proteins during oocyte growth is lim-

ited to a few abundant proteins or enzymes that can be easily assayed (see Schultz, 1986).

Enzyme activity of both glucose-6-phosphate dehydrogenase (G6PD) and lactate dehydrogenase (LDH) increases during mouse oocyte growth. Only the specific activity of LDH increases with growth while that of G6PD remains essentially constant during growth (Mangia and Epstein, 1975; Mangia *et al.*, 1976; Casico and Wassarman, 1982). Likewise, mouse oocytes contain the brain isozyme of creatine kinase (up to 1.4% of total protein) and its activity increases during oocyte growth (Iyengar *et al.*, 1983). The activity of these enzymes may be related to oocyte metabolism. Thus, G6PD is probably needed for generation of NADPH, LDH in energy metabolism and creatine kinase for the maintenance of a high ATP/ADP ratio which is essential for biosynthetic activity of the oocyte during the period it cannot utilize glucose as an energy source (Biggers *et al.*, 1967; Donahue and Stern, 1968; Biggers, 1971, 1972).

The synthesis of tubulin (Schultz *et al.*, 1979a,b), actin (Kaplan *et al.*, 1982), histone H4 (P.M. Wassarman and Mrozak, 1981), ribosomal proteins (La Marca and Wassarman, 1979) and mitochondrial proteins (Mangia and Canipari, 1977; Cascio and Wassarman, 1981) has been examined in growing mouse oocytes. The mechanisms regulating the translation of c-*mos*, c-*kit*, *mZP3*, t-PA and LDH during mouse egg development were reviewed recently (P.M. Wassarman and Kinloch, 1992).

(c) The development of meiotic competence

The pioneering observation of Pincus and Enzmann (1935) that rabbit oocytes removed from their follicles resume the meiotic process *in vitro* has been confirmed and was extended to many other mammalian species (Donahue, 1972; Schuetz, 1974; Tsafriri, 1978). However, more recent studies have revealed that the ability of such explanted oocytes to undergo maturation *in vitro* (i.e. meiotic competence) is attained only at an advanced stage of follicle and oocyte growth; oocytes collected from immature mice prior to day 15 post partum failed to resume maturation when cultured. On the other hand, oocytes harvested from young mice 15 days post partum and older matured *in vitro* and the incidence of oocytes achieving maturation increased with the age of the animal at explantation (Szybek, 1972; Sorensen and Wassarman, 1976). Meiotic competence is acquired between days 15 and 21 of age in mice (Szybek, 1972; Sorensen and Wassarman, 1976), at 23 days in hamsters (Iwamatsu and Yanagimachi, 1975) and between days 20 and 26 in rats (Bar-Ami and Tsafriri, 1981). In mouse littermates the mean diameter of competent oocytes was larger than that of incompetent oocytes (Sorensen and Wassarman, 1976). In the pool of oocytes explanted from rats between 15 and 31 days post partum there was a high correlation ($r = 0.98$) between the ability of oocytes to resume meiosis in culture and oocyte diameter (Bar-Ami and Tsafriri, 1981). However, in the rat the oocyte diameter is probably not the only determinant of meiotic competence, as the average diameter of the few competent oocytes on day 20 (61.8 ± 1.2 μm) was below the average diameter of incompetent oocytes on day 26 (76.5 ± 0.8 μm; $P < 0.001$). Likewise, dissociation between acquisition of meiotic competence and oocyte growth was observed in mouse oocytes cultured *in vitro*. Incompetent denuded oocytes attained competence when cultured with fibroblast monolayers, although growth was arrested (Canipari *et al.*, 1984).

It was suggested that meiotic competence is reached at the time of antrum formation (Brambell, 1928; Pincus and Enzmann, 1937). Erickson and Sorensen (1974) demonstrated in mice that only oocytes explanted from antral, but not from preantral, follicles of adult animals resumed meiosis in culture. In histological sections of ovaries obtained from

20-, 24- and 26-day-old rats, there was an increase in the percentage of antral follicles from 14.3 to 38.8%, *pari passu* with the acquisition of meiotic competence (Bar-Ami and Tsafriri, 1981). In contrast to rodents, in the pig, only 15% of the oocytes explanted from small antral follicles (approximately 1–2 mm in diameter) matured in culture, whereas 80% of oocytes explanted from large follicles (6–12 mm) were meiotically competent (Tsafriri and Channing, 1975a). In a more detailed study, in which follicles were first dissected and measured accurately, it was found that more than 80% of oocytes from follicles 0.3–0.7 mm in diameter remained immature, while 66, 94.3 and 100% of oocytes from follicles 0.8–1.6, 1.7–2.2 and 3.5 mm in diameter, respectively, resumed maturation within 24 h of culture (Motlik *et al.*, 1984a).

Studies with oocytes of various species, such as those from immature rabbits (Thibault, 1972), mice (Sorensen and Wassarman, 1976), rats (Bar-Ami and Tsafriri, 1981) and small antral follicles of the pig (Tsafriri and Channing, 1975a; Motlik *et al.*, 1984a), showed high incidence of incomplete oocyte maturation (mainly arrest at metaphase I). In human oocytes, explanted from large follicles (9–15 mm), a higher proportion of oocytes resuming maturation *in vitro* extruded the polar body, as compared with those from smaller follicles (< 9 mm) (Tsuji *et al.*, 1985). Likewise, all oocytes resuming meiosis in culture with fibroblast monolayer were arrested at metaphase I of meiosis (Canipari *et al.*, 1984). Apparently, the capability of oocytes to mature is acquired gradually; the ability to resume meiosis and to undergo germinal vesicle breakdown (GVB) is attained earlier than the ability to reach metaphase II.

(d) Cytoplasmic factors and meiotic competence

It was demonstrated that fusion of incompetent mouse oocytes with oocytes that have resumed meiosis results in meiotic changes in the incompetent nucleus (Balakier, 1978; Tarowski and Balakier, 1980). This cytoplasmic activity is ascribed to a maturation promoting factor (MPF), involved in G_2 to M transition in both mitotic and meiotic cells (Masui and Clarke, 1979; Gerhart *et al.*, 1984). Currently, a more appropriate name for the MPF abbreviation is used: M-phase promoting factor (Gerhart *et al.*, 1984; H.H. Hashimoto and Kishimoto, 1988). MPF activity in cytoplasm of mature mouse oocytes was confirmed by injection of cytoplasm into *Asterina pectinifera* (Kishimito *et al.*, 1984) or *Xenopus laevis* (Sorensen *et al.*, 1985) oocytes. In both cases mouse cytoplasm induced resumption of meiosis in the absence of the hormonal stimulator of meiosis, progesterone in *Xenopus* and 1-methyladenine in *Asterina*.

Recently, evidence for the presence of an ooplasmic meiosis-inhibiting activity (MIA) has been obtained. Thus, fusion of growing incompetent oocytes with competent ones prevented the resumption of meiosis by the competent nucleus. Fusion of incompetent mouse or porcine oocytes prevented maturation of oocytes of the same species, and growing porcine oocytes prevented the maturation of mouse competent oocytes (Fulka, 1985; Fulka *et al.*, 1985). When the competent porcine oocytes were preincubated for 12–14 h, meiosis was resumed by nuclei after fusion (Fulka *et al.*, 1985). The precise molecular mechanisms involved in acquisition of meiotic competence remain to be elucidated. The recent purification of MPF (Gautier *et al.*, 1988; Lohka *et al.*, 1988), the demonstration of its protein kinase activity and the role of phosphorylation/dephosphorylation cascade in the regulation of mitotic cell cycle and of meiosis (Gautier *et al.*, 1989; Murray and Kirschner, 1989; Murray *et al.*, 1989) offer plausible mechanisms which may be involved in the acquisition of meiotic competence in mammalian oocytes. Indeed, microinjection of an inhibitor of cAMP-dependent protein kinase (PKI) failed to induce GVB in incompetent oocytes, but did so

readily in fully grown ones (Bornslaeger *et al.*, 1988).

(e) Does the development of meiotic competence depend on hormonal stimuli?

The development of follicular antrum appears to be dependent upon gonadotrophic stimulation (Richards, 1980). The correlation between antrum formation and acquisition of meiotic competence in rodents may suggest that the latter is also dependent upon gonadotrophins. Hypophysectomy of immature rats, prior to the acquisition of meiotic competence, was performed in order to test this hypothesis (Bar-Ami and Tsafriri, 1981). Hypophysectomy of rats on day 20 of age affected only slightly the ability of oocytes to resume maturation when explanted on day 26 (the percentage of oocytes undergoing GVB was reduced by hypophysectomy by 9.9 ± 5.8%). On the other hand, hypophysectomy on day 15 of life reduced the percentage of competent oocytes on day 26 by 58.1 ± 4.9% and their absolute number (3.9 ± 0.7 per rat in hypophysectomized rats as compared with 46.3 ± 3.9 competent oocytes per rat in intact rats of the same age) (Figure 1.6; Bar-Ami and Tsafriri, 1981).

Administration of PMSG (3 i.u.) on days 25, 27 and 29 of age resulted in a gradual increase in the percentage of competent oocytes during the 6-day treatment, from 41.9 ± 1.5 on day 27 to 94.5 ±1.5 on day 31. PMSG also increased the number of competent oocytes (46.8 ± 0.5 oocytes per rat as compared with 3.9 ± 0.7 per rat in hypophysectomized rats which were not treated with PMSG). The action of PMSG on meiotic competence appears to be due to its FSH-like activity: only FSH (NIAMD-rat-FSH) but not LH (NIAMD, purified-ovine-LH, Batch 21), was able to elicit this response when injected on days 25–28 to rats hypophysectomized on day 15 (Bar-Ami *et al.*, 1983).

The action of FSH (or PMSG) to increase the number and the percentage of competent oocytes is, at least partly, mediated by ovarian oestrogen production. Inhibitors of steroidogenesis such as aminoglutethimide (of cholesterol 20α-hydroxylase; Kahnt and Neher, 1966) and of aromatase (Thompson and Siiteri, 1974), 17β-formamidoandrost-4-en-3-one (of 17 – 20 lyase; Arth *et al.*, 1971) or of aromatase such as 1,4,6-androstatriene-3,17-dione (Schwarzel *et al.*, 1973) or 4-hydroxy-androstene-3,17-dione (Brodie *et al.*, 1977) prevented the effect of FSH on the

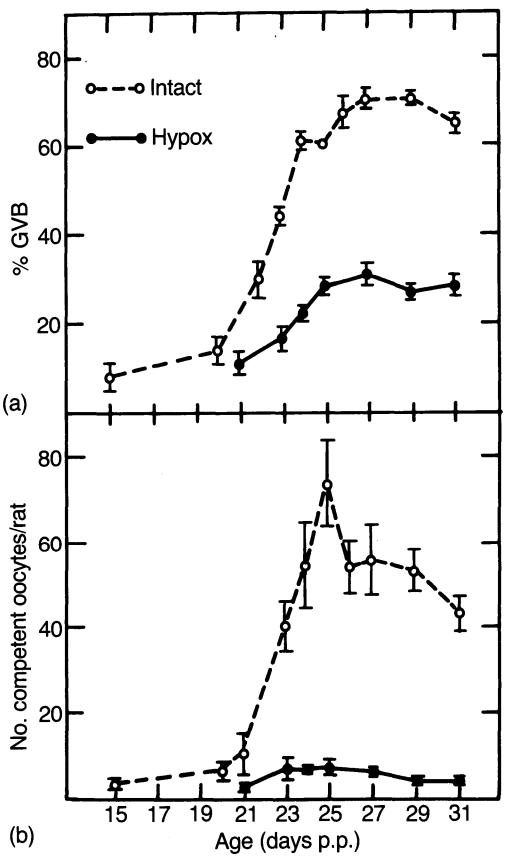

Figure 1.6 The acquisition of meiotic competence with age in intact and rats hypophysectomized (Hypox) on day 15 post partum (p.p.). Competence was tested by culture of isolated ova for 6 h. Mean and SEM are indicated. (Data from Bar-Ami and Tsafriri, 1981.)

acquisition of meiotic competence. But when oestradiol was administered together with these inhibitors of steroidogenesis, the effect of FSH on the development of meiotic competence was not disturbed (Bar-Ami *et al.*, 1983). The hormonal treatments (PMSG or oestradiol) induced meiotic competence provided that the treatment started after day 20 of age. Hormonal treatments at an earlier age were not effective in inducing meiotic competence (Bar-Ami and Tsafriri, 1986). Hypophysectomy of rats on day 30 (Erickson and Ryan, 1976b) or of mice on days 23–27 (Smith and Tenney, 1979) did not cause any consistent change in the percentage of oocytes undergoing GVB in culture, but it did reduce the number of oocytes arrested before reaching the second metaphase and giving off the polar body. Furthermore, the effect of hypophysectomy on the completion of meiosis in mouse oocytes was partially overcome by administration of PMSG or oestrogen. It appears then that hypophyseal gonadotrophins are involved also in the development of the capacity to complete the first meiotic division. Collectively, these observations support the notion that the development of meiotic competence is dependent upon hormonal stimulation.

By contrast, other observations support another view, that development of meiotic competence is a programmed event independent of hormonal stimulation. Thus, even in hypophysectomized rats there is no absolute depletion of competent oocytes (Bar-Ami and Tsafriri, 1981, 1986). Furthermore, a small proportion of incompetent oocytes cultured *in vitro* within their cumulus cells (Eppig, 1977), or on monolayers of follicle cells (Bachvarova *et al.*, 1980) or even fibroblasts (Canipari *et al.*, 1984), attained meiotic competence. Finally, grown oocytes (diameter ± 40 μm) from immature hypogonadal (hpg) mice that are deficient in hypothalamic gonadotrophin-releasing hormone and have thread-like uteri and very small ovaries (Cattanach *et al.*, 1977) resume meiosis to the same extent as their littermate controls (Schroeder and Eppig, 1989). It should be noted that in all cases of apparently autonomous acquisition of meiotic competence only a small number of oocytes became competent. Treatment of hpg mice with gonadotrophin promotes the development of meiotic competence by virtually all the oocytes (Schroeder and Eppig, 1989). Therefore, the normal extent of meiotic competence appears to require gonadotrophic support.

In conclusion, it seems that the development of meiotic competence includes both programmed events which cannot be triggered precociously by hormonal treatments (Bar-Ami and Tsafriri, 1986) and changes depending on endocrine stimulation. The latter are probably of a permissive nature and are required for the full extent of normal development of meiotic competence. As there is no conclusive evidence for gonadotrophin or oestrogen receptors in mammalian oocytes, the action of these hormones on meiotic competence is probably exerted indirectly through their action on the somatic compartment of the follicle.

1.7 OVULATORY CHANGES

The ovulatory response is a composite one, encompassing a multitude of biochemical changes, primarily in the mature follicle(s), but also in other ovarian compartments. In biological terms, at least three distinct components of ovulation can be discerned: the reinitiation of the meiotic process in the oocyte; a shift from follicular oestrogen to progesterone production with early luteinization; and finally, the rupture of follicular wall with delivery of a fertilizable oocyte. As ovarian steroidogenesis is the subject within a forthcoming volume in this series we shall follow here the life history of the mammalian ovum and discuss the resumption of meiosis and the release of the mature ovum with the rupture of the follicle.

1.7.1 RESUMPTION OF OVUM MATURATION

As already described (section 1.4), the meiotic process is arrested in mammals at the diplotene stage. Meiosis is reinitiated in healthy follicles only a few hours prior to follicular rupture at ovulation. Reinitiation of meiosis includes (McGaughey, 1983): (i) chromatin condensation in the germinal vesicle; (ii) disintegration of the nuclear membrane, germinal vesicle breakdown (GVB); (iii) formation of the first meiotic spindle; (iv) completion of the first meiotic division and abstriction of the first polar body; and (v) formation of the second meiotic spindle (Figures 1.1 and 1.7).

In most mammals, at follicular rupture, a secondary oocyte arrested at the metaphase of the second meiotic division is released. We shall refer to all these changes as **oocyte maturation**. Since GVB is the first prominent change readily observed in living oocytes of many species by interference or phase-contrast microscopy, this is taken as the criterion for resumption of the meiotic process (Figure 1.7). Therefore, the use of the terms **resumption of oocyte maturation** or **of meiosis** is preferable when only GVB was observed. While the presence of intact germinal vesicle is a valid criterion for confirming that the meiotic process is still arrested, only the abstriction of the first polar body and the presence of second meiotic spindle confirm the completion of oocyte maturation. Nevertheless, these nuclear changes do not necessarily assure physiological maturation of the ovum and its ability for normal fertilization and embryonic development (Moor *et al.*, 1980b; Osborn *et al.*, 1986). Nuclear maturation is accompanied by changes in the structure and organization of the cytoplasm (Zamboni, 1970; Van Blerkom and Motta, 1979; Van Blerkom and Runner, 1984) and the plasma membrane (Johnson *et al.*, 1975; Nicosia *et al.*, 1977; Maro *et al.*, 1986). Changes at the molecular level will be addressed in later sections.

Using nocodazole, a potent inhibitor of microtubule polymerization and transfer of bivalent chromosomes, Van Blerkom and Bell (1986) demonstrated the role of chromosomes for cytoplasmic and plasma membrane differentiation in maturing mouse oocytes. Furthermore, the capacity of the cytoplasm and plasma membrane to differentiate in response to the presence of a chromosome is acquired before GVB.

(a) Gonadotrophins and resumption of oocyte maturation *in vivo*

Oocyte maturation, like other ovulatory processes, is triggered by pituitary gonadotrophins. Thus, administration of hCG induces meiosis in the mouse (Edwards and Gates, 1959) and the pig (Hunter and Polge, 1966). Blocking the preovulatory surge of gonadotrophins in the rat by Nembutal or similar drugs also prevents the resumption of meiosis (Ayalon *et al.*, 1972). Likewise, hypophysectomy (Vermeiden and Zeilmaker, 1974) or administration of an antiserum to the β-subunit of LH (Tsafriri *et al.*, 1976d) blocks oocyte maturation. Conversely, administration of exogenous LH to such Nembutal-treated rats results in GVB within 2.5–3.5 h (Vermeiden and Zeilmaker, 1974; Magnusson *et al.*, 1977).

Both LH and FSH preparations are capable of inducing ovulation (Harrington *et al.*, 1970; Nuti *et al.*, 1974; Schwartz *et al.*, 1975). Furthermore, the preovulatory surge of gonadotrophins includes FSH as well as LH. Therefore, it was of interest to test whether the FSH released during the surge can trigger ovulation by itself. Indeed, immunopurified (Tsafriri *et al.*, 1976a) or human recombinant FSH (Galway *et al.*, 1990) induced the ovulatory response. Nevertheless, administration of an antiserum to β-LH to rats on the afternoon of pro-oestrus prevented ovum maturation and ovulation (Tsafriri *et al.*, 1976a). Hence, it was concluded that in the rat the amount of FSH secreted is not sufficient to

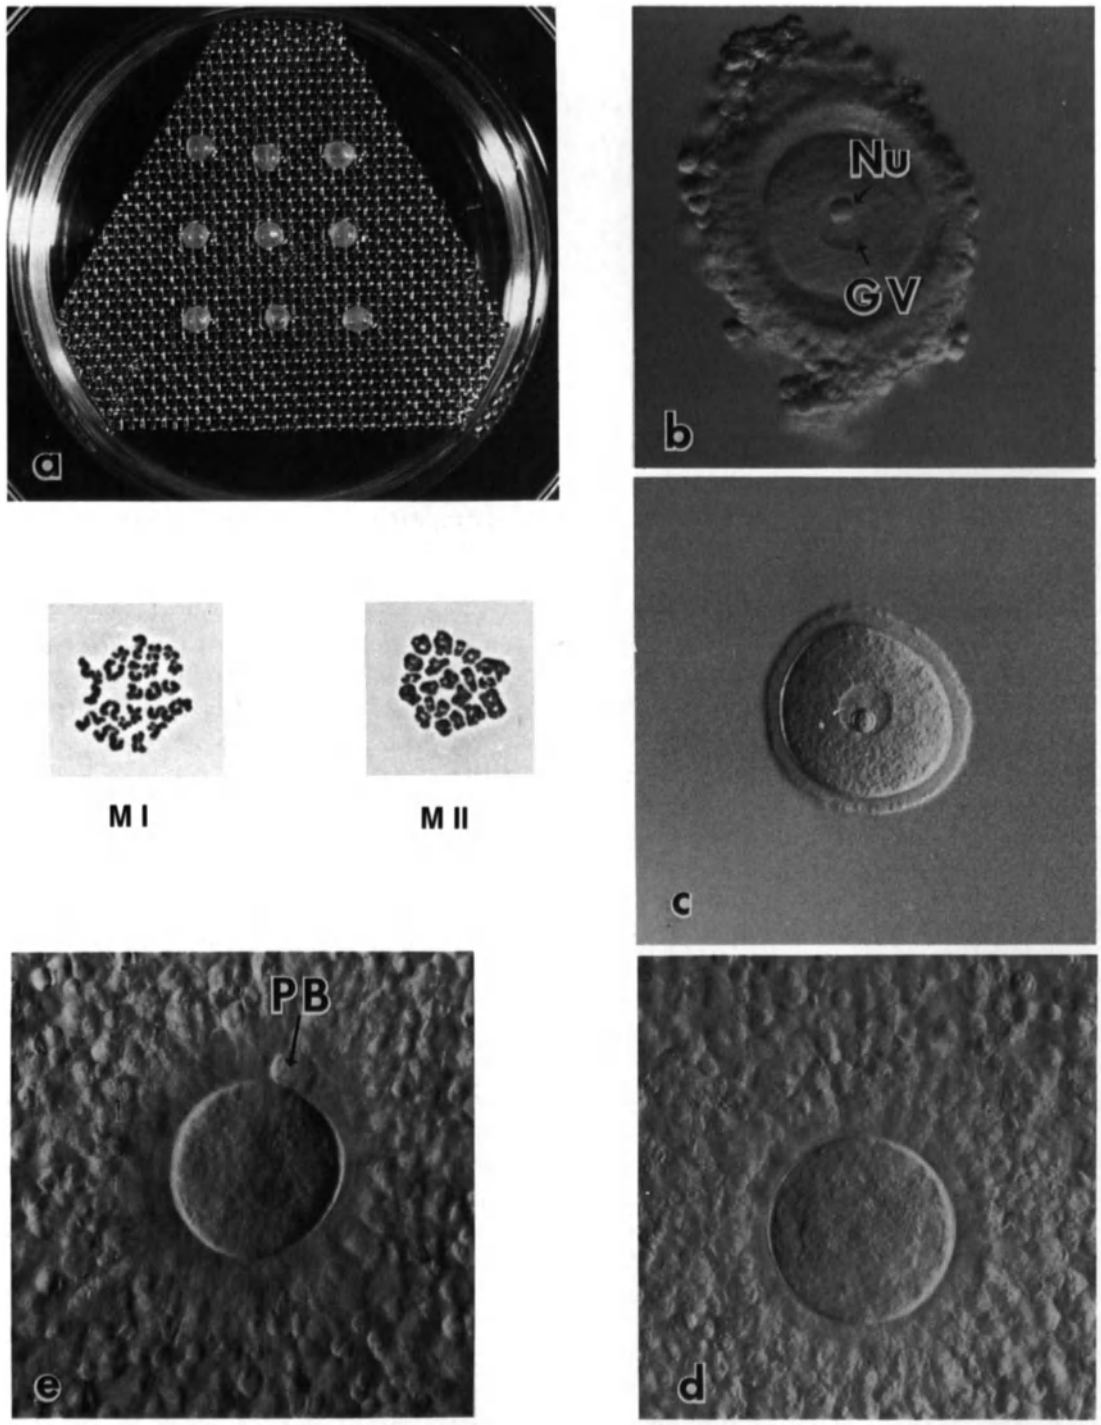

Figure 1.7 Oocyte maturation in the rat. (a) Explanted preovulatory follicles (b–e) Oocytes viewed with Nomarski interference optics; isolated oocyte with its intact cumulus mass (b). GV, germinal vesicle; Nu, nucleolus. (c) Denuded oocyte. (d) GVBD; M I (inset), bivalents in metaphase I. (e) Secondary oocyte. PB, polar body; M II (inset), chromosomes (dyads) seen at metaphase II. Chromosomes were prepared according to the method of Tarkowski (1966) and photographed under phase contrast. (From Tsafriri, 1985.)

induce ovulation and LH is the physiological trigger of ovulatory changes. The action of FSH on ovulation in these experiments must be regarded as merely a pharmacological effect.

In naturally ovulating mice, rats and pigs, oocyte maturation and follicular rupture at ovulation are separated only rarely, and only few immature oocytes can be detected in the fallopian tube. Hormonal stimulation of ovulation increases the number of immature ova released (Donahue, 1972). Precocious treatment of pigs by hCG resulted in ovulation of only immature ova (Hunter *et al.*, 1976).

(b) Oocyte maturation *in vitro*

Maturation of oocytes *in vivo* does not allow detailed examination of the mechanisms involved in the control of meiosis. Therefore, several *in vitro* model systems have been employed. These allow experimentation directed at identifying both the mechanisms involved in the maintenance of meiotic arrest in competent oocytes and those involved in the resumption of meiosis as a result of gonadotrophic stimulation. The simplest *in vitro* system employed for studying oocyte maturation was first established by Pincus and Enzmann (1935), showing that rabbit oocytes liberated from their follicles undergo maturation *in vitro* spontaneously without requiring hormonal stimulation. This phenomenon has been confirmed in all mammalian species examined (reviewed by Donahue, 1972). Isolated oocytes, denuded from their enclosing cumulus oophorus cells or within their cumulus complex, are widely employed for studying some physiological aspects of oocyte maturation (Figure 1.7b and c). This model, however, does not represent the physiological events, since oocyte maturation *in vivo* is dependent upon the release of hypophyseal gonadotrophin. It is possible that the removal of the oocyte from its follicular environment triggers the resumption of meiosis by a specific or unspecific signal.

Explantation of preovulatory follicles (Figure 1.7a) provides an *in vitro* model in which the normal association between various follicular cell types and compartments is maintained. In this model resumption of meiosis is dependent on hormonal stimulation (Tsafriri *et al.*, 1972a; Neal and Baker, 1973; Thibault and Gerard, 1973; Moor and Trounson, 1977; Thibault, 1977; Meinecke and Meinecke-Tillman, 1981). This model permitted the analysis of several mechanisms underlying the hormonal induction of meiosis: the clarification of the role of gonadotrophins, steroids, prostaglandins, cyclic AMP, macromolecular synthesis and follicular energy metabolism (Tsafriri, 1978). However, being a multicompartmental model it does not allow the localization of the primary site of gonadotrophin action in the induction of meiosis or the elucidation of the cascade of events involved in this response.

The contrasting behaviour of the isolated oocyte and of follicle-enclosed oocyte led to the hypothesis that the maturation of mammalian oocyte is normally prevented by an inhibitory action exerted by the follicular cells and that LH induces the resumption of meiosis by removing this restraint rather than by providing a positive stimulus. In order to test this hypothesis a third model was developed: co-culture of isolated oocytes with various follicular components (Foote and Thibault, 1969; Tsafriri and Channing, 1975b; Leibfried and First, 1980a). This approach, however, may be difficult to interpret as the oocyte as well as follicle cells are removed from their natural environment, which may result in changes relevant to meiosis in both compartments. Furthermore, the normal association between the oocyte and the follicle cells, as well as between follicle cells themselves, is disrupted and the system is still too complex to allow localization of specific cellular responses. Nevertheless, the isolated oocytes in culture, whether alone or with other follicular constituents, provide an indispensable approach for examination of mechanisms in-

volved in the maintenance of meiotic arrest. Recently, hormonal stimulation of granulosa cell–oocyte co-cultures has been proven as a convenient method for obtaining mature and developmentally competent ovine (Crosby *et al.*, 1981; Staigmiller and Moor, 1984), bovine (Hensleigh and Hunter, 1985; Critser *et al.*, 1986; Gordon and Lu, 1990) and porcine (Mattioli *et al.*, 1988a,b) ova (reviewed by Racowsky, 1991).

(c) Maturation of follicle-enclosed oocytes

Extensive studies on the maturation of follicle-enclosed oocytes were carried out in the rat. Similar results were obtained whether the preovulatory follicles were explanted from pro-oestrous mature cyclic rats (Tsafriri *et al.*, 1972a) or from immature PMSG-treated rats (Hillensjö, 1976). It was shown that oocytes explanted within their follicle on the day of pro-oestrus before 14:00 h, that is before the preovulatory surge of LH, remain in the dictyate stage throughout the 24 h culture period. By contrast, when the follicles were explanted after the endogenous surge of gonadotrophins, the oocytes matured in hormone-free medium.

Preovulatory follicles that are explanted prior to the surge of gonadotrophins can be used to test the meiosis-inducing action of hormones and other drugs. Meiosis is triggered in such rat follicles by LH, hCG, FSH or prostaglandin E_2 (PGE_2) (Tsafriri *et al.*, 1972a; Hillensjö, 1976). All these hormones induce a rise in follicular cyclic AMP (Lindner *et al.*, 1974), and their meiosis-inducing action is most probably mediated by this response. The recent demonstration that forskolin, a potent activator of adenylate cyclase, can by itself induce maturation of follicle-enclosed rat oocytes supports this notion (Dekel and Sherizly, 1983). The possible role of other follicular responses to LH in the mediation of its meiosis-inducing action was explored. Thus, inhibition of follicular steroidogenesis did not prevent the meiosis-inducing action of LH (Lieberman *et al.*, 1975). The role of steroids in the regulation of oocyte maturation will be discussed in detail. Inhibition of the stimulatory effect of LH on follicular lactate production did not prevent its action on resumption of meiosis (Tsafriri *et al.*, 1976b). By contrast, inhibition of protein synthesis by cycloheximide or puromycin abolished both resumption of meiosis and the enhancement of steroidogenesis (Lieberman *et al.*, 1976).

Resumption of meiosis was induced by gonadotrophins in follicle-enclosed oocytes of sheep (Hay and Moor, 1973; W.A. Miller and Jagiello, 1973; Moor and Trounson, 1977), cow (Thibault *et al.*, 1975a,b), pig (Gérard *et al.*, 1979; Meinecke and Meinecke-Tillman, 1981), monkey (Thibault *et al.*, 1976), rabbit (Thibault and Gérard, 1973) and hamster (Gwatkin and Andersen, 1976). Furthermore, in the rabbit (Thibault *et al.*, 1975a,b) and in the sheep (Moor and Trounson, 1977), the birth of normal young oocytes which had matured in follicles cultured in the presence of gonadotrophins was achieved.

Meiosis was also induced in follicle-enclosed rat oocytes by factors which do not enhance follicular cyclic AMP production. Thus, the hypothalamic gonadotrophin-releasing hormone (GnRH) or its agonistic analogue induced resumption of meiosis both *in vivo* (Ekholm *et al.*, 1981) and *in vitro* (Hillensjö and LeMaire, 1980). Whereas a GnRH antagonist abolished the meiosis-inducing action of GnRH or its analogue, it did not block this effect of LH (Ekholm *et al.*, 1982; Dekel *et al.*, 1983). It appears, therefore, that GnRH or a similar ovarian factor does not mediate the effect of LH on meiosis. GnRH induces follicular prostaglandin synthesis (M.R. Clark *et al.*, 1980), and $PGF_{2\alpha}$ was shown to induce resumption of meiosis (Tsafriri *et al.*, 1972a). However, indomethacin, a potent prostaglandin synthetase inhibitor, blocked the effect of GnRH analogue on ovulation but not on oocyte maturation (Ekholm *et al.*, 1982), suggesting that induction of meiosis by GnRH is not mediated by

follicular prostaglandin synthesis. The effect of GnRH is probably exerted via the activation of protein kinase C (Dekel *et al.*, 1989).

Other drugs induce resumption of meiosis in follicle enclosed oocytes: clomiphene citrate (0.01–0.5 nM) (Laufer *et al.*, 1982); tetrahydrocannabinol (100–200 μ), the major psychoactive ingredient of marihuana and cannabidiol (100–200 μ), one of its non-psychoactive constituents (Reich *et al.*, 1982). Likewise, epidermal growth factor (Dekel and Sherizly, 1985) and transforming growth factor alpha (Tsafriri *et al.*, 1989a) induce maturation of follicle-enclosed rat oocytes. The demonstration that activators of protein kinase C, such as phorbol ester, synthetic diacylglycerol and phospholipase C, also induce meiosis in follicle-enclosed oocytes (Aberdam and Dekel, 1985; Dekel *et al.*, 1989) suggests that a cyclic AMP-independent mechanism may also be involved in oocyte maturation. Nevertheless, the precise role of mechanisms involving protein kinase C in regulation of oocyte maturation remains to be elucidated (see Protein phosphorylation).

(d) Follicular control of oocyte maturation

Inhibitory effect of granulosa cells and follicular fluid

The spontaneous maturation of isolated oocytes in culture led Pincus and Enzmann (1935) to suggest that follicle cells in mammals 'supply to the ovum a substance or substances which directly inhibit nuclear maturation'. This suggestion was supported by the inhibition of the resumption of meiosis of porcine oocytes co-cultured with segments of follicle wall, but not with its theca layer (Foote and Thibault, 1969; Tsafriri and Channing, 1975b) or ovarian bursa (Leibfried and First, 1980a). Likewise, meiosis was inhibited in porcine oocytes transferred to host follicles (Meinecke and Meinecke-Tillmann, 1981; Fleming *et al.*, 1985) or planted onto extroverted follicles (Mattioli *et al.*, 1986) and cultured in hormone-free medium, and maturation of rat oocytes injected into porcine follicles was markedly delayed (Fleming *et al.*, 1985). Further, co-culture of porcine oocytes with porcine granulosa cells inhibited the spontaneous resumption of meiosis (Tsafriri and Channing, 1975b; Sato and Ishibashi, 1977). The inhibitory effect of granulosa cells depended upon their concentration in culture. Granulosa cells collected from small follicles inhibited meiosis more effectively than cells from medium or large follicles (Tsafriri and Channing, 1975b; Centola *et al.*, 1981). Similarly, when rat oocytes were added to rat granulosa cells previously cultured for 24 or 48 h, resumption of meiosis was suppressed and the degree of inhibition depended upon the number of granulosa cells in the culture. This inhibitory effect of rat granulosa cells was reversed by the addition of LH to the co-cultures (Tsafriri *et al.*, 1977; Tsafriri, 1979). Nuclear maturation of rabbit oocytes was significantly delayed when cultured with granulosa cells (Motlik and Fulka, 1981). Likewise, the spontaneous maturation of bovine oocyte was suppressed by co-culture with granulosa cells (Sirad and Bilodeau, 1990a,b).

Extracts of granulosa cells, as well as granulosa cell-conditioned medium, i.e. a medium in which granulosa cells were cultured previously, inhibited the resumption of meiosis (Tsafriri *et al.*, 1976c; Sato and Ishibashi, 1977; Centola *et al.*, 1981). Collectively, these results suggest that within the follicle meiosis is arrested by an oocyte maturation inhibitor (OMI) produced by granulosa cells. It was found that addition of FSH or prolactin to suspension cultures of porcine granulosa cells increases OMI activity in the medium, whereas testosterone or dihydrotestosterone reduces it (Channing *et al.*, 1982).

Follicular fluid (FF) from ovaries of rabbit, ovine, bovine, porcine, hamster and human origin exerted an inhibitory effect upon the spontaneous maturation of isolated oocytes

(Chang, 1955; Tsafriri and Channing, 1975b; Gwatkin and Andersen, 1976; Jagiello *et al.*, 1977; Tsafriri *et al.*, 1977; Hillensjö *et al.*, 1978a). This inhibitory effect is not species specific; thus human FF inhibited the maturation of porcine (Hillensjö *et al.*, 1978a) and rat oocytes (Chari *et al.*, 1983), bovine FF inhibited hamster oocytes (Gwatkin and Andersen, 1976) and porcine FF inhibited the maturation of rat oocytes (Tsafriri *et al.*, 1977). The OMI activity in porcine FF appears to decline in the course of follicular growth. This was demonstrated by assaying FF freshly collected from small, medium and large follicles (Stone *et al.*, 1978) or fluid collected from pigs on specified days of their reproductive cycle (van de Wiel *et al.*, 1983). Similarly, in FF collected from women participating in an *in vitro* fertilization–embryo transfer programme, the OMI activity was significantly lower in follicles yielding mature and fertilizable oocytes as compared with follicles yielding immature or atretic oocytes (Channing *et al.*, 1983; Hillensjö *et al.*, 1985).

OMI purification and characterization

The work on purification and chemical characterization of follicular OMI activity is hampered by difficulties, particularly in two areas; the assay systems used to monitor purification and insufficient resolution of the purification procedures. The *in vitro* assays employed for OMI activity are slow and cumbersome and their relevance to physiological regulation of oocyte maturation is sometimes questionable. Moreover, the lack of standard preparations and assay procedures makes it very difficult to compare results of different research teams. The most commonly employed sources of OMI, follicular fluid and ovarian extracts, are extremely complex and vary as a result of subtle physiological and endocrine conditions and, therefore, impose high demands of the purification procedure. Finally, the active factor isolated from follicular fluid or other biological sources may not be the potent native hormone but a chemically modified product retaining some of the original activity or mimicking the action of an unrelated hormone.

Pig oocytes from either medium or large follicles were frequently employed for bioassay of OMI (Tsafriri and Channing, 1975b; Hillensjö *et al.*, 1978a; Stone *et al.*, 1978). This assay requires a steady source of a large number of porcine ovaries, a long incubation period (42–44 h) and fixation and staining of the ova after the incubation. Rat (Tsafriri *et al.*, 1977) and mouse (Downs and Eppig, 1984, 1985) oocytes were also used for assaying OMI. Murine oocytes are widely available and the culture period is much shorter (up to 4–6 h). Nevertheless, OMI assays involving mammalian ova are cumbersome and tedious, require experienced personnel and can be applied only to a limited number of samples. Inhibitory effects of human follicular fluid on maturation of amphibian oocytes was demonstrated (Schuetz and Rock, 1982; Cameron *et al.*, 1983). It is postulated that the inhibition resulted from the presence of OMI in this fluid and hence it may be employed for purification of OMI.

At the present, two biochemically different entities are proposed as putative follicular OMI, a yet unidentified peptide and hypoxanthine or other purine bases or metabolites. These studies will be reviewed in the following sections.

OMI as a peptide

OMI passed through an Amicon PM-10 filter which has a molecular weight cut-off 10 000. Chromatography of the concentrated filtrate on Sephadex G-25 (Tsafriri *et al.*, 1976d; Stone *et al.*, 1978) revealed that OMI had a molecular weight < 2000 and that two peaks of activity were present. FF lost OMI activity when it was treated with trypsin but retained its activity on freezing and thawing, treatment with charcoal and when it was heated to 60°C for 20 min (Tsafriri *et al.*, 1976d).

Unpublished experiments (S.H. Pomerantz, personal communication) showed that bacterial protease from *Streptomyces griseus* (Sigma) destroyed all of the OMI activity of a partially purified Biogel P2 fraction. Treatment of the same fraction with trypsin left no significant activity. These results are all consistent with OMI being a peptide of low molecular weight. OMI from bovine FF and granulosa cells appears to have similar properties (Gwatkin and Andersen, 1976; Sato *et al.*, 1978; Sato and Koide, 1984).

After lyophilization to dryness of the PM-10 filtrate, OMI could be extracted with acetic acid dissolved in methanol (Channing *et al.*, 1982). This step was then followed by gel filtration chromatography on Sephadex G-25 or Biogel P2 (S.A. Pomerantz and P.A. Bilello, unpublished experiments). After gel filtration, ion-exchange chromatography on OM-Sephadex and DEAE-Sephadex was applied (Pomerantz *et al.*, 1979; Channing *et al.*, 1982). These steps showed OMI to be an acidic compound since it was bound to DEAE – but not OM-Sephadex. However, these procedures resulted in a modest purification and a poor yield, and a lengthy period of time was required.

The current procedure exploits the acidic nature of OMI. First, pig FF is filtered through an Amicon PM-10 filter, and the filtrate passed through a YCO5 filter. The retentate is diluted to 50 mosmol/kg and passed onto a column of QAE-Sephadex. This strongly basic ion-exchange resin binds OMI; the latter is eluted from the column with a steep gradient of ammonium bicarbonate. Two peaks of OMI activity are detected by assays with pig oocytes. The active peaks combined are then treated by chromatography on reversed-phase and gel filtration high performance liquid chromatography (HPLC). Two active fractions were obtained. The fold purification from FF reaches about 20 000 with a combined recovery of about 34% (Pomerantz *et al.*, 1989).

The inhibition of spontaneous maturation of rat, but not mouse, oocytes by Müllerian inhibiting substance (MIS) was reported by Takahashi *et al.* (1986). However, by using a more purified preparation (Picard and Josso, 1984; Picard *et al.*, 1986) we could not detect OMI-like activity on rat oocytes (Tsafriri *et al.*, 1988). It appears, therefore, that the observed OMI activity should be ascribed to a contaminant of the MIS preparation. The inhibition of maturation by human recombinant MIS was dependent upon the presence of a detergent, Nonidet P-40 (Ueno *et al.*, 1988), which by itself may suppress maturation (Tsafriri *et al.*, 1991b). It remains to be determined whether MIS has OMI activity independent of the detergent and, if so, whether it is involved in the regulation of meiosis *in vivo*.

Two additional ovarian hormones were recently implicated in the regulation of oocyte maturation: inhibin (O *et al.*, 1989) and the 35-kDa, but not 32-kDa follistatin (see Esch *et al.*, 1987, for follistatin sequence; Buscaglia *et al.*, 1989). Furthermore, an antiserum towards the 27 amino acid carboxy terminus of the 35-kDa follistatin neutralized the OMI activity of porcine FF (Buscaglia *et al.*, 1989) or of partially purified OMI standard preparations (our unpublished observations). Thus, it is possible that the OMI peptide is a fragment of the carboxy terminus of 35-kDa follistatin. The very acidic nature of partially purified OMI (Pomerantz *et al.*, 1989) from porcine FF and of the carboxy terminus of 35-kDa follistatin support this possibility. Further studies are required in order to confirm these interesting observations and to identify OMI as any of the known ovarian hormones or their fragments.

Inhibition of oocyte maturation by purine bases and their metabolites

By the use of mouse oocytes as an assay system, an inhibitory effect of porcine FF was demonstrated and this inhibition was potentiated by cyclic AMP (Downs and Eppig, 1984, 1985). Downs *et al.* (1985) reached the

conclusion that hypoxanthine is the predominant low molecular weight component of porcine FF that inhibits mouse oocyte maturation. This conclusion is based on the findings that the potent inhibitory fraction (i) had an absorption maximum (250 nm) identical to that of hypoxanthine; (ii) had a retention time on HPLC of pure hypoxanthine; (iii) exerted inhibition of oocyte maturation identical to that exhibited by a commercial preparation of hypoxanthine; and (iv) hypoxanthine concentration of about 1.41 mM could account for the majority of the inhibitory activity of porcine FF1 on mouse oocytes. The concentrations of hypoxanthine (2–4 nM) and of adenosine (0.35–0.70 mM) in mouse FF could account for inhibition of oocyte maturation, since even lower concentrations of these purines when combined together inhibited the spontaneous maturation of mouse oocytes during a 24 h incubation period *in vitro* (Eppig *et al.*, 1985). Nevertheless, the same authors were unable to detect a reduction in FF hypoxanthine and adenosine concentration 2 h after hCG administration, i.e. just before GVB. It is possible that the concentration of these purines in FF does not necessarily reflect their levels within the oocyte, which are probably more relevant for maintenance of meiotic arrest. Hypoxanthine and adenosine were not detected in bovine FF, in spite of the presence of a low molecular weight component which was inhibitory for ovum maturation (J.J. Eppig, personal communication). Guanosine and hypoxanthine inhibited, dose-dependently, the spontaneous maturation of rat oocytes, with guanosine the more effective, 50 μM inhibiting resumption of meiosis to the same extent as 2 mM hypoxanthine, and FSH potentiated the inhibitory action of both purines (Billig *et al.*, 1985). By contrast, in another study, 30 μM adenosine, but not adenine, inosine, hypoxanthine or guanosine, synergized with FSH in inhibiting maturation of rat oocytes (J.G.O. Miller and Behrman, 1986). Purine bases were demonstrated to modulate oocyte levels of cAMP, most probably by inhibiting cAMP phosphodiesterase activity (Downs *et al.*, 1989). Furthermore, microinjection of oocytes with an inhibitor of cAMP-dependent protein kinase (PKO) induced the resumption of meiosis in oocytes cultured in medium containing hypoxanthine or guanosine (Eppig, 1989). It seems, therefore, that purines affect resumption of meiosis by raising oocyte cAMP to levels inhibitory for meiosis (see review by Törnell *et al.*, 1991). Such action of purine bases does not exclude the possibility of other follicular factors suppressing in parallel the resumption of meiosis. Indeed, Downs *et al.* (1985) observed an additional inhibitory fraction in FF which was not removed by charcoal extraction. The resistance of OMI activity to proteolysis cannot be taken as conclusive evidence that OMI is not a peptide. A small peptide may be a very poor substrate for proteases and/or the appropriate sensitive peptide bonds may not be present. Hence, the final identification of OMI as a purine base or a peptide must await confirmation in several mammalian test systems. Of course, the coexistence of follicular mechanisms suppressing meiosis by a peptide and by purine base(s) is a possibility which cannot be dismissed at the present. We shall further discuss this issue in the next section.

OMI as a physiological regulator of ovum maturation

In order to serve as a physiological regulator of meiosis, a substance has to fulfil the following criteria: (i) it should be present in a compartment relevant to regulation of meiosis at the proper timing; (ii) its action should be reversible with no adverse effects on further stages of ovum maturation, fertilization and embryonic development; (iii) the physiological trigger of resumption of meiosis, gonadotrophin, should be able to either supersede its inhibitory action or cause its

degradation or removal from the relevant compartment. The inhibitory action of porcine FF and of its partially purified fractions could be reversed by either transferring the oocytes after an initial 24-h incubation with the inhibitor to a medium without OMI (Stone *et al.*, 1978; Hillensjö *et al.*, 1979a,b) or by the addition of an antibody prepared against the low molecular weight fraction of porcine FF (Tsafriri, 1979). Likewise, the inhibition of maturation of mouse oocytes by hypoxanthine and adenosine was completely reversible by withdrawal of the purines (Eppig *et al.*, 1985). Oocytes arrested *in vitro* and matured after withdrawal of the drug could be fertilized and developed to the expanded blastocyst stage. Addition of FSH further increased development to two-cell and blastocyst stages and 11% of transferred morulae produced live young as compared with 14% in control oocytes which were not arrested by purines (Downs *et al.*, 1986a). Thus, the inhibition of meiosis, by both the apparently peptide OMI from porcine FF and of hypoxanthine and adenosine appears, not to be due to a toxin and irreversible action.

In vivo or in follicle-enclosed oocytes *in vitro*, resumption of meiosis is induced by LH. Hence the ability of LH (or other gonadotrophins) to overcome the inhibition of meiosis by FF or by co-culture with granulosa cells lends support for the physiological role of OMI in the regulation of meiosis. It was found that the addition of LH to cultures of porcine oocytes with porcine FF or its purified fractions overcame their inhibition of meiosis (Tsafriri and Channing, 1975b). Also, the inhibitory action of bovine or hamster FF (Gwatkin and Andersen, 1976), of porcine FF and of rat granulosa cell conditioned medium as well as co-culture with rat granulosa cells (Tsafriri *et al.*, 1977; Tsafriri, 1979) were all alleviated by the addition of LH, closely resembling the regulation *in vivo* of oocyte maturation. Likewise, recent studies demonstrated the ability of FSH to induce resumption of meiosis in the continued presence of hypoxanthine (Eppig and Downs, 1986). Furthermore, perturbants of purine metabolism induced resumption of meiosis *in vitro* in meiotically arrested oocytes in the presence of hypoxanthine (Downs *et al.*, 1986b) or *in vivo* in PMSG-primed immature mice (Downs and Eppig, 1986). Thus, mycophenilic acid and bredinin, drugs inhibiting the enzyme inositol monophosphate (IMP) dehydrogenase and hence the conversion of hypoxanthine product IMP to guanyl and/or xanthyl compounds, induced resumption *in vivo* and *in vitro*. Also, azastene, an inhibitor of *de novo* purine synthesis, induced meiosis in a dose-dependent manner. These data support the essential role of guanyl and/or xanthyl derivatives in the maintenance of meiotic arrest within the follicle.

Follicular OMI activity has been demonstrated by several laboratories and by a variety of approaches. Some investigators, however, were unable to confirm the presence of OMI activity in various follicular preparations. These varying findings may be related, at least in part, to the low OMI activity of follicular fluid and of granulosa cell cultures; the finding that fluid and granulosa cells from large follicles are devoid of inhibitory activity; the relative instability of OMI and to differences in the methods of oocyte collection and culture. Furthermore, some of the groups that initially have reported negative results confirmed the inhibition of meiosis in a later study. Thus, bovine FF was found to inhibit the maturation of bovine oocytes (Sirad and First, 1988) in contrast to an earlier report (Leibfried and First, 1980a,b). Likewise, both FF and granulosa cells were found to inhibit the maturation of hamster oocytes, the granulosa cells persistently and FF only transitorily (Racowsky and Baldwin, 1989), contrary to earlier reports (see Racowsky and McGaughey, 1982a).

Collectively, the studies reviewed above clearly support the role of local paracrine mechanisms in regulation of oocyte maturation. Both the yet unidentified peptide OMI

and purine bases fulfil several criteria of physiological regulators of meiosis. In the following sections we shall review additional mechanisms involved in oocyte maturation. Such multiple mechanisms afford the notion that more than one type of molecule is involved in the maintenance of meiotic arrest.

(e) Other factors involved in the regulation of meiosis

Steroids

Steroids as follicular inhibitors of meiosis Studies testing the effect of steroids on spontaneous maturation of isolated oocytes led to conflicting results regarding their putative role in arrest of meiosis (reviewed by McGaughey, 1983; Eppig and Downs, 1984; Tsafriri, 1985; Schultz, 1991). For example, authors from one laboratory reported significant inhibitory action of testosterone (Rice and McGaughey, 1981), while in a later study no such inhibition was observed (Racowsky, 1983). Also, the reported inhibition of meiosis by oestrogen (Richter and McGaughey, 1979) was shown to be exerted only in the absence of added proteins in the medium (Racowsky and McGaughey, 1982b). Since follicular fluid has a high protein content, it has been concluded that oestradiol does not play a direct physiological role in maintaining meiotic arrest (Racowsky and McGaughey, 1982b). The inconsistent effects of steroids on resumption of meiosis render their suggested role in maintaining meiotic arrest doubtful (see also Tsafriri, 1985). Nevertheless, a modulatory action of steroids on resumption of meiosis seems more acceptable. Several steroids, such as oestradiol-17β, testosterone, dihydrotestosterone, or progesterone potentiate the inhibitory action of dibutyryl-cAMP, 8-bromo-cAMP or forskolin (Rice and McGaughey, 1981; Eppig *et al.*, 1983; Racowsky, 1985a). An antioestrogen, tamoxifen, counteracts the synergistic inhibition of GVB elicited by forskolin and oestradiol (Racowsky, 1985b). The modulatory actions of steroids on meiosis are exerted probably directly on the oocyte (Eppig and Downs, 1984) and may be related to their ability to inhibit oocyte cyclic nucleotide phosphodiesterase activity (Kaji *et al.*, 1987; see also Schultz, 1991).

Do steroids mediate the meiosis-inducing action of LH? Following a gonadotrophic stimulus, a prompt rise in follicular steroidogenesis, especially progesterone, occurs (see reviews by Lindner *et al.*, 1974; Channing and Tsafriri, 1977). The role of progesterone in mediation of the meiosis-inducing action of gonadotrophin is well established in fish and amphibia (Schuetz, 1985). Therefore, the rise in follicular steroidogenesis could admit the involvement of progesterone in triggering resumption of meiosis in mammals.

Addition of steroids to the culture medium did not induce the maturation of bovine, porcine (Foote and Thibault, 1969) or rat (Tsafriri *et al.*, 1972a) follicle-enclosed oocytes. Furthermore, suppression of follicular steroidogenesis by specific inhibitors, which reduced progesterone to a level below that seen in LH-free control follicles in which germinal vesicle breakdown fails to occur, did not impair the ability of LH (or PGE_2) to induce GVB in rat follicle-enclosed oocytes (Lieberman *et al.*, 1976). Similar results were obtained by Moor (1978) in the sheep. Dissociation of the steroidogenic and meiosis-inducing action of LH was observed under two additional conditions: (i) during selective inhibition of RNA synthesis by actinomycin D (Tsafriri *et al.*, 1973; Lieberman *et al.*, 1975) and (ii) during inhibition of aerobic glycolysis by iodoacetate (Tsafriri *et al.*, 1976b). In both instances, progesterone production was inhibited, whereas germinal vesicle breakdown went on undisturbed. Thus, the abolition or suppression of LH-induced changes in follicular steroidogenesis by several inhibitors fails to prevent the action of LH on GVB, while none of the

Table 1.3 Oocyte cAMP levels and their relationship to resumption of meiosis (data from Dekel, 1987)

Treatment	*Meiotic stage*	*cAMP (fmol per denuded oocytes)*
(a) Denuded oocytes		
Freshly isolated from the ovary	Immature	1.23±0.3
Freshly isolated from the oviduct	Mature	0.81±0.2[a]
Incubated for 2 h	Mature	0.80±0.1[a]
Incubated for 2 h with IBMX (0.2M)	Immature	1.21±0.1
(b) Cumulus–oocyte transfer of cAMP[b]		
Cultured denuded	Immature	1.19±0.47
Cultured within intact cumulus oocyte complex	Immature	3.51±0.53[c]

[a] $P < 0.01$ *vs.* immature oocytes.
[b] Denuded or cumulus-enclosed oocytes were incubated for 1 h with 100 μM forskolin + 0.2 mM IBMX.
[c] $P < 0.01$ *vs.* oocytes cultured denuded.

steroids examined was able to substitute for LH in initiating meiosis. It appears, therefore, that steroids do not mediate the action of LH on resumption of meiosis in mammals. Nevertheless, this does not preclude an essential role of steroids in the acquisition of the ability of oocytes to undergo meiosis (see above) or to complete the process and to develop normally after fertilization (Moor *et al.*, 1980b; see Osborn and Moor (1983b) and Osborn *et al.* (1986); see also Chapter 2, this volume).

Cyclic AMP

Many of the agents inducing the maturation of follicle-enclosed oocytes *in vitro* also stimulate production of cAMP (Tsafriri *et al.*, 1972a; Lindner *et al.*, 1974). Injection of the cAMP derivative dibutyryl cAMP (dbcAMP) into the follicular antrum (Tsafriri *et al.*, 1972a) or short-term exposure of follicles to 8-bromo-cAMP (Hillensjö *et al.*, 1978b), dbcAMP or isobutyl methyl xanthine (IBMX) (Dekel *et al.*, 1981) triggered the resumption of meiosis. By contrast, the continuous presence of cAMP derivatives or several inhibitors of phosphodiesterase prevented the induction of meiosis by LH (Hillensjö *et al.*, 1978b; Dekel *et al.*, 1981). The spontaneous maturation of isolated oocytes from mice and rats was prevented in the presence of cAMP derivatives or phosphodiesterase inhibitors (Cho *et al.*, 1974; Hillensjö, 1976; Dekel and Beers, 1978; Hillensjö *et al.*, 1978b).

It seems, therefore, that enhanced production of cAMP in the somatic cell compartment of the follicle is involved in the mediation of the meiosis-inducing action of LH, while elevated cAMP in the oocyte inhibits the resumption of meiosis. It has been suggested that cAMP serves as a physiological regulator of meiosis in mammalian oocytes (Lindner *et al.*, 1974; Schultz and Wassarman, 1977b; Dekel and Beers, 1978, 1980; Moor *et al.*, 1980a; Dekel *et al.*, 1981; Dekel and Sherizly, 1983; Sherizly *et al.*, 1988). Indeed, a decrease in murine oocyte cAMP levels precedes resumption of meiosis, and when this decrease is prevented resumption of meiosis is blocked or substantially delayed (Table 1.3; Schultz *et al.*, 1983a,b; Vivarelli *et al.*, 1983; Aberdam *et al.*, 1987).

Likewise, incubation of rat oocytes with an invasive adenylate cyclase from bacteria of the genus *Bordetella*, elevated oocyte cAMP levels and inhibited resumption of meiosis, while removal of the enzyme resulted in a drop of oocyte cAMP levels and resumption of meiosis (Dekel *et al.*, 1985; Aberdam *et al.*,

1987). These results support the notion that elevated levels of oocyte cAMP maintain meiotic arrest and that an intraoocyte drop in cAMP allows the resumption of meiosis. In ovine oocytes an increase, rather than decrease, in cyclic AMP levels was observed at 1 and 12–18 h after gonadotrophic stimulation of explanted follicles *in vitro* (Moor and Heslop, 1981). Nevertheless, the relatively long interval between the meiosis-inducing stimulus and GVB in ovine oocytes still allows for a transient decrease in oocyte cAMP levels which has not been detected.

Studies employing forskolin, a potent and reversible activator of adenylate cyclase, provide further support for this hypothesis. Addition of forskolin to the medium induced resumption of meiosis in rat follicle-enclosed oocytes (Dekel and Sherizly, 1983). Likewise, perfusion of rabbit ovaries with forskolin resulted in the resumption of meiosis (Yoshimura *et al.*, 1992a,b). By contrast, forskolin inhibited the spontaneous maturation of cumulus-enclosed oocytes and had no effect on the maturation of denuded oocytes (Dekel *et al.*, 1984a; Racowsky, 1984; Yoshimura *et al.*, 1992a,b). Similar results were obtained when cholera toxin was used (Dekel and Beers, 1980). These results seem to indicate that (i) activation of adenylate cyclase in the somatic compartment of the follicle induces resumption of meiosis; (ii) activation of adenylate cyclase in the cumulus–oocyte complex results in inhibition of meiosis; (iii) the rat oocyte is devoid of adenylate cyclase or the level of cAMP produced by the oocyte is not sufficient to maintain meiotic arrest. Indeed, evidence for transfer of cyclic AMP from the cumulus cells to the ovum has been obtained in rat, mouse, hamster and porcine oocytes (Table 1.3; Dekel *et al.*, 1984a; Racowsky, 1984, 1985a–c; Bornslaeger and Schultz, 1985; Sherizly *et al.*, 1988). Studies with follicle-enclosed hamster and mouse oocytes support the same conclusions in spite of somewhat divergent results. In these species, continuous exposure to forskolin did not induce resumption of meiosis and, furthermore, it blocked LH-induced maturation. By contrast, transient exposure to forskolin triggered maturation of follicle-enclosed oocytes in the hamster (Hubbard, 1985) and the mouse (N. Hashimoto *et al.*, 1985). The inhibition of maturation of hamster and mouse follicle-enclosed oocytes by forskolin is probably associated with the sustained increase in oocyte cAMP observed in these species, as compared with the rat (Ekholm *et al.*, 1984; Racowsky, 1984). These studies leave little doubt regarding the important role of oocyte cAMP in the resumption of meiosis in mammals. However, the question of whether the oocyte synthesizes a sufficient amount of cAMP to inhibit meiosis, and whether cAMP is transferred from the cumulus to the oocyte, was answered by contrasting experimental results. Thus, while forskolin did not affect the resumption of meiosis in denuded oocytes of the rat (Dekel *et al.*, 1984a; Racowsky, 1984), and only partially in the hamster (Racowsky, 1985b), in other studies it was inhibitory in mouse (Schultz *et al.*, 1983a; Urner *et al.*, 1983), rat (Olsiewski and Beers, 1983) and pig (Racowsky, 1985a) denuded oocytes. The varying results may be related, at least in part, to species and strain differences, as well as to the experimental procedures explored. The interpretation of the results may be complicated by the effects on oocyte adenylate cyclase and phosphodiesterase activity (see Bornslaeger and Schultz, 1985).

The inhibition of oocyte maturation by IBMX supports the notion that phosphodiesterase plays a role in regulation of meiosis. Furthermore, the degree of suppression of phosphodiesterase activity by three pharmacological inhibitors of the enzyme in oocyte extracts correlated with their ability to inhibit GVB (Bornslaeger *et al.*, 1984). The activity of oocyte phosphodiesterase is most likely modulated by calmodulin, which constitutes 0.3% of total oocyte protein (Bornslaeger *et al.*, 1984). That a calmodulin-dependent step

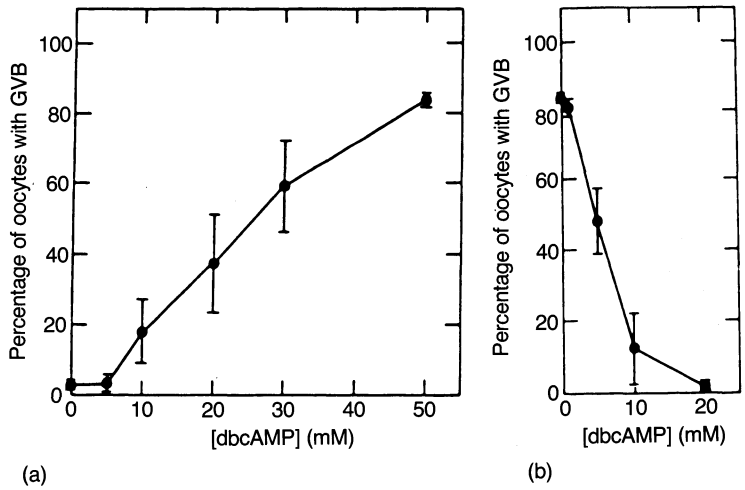

Figure 1.8 Effect of dbcAMP on maturation of follicle-enclosed rat oocytes. (a) Induction of oocyte maturation: preovulatory follicles were explanted on the day of pro-oestrus and incubated in the presence of the indicated concentrations of dbcAMP. After 20 h the follicles were rinsed (×4) and incubated further for 5 h in a medium without dbcAMP, the oocytes isolated and the presence of GV observed by interference contrast microscopy. The mean ±SEM of three different experiments is presented; at least 100 oocytes were examined at each dbcAMP concentration. (b) Inhibition of oocyte maturation: preovulatory follicles were incubated in the presence of 5 μg/ml ovine LH (NIH) with or without the indicated concentration of dbcAMP. After 20 h the oocytes were isolated and GVB scored. Each point is based on four different experiments. Other details as in (a). (From Dekel, 1987.)

is involved in maturation is suggested by the inhibition of maturation by calmodulin inhibitors, trifluoperazine, calmidizolium, W7 and W13. Nevertheless, since W7 at concentrations that inhibit maturation does not prevent the decrease in oocyte cAMP it seems that a calmodulin-mediated process, other than phosphodiesterase, is involved in oocyte maturation. This could be a calmodulin-modulated protein phosphatase (see Schultz, 1985). The involvement of phosphorylation in control of meiosis will be discussed in the next section. Collectively, the essential role of oocyte cAMP in the regulation of mammalian meiosis seems well established. The observed synergism of cAMP and OMI or purines in inhibiting spontaneous maturation *in vitro* of isolated oocytes (Eppig and Downs, 1984; Törnell *et al.*, 1984; Tsafriri and Pomerantz, 1984) is suggestive of interaction of cAMP and follicular OMI in the control of oocyte maturation. This concept further emphasizes the multifactorial control of resumption of meiosis.

The dual role of cAMP in the regulation of oocyte maturation was elegantly demonstrated by Dekel *et al.* (1988). Inhibition of resumption of meiosis in follicle-enclosed ova stimulated by LH or in cumulus-enclosed ova maturing spontaneously was achieved by continuous culture in the presence of IBMX (ED_{50}= 0.03 mM) or dbcAMP (ED_{50}= 5.0 mM). By contrast, induction of ovum maturation in follicle-enclosed oocytes was achieved by transient exposure to IBMX (ED_{50}= 0.13 mM) or dbcAMP (ED_{50}= 25 mM; Figure 1.8).

Thus, the induction of maturation is achieved by much higher concentrations of the phosphodiesterase inhibitor or the cyclic nucleotide analogue. These findings show that basal levels of follicular cAMP maintain meiotic arrest, while LH-stimulated surge of the nucleotide reaching higher levels is

required for the maturation-inducing action of the hormone. Furthermore, these divergent actions of the nucleotide are related to two different target cells; the inhibitory action is exerted at the oocyte, while the surge of cAMP in the somatic granulosa and cumulus cells leads to the resumption of meiosis.

Studies in the hamster implicate also cyclic GMP (or the cAMP/cGMP ratio) in the regulation of oocyte maturation. Thus, 8-bromocyclic GMP inhibited the spontaneous maturation of hamster cumulus-enclosed oocytes and this was overcome by LH (Hubbard and Terranova, 1982). Hamster follicular levels of cyclic GMP were decreased after gonadotrophic stimulation, and LH-induced maturation in hamster follicle-enclosed oocytes was enhanced by dbcGMP (Hubbard and Terranova, 1982).

Role of cumulus cells and of cumulus–oocyte communication

The cumulus cells appear to have an important role in the regulation of meiosis. Whereas OMI from porcine follicular fluid inhibited the resumption of meiosis by oocytes cultured within their intact cumuli, it did not interfere with the maturation of denuded oocytes of the pig (Hillensjö *et al.*, 1979b) or rat (Tsafriri and Bar-Ami, 1982). By contrast, porcine FF attenuated maturation of mouse denuded oocytes. Nevertheless, this study also showed that the suppression of resumption of meiosis in mouse denuded oocytes was consistently less than in cumulus-enclosed oocytes (Downs and Eppig, 1984). The uptake and metabolism of hypoxanthine and adenosine were augmented in intact cumulus complexes as compared with denuded oocytes (Downs *et al.*, 1986b). It therefore appears that the inhibitory action of OMI upon meiosis is exerted, at least partially, through the mediation of cumulus cells.

The cumulus cells are, apparently, involved also in the mediation of the meiosis-inducing action of LH. Whereas it was not possible to demonstrate specific receptors for LH on the oocyte, specific LH/hCG receptors were demonstrated on cumulus cells (Lawrence *et al.*, 1980; Channing *et al.*, 1981). This finding was further supported by the response of the whole oocyte–cumulus complex to gonadotrophins, involving enhanced steroidogenesis (Nicosia and Mikhail, 1975; Hillensjö *et al.*, 1980), lactate production (Billig *et al.*, 1983), cumulus mucification (Dekel and Kraicer, 1978; Hillensjö and Channing, 1980) and activation of adenylate cyclase (Eppig *et al.*, 1983). LH accelerated resumption of meiosis in mouse and rat oocytes pretreated with dbcAMP and IBMX, and LH was effective only in oocytes cultured within their cumulus complex but not in denuded oocytes (Dekel and Beers, 1978, 1980; Freter and Schultz, 1984). It was suggested that acceleration of meiosis by LH is mediated by an increase in cumulus cell cAMP levels, which promotes a decrease in maturation inhibitors. The finding that the prevention of the LH-induced increase in cAMP with *N*-α-*p*-tosyl-L-lysine chloromethyl ketone, also inhibited the LH-induced acceleration of oocyte maturation lends support to this notion (Freter and Schultz, 1984). Germinal vesicle breakdown in rat (Tsafriri, 1979), mouse (Eppig, 1982; Salustri and Siracusa, 1983), and rabbit (Thibault *et al.*, 1976) oocytes maturing spontaneously occurs earlier than GVB in follicle-enclosed oocytes stimulated by gonadotrophin. This suggests that, by isolating an oocyte from its follicle, some regulatory step(s) essential for triggering meiosis *in vivo* is bypassed. This may include merely the removal of the inhibitory signal (OMI) by decreased synthesis, increased degradation or a combination of both or, alternatively, the generation of a positive signal which triggers the resumption of meiosis. Some of these alternative regulatory mechanisms of meiosis were reviewed and compared in mammalian, amphibian and echinoderm oocytes (Schuetz, 1985). In

immature oocytes the cumulus cells are closely apposed to the zona pellucida, which is studded with numerous cytoplasmic projections, whereas the cumulus cells encircling mature oocytes are loosely organized and very few projections are present in the zona pellucida (Zamboni, 1972; Szöllösi, 1975; Szöllösi *et al.*, 1978). Also, ionic coupling and transfer of molecules were maximal before gonadotrophic stimulation and decreased gradually afterwards (Gilula *et al.*, 1978; Sherizly *et al.*, 1988). These findings led to the hypothesis that the release of the oocyte from follicular suppression of meiosis is a result of the uncoupling of cumulus–oocyte communication, possibly induced by the ovulatory hormone (Lindner *et al.*, 1974; Dekel and Beers, 1978, 1980; Gilula *et al.*, 1978; Moor *et al.*, 1980a). The influence of LH on the resumption of meiosis may be secondary to its action on the sequestration of the oocyte. However, several of the initial observations were in contradiction with this suggestion. Thus, the disruption of oocyte–cumulus cell communication followed, rather than preceded, germinal vesicle breakdown. This was inferred from the observed reduction of the transport of choline or uridine to ovine, mouse, porcine and rat oocytes (Moor *et al.*, 1980a; Eppig, 1982; Racowsky, 1984; 1985a) and from the termination of ionic coupling of the cumulus cells and the oocyte in the rat (Dekel *et al.*, 1981).

Similarly, there was no consistent relation between cumulus dissociation and resumption of meiosis in porcine oocytes (Gérard *et al.*, 1979). Furthermore, it was possible to dissociate between germinal vesicle breakdown and the disruption of cumulus–oocyte communication as revealed by choline transport; whereas a low dose of FSH (50 ng/ml) suppressed intercellular coupling but did not induce resumption of meiosis, LH (100–500 ng/ml) induced resumption of meiosis but not disruption of coupling (Moor *et al.*, 1981).

Recent studies demonstrated that transfer of amino acids (Colonna and Mangia, 1983) and uridine (Salustri and Siracusa, 1983) to the oocyte is linearly dependent on their uptake by cumulus cells. Hence, under conditions entailing changes in precursor uptake by the cumulus cells, expressing oocyte uptake as a fraction of that of the cumulus appears to be a more proper index of oocyte–cumulus metabolic coupling than the comparison of absolute values of label incorporation used in the above-mentioned studies. Indeed, when the relative uptake was examined, there was a strict correlation between the resumption of meiosis and oocyte–cumulus uncoupling in mouse oocytes (Salustri and Siracusa, 1983). Furthermore, when rat follicle-enclosed oocytes were examined at various time intervals after LH/hCG stimulation, a 50% reduction in uridine uptake was observed already 1 h after the hormonal stimulus *in vivo* or *in vitro*, when GVB is still present in all oocytes (Dekel *et al.*, 1984b; Dekel, 1986; Sherizly, *et al.*, 1988). Similarly, a reduction in oocyte–cumulus dye and metabolic coupling was observed in hamster oocytes concomitantly with GVB (Racowsky and Satterlie, 1985). Also, when resumption of meiosis was triggered by epidermal growth factor (EGF), oocyte–cumulus communication was reduced prior to GVB in rat follicle-enclosed oocytes (Dekel and Sherizly, 1985). In a more recent study, it was demonstrated that heptanol, a seven-carbon alcohol that blocks cell-to-cell communication in various experimental systems, including the cumulus–oocyte complex, reduced intraoocyte concentrations of cAMP and promoted maturation of rat follicle-enclosed oocytes (Dekel and Piontkewitz, 1991).

Quantitative analysis of freeze-fractured rat cumulus–oocyte complexes revealed a dramatic decrease in the net area of cumulus gap junctions following the ovulatory stimulus and prior to GVB (W.J. Larsen *et al.*, 1986), thus providing structural basis for the observed reduction in cumulus–oocyte com-

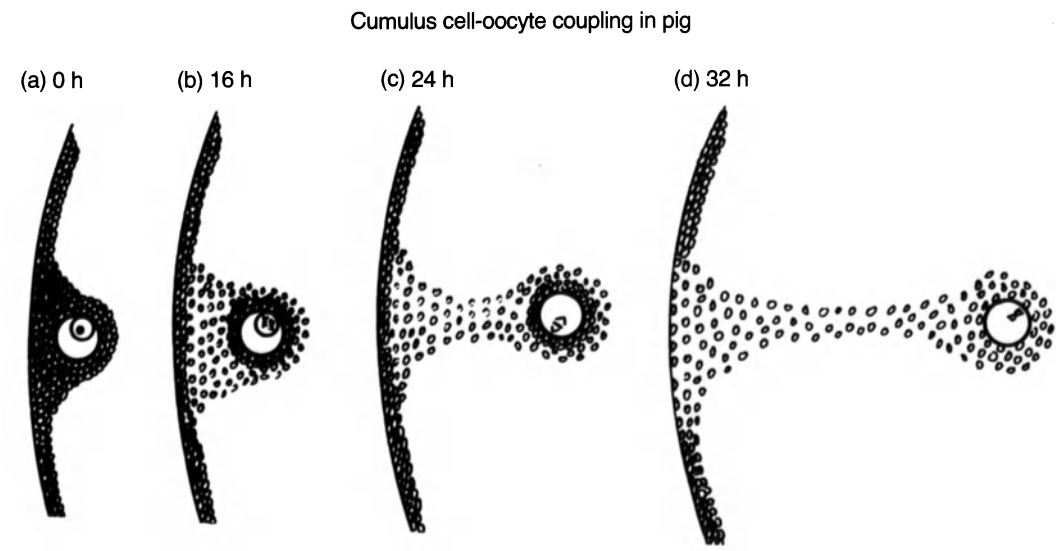

Figure 1.9 Preovulatory changes in the granulosa cell–oocyte complex in pigs. The first signs of cumulus expansion and matrix deposition are observed 16 h after hCG administration in the area of the connection between the cumulus and mural granulosa cells (b). (From Motlik *et al.*, 1986.)

munication. An additional consideration regarding oocyte–follicle cell communication was raised in a recent study by Motlik *et al.* (1986). Examination of the changes in association between cumulus oophorus and mural granulosa in follicles from PMSG, hCG-treated pigs, revealed deposition of mucous matrix already 16 h after hCG stimulation, prior to GVB, which occurs 20–24 h after hCG (Figure 1.9; Motlik and Fulka, 1976).

The importance of mural granulosa–cumulus coupling in regulation of meiosis has been suggested already by Foote and Thibault (1969). Racowsky *et al.* (1989) observed a significant progressive decrease in gap junction area with increasing percentage of oocytes committed to mature after stimulation of ovulation by hCG in the membrana granulosa underlying the cumulus cell stalk in the hamster.

Collectively, these data are compatible with the suggested communication of an inhibitory signal from the somatic cell compartment of the follicle to the oocyte. The rate of transfer of the inhibitory signal may be modulated at several points: oocyte–cumulus, cumulus–cumulus or cumulus–mural granulosa or even granulosa–granulosa junctions. At the present, there is sufficient evidence supporting the transfer of cAMP to the oocyte. Further studies are required to determine whether other regulators of meiosis are transmitted to the ovum or their effect is exerted at the level of the follicular somatic compartment.

Protein phosphorylation

The detailed mechanism(s) by which oocyte cyclic AMP maintains meiotic arrest is not yet known. Nevertheless, since cAMP acts in many eukaryotic systems by activating cAMP-dependent protein kinase (PK-A), a model involving phosphorylation–dephosphorylation of an oocyte protein(s) was suggested (Bornslaeger *et al.*, 1986, see also Schultz, 1991; Tsafriri and Dekel, 1993). This model (Figure 1.10) proposes that a phosphoprotein X-P, a substrate of PK-A, maintains meiotic arrest.

A decrease in PK-A activity caused by a decrease in oocyte cAMP concentration

would, due to phosphoprotein phosphatase activity, result in a net dephosphorylation of X-P; the dephosphorylated protein, X, would then promote resumption of meiosis. In support of this model, an increase in protein phosphorylation–dephosphorylation during maturation of mouse (Schultz *et al.*, 1983a; Bornslaeger *et al.*, 1986; Endo *et al.*, 1986) and sheep oocytes (Crosby *et al.*, 1984; Moor and Crosby, 1986) was observed. Furthermore, microinjection into oocytes of the heat-stable inhibitor of P-A, PKI, induced GVB in the presence of dbcAMP or IBMX. Conversely, microinjection of the catalytic subunit of PK-A maintained meiotic arrest in a dose-dependent manner, provided that PKI was not co-administered (Bornslaeger *et al.*, 1986). Addition of cyclic adenosine 3,5-pyrophosphate, an inhibitor of protein kinase, blocked the spontaneous maturation of mouse oocytes *in vitro*. Furthermore, a fraction of bovine follicular fluid exhibited both actions, inhibition of protein kinase and resumption of meiosis (Sato *et al.*, 1985). Likewise, a puromycin analogue, 6-dimethylaminopurine, which inhibited protein phosphorylation in mouse oocytes, also blocked the resumption of meiosis, without markedly altering protein synthesis in the oocyte (Rime *et al.*, 1989).

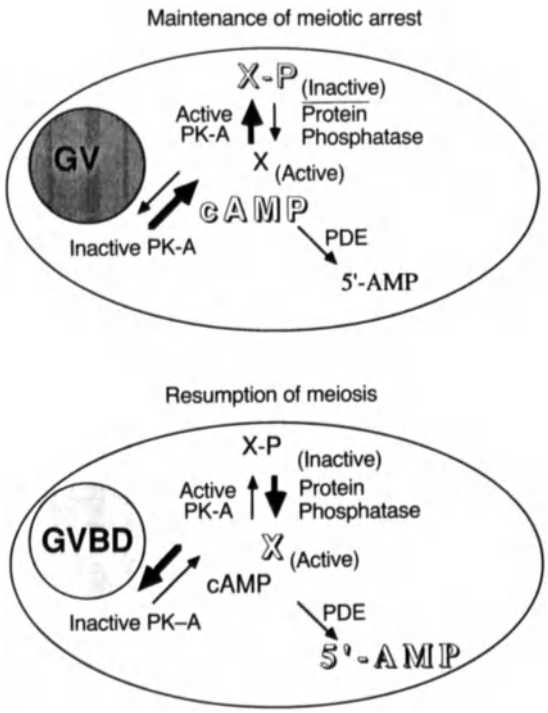

Figure 1.10 Model for maintenance and resumption of meiosis. The bold, open symbols depict the predominating form of a hypothetical maturation-regulating protein 'X' or its phosphorylated inactive form 'XP', as well as cAMP or 5-AMP. (From Bornslaeger *et al.*, 1986.)

Similarly, cAMP-independent kinases may also be involved in regulation of resumption of meiosis. Phorbol esters which activate protein kinase C (PKC) inhibited the spontaneous maturation of mouse oocytes (Urner and Schorderet-Slatkine, 1984; Bornslaeger *et al.*, 1986) and partially inhibited the specific changes in oocyte phosphoprotein metabolism associated with resumption of meiosis (Bornslaeger *et al.*, 1986). Since the phorbol ester did not inhibit the decrease in oocyte cAMP and administration of PKI did not result in GVB in the presence of the phorbol ester, it was concluded that activators of PKC inhibit meiosis by acting distal to a decrease in cAMP-dependent protein kinase, but prior to changes in oocyte phosphoprotein metabolism required for GVB. In contrast, studies with rat oocytes demonstrated the ability of PKC activators to induce meiosis in follicle-enclosed oocytes (Aberdam and Dekel, 1985). Furthermore, the induction of oocyte maturation by GnRH seems to be the result of PKC activation. These findings suggest that PKC may be involved in the control of oocyte maturation. However, the precise physiological role of PKC in the regulation of meiosis remains to be elucidated.

The resumption of meiosis in oocytes of amphibia is triggered by a steroid interacting with a plasma membrane receptor (Sadler and Maller, 1982). This results in a decrease in adenylate cyclase activity (Finidori-Lepicard *et al.*, 1981; Jordana *et al.*, 1981; Sadler and Maller, 1981) and hence decrease in oocyte cAMP levels. The decrease in

oocyte cAMP is followed, among other changes, by increase in protein phosphorylation (see Baulieu and Schorderet-Slatkine, 1983; Maller, 1985). The recent elucidation of MPF and the identification of its catalytic subunit with the product of the *cdc2* (cell division cycle) gene in fission yeast (Gautier *et al.*, 1988, 1989) and the regulatory subunit with cyclins (Murray *et al.*, 1989; Murray and Kirschner, 1989), its conservation throughout eukaryotes and its role in regulation of both mitotic cycle and meiosis may lead to the identification of the mechanisms operating in mammalian ooplasm. In spite of the different stimulus for resumption of meiosis in mammals, and the crucial role of follicular granulosa and cumulus cells in regulation of the meiotic process, it seems most likely that similar, if not identical, mechanisms operate in the ooplasm of amphibian and mammalian oocytes. The demonstration of MPF activity in the cytoplasm of mouse oocytes (H. Hashimoto and Kishimoto, 1988) supports this notion.

Macromolecular synthesis

In rat follicle-enclosed oocytes addition of inhibitors of protein synthesis, but not of RNA synthesis, blocked LH-induced resumption of meiosis (Tsafriri *et al.*, 1973; Lieberman *et al.*, 1975). This effect was most probably exerted in the somatic compartment of the follicle.

In full-grown mouse oocytes low, but significant, incorporation of precursors into nuclear and cytoplasmic RNA *in vivo* (Rodman and Bachvarova, 1976) and *in vitro* (Bloom and Mukherjee, 1972; P.M. Wassarman and Letourneau, 1976) was detected. Nevertheless, this activity is lower in full-grown oocytes than in growing ones. Likewise, a fall in RNA polymerase activity was observed in full-grown oocytes (Moore and Lintern-Moore, 1978). With resumption of meiosis RNA synthesis is reduced to undetectable levels at GVB (Rodman and Bachvarova, 1976; P.M. Wassarman and Letourneau, 1976; Motlik *et al.*, 1984b; Motlik and Fulka, 1986). During oocyte maturation a 50% decline in polyadenylated RNA (Brower *et al.*, 1981; Bachvarova *et al.*, 1985) and a 20% drop in total RNA (Bachvarova *et al.*, 1985) was estimated. In contrast, protein synthesis continues throughout maturation and exhibits marked quantitative and qualitative changes.

The absolute rate of protein synthesis drops by about 25% from 43 to 31 pg/h in maturing oocytes (Schultz *et al.*, 1978). Changes in the pattern of oocyte proteins were detected after GVB by two-dimensional gel electrophoresis in several mammalian species (sheep, Warnes *et al.*, 1977; pig, McGaughey and Van Blerkom, 1977; rabbit, Van Blerkom and McGaughey, 1978; and mouse, Schultz and Wassarman, 1977a; Van Blerkom, 1980; Richter and McGaughey, 1981). Evidence for post-translational modification of oocyte proteins during maturation has been presented (Van Blerkom, 1981; see Van Blerkom, 1985). The relative contribution of newly translated proteins from preformed mRNA and of post-translational-modified proteins to the changes in the pattern of proteins during resumption of oocyte maturation remains to be determined.

The electrophoretic pattern of proteins synthesized in rabbit oocyte maturing *in vivo* or *in vitro* was similar (Van Blerkom and McGaughey, 1978). In contrast, different protein patterns were observed when sheep oocytes were matured spontaneously *in vitro* as compared with oocytes triggered by gonadotrophins to mature *in vivo* or *in vitro* in follicles or granulosa cell co-cultures (Warnes *et al.*, 1977; Crosby *et al.*, 1981).

Studies with inhibitors of macromolecule synthesis also demonstrate differences between two groups of mammals. Actinomycin D arrests the maturation of mouse oocytes (Bloom and Mukherjee, 1972; Golbus and Stein, 1976), but this effect is probably

exerted through mechanisms other than inhibition of RNA synthesis (Golbus and Stein, 1976). Indeed, lower concentration of actinomycin does not inhibit GVB in mouse oocytes (Jagiello, 1969; Golbus and Stein, 1976; Crozet and Szöllösi. 1980). In contrast, α-amanitin and cordycepin inhibited GVB in sheep oocytes cultured within their cumulus cells, but did not affect resumption of meiosis in denuded oocytes (Osborn and Moor, 1983a). It seems, therefore, that the effect of RNA synthesis inhibitor on maturation of sheep oocytes is exerted at the cumulus cells.

Inhibition of protein synthesis by puromycin (10–100 μg/ml) or cycloheximide (1 μg/ul) does not prevent spontaneous GVB in cultured mouse oocytes, but meiosis is arrested at the circular bivalent or metaphase I stage (Golbus and Stein, 1976; Schultz and Wasserman, 1977a; Motlik *et al.*, 1986). This result would suggest that GVB in this species is independent of protein synthesis. Nevertheless, experiments employing rat oocytes in which GVB was prevented by culture with dbcAMP and puromycin result in inhibition of maturation when the oocytes are transferred into a medium containing only puromycin (Ekholm and Magnusson, 1979). It seems, therefore, that in mouse and rat oocytes GVB is dependent on the presence of short-lived proteins, which are available in fully grown oocytes and hence GVB can proceed normally even in the presence of protein synthesis inhibitors. In pig oocytes, however, GVB is dependent upon protein synthesis, since cycloheximide (1 μg/ml) prevents GVB in culture (Fulka *et al.*, 1986). Likewise, protein synthesis is required for GVB in ovine and bovine oocytes. Furthermore, synthesis of a polypeptide with M_r47 kDa immediately before GVB was identified in ovine oocytes. Synthesis of this polypeptide was suppressed by inhibition of transcription by α-amanitin (Moor and Crosby, 1986).

On the basis of these observations, it seems that differences exist between mammalian species, such as the sheep and the pig, in which a relatively long interval separates the meiosis-inducing stimulus (gonadotrophin or explantation *in vitro*) and GVB, and species like the mouse, the rat and the rabbit, having a short stimulus–GVB interval. In the latter, puromycin does not block GVB, there is no difference between the pattern of proteins synthesized in the oocytes *in vivo* and *in vitro*, there is no need for undisturbed steroidogenesis during this interval (Moor *et al.*, 1980b), and finally, spontaneously matured oocytes *in vitro* have normal developmental capacity (Schroeder and Eppig, 1984). Conversely, in species with long intervals between the meiosis-inducing stimulus and GVB, full developmental competence is dependent upon follicular environment (Moor and Osborn, 1983), undisturbed steroidogenesis (Moor *et al.*, 1980b; Osborn and Moor, 1983b) and this may be reflected in the difference in the pattern of steroids synthesized in the follicle and in the isolated oocyte (see Thibault *et al.*, 1987). This working hypothesis should be examined systematically in several species.

1.7.2 FOLLICULAR RUPTURE

The follicular response to the surge of gonadotrophins culminates in the rupture of the follicle wall and the release of the fertilizable ovum. Several reviews were published on various aspects of follicular rupture (Rondell, 1970a,b; Lipner, 1973; Espey, 1974; 1978; 1980; LeMaire and Marsh, 1975; Parr, 1975; Wallach *et al.*, 1980; Murdoch, 1985; Thibault and Levasseur, 1988; LeMaire, 1989; Goetz *et al.*, 1991; Tsafriri *et al.*, 1991a). Clearly, multiple mechanisms are involved in the process and many more were considered. Lipner (1988) has reviewed in detail all putative processes suggested to be involved in ovulation. Recently, studies on the role of proteolysis, steroids and of metabolites of arachidonic acid in follicular rupture were undertaken, and these will be reviewed here in brief.

(a) Proteolysis and follicular rupture

The mature preovulatory follicle is embedded within the connective tissue matrix of the ovary, only a small part of which protrudes from the ovarian surface. At its apex the following layers are distinguishable; (i) a single layer of surface epithelium; (ii) collagenous connective tissue consisting of the tunica albuginea and of theca externa – this contributes most of the tensile strength of the follicle wall (Espey, 1967a); (iii) theca interna, a well-vascularized layer containing differentiated fibrocytes very active in steroidogenesis; (iv) granulosa cells, which are separated from the theca interna by the basal lamina and enclose the follicular fluid-filled cavity.

An increase in intrafollicular pressure was for long assumed to be the cause of rupture and extrusion of the oocyte–cumulus complex. Direct measurements of intrafollicular pressure, however, did not reveal any significant increase in rat (Blandau and Rumery, 1963), rabbit (Espey and Lipner, 1963; Rondell, 1964) and pig (Bronson *et al.*, 1979) follicles approaching ovulation. Nevertheless, the preovulatory surge of gonadotrophins is followed by a dramatic increase in the volume of ovulatory follicle(s). Follicular oedema is most probably the result of increased ovarian blood flow (Wurtman, 1964; Blasco *et al.*, 1975; Janson, 1975; Lee and Novy, 1978; Murdoch *et al.*, 1983) and capillary permeability (Lipner and Smith, 1971; Bjersing and Cajander, 1974b; Parr, 1974; Abisogun *et al.*, 1986). In the face of a rapid increase of follicular volume, constant pressure can be maintained only by a concurrent increase in the distensibility of follicular wall. Indeed, as ovulation approaches, a decrease in the tensile strength of follicular wall was observed (Espey, 1967a; Rondell, 1970a,b).

Microscopic examination of the wall of ovulatory follicles revealed marked dissolution of the connective tissue matrix and of collagen fibres in the tunica albuginea and of the theca externa (Espey, 1967b; Bjersing and Cajander, 1974b; see Espey, 1978; Espey *et al.*, 1981). Both the degradative changes and the reduction in follicular tensile strength evidence the pivotal role of proteolytic enzymes in follicular rupture. Involvement of proteolysis in ovulation was suggested already in 1916 by Schochet.

Many enzymes have been identified in follicular tissue or fluid, including proteolytic enzymes (Reichert, 1962; Espey and Rondell, 1967), hyaluronidase (Zachariae and Jensen, 1958), acid phosphatases and esterases (Banon *et al.*, 1964), collagenase-like activity (Espey, 1975; Espey and Coons, 1976; Morales *et al.*, 1978; Fukumoto *et al.*, 1981; Curry *et al.*, 1985; Reich *et al.*, 1985a) and plasminogen activator (PA) (Beers, 1975; Beers *et al.*, 1975; Strickland and Beers, 1976; Canipari and Strickland, 1985; Ny *et al.*, 1985; Reich *et al.*, 1985b, 1986). Furthermore, injection of proteolytic enzymes into the follicular antrum resulted in follicular rupture (Espey and Lipner, 1965), and application of enzyme solutions to follicular wall resulted in ovulatory changes (Espey, 1967a; Espey and Rondell, 1967; Rondell, 1970b).

Studies with preovulatory follicles of mice (Byskov, 1969) and of rabbits (Bjersing and Cajander, 1974c; Cajander, 1976) suggested that the surface epithelium is the source of hydrolytic enzymes which cause ovulation and that dense granules in the cytoplasm of these cells are lysosomes. However, other investigators noticed that ovulation could occur even when the surface epithelium was removed from the follicles (Rawson and Espey, 1977). Another source of proteolytic enzymes are thecal fibroblasts with prominent multivesicular structures, which increase in number following the ovulatory stimulus (Espey, 1971a,b; Espey *et al.*, 1981). The granulosa cells are the major source of follicular PA activity (Reich *et al.*, 1986).

(b) The plasmin activating system and ovulation

The presence of PA was demonstrated in extracts of human and bovine ovarian tissues and in follicular fluid (Albrechtsen, 1957; Beers, 1975; Weimer *et al.*, 1984; Rom *et al.*, 1987). An increase in PA secretion by rat granulosa cells was demonstrated as ovulation approached (Beers *et al.*, 1975; Beers and Strickland, 1978). A preferential increase in PA activity was observed in the apical portion of sow preovulatory follicles (Smokovits *et al.*, 1988). Furthermore, plasmin, the product of PA action on plasminogen, was shown to decrease the tensile strength of Graafian follicle wall (Beers, 1975). All these findings led to the hypothesis that PA is involved in ovulation. It was suggested that plasmin activates latent collagenase and thus initiates the proteolytic changes leading to follicular rupture (Strickland and Beers, 1976; Espey, 1978).

Rat granulosa cell PA activity was stimulated by LH, FSH, cAMP derivatives and prostaglandins E_1 and E_2 (Beers *et al.*, 1975; Strickland and Beers, 1976). In these studies, however, FSH was much more effective than LH in stimulating granulosa cell PA activity (Strickland and Beers, 1976; Martinat and Combarnous, 1983). This is in contrast to the physiological role of LH, and not FSH, as the ovulation-inducing hormone (Schwartz *et al.*, 1973; Tsafriri *et al.*, 1976c). Recent studies seem to resolve this discrepancy. It was found that FSH and LH were equally potent in enhancing rat granulosa cell PA activity provided that the cells were first properly stimulated to induce LH receptors by FSH or dbcAMP (Wang and Leung, 1983). Likewise, FSH, LH, prostaglandin E_1 and relaxin were equally effective in stimulating rat granulosa cell PA, provided that the cells were from mature follicles (Too *et al.*, 1984). Furthermore, in rat pro-oestrous follicles LH and FSH were equally effective in stimulating PA activity (Reich *et al.*, 1985b).

Comparison of *in vitro* accumulation of PA in cultures of rat granulosa cells, whole follicles and the residual tissue, mainly theca with some interstitial tissue (Reich *et al.*, 1986), revealed that the granulosa cells contribute 80–90% of total follicular PA activity. Furthermore, whereas most of granulosa PA activity is secreted into the culture medium, that of intact follicles or residual tissue is retained within the follicle and should be extracted from the tissue (Reich *et al.*, 1985b, 1986). This finding suggests that the theca compartment serves as a specific barrier which prevents the secretion of PA into extrafollicular compartment and, therefore, allows localized action of PA in follicular wall.

Two different molecular types of PA have been identified in mammals, the urokinase type (u-Pa) and the tissue type (t-PA). The two types are products of different genes (Ny *et al.*, 1984; Suenson *et al.*, 1984; Riccio *et al.*, 1985). Two molecular types of PA were identified in rat preovulatory follicles which, on the basis of electrophoretic mobility and immunoabsorption with t-PA antiserum, could be characterized as t-PA and u-PA (Figure 1.11).

The two molecular types were present both in the granulosa and in the theca compartments, the granulosa cells contributing 80–90% of the total follicular activity. Upon gonadotrophin stimulation, a highly significant ($P > 0.001$) increase in t-PA was observed in whole follicles and in the granulosa cells (Reich *et al.*, 1986). Likewise, rat granulosa cells and cumulus–oocyte complexes responded to gonadotrophins by enhanced accumulation of t-PA (Ny *et al.*, 1985; Y.X. Liu *et al.*, 1986). In contrast, measuring only the secreted PA, Canipari and Strickland (1985, 1986) reached the conclusion that the theca (or the whole follicle) secretes u-PA and that this type is stimulated by the gonadotrophin. However, the data of Reich *et al.* (1985b, 1986) indicate that only a minor fraction of follicular PA is secreted into the medium, thus reconciling these apparent discrepancies. A similar

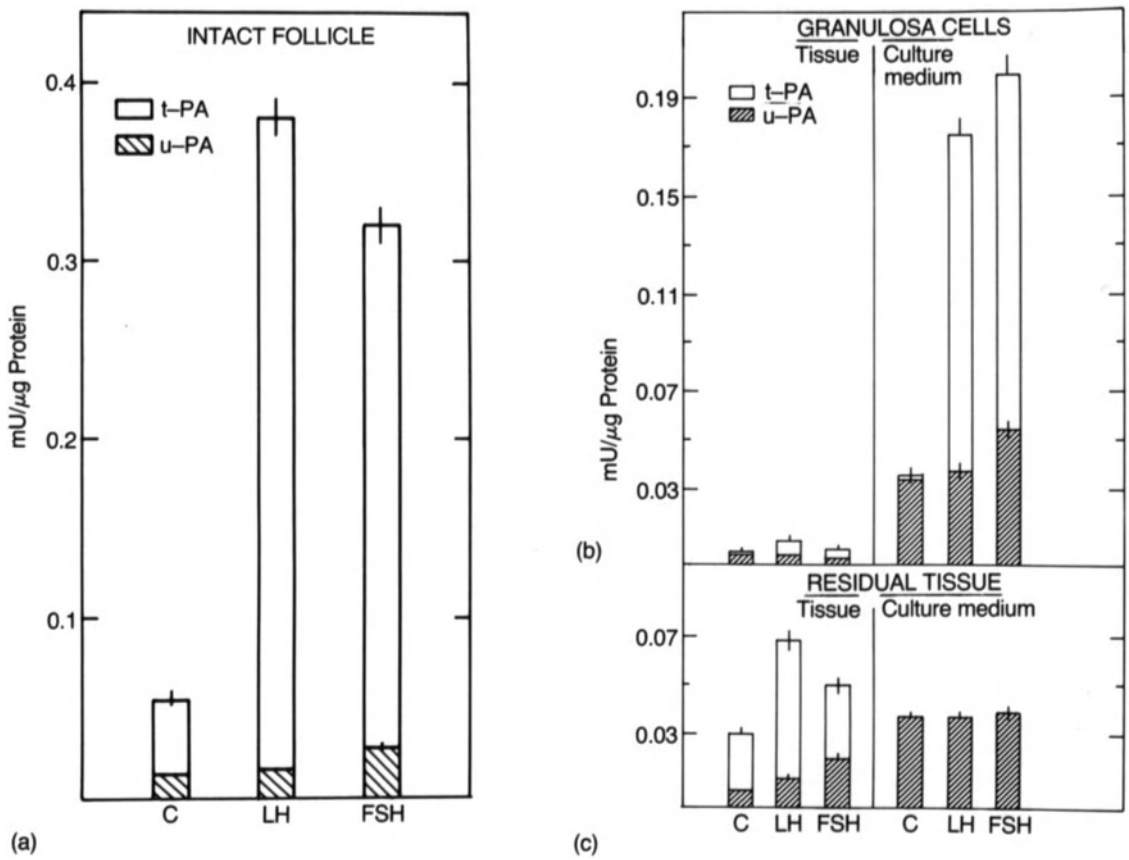

Figure 1.11 Stimulation of follicular PA activity *in vitro* by gonadotrophins (a) in explanted follicles, (b) in cultured granulosa cells and (c) in residual tissue, mainly theca tissue with some interstitial and granulosa cells. PA activity was assayed by quantitative zymographic analysis. (From Reich *et al.*, 1986.)

increase in t-PA in human granulosa cells was observed (Reinthaller *et al.*, 1990). Nevertheless, in mice urokinase seems to be the PA stimulated by the preovulatory surge of gonadotrophins (Canipari *et al.*, 1987).

The involvement of PA in follicular rupture was confirmed by a pharmacological approach. Several inhibitors of serine proteases prevented ovulation in rats *in vivo* (Akazawa *et al.*, 1983a,b; Reich *et al.*, 1985b) and in hamster ovaries *in vitro* (Ichikawa *et al.*, 1983a). Likewise, an antibody to t-PA and a serum-derived inhibitor of plasmin, α_2-antiplasmin (α_2-AP), blocked ovulation when administered to pro-oestrous rats Tsafriri *et al.*, 1989b). The inhibitors of serine proteases anti t-PA and α_2-AP suppressed ovulation effectively only up to 3 h after administration of hCG (Reich *et al.*, 1985b; Tsafriri *et al.*, 1989b) indicating that serine proteases are involved in early changes leading to follicular rupture. Interestingly, suppression of ovulation by anti t-PA and α_2-AP was frequently accompanied by the breakdown of follicular basement membrane and escape of the ovum into the thecal compartment. These results provide the clearest evidence to date for the involvement of t-PA and plasmin in ovulation.

Local PA activity is regulated by specific inhibitors (Hekman and Loskutoff, 1988), plasminogen activator inhibitor type 1 (PAI-1) being the primary physiological inhibitor of both, t-PA and u-PA (Vassali *et al.*, 1991). Granulosa cells secrete PAI-1 and FSH suppressed this activity (Ny *et al.*, 1985). Increased levels of PAI-1 activity were found in human preovulatory follicular fluid (Reinthaller *et al.*, 1990), in ovarian extracellular fluid of hCG-treated immature rats primed with PMSG (Y.X. Liu *et al.*, 1991) and in preovulatory follicles of prepubertal gilts treated with eCG and hCG (Politis *et al.*, 1990). Y.X. Liu *et al.* (1991) using Northern blot analysis demonstrated that the expression of PAI-1 mRNA is regulated by gonadotrophins differentially in granulosa and theca–interstitial cells during the preovulatory period. The expression of PAI-1 mRNA in theca–interstitial cells is maximal at 6 h after LH/hCG stimulation, and in granulosa cells it reaches maximum only 24 h after the stimulation (Y.X. Liu *et al.*, 1991). By *in situ* hybridization only negligible expression of PAI-1 mRNA limited to theca cells was observed before hCG stimulation of ovulation. Following hCG administration, increased expression of PAI-1 mRNA was observed in theca cells of most antral follicles, whereas granulosa cell expression was limited to preovulatory follicles and only to areas where the basal membrane was dissociated (Chun *et al.*, 1992). Glucocorticoids were shown to suppress plasminogen-dependent fibrinogen activity in conditioned medium of a rat hepatoma cell line, and this was later demonstrated to be due to an increase in PAI-1 (Gelehrter *et al.*, 1987; Heaton and Gelehrter, 1990). Curiously, in rat granulosa cells glucocorticoids did not affect PAI-1 activity, but did stimulate PA (Wang and Leung, 1989). This effect of glucocorticoids on granulosa cell t-PA activity probably underlies the observed increase in ovulation rate in the rat after dexamethasone treatment (de Greef and van der Schoot, 1987).

(c) Collagenolysis

The extensive changes in follicular collagen observed prior to ovulation suggest that collagen-degrading enzymes play a central role in ovulation. Collagenase-like activity was demonstrated in ovarian tissues (Morales *et al.*, 1978, 1983; Fukumoto *et al.*, 1981).

Until very recently, experiments to extract follicular collagenase and to demonstrate its ability to degrade follicular wall were not successful (Espey and Stacy, 1970), nor has a correlation between collagenase activity and ovulatory changes been demonstrated (Morales *et al.*, 1978, 1983). This failure should probably be attributed to the fact that collagenase regulation *in vivo* is a multifactorial process involving both cellular and microenvironmental factors. These include cellular factors modulating collagenase proenzyme release and control of its activity by activators, inhibitors and changes in substrate susceptibility. In extracts of rat ovaries an increase in three distinct inhibitors of metalloproteinases, including tissue inhibitor of metalloproteinase (TIMP), was demonstrated after stimulation of ovulation by hCG (Woessner *et al.*, 1989).

In order to circumvent the difficulties in demonstrating gonadotrophin-induced changes in ovarian collagenase activity collagen was labelled by local administration of [^{3}H] proline ([^{3}H] Pro). Some of the [^{3}H] Pro incorporated into collagen molecules is enzymatically hydroxylated into hydroxyproline (Hyp). The presence of the latter is unique to collagen. Ovarian collagen content and collagenolysis were assessed by separating [^{3}H] Hyp from acid hydrolysate of ovarian tissue by high-performance liquid chromatography (Reich *et al.*, 1985b).

Using this approach, significant degradation of labelled collagen was detected after the preovulatory surge of gonadotrophins. Collagen degradation was blocked by Nembutal – a drug which prevents the secretion of gonadotrophins, and hence

ovulation. Moreover, upon administration of hCG on the morning of pro-oestrus, the level of [^{3}H] Hyp in preovulatory follicles was reduced by 43% within 10 h.

Curry *et al.* (1985), employing rigorous extraction procedures and *in vitro* activation of ovarian collagenase by reduction with dithiothreitol, alkylation by iodoacetamide and activation with aminophenylmercuric acetate, confirmed the LH/hCG-induced rise in ovarian collagenase activity. Similar results were obtained by somewhat different extraction procedures, but in these experiments there was no need for collagenase activation *in vitro* (Reich *et al.*, 1987). In view of the difficulties in measuring collagenase activity, examination of ovarian transcription of collagenase mRNA during the periovulatory period may be informative. Indeed, by hybridizing human cDNA of collagenase I with rat ovarian mRNA prepared at various time intervals after triggering ovulation with hCG revealed a stimulation of collagenase mRNA transcription by the hormone, 3–6 h after hCG (Reich *et al.*, 1991).

The role of collagenase in follicular rupture was corroborated indirectly by intrabursal administration of cysteine. It prevented ovarian collagenolysis as well as ovulation, and these two actions were dose related (Reich *et al.*, 1985a). Similarly, a microbial metalloprotease inhibitor, talopeptine, inhibited ovulation *in vitro* from hamster ovaries (Ichikawa *et al.*, 1983b). Finally, a specific inhibitor of mammalian tissue collagenase blocked ovulation in perfused rat ovaries (Brännström *et al.*, 1988) and *in vivo* (D. Daphna-Iken, unpublished observations).

Metalloproteinases, the enzymes including the collagenases, are locally regulated by specific serum and tissue inhibitors. Recently, TIMP has been identified in ovarian tissues (Curry *et al.*, 1989; Woessner *et al.*, 1989) and shown to be induced by gonadotrophins (Curry *et al.*, 1989; Mann *et al.*, 1991; Reich *et al.*, 1991). *In situ* hybridization revealed low constitutive expression of TIMP-1 mRNA in theca cells, which became markedly stimulated within 9 h after hCG stimulation of ovulation in antral and preovulatory follicles. TIMP-1 mRNA expression in granulosa cells was increased by hCG only in preovulatory follicles (Chun *et al.*, 1992).

LH/hCG seem to stimulate ovarian coexpression of both proteolytic enzymes as t-PA and collagenase and their respective inhibitors, PAI-1 and TIMP-1. The preovulatory stimulation of thecal PAI-1 and TIMP-1 even in small antral follicles seems to protect them against the proteolytic activity diffusing from ovulating follicles and thus allows their development in subsequent cycles to the ovulatory stage.

1.7.3 ROLE OF OVARIAN STEROIDS IN FOLLICULAR RUPTURE

Follicular steroidogenesis increases markedly after the preovulatory surge of gonadotrophins. This overall stimulation in steroid production is followed in rat follicles 4–6 h later by an inhibition of androgen and oestrogen synthesis, whereas the secretion of progesterone further increases during the preovulatory period (Lieberman *et al.*, 1975). The involvement of ovarian steroidogenesis in follicular rupture in the rat was suggested by Lipner and Wendelken (1971) and Lipner and Greep (1971), who inhibited follicular rupture by administration of aminoglutethimide and cyanoketone, drugs that block the synthetic pathway to progesterone. Assuming that the failure of ovulation was due to a lack of essential steroid(s) in the presence of the inhibitor, a model suggesting LH stimulation of a steroid which initiates the subsequent events leading to follicular rupture was constructed (Lipner and Greep, 1971). Evidence supporting such a two-step mechanism was presented by Takahashi *et al.* (1974): hypophysectomy of rats at 15:50 h of pro-oestrus resulted in blockage of follicular rupture, and this was effectively reversed by

three consecutive injections of progesterone (5–10 mg each). This concept was challenged by Bullock and Kappauf (1972), who could dissociate the effects of aminoglutethimide and cyanoketone on plasma progesterone and on follicular rupture; thus, they could induce ovulation by hCG when its effect on steroidogenesis was inhibited by aminoglutethimide, and cyanoketone prevented ovulation even when steroid levels in plasma remained unchanged. Nevertheless, it is possible that plasma levels of progesterone are not a precise indicator of follicular levels of steroids, which are probably involved in follicular rupture. The ability of another inhibitor of 3β-hydroxysteroid dehydrogenase, epostane, to inhibit follicular rupture in the rat was demonstrated, and this inhibition was overcome by administration of progesterone (Snyder *et al.*, 1984). Ovulation in the ewe was blocked by an inhibitor of progesterone synthesis (Murdoch *et al.*, 1986). Furthermore, administration of the progesterone receptor antagonist RU 38486 partially blocked ovulation in mature and immature rats in which ovulation was triggered by hCG (Tsafriri *et al.*, 1987). Iwamasa *et al.* (1992) went further and demonstrated that RU 38486 was effective in inhibiting ovulation only when injected up to 4 h after hCG, and this effect was reversed by oxogenous progesterone. The inhibition of ovulation was related to suppression of proteolytic enzymes, most probably metalloproteinases, and their activity was restored by administration of progesterone. This supports the paracrine role of progesterone, exerted through its interaction with cellular receptors, in the mediation of LH/hCG induction of follicular rupture.

Another approach employed was the use of antibodies to steroids. Thus, intrafollicular injections of progesterone antiserum to rabbits blocked ovulation (Swanson and Lipner, 1977). Likewise, administration of progesterone (Mori *et al.*, 1977a) or testosterone (Mori *et al.*, 1977b) antiserum to PMSG–hCG-treated immature rats inhibited follicular rupture and this was overcome by exogenous progesterone, testosterone and 5α-dihydrotestosterone, but not by oestradiol-17β. Thus, *in vivo* studies seem to suggest the role of follicular steroids in follicle rupture.

The role of ovarian steroids was closely examined in the model of perfused ovary which affords study of follicular rupture *in vitro* (Lambertsen *et al.*, 1976; Janson *et al.*, 1982). In perfused rabbit ovaries inhibition of cholesterol chain cleavage enzyme by aminoglutethimide or of 3β-hydroxysteroid dehydrogenase did not affect follicle rupture induced by gonadotrophin (Holmes *et al.*, 1985; Yoshimura *et al.*, 1986). By contrast, an inhibitor of 3β-hydroxysteroid dehydrogenase significantly reduced the ovulation from perfused rat ovaries stimulated by a combination of LH and IBMX (Brännström and Janson, 1989). The preovulatory decline in follicular oestrogen is not required for follicular rupture in the rabbit, since addition of oestrogen (10 μg/ml) to the perfusate did not inhibit ovulation, in spite of a more than twofold increase in follicular oestradiol-17β content (LeMaire *et al.*, 1982). Likewise, blockade of the early rise in oestrogen by an inhibitor of aromatase did not affect follicular rupture in perfused rat ovaries (Koos *et al.*, 1984; Morioka *et al.*, 1988).

While inhibition of steroidogenesis did not affect ovulatory response of perfused ovaries in the rabbit, addition of progesterone into the perfusate modified it. Progesterone (6.7 μg/ml) somewhat enhanced follicular rupture in one study (Hamada *et al.*, 1979), and it reduced the number of ovulating ovaries in another employing a higher dose of progesterone (10 μg/ml) (Holmes *et al.*, 1985). Thus, a modulatory role of progesterone in follicular rupture *in vitro* cannot be excluded. Collectively, the data presented seem to suggest the involvement of steroids, most probably progesterone, in follicular rupture. Nevertheless, their specific role remains obscure and species differences may exist.

Addition of steroids (1 μg/ml) into the medium in which unstimulated preovulatory rat follicles were cultured did not change follicular PA activity during a 6 h incubation period. By contrast, addition of oestradiol-17β, progesterone or testosterone, but not 5α-dihydrotestosterone (all 1 μg/ml) to LH-stimulated follicles further enhanced PA activity. Furthermore, addition of inhibitors of steroidogenesis or of aromatase inhibited the LH-stimulated activity of PA ($P > 0.001$). LH-stimulated follicular PA activity could be restored in the presence of inhibitors by the addition of progesterone, testosterone and oestradiol-17β, but not in the non-aromatizable 5α-dihydrotestosterone (Reich *et al.*, 1985b). More recently, the ability of the antiprogesterone RU 38486 to suppress ovarian proteinases, most probably metalloproteinases, was demonstrated (Iwamasa *et al.*, 1992), thus suggesting a mediatory role for steroids in gonadotrophic stimulation of proteolysis, required for follicle rupture.

1.7.4 ROLE OF EICOSANOIDS

Several studies demonstrated an increase in follicular prostaglandin synthesis after gonadotrophic stimulation (LeMaire *et al.*, 1973; Ainsworth *et al.*, 1975; Armstrong and Zamecnik, 1975; Bauminger and Lindner, 1975). It was shown that this action of LH is not dependent upon steroid synthesis (Bauminger *et al.*, 1975), and that most follicular responses to LH, such as ovum maturation, activation of adenyl cyclase, steroidogenesis and luteinization proceed while prostaglandin synthesis is inhibited by drugs (reviewed by Zor and Lamprecht, 1977). The exception is follicular rupture, which is prevented by administration of indomethacin (rats, Armstrong and Grinwich, 1972; Orczyk and Behrman, 1972; Tsafriri *et al.*, 1972b; rabbits, Grinwich *et al.*, 1972; O'Grady *et al.*, 1972; gilts, Ainsworth *et al.*, 1979: rhesus monkeys, Wallach *et al.*, 1975; marmoset monkeys, Maia *et al.*, 1978; human, Killick and Elstein, 1987), or intrafollicular injection of antiserum to $PGF_{2\alpha}$ in rabbits (Armstrong *et al.*, 1974), or intravenous injection of an antiserum to cyclooxygenase in rats (Satoh *et al.*, 1981). The inhibitory action of indomethacin was overcome by administration of PGE_2 to rats (Tsafriri *et al.*, 1972b) or $PGF_{2\alpha}$ to rhesus monkeys (Wallach *et al.*, 1975).

Furthermore, in the perfused rabbit ovary $PGF_{2\alpha}$ was able to induce follicular rupture by itself or in hCG-indomethacin treated ovaries (Holmes *et al.*, 1983). Collectively, these results suggest that prostaglandins have a physiological role in follicular rupture (see Zor and Lamprecht, 1977; Patrono, 1983; Lipner, 1988).

The recent elucidation of the lipoxygenase pathway of arachidonic acid cascade and availability of specific inhibitors of lipoxygenase led to examination of their role in ovulation. Unilateral administration of lipoxygenase inhibitors into the ovarian bursa of PMSG-stimulated immature or mature rats resulted in a dose-dependent suppression of ovulation, without affecting the contralateral ovary (Reich *et al.*, 1983, 1987). Furthermore, ovarian lipoxygenase activity was demonstrated in homogenates of rat ovaries and follicles (Reich *et al.*, 1985c, 1987) and of human granulosa cells (Feldman *et al.*, 1986). In ovarian tissue of both the rat and the human, products of 5-, 12- and 15-lipoxygenases were identified (Feldman *et al.*, 1986; Reich *et al.*, 1987) and their activity in the rat was stimulated considerably by hCG treatment. These studies suggest the involvement of lipoxygenase products in follicular rupture of ovulation. The scarcity of stable analogue has not yet allowed the identification of the metabolites involved in ovulation. Nevertheless, a specific inhibitor of 5-lipoxygenase, MK 886, suppressed ovulation in immature rats (Tsafriri *et al.*, 1993).

Collectively, both cyclooxygenase and lipoxygenase products of arachidonic acid metabolism seem to be involved in follicular rupture. The finding that specific inhibition

of any of these pathways blocks ovulation further demonstrates the multiple regulation of the process. Arachidonic acid metabolites are involved in a multitude of physiological processes (Piper, 1983; Hayaishi and Yamamoto, 1985), and experimental evidence for their involvement in ovulation through their action on ovarian proteolysis and vasculature is available.

In several studies, doses of indomethacin which inhibited ovulation did not affect LH/hCG-induced increase in PA activity (Shimada *et al.*, 1983; Espey *et al.*, 1985; Reich *et al.*, 1985b). In spite of the fact that higher doses of indomethacin inhibited PA production *in vivo* (Espey *et al.*, 1985) or *in vitro* (Canipari and Strickland, 1986), it seems that the inhibition of prostaglandin synthesis blocks ovulation through mechanism(s) which are not related to PA. Likewise, inhibitors of lipoxygenase which blocked ovulation did not affect follicular PA production (Reich *et al.*, 1985b). This finding does not imply that PA is not involved in follicular rupture, but that increase in PA activity by itself is not a sufficient trigger of ovulation.

Conversely, inhibitors of arachidonic acid metabolism prevented LH/hCG induced collagenolysis in rat ovaries and follicles (Reich *et al.*, 1985b; Tsafriri *et al.*, 1993) and collagenase activity in rabbit ovaries (Kawamura *et al.*, 1986) and ewe follicles (Murdoch *et al.*, 1986). It therefore appears that preovulatory activation of collagenase by LH/hCG is mediated by products of arachidonic acid. It should be noted, however, that the inhibitors of cyclooxygenase or lipoxygenase did not inhibit the activity of ovarian collagenase *in vitro* (Reich *et al.*, 1985b), nor did indomethacin reduce collagenase activity assayed *in vitro* following extraction of and activation (Curry *et al.*, 1986). It seems, then, that while eicosanoids do not affect directly collagenase activity they are involved in the mediation of gonadotrophic activation of the enzyme required for ovulation.

Periovulatory changes in ovarian and follicular microcirculation were described (Janson, 1975; Lee and Novy, 1978; Murdoch *et al.*, 1983). These studies revealed initial increase in blood flow, which in the sheep was followed by a decrease (Murdoch *et al.*, 1983). It is possible that eicosanoids are involved in ovulation by modulating follicular microcirculation. Indeed, in the rabbit, indomethacin reduced the LH-induced hyperaemic response (Lee and Novy, 1978), and in the ewe it prevented the second-phase reduction in follicular blood flow (Murdoch *et al.*, 1983). In the rat, inhibitors of cyclooxygenase and of lipoxygenase prevented the hCG-induced increase in uptake of labelled iodinated bovine serum albumin. By contrast, they did not attenuate the hCG-increased blood flow, as measured by radioactive microspheres (Abisogun *et al.*, 1988b). While the precise mechanisms involved remain to be determined, all these results support the suggested role of eicosanoids in periovulatory changes in ovarian microcirculation and thereby also in ovulation. Thus, eicosanoids are involved in follicular rupture through their modulation of LH/LCG action on ovarian collagen degradation and on microcirculation.

1.7.5 PLATELET-ACTIVATING FACTOR (PAF)

PAF (1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine) is a potent bioactive phospholipid. In addition to triggering aggregation and degranulation of platelets, PAF induces margination and activation of neutrophils. Furthermore, PAF is released upon activation of leucocytes. We have demonstrated a preovulatory increase in ovarian and follicular neutrophils, triggered by hCG (Tsafriri *et al.*, 1989c). In view of these changes common to ovulation and inflammation, we have examined the possible involvement of PAF in ovulation. Unilateral injection into the ovarian bursa of a specific PAF antagonist, BN52021, isolated from the Chinese tree *Ginkgo biloba* (Braquet *et al.*, 1985), or its analogue BN52111

resulted in a dose-dependent inhibition of follicle rupture from the treated ovary. The inhibition was prevented when the inhibitors and PAF were administered simultaneously. However, PAF was unable to induce ovulation on its own when administered to rats that were not stimulated by exogenous hCG and had their endogenous surge of LH blocked by LH (Abisogun *et al.*, 1989; Daphna-Iken *et al.*, 1989). A decrease in ovarian PAF was observed after stimulation of ovulation by hCG (Espey *et al.*, 1989).

The PAF antagonist, in addition to inhibiting follicle rupture, suppressed the hCG-stimulated increase in ovarian collagen degradation and vascular permeability, similar to the action of eicosanoid synthesis inhibitors. These results were confirmed in studies employing additional PAF antagonists: in the rat using Y24180 (Li *et al.*, 1991) and in the mouse CV3988 (Kikukawa *et al.*, 1991). PAF was detected in follicular fluid collected from women undergoing *in vitro* fertilization–embryo transfer (Amiel *et al.*, 1991), and the secretion of PAF from ovine follicles *in vitro* was stimulated after the LH surge (Alexander *et al.*, 1990). Conversely, a decrease in rat ovarian PAF was reported after stimulation of ovulation by hCG (Espey *et al.*, 1989). These results support the participation of PAF in follicular rupture. Nevertheless, the precise mechanism of PAF involvement in follicular rupture, as well as its cellular origin and targets in the ovary, remain to be determined.

1.8 CONCLUDING REMARKS

The evolution of the vertebrate ovary shows examples of stable and labile systems (Jones, 1978). This is also clearly demonstrated during the life history of the mammalian female germ cell and its accompanying follicle cells.

Oogenesis in most mammalian species differs from that of several major vertebrate groups in the absence of oogonial mitoses in adult ovaries. By contrast, in teleosts, amphibia and reptiles, oogonia persist in adult ovaries and they continue to divide and differentiate into oocytes. In most vertebrates large crops of oocytes mature simultaneously. In mammals, the evolution of cyclic ovulation of one (in monotocous species) or more (in polytocous species) ova has resulted in hierarchical development of follicles and oocytes. The coexistence of follicles and oocytes at different stages of development in mammals requires mechanisms allowing stage-specific responses to similar endocrine cues. Variability in sensitivity to hormones due to stage-dependent changes in hormone receptors, differential distribution of ovarian microcirculation and hence exposure to varying hormone concentrations, as well as action of locally produced autocrine and paracrine hormones which modulate cellular responses, may all be involved, among other mechanisms, in supporting differential responses. Thus, in mammals during discrete stages of the reproductive cycle, dominant structures, such as follicles or corpora lutea, assume a leading role in ovarian function, rather than the entire ovary. Furthermore, throughout follicular growth a delicately balanced synchronization of the development of the germ cell and its surrounding somatic cells occurs.

Vertebrate egg components are synthesized in the oocyte and in extraoocyte tissues such as the oviduct, liver and, probably, follicle cells (Tate, 1986). The extraoocyte synthesis of its components is clearly coordinated by hormones, hypophyseal gonadotrophins and ovarian oestrogen(s). The role of hormonal signals from endocrine glands or paracrine secretions in the regulation of oocyte autosynthetic activity is, however, less obvious. In oviparous vertebrates, the extraoocyte tissues contribute a relatively small number of specialized products in large amounts that constitute a major fraction of egg mass. In mammals, viviparity eliminated the need for massive contribution of extraoocyte tissues to the oocyte. Whether there

exists any extraoocyte contribution to the mammalian oocyte has yet to be determined.

In fishes and amphibia, pituitary gonadotrophins induce resumption of meiosis through the mediation of follicular (or interrenal) steroids (W.J. Wasserman and Smith, 1978; Schuetz, 1985). By contrast, LH-stimulated steroidogenesis does not seem to mediate the meiosis-inducing action of LH in mammals. Furthermore, the regulation of follicular development and of oocyte maturation seems to be more complicated, including both stimulatory and inhibitory signals by endocrine and paracrine hormones. This increased complexity, as well as the involvement of multiple control mechanisms, is probably associated with hierarchical oocyte/follicle development in mammals. As usual, these multiple regulatory mechanisms utilize hormones which in lower forms serve other functions.

However, only the extraoocyte mechanisms regulating oocyte maturation seem to be divergent in mammals; the molecular changes within the ooplasm, as far as known at the present, seem to be conserved. Thus, MPF from maturing mouse oocytes induced resumption of meiosis when injected into starfish (Kishimoto *et al.*, 1984; H. Hashimoto and Kishimoto, 1988) and toad oocytes (Sorensen *et al.*, 1985). It therefore seems that evolution of the mammalian ovary entails primarily changes in oocyte–follicle interrelationships and in the biochemical mechanisms associated with the follicle control of meiosis. We have discussed the apparent difference between oocytes of various mammals in adenylate cyclase activity and in the resulting dependence on transfer of cyclic AMP from the somatic cells of the follicle.

One of the most striking features of oogenesis is selection. Thus, germ cells are eliminated at various stages of their development. Degeneration afflicts both oogonia and oocytes. Only a limited number of oocytes within primordial follicles initiate their growth during any time interval. Finally, the vast majority of growing follicles undergo atresia rather than ovulation. It seems that rescue from atresia is primarily a matter of synchronization between follicular stage of development and hormonal environment. Only 'follicles being at the right stage and place, at the right time' (Ryan, 1981) are selected and reach ovulation (see Tsafriri and Braw, 1984). Thus, hormonal cues appear to play a major role in atresia. The role of hormones at earlier stages of oocyte degeneration and follicle selection is less obvious. Preprogrammed events are probably also involved in initiation of meiosis and follicular growth and in the development of meiotic competence. The precise interrelationship of preprogrammed changes and hormonal cues in mammalian oogenesis remains to be defined.

Oocytes of the mouse, spontaneously matured *in vitro*, have normal developmental capacity (Schroeder and Eppig, 1984), while those of sheep fail to develop, upon transfer to appropriate recipients. Full developmental potential of sheep and bovine oocytes is dependent upon hormonal stimulation of the intact follicle or co-cultured granulosa cells (Moor *et al.*, 1980b; Moor and Osborn, 1983; Critser *et al.*, 1986). This difference is probably related to the time interval between the meiosis-inducing stimulus and GVB in these species and is reflected as well in their dichotomy regarding the need for undisturbed macromolecular and steroid synthesis during this period. More systematic examination of additional mammalian species is required to test this hypothesis. Clearly, these are only a few of the open questions concerning development of the mammalian ovum, which were alluded to hitherto.

Scientific inquiry is a continuum, and our understanding of ovum development is no exception. In this chapter, we have attempted to present a current account of the life history of the mammalian ovum. Care was taken to represent fairly major advances and divergent approaches and opinions. The

extent of our success is left to the discretion of the reader. We were helped by standing on the shoulders of the giant contributors in this field. It is impossible to mention all their names here, but the seminal contributions of three active scientists who laid the foundations of the current work on mammalian ova deserve special mention, C.R. Austin, M.C. Chang and C. Thibault. Their pioneering studies and insight, we believe, have inspired many of the studies reviewed here.

ACKNOWLEDGEMENTS

This review was started for an earlier publication and updated in 1993 (see Editor's preface). We apologize for the inconsistencies and the selective coverage of the most recent studies. The meticulous secretarial help of Mrs M. Kopelowitz is gratefully acknowledged. We are indebted to Prof. D.T. Baird, Dr N. Dekel, Dr J.J. Eppig, Dr H. Lipner, Dr S.H. Pomerantz, Dr R.M. Schultz and Dr C. Thibault for providing their unpublished manuscripts. We thank Dr R.H. Braw, Dr N. Dekel, Dr A.B. Fajer and Dr A.M. Kaye for their helpful comments on the manuscript and Mrs R. Slager and A. Tsafriri for their expert and devoted technical assistance. The studies in our laboratory were supported by grants from the United States–Israel Binational Science Foundation (BSF), Jerusalem, the United States–Israel Binational Agricultural Research and Development Fund (BARD), the German–Israeli Foundation for Scientific Research and Development (GIF), Jerusalem, and the Israel Science Foundation of the Israel Academy of Sciences and Humanities, Jerusalem.

2.1 INTRODUCTION

This chapter has interests in common with four chapters in the third edition of *'Marshall'*, and in many instances reference to these is still well justified. The main theme of 'pre-implantation development' ran through Chapter 14 ('Cleavage, early development and implantation of the egg' by J.D. Boyd and W.J. Hamilton, 1952), while pre-implantation stages of parthenogenesis were included in Chapter 10 ('Fertilization' by C.R. Austin and A. Walton, 1960), early anomalies, embryonic losses and delayed implantation (diapause) were considered in Chapter 14 as well as in Chapter 32 ('The endocrinology of pregnancy and foetal life' by R. Deanesly, 1966) and placentation in marsupials was discussed in Chapter 15 ('Placentation' by E.C. Amoroso, 1952). While Chapters 10, 14 and 15 of the third edition contained much information on non-mammalian species, in the present account attention is largely restricted to mammals, in keeping with the title of this volume, brief mention of features in non-mammals being made when perspective may benefit thereby.

It is fitting next to clarify the use of certain terms. 'Egg' has commonly been employed in the past for the developing entity at stages up to and including implantation, and if the same general size and form are retained, as in man and several other mammals, the label is appropriate. But it is less apt after implantation, or even before implantation in ungulates, because of major changes in morphology, and it carries quite a different connotation when applied to the much larger and more nutrient-laden egg of the monotreme. 'Ovum' has similar virtues and faults; in addition, in the medical literature, the word can denote the entire implanted structure, or even be employed in abnormal states when only membranes persist, as in 'amniotic ovum', an amniotic sac expelled after abortion and resembling a complete conceptus; 'blighted ovum', in which there is a chorion but no embryo; and 'dropsical ovum', a hydramniotic conception sac also lacking an embryo. 'Conceptus' has wide currency and a general connotation, for it is appropriate throughout pregnancy; by contrast, 'zygote' (the fusion product of gametes: Gk: *zygon*, a yoke) is a bit ambiguous, for though it seems properly restricted in its use to describing the fertilized egg during the period between syngamy and cleavage, a very brief phase in mammalian development, many authors grant it an indefinitely longer life.

The most popular label is 'embryo' (Gk: signifying 'something growing within'), but here too there are difficulties, and these will be discussed in some detail for it is important that our terms should be as unambiguous as possible. In human medicine, 'embryo' is commonly used from the time of fertilization to about the eighth week of pregnancy, by which time resemblance to the human form is undeniable; thenceforth until birth, the little creature is a 'fetus'. In the study of other mammalian species, the term embryo has been employed up to the time of birth (or hatching, in monotremes). Both usages are open to objection for they imply the occurrence of no major change, other than increasing size and complexity – a notion apparently deriving from invertebrate embryology. But in mammals the fertilized egg and its pre-implantation products are not equivalent to the fetus or the future individual – much more than that, they also give rise to the placenta and fetal membranes, which in the early stages possess far greater mass and detail.

We should also ponder the following relevant points. After fertilization, the succession of cell divisions or 'cleavage' begins, whereby a ball of cells, the 'morula', is formed, in which all cells have full developmental potential and are therefore said to be 'totipotent'. With further cell division and the formation of a cavity, the morula becomes a

'blastocyst'; in this there are two cell types, making up the 'inner cell mass' and the 'trophectoderm'. The more numerous trophectoderm cells early undergo some differentiation and become irrevocably committed to the formation of placenta and fetal membranes, and they cannot then function as contributors to the fetus itself. By contrast, the cells of the inner cell mass are initially uncommitted and so described as 'pluripotent'. As development proceeds, the inner cell mass differentiates into 'primitive ectoderm' and 'primitive endoderm' (see Table 2.1) and among the subsequent products of the former a small group of cells becomes distinguishable that alone is destined to constitute the fetus. It is this select little tribe that properly merits the term 'embryo'. This distinction has important developmental and functional significance.

In work involving human pre-implantation development, there may well be ethical and legal reasons for pursuing the matter of definition further, for the embryo, at the stage just described, could be held equivalent to the future 'person'. However, some developmental flexibility yet remains. In the human subject, the group of cells constituting the embryo becomes clearly identifiable during the second week after fertilization as the 'embryonic disc', and this is capable of dividing into two or more discs, thus giving rise to twins, triplets, quadruplets, etc. Only after that phase is over do embryos have strict individuality. The term 'embryo' as thus defined creates a need for appropriate labelling of the entire complex of cells that existed prior to the appearance of the embryonic disc, and 'proembryo' would appear to be a sensible choice. (The proposed use of this term here, already well established in the botanical literature, is consistent with its definition as given in *Encylcopeadia Britannica* (including *Macropaedia* and *Micropaedia*), *Henderson's Dictionary of Biological Terms*, *Chambers Science and Technology Dictionary* and other works of reference. Some writers use the spelling 'pre-embryo', but 'proembryo' is etymologically preferable.)

The range of development that can be described as 'pre-implantation' varies with the species. In man and several other mammals, attachment and implantation (nidation) occur relatively early and involve the unilaminar unexpanded blastocyst. At the other extreme, the blastocyst in ungulates undergoes enormous expansion together with the formation of additional structures, and it is indeed an 'embryo' (no longer a proembryo), with chorion, yolk sac and allantois, when it eventually forms attachment to the endometrium. Finally, in monotremes and some marsupials, integration of embryonic membranes with the endometrium never occurs, so that the terms 'attachment' and 'implantation' have no relevance; for these animals, it seems most reasonable in this chapter to follow development to the point at which birth or hatching takes place.

In this introduction, the contributions made by earlier workers to our understanding of the pre-implantation stages of development merit at least brief mention. One of the first to accept the notion of the ovary as the source of eggs, in mammals as in birds, was de Graaf (1672), and he looked for and found eggs in the oviduct and uterus, but thinking that the ovarian follicle was the egg at source was bewildered at the difference in size. Nobody could confirm his findings in the oviduct and uterus or was willing to support his concept until over 100 years later, when Cruickshank (1797) reported that he had recovered eggs from the rabbit oviduct, from 3 days after coitus onwards, and also from the uterus, but he could not trace eggs back to their origin. So it fell to von Baer (1827, 1837) to be the first to identify the ovarian egg (in the dog and sheep), and then Barry (1838, 1839) provided some very clear illustrations of two- and four-cell eggs and morulae of the rabbit. Shortly afterwards, Bischoff (1842a,b, 1845, 1852, 1854) described many cleavage stages with even greater precision in the rab-

bit, dog, guinea pig and deer. In this way, the initial stages of mammalian development came to be appreciated, but purely in a pictorial sense, for the true nature of eggs and blastomeres as specialized cells was not understood, and the details and significance of cell division and fertilization had yet to be elucidated.

The beginnings of a deeper understanding came with the foundation of the 'cell theory', a component of which was Brown's recognition in 1831 of the nucleus as an essential element in the cell, and the principle of which was first clearly stated in 1838 and 1839 by Schleiden and Schwann (as helpfully explained by Nordenskiöld, 1928, and Wilson, 1928). Further elaboration and refinement was made by several other authors during the succeeding half-century, and this, together with the demonstration by Gegenbaur in 1861 that the egg is a single cell, led to the realization that all tissues and organs – and organisms – were composed of cells, and that cells always arose from pre-existing cells, generation after generation, as a continuum reaching back to the primordial forms of life. At last, cleavage began to have meaning as the initial assemblage of building blocks for the ordered construction of the new individual.

2.2 THE CLEAVING EUTHERIAN EGG AND THE BLASTOCYST

2.2.1 CLEAVAGE AND TRANSPORT PATTERNS AND RATES

Cleavage consists in successive nuclear and cytoplasmic divisions of the fertilized or otherwise activated egg, the products being held together initially by the encircling zona pellucida. Cleavage, following fertilization of the eutherian egg, resembles superficially that of certain marine invertebrate eggs which have been studied in great detail (see Wilson, 1928). In coelenterates and sponges, cleavage is random and unrelated to the distribution of cytoplasmic components, but in most other invertebrate groups it proceeds in an orderly manner according to a clear-cut pattern, so that the egg components are segregated in conformity with the nature of the cells and tissues that will develop in the embryo and later in the adult organism. These random or ordered systems are distinguished by the terms 'indeterminate' and 'determinate' cleavage respectively. Eutherian eggs conform rather to the former system, at least during the first few cleavage divisions (Figure 2.1, and see Figures 14.9–14.16 in the third edition of *Marshall*); subsequently, order and pattern become distinguishable, and the cleavage form can then be classed as determinate. The later segregation of cell types in mammalian development is unique in that among miolecithal eggs it is only those of mammals that are called upon to produce placenta and extraembryonic membranes in addition to the future organism (Table 2.1).

Rates of cleavage are moderately consistent among the eutherian species that have been studied, the first division occurring about 24 h after ovulation – that is, with intercurrent fertilization, for parthenogenetic cleavage is initiated a little later.

Subsequent divisions take place at about 12-h intervals; this is an average figure, for divisions in any one egg are not exactly synchronous and eggs with odd numbers of blastomeres are not uncommon. There is some evidence that ungulate eggs cleave more slowly than those of other eutherians, but published figures show much variation. In the mouse, it has been shown that the rate of cleavage is to some extent genetically determined (Whitten and Dagg, 1961). In polytocous animals, eggs in the same individual often differ by one or more divisions, the asynchrony increasing as cleavage proceeds. (Data on cleavage rates have been tabulated by Boyd and Hamilton, 1952; Blandau, 1961; Brinster, 1972; and McLaren, 1982.) Tsunoda *et al.* (1985a) have reported finding that fast-cleaving mouse eggs gave rise after transfer

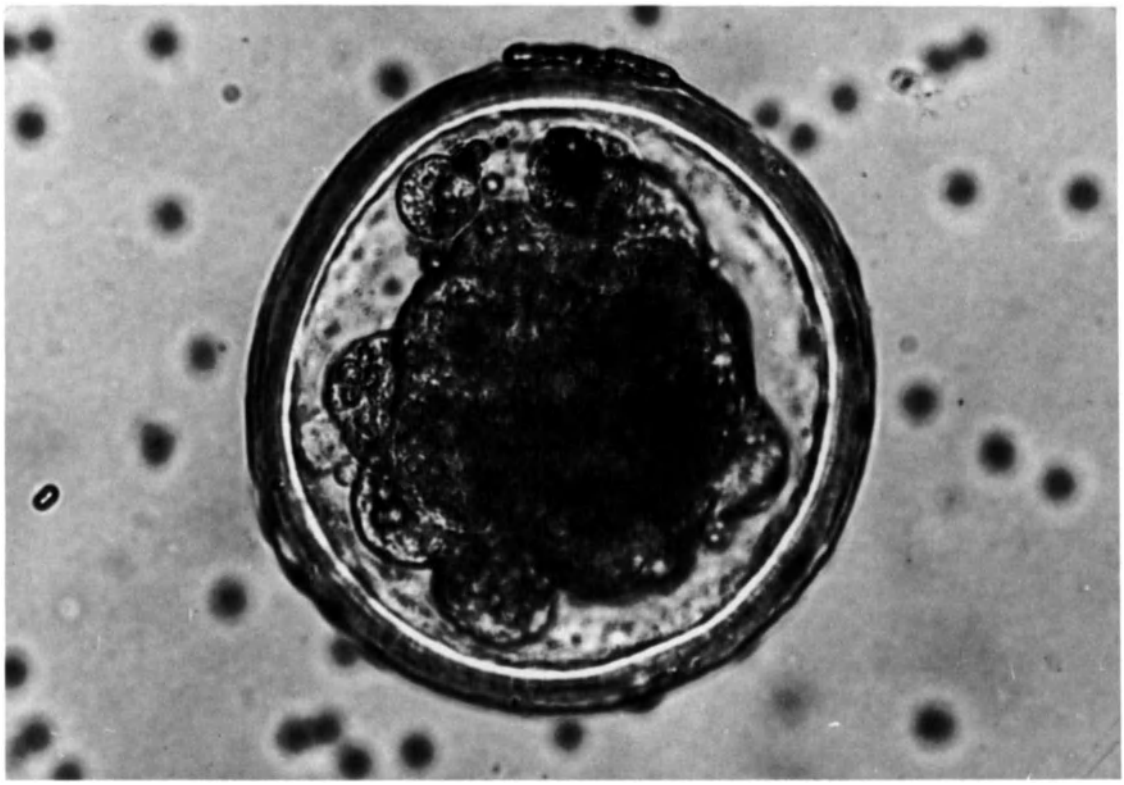

Figure 2.1 Sixteen-cell egg from a swamp buffalo *Bubalus bubalis*, 150μm in diameter. (Micrograph by courtesy of Professor Maneewan Kamonpatana, Faculty of Veterinary Science, Chulalongkorn University, Bangkok, Thailand.)

into recipients to 71% male mice, whereas the slow-cleaving eggs yielded 80% female mice.

Cleavage of the fertilized or parthenogenetically activated egg continues until cell size and nucleocytoplasmic ratio are similar to those of the average tissue cell. With each division, the cytoplasmic volume of blastomeres is approximately halved. The total cytoplasmic volume does not remain constant but slowly and progressively diminishes, presumably because yolk materials are used up to yield components necessary for maintenance and in division; in addition, as explained later, energy resources are taken up from the surrounding medium. The reduction in cell volume from the one-cell stage to the eight-cell stage has been found to be about 20% in the cow, 40% in the sheep, 30% in the ferret and 25% in the mouse (Hamilton and Laing, 1946). The nature of the cue for each cleavage division is not understood; with tissue cells which grow in size during interphase, the cue is evidently the acquisition by the cell of a critical volume, but in cleavage the cells become progressively smaller. Because divisions are not exactly equal, the blastomeres in the morula tend to be graded in size and they aggregate accordingly; the gradation was thought to portend different fates (Boyd and Hamilton, 1952), especially if associated with differences in cytoplasmic features, including staining

Table 2.1 Cell lineages during pre-implantation and early post-implantation development, as determined for the mouse (see Gardner, 1982). Numbers in parenthesis represent the average numbers of cells recorded. Italicized items are those that will constitute the embryo (as distinct from proembryo – a point discussed in the Introduction).

properties (Dalcq, 1957). Current views on cell fates in early development are discussed later in section 2.2.4.

Fertilization in most mammals takes place in the ampulla of the oviduct, being completed within about 24 h of ovulation. As the egg undergoes cleavage, it is moved along the oviduct and into the uterus – in 2–3 days in most instances, but some 5-6 days in the dog, cat and ferret, and 8 days in the mink. (Times of entry into the uterus in various animals have been tabulated by Boyd and Hamilton 1952; Blandau, 1961; Brinster, 1972; and McLaren, 1982.) Transport is attributed to contractions of muscle layers in the wall of the oviduct, and the activity of these muscle cells is readily influenced by certain hormones and drugs (see Coutinho, 1974). Ciliary action may also play a part in transport of the cleaving egg (the evidence for such a function is much more convincing during transfer of the just ovulated egg to the ampulla of the oviduct – Blandau, 1973). Mysteriously, while fertilized eggs in the horse are transported into the uterus, unfertilized eggs tend to be left behind in the oviduct (Betteridge and Mitchell, 1974). Apparently uniquely, in man normal transport may occasionally fail so that the egg becomes implanted in the oviduct, or, being lost from the oviduct through retrograde transport, passes into the peritoneal cavity and implants there; under both circumstances, the result can be an 'ectopic' pregnancy. (For a WHO report on factors considered conducive to ectopic pregnancy, see Anon., 1985.) In animals lacking a complete ovarian capsule, it is possible for eggs to pass across the peritoneal cavity from the ovary on one side to the contralateral oviduct, be fertilized there and implant in the corresponding uterine horn. This adventure is termed 'external migration'; its occurrence posited by some and denied by others, an experimental enquiry yielded negative results (Parkes, 1924). Oviduct function is well

reviewed in a text edited by Hafez and Blandau (1969).

2.2.2 DISTRIBUTION IN UTERUS

Blastocysts in polyoestrous animals may be moved around a great deal after entering the uterus and before implantation or attachment, a period that ranges from a day or two in the mouse and rat to 24–30 days in the horse and more than 30 days in the cow. Much longer periods are, of course, met with in animals that exhibit diapause. The movement is effected by muscular activity in the wall of the uterus, which can be demonstrated to distribute other objects as well, such as sea urchin eggs, small pieces of muscle tissue and plastic beads. Where there is free communication between the two horns of the uterus, as in the horse, sheep, pig, goat and dog, blastocysts deriving from the ovary on one side often become implanted or attached in the contralateral uterine horn (as observed in the dog by Bischoff, 1845). Movement of this kind is sometimes called 'internal migration' (Boyd and Hamilton, 1952, gave a list of 18 species in which it has been recorded, including five species of bats that exhibit implantation nearly always in the right horn, although ovulation occurs in either ovary). It would be most unlikely to take place in animals like the rat, in which the lumina of the cervical canals remain separate for their full extent; it is rare in the mouse, in which the cervical canals anastomose only a short distance from the external os. Internal migration was early shown to be a common occurrence in the sheep by Boyd *et al.* (1944); by contrast, it is rare in the cow.

2.2.3 CYTOLOGY OF CLEAVAGE AND COMPACTION

Fundamental to the processes of fertilization, and for cleavage and compaction (this section) and the fusion of oocytes for the initiation of development (discussed later under Induction of parthenogenesis, section 2.4.4), are the properties of the plasma membrane, which have been the subject of a review by Wolf (1983).

Following the aggregation of chromosome groups at syngamy, which can be considered the concluding step of fertilization, a series of mitotic cell divisions occurs, constituting the process of cleavage. During each interphase, DNA replication takes place in the 'S' phase, preceded and followed by 'gap' phases (G_1 and G_2). During G_1, RNA and protein are synthesized in preparation for DNA replication, and during G_2 the same syntheses occur for cell division. G_1 is lacking in the first few cleavage divisions (see Grant, 1978).

In the eight-cell mouse egg, a distinctive change is soon evident, marked by closer and more extensive apposition between blastomeres (Figure 2.2).

The cells become wedge-shaped rather than oval, and are now polarized so that their inner and outer regions exhibit different characteristics. The outline of the cell mass becomes more even and barely suggests the existence of separate cells. This change is called 'compaction'; it has been recognized in all species investigated for its occurrence and is evidently an essential step towards the next new feature, the development of a fluid-filled cavity among the blastomeres, leading to the formation of the blastocyst (the series of events is well illustrated in Figure 2.3, from Kaufman, 1983; ultrastructural changes during the corresponding stages of development in the mouse egg have been described by Cech and Sedlackova, 1983).

Maintenance of the fluid-filled cavity depends on the presence of zonular tight junctions between contiguous cells and the ultrastructure of these components can be seen to develop during the life of the eight-cell egg (Ducibella and Anderson, 1975; Ducibella *et al.*, 1975; Ducibella, 1977) (Figure 2.2). Such tight junctions prevent the escape of fluid and limit the movement of ions, thus maintaining a distinctive environment in the

cavity of the blastocyst (the blastocoele). 'Gap junctions' are also present, having the inferred function of enabling communication between cells by the passage of electrolytes and other solutes. (The nature and significance of compaction are discussed by Johnson *et al.*, 1981.)

2.2.4 THE BLASTOCYST

The eutherian blastocyst resembles the blastula of many marine invertebrate animals in a general way, but differs in the fact that the entire blastula goes to form the new individual, whereas only a small proportion of cells of the blastocyst subserves this function. (The distinction between the two terms is not universally recognized but will be observed in this chapter.)

For early observers of eutherian eggs in late cleavage it was tempting to interpret differentiation along similar lines to those previously demonstrated for invertebrate eggs of the 'mosaic' variety, and there were claims that appropriately disposed cytoplasmic determinants existed, distinguishing the cells destined to constitute the outermost (enclosing) layer, now identified as the 'trophectoderm', from the enclosed group of cells which form the 'inner cell mass' (ICM) (Dalcq, 1957; Mulnard, 1965). But later investigators, including Kelly (1975, 1979), were not able to support these claims, finding that individual blastomeres of the eight-cell egg could contribute to either trophectoderm or ICM.

The basis for present-day thought on the subject was established by Tarkowski and Wroblewska (1967), who proposed that the blastomeres of the early cleavage stages were intrinsically capable of differentiating as trophectoderm cells, but could gain the capacity to become ICM cells through residence in an intercellular environment – this was their 'inside-outside hypothesis'. The formation of a distinctive intercellular environment follows from the establishment of the system of tight junctions, which distinguishes the regions of contact between trophectoderm cells and which enables blastocyst expansion to occur; the tight junctions become recognizable when compaction occurs.

An alternative mechanism has been proposed by Johnson and his colleagues (Johnson, 1981; Johnson *et al.*, 1981), and this involves two processes: the 'conditioning' of cells by contact with others for further contacts (the progeny of the first cell of the two-cell egg to divide will have more contacts and

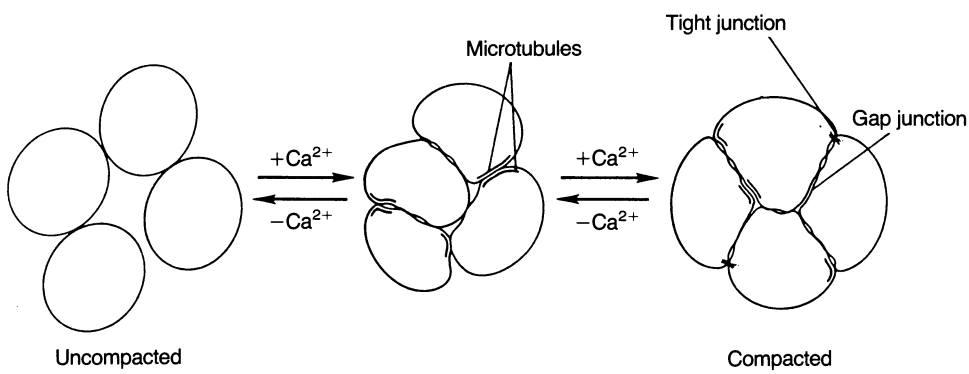

Figure 2.2 Diagram illustrating the process of compaction as seen occurring between four cells of an eight-cell egg. Changes involve the close approximation of cell surfaces and the development of tight junctions, which will later make possible the accumulation of blastocyst fluid. Surface and junctional changes depend on the presence of calcium ions in the medium, and compaction is reversed if the egg is placed in a calcium-free medium. (After Ducibella, 1977.)

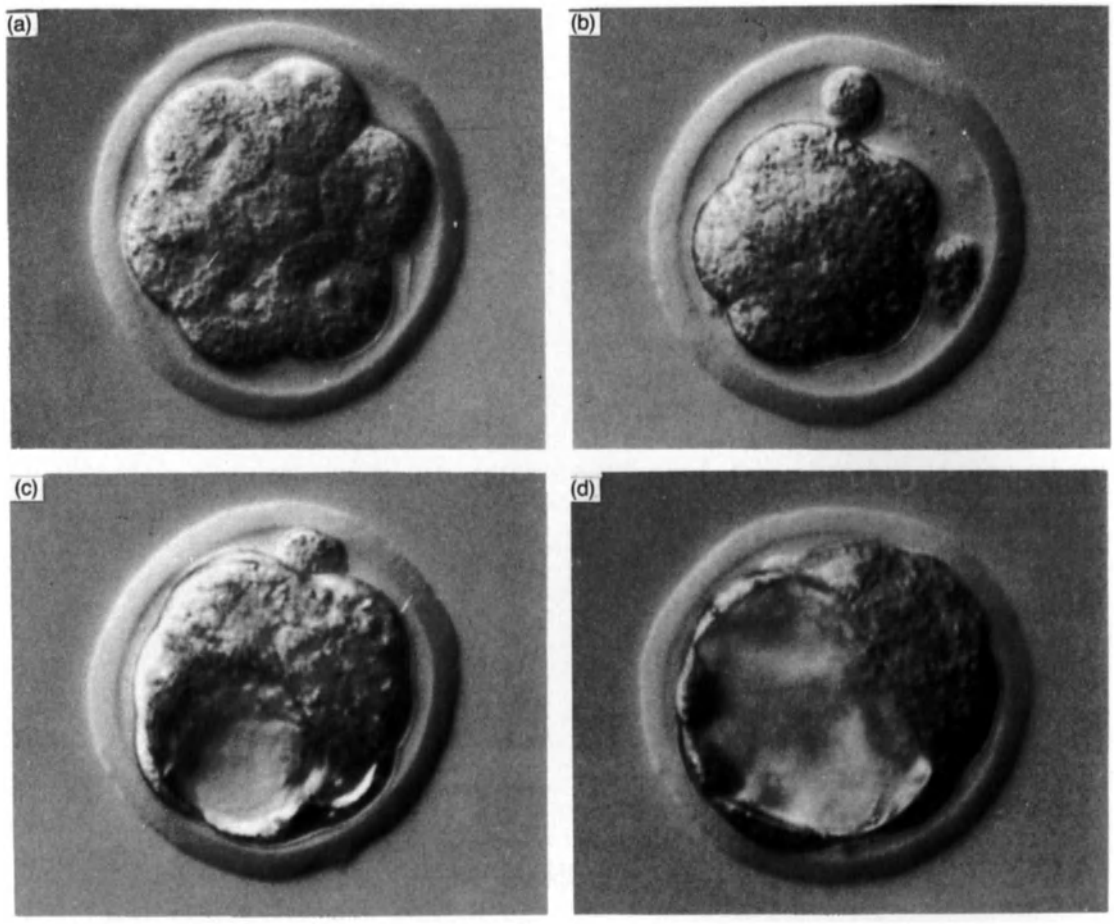

Figure 2.3 Compaction and blastocyst development as seen by interference microscopy in living mouse eggs. (From Figure 6.2 in Kaufman, 1983.)

so become more amenable to contact) and the 'polarization' of blastomeres at the eight-cell stage, as a result of which each cell comes to possess a limited region of 'outer' surface characterized by the presence of microvilli. Division of blastomeres at the eight-cell stage can either bisect the microvillus area (creating two potential trophectoderm cells) or segregate it into one daughter cell; daughter cells without this surface area become internalized and later form the ICM. Commitment to an ICM fate may not be final, however, for there is evidence that cells in the early ICM may come to take part in the trophectoderm (Rossant, 1986).

For further discussion of these subjects see Adamson and Gardner (1979), Johnson *et al.* (1984), Nichols and Gardner (1984), Johnson (1985) and Mulnard (1986).

2.2.5 SPECIES DIFFERENCES IN BLASTOCYST DEVELOPMENT

In animals whose blastocysts do not exhibit an inner cell mass, but instead a group of cells specialized for functions equivalent to those of the inner cell mass though taking up a position alongside cells constituting the trophectoderm, as in the pig (Heuser and Streeter, 1929), the goat (Amoroso *et al.*, 1942)

(Figure 2.4) and the sheep (Bryden *et al.*, 1972), and in marsupials (see Chapter 7), it is still uncertain how the distinction between the two groups of cells arises. The cleavage stage at which blastocyst formation begins varies (Figure 2.5).

In mouse, rat and man, the first evidence of the blastocoele (Gk: *koilos*, hollow) appears shortly after compaction, when there are between 16 and 32 cells present; in the rabbit, the corresponding cell number is around 100–200. Experiments with rodent and rabbit eggs, however, have shown that the time of cavitation is not directly dependent on the number of blastomeres that have been formed. If blastomeres are removed from mouse early cleavage stages, even as many as three from the four-cell egg, intercellular fluid will still accumulate at the usual time, producing in this instance a 'blastocyst' with only three or four cells – sometimes, miraculously, when only two cells are allowed to remain they may contrive to embrace a blastocoele between them. Available evidence indicates that the time of fluid accumulation is linked to the number of mitoses that have occurred, and not to the number of cell divisions (which can be independently suppressed).

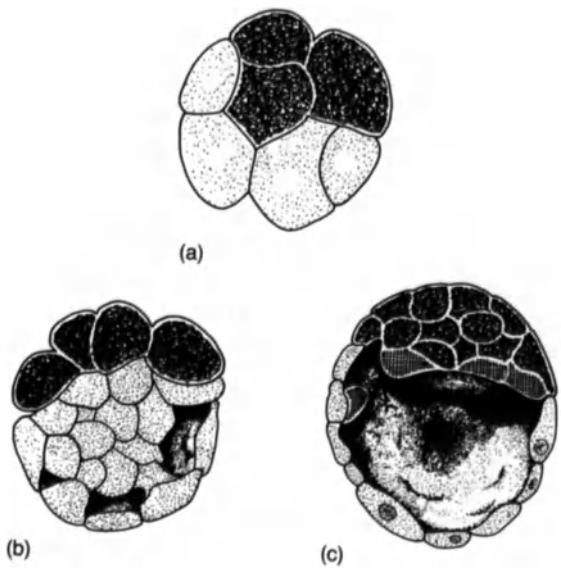

Figure 2.4 Blastocyst formation in the goat egg is characterized by the lack of development of an inner cell mass. The future embryo derives from some of the surface cells, distinguished here by white stipple on a black background. Cross-hatched cells are those of the developing endoderm. (After Amoroso *et al.*, 1942).

In mouse, rat, hamster, guinea pig, some bats, monkey and man, formation of the blastocyst involves increase in size of the blastocoele and in the volume of blastocoelic fluid, with little if any increase in the overall diameter, accommodation being provided by decrease in cytoplasmic mass of the cells and virtual disappearance of the perivitelline space. Some further expansion occurs when the blastocyst escapes ('hatches') from the zona pellucida, but at implantation the diameter of the blastocyst is only about 50% greater than that of the morula. Hatching is made possible through erosion of the zona by lytic action of the uterine secretions, a property that appears to be under hormonal control for it exists only at about the time that implantation normally occurs. Some lytic action is also exerted by cells of the blastocyst, especially those developing the pseudopodia-like protrusions that extend from the pole opposite to that occupied by the inner cell mass, as clearly demonstrated in the guinea pig by Blandau (1949).

In some bats, insectivores, and the cat and dog, some expansion of the blastocyst occurs, while in the rabbit and hare the diameter increases much more, reaching 3–4 mm, compared with about 90 μm for the morula without zona or mucin layer. Expansion of the rabbit blastocyst has drawn a good deal of research attention because of the evidence that this event depends on the presence of a specific protein in uterine secretions, which become especially abundant as the time of implantation approaches (named 'uteroglobin' by Beier, 1968, and 'blastokinin' by Krishnan and Daniel, 1967, 1968). Recently, however, expansion has been reported to

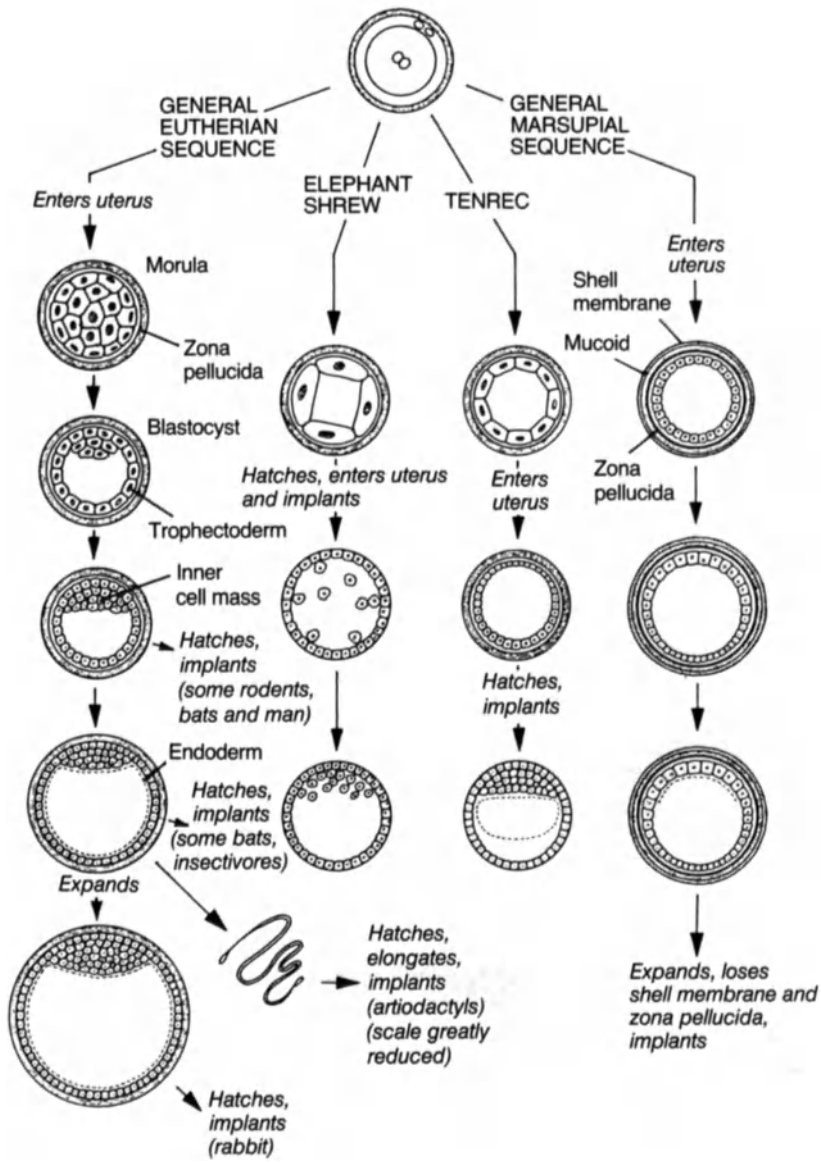

Figure 2.5 Stages in the development of the blastocyst in different mammalian groups. (From McLaren, 1982, after Wimsatt, 1975.)

occur in a simple synthetic medium (see McLaren, 1982). In the pig, a uterine-specific protein has been described with a purple fluorescence (and therefore called 'purple protein'); its synthesis is stimulated by progesterone and its function is thought possibly to be promotion of placental development (Murray *et al.*, 1972).

In the horse and its relatives, the blastocyst expands greatly, achieving a large, more or less spherical structure, before implanting on day 28 after ovulation. Expansion in the

sheep, cow, goat, pig, deer, etc. is also considerable, but the distinctive feature here is the extreme elongation and attenuation that the blastocyst undergoes, assuming a tubular form which can reach a length of a metre and a half or more in the pig (Perry and Rowlands, 1962). Implantation occurs relatively late, from some 15 days after ovulation in the pig up to 35 days in the cow. Development, however, proceeds apace during the long pre-implantation period, and reaches a much more advanced stage than in animals with early-implanting blastocysts.

It is at the blastocyst stage that the first clear evidence of differentiation appears, with the presence of two types of cell, but their disposition varies among mammals. In a number of species, such as the laboratory rodents, rabbit and man, the 'outside' cells of the late morula predominantly differentiate into the trophectoderm (Gk: *trophe*, nourishment, *ekto*, outside, *derma*, skin), which makes up the enclosing wall of the blastocyst, while the 'inside' cells remain undifferentiated and form the inner cell mass, a distinctive group at one pole. Shortly before implantation, the inner cell mass differentiates into primitive ectoderm and primitive endoderm; from some of the cells of the former the embryo later develops (Table 2.1). In ungulates, such as the sheep and goat, the initial differentiation appears to be directly into trophectoderm and primitive ectoderm; the latter makes a group of cells that projects into the blastocoele but also forms part of the outer wall, the remainder of the wall being trophectoderm. The primitive ectoderm is the homologue of the inner cell mass; that term is clearly inappropriate here. Other variations in the process of blastocyst formation also exist among eutherian mammals (see Wimsatt, 1975) (Figure 2.5).

In animals with a long pre-implantation or preattachment period, a fourth type of cell becomes identifiable, forming the mesoderm. The blastocyst has thus advanced from its initial state of unilaminar through bilaminar to trilaminar, the layers soon coming to constitute the embryonic membranes 'chorion', 'amnion', 'yolk sac' and 'allantois'. The remaining cells of the primitive ectoderm become organized as a flat oval or pear-shaped body known as the 'embryonic disc', soon to be embellished with the 'primitive streak', consisting of two folds with a groove in between. In the sheep, the embryonic disc is evident at 13 days after ovulation, being about 0.42 mm in length. 'Neural folds' appear on either side of the primitive streak by the 15th day, seven somites then develop and the embryo reaches about 1.60 mm in length; during this period, there is a rapid decline in glucose incorporation by the developing tissues (Cuneo, 1986). The neural groove closes on the 16th day and the 'heart bulge' is discernible by the 17th (Bryden *et al.*, 1972). By day 19, the embryo has reached 7.76 mm in length and shows a 60-fold increase in dry weight as compared with day 13 (Cuneo, 1986). The first evidence of a reaction in the endometrium to the presence of the embryo is seen about days 15–16 (Boshier, 1969) and the first responsive changes in the trophoblast cells at days 13–15 (Guillomot *et al.*, 1982).

2.2.6 X-INACTIVATION

In most eutherian mammals, the compensating mechanism avoiding the aneuploidy otherwise due to the presence of two X chromosomes in female tissues involves inactivation of one of them (Lyon, 1961). Studies on the development of sex chromatin (or Barr body) in man, macaque, cat and rabbit indicated that inactivation occurs at the blastocyst stage; sex chromatin becomes visible first in the trophectoderm, and later in the derivatives of this tissue, namely the primitive ectoderm and primitive endoderm. (In eutherian mammals, inactivation can be of either the paternal or maternal X chromosome, and in a random manner, except in the

extraembryonic membranes where inactivation is preferentially of the paternal X. In marsupials, it is the paternal X chromosome that is inactivated in both tissues.) Replication asynchrony of X chromosomes is also detected first at the blastocyst stage, in conformity with the observations on sex chromatin.

On the other hand, there is good evidence from the X-linked gene dosage effect on enzyme synthesis that both X chromosomes in female embryos are transcriptionally active at the eight-cell stage and probably earlier. No evidence of dosage compensation has been detected, so it is inferred that only a very small part of the genome is active at this time. Dosage studies have also shown that X-inactivation at the genetic level must begin earlier than that indicated by the appearance of sex chromatin, perhaps as early as the morula stage, and then progressively increases.

The first appearance of sex chromatin in the trophectoderm may have a further point of significance, for there is accumulating evidence that X-inactivation occurs as cells differentiate, supporting observations on teratocarcinoma cells that were induced to differentiate (see Lyon, 1972; Gartler and Cole, 1981; Monk and Harper, 1979, for further details on these and preceding observations).

2.2.7 VIRUS-LIKE PARTICLES

There have been numerous reports on the presence in cleaving eggs of small round objects, 50–110 nm in diameter, that resemble RNA tumour viruses. They have electron-dense shells and commonly look as if they were budding off the outer layer of the nuclear envelope or from the endoplasmic reticulum, but often, too, they are found free in the cytoplasm. They appear to exist in three different forms, which have been labelled types A, B and C (Dalton, 1972). The particular form exhibited appears to depend on the developmental state of the egg. The particles have been found in early germ cells, in gonocytes and oogonia, and in immature oocytes up to the dictyate stage (Larsson *et al.*, 1981), but never in unfertilized one-cell eggs. After fertilization, they are first seen in the late two-cell egg and then in all stages up to the egg cylinder. Calarco and Szollosi (1973) noted the apparent coincidence between the presence of the particles after fertilization and the beginning of RNA synthesis by nucleoli. They have also been seen in fetal tissues. Sometimes crystalloid aggregates are also seen in eggs that contain virus-like particles, particularly at the two-cell stage (Szollosi, 1976). Dvorak *et al.* (1985) did not record virus-like particles, but found crystalloid inclusions to increase in abundance from the four-cell stage onwards; fibrillar proteins were found to be components of these inclusions.

Most of the observations mentioned so far were made in the mouse, but there have been scattered sightings in the guinea pig, hamster and some other animals. Virus-like particles have also been noted in parthenogenetically activated mouse eggs, first at the two-cell stage and in smaller numbers up to the morula (Van Blerkom and Runner, 1976). Daniel and Chilton (1978), who present a comprehensive review of this field, propose that virus-like particles could represent messengers for cell-to-cell communication during embryonic development.

More recently, Yotsuyanagi and Szollosi (1980, 1981) have described what appears to be a new type of inclusion, termed 'epsilon particle', found in mouse eggs from the two-cell stage to the morula. In the earlier eggs, the particles seemed not to exert any ill-effect, but the presence of large numbers in the morula appeared to be associated with loss of contact between an affected blastomere and neighbouring cells, which might lead to its exclusion from the blastocyst.

2.2.8 DIAPAUSE

This term denotes an arrest of development occurring as a normal but not invariable event in early pregnancy; it is also known as 'delayed implantation' and 'discontinuous development'. The qualifications 'facultative' and 'obligatory' are often met with, but the corresponding terms 'seasonal' and 'lactational' are preferred because the imputations are clearer. The literature on diapause was thoroughly reviewed by Deanesly (1966) in the third edition of *Marshall*; she listed 18 eutherian species on which information had been published (see also the reviews by Aitken, 1977; Bergstrom, 1978; Renfree, 1978; Flint *et al.*, 1981).

Seasonal diapause became known first in the roe deer *Capreolus capreolus* and the nine-banded armadillo *Dasypus novemcinctus*. In the roe deer, fertilization, implantation and birth usually occur in August, December and May, in that order; for the armadillo, the relevant months are July, November and March–April. For both animals, the time between the first two events represents more than 40% of the whole pregnancy period. Even more striking is the European badger *Meles meles*, in which the three events occur in July, February and March, the pre-implantation interval here approaching 90% of pregnancy. In these species, delay of implantation ensures that birth of young occurs in a favourable season of the year, and so is appropriately termed 'seasonal diapause'. The stimulus for this reaction evidently has to do with the photoperiod since the artificial provision of 'increasing day length' has been found to induce premature implantation. Temperature and nutrition are also involved.

Lactational diapause has long been known in rats and mice, which can mate at the first post-partum oestrus and would thus be suckling a litter when the blastocyst enters the uterus. It involves an additional interval of up to 20 days in the blastocyst's intrauterine existence, the actual duration being proportional to the number of young being suckled. Usually at least five young in the rat and three in the mouse are necessary for the response. Studies in the mouse have shown that the metabolic rate of diapaused blastocysts, as indicated by the rate of glycolysis, is much reduced. Lactational diapause has also been reported in the shrew *Sorex araneus*.

The mechanism in rodents involves a balance between oestrogen and progesterone. If very small amounts of oestrogen are injected into mated lactating mice and rats on days 5–6, implantation occurs normally, while delay ensues in the controls, but if the animals are ovariectomized and maintained on progesterone, the blastocysts remain unimplanted (see McLaren, 1973; Weitlauf, 1974). In mice, blastocysts can be induced to enter diapause by transfer to the oviducts of immature mice; reactivation follows removal to pseudopregnant mice or culture *in vitro* (Papaioannou, 1986). In the rabbit, hamster, guinea pig, sheep and rhesus monkey, diapause induced by ovariectomy can be terminated and implantation follows if progesterone alone is administered, oestrogen apparently being unnecessary (Renfree, 1982). Naaktgeboren *et al.* (1986) have recently described eight cases of induced human pregnancies in which there was evidence of delayed implantation; two pregnancies went to term with healthy births.

2.2.9 METABOLISM

Some of the earliest observations on the metabolism of the pre-implantation stages of development were concerned with respiratory activity and were made by Boell and Nicholas (1948) in the rat and A.H. Smith and Kleiber (1950) in the rabbit, and these were followed by the investigations of Fridhandler *et al.* (1957) and Fridhandler (1961) in the rabbit and Sugawara and Umezu (1961) in the rat. Oxygen uptake was measured by the Cartesian diver technique. It was noted in the rabbit that later pre-implantation stages

had higher oxygen consumption rates, and that the earlier stages were evidently not dependent on the presence of substrate metabolites, though these stimulated oxygen uptake in the more advanced stages. Subsequent research revealed an increasing metabolic capability in the pre-implantation stages of the mouse: in the oocyte and ootid, only pyruvate and oxaloacetate could be metabolized in significant amounts; at the two-cell stage, phosphoenolpyruvate and lactate could additionally be utilized, and at the eight-cell stage the list included also glucose, α-ketoglutarate, malate and acetate (Table 2.2).

Despite these differences, all stages from two-cell to eight-cell were found to be equally permeable to glucose. In the eight-cell and morula stages, about half the glucose metabolized enters pathways leading to the synthesis of proteins, lipids and nucleic acids. (For references see Biggers *et al.*, 1967; Biggers and Borland, 1976; Brinster, 1967a,b, 1972; Wales and Brinster, 1968; Wales, 1973, 1986; Sherman, 1979.)

The oxygen consumption of human oocytes and blastocysts, the latter arising from *in vitro* fertilization (IVF), was found to be essentially similar (ranging from 0.34 to 0.53 nl/h) by Magnusson *et al.* (1986), and Leese *et al.* (1986) reported that the pyruvate uptake by human oocytes decreased after fertilization but rose again just before the morula stage, the changes being considered of possible value for assessing viability. Gott *et al.* (1990) found that more pyruvate than glucose was taken up by human IVF embryos in the earlier stages, but glucose was the preferred substrate for the blastocyst. The production of lactate was relatively high throughout, values observed beginning at 43.6 pmol/embryo/h on day 2.5 and rising to 95.4 pmol/embryo/h by day 5.5. The authors consider that only about half the lactate produced could have come from the glucose taken up, the rest deriving most likely from glycogen.

The metabolism of glucose and lactate in pre-implantation mouse embryos was increased by 62% and 18%, respectively, by culture in the presence of platelet-activating factor (PAF), as reported by Ryan *et al.* (1990a,b), who suggest that embryo-derived PAF has a role in pre-implantation development, augmenting the viability of the embryos themselves.

Important reserves of energy for the cleaving egg are the glycogen stores observed in mouse eggs by Thomson and Brinster (1966) and Stern and Biggers (1968). The distribution of glycogen granules and aggregates at different developmental stages has been

Table 2.2 Metabolites that can provide energy for the oocyte, ootid and cleaving mouse egg (From Brinster, 1972)

Ribose			−	−

described from electron microscopic studies by Dvorak *et al.* (1985) in the mouse. Stores were low in the oocyte but began to increase during fertilization and rose steeply up to the eight-cell stage; after that, the level was maintained until the blastocyst stage and then decreased in eggs recovered from the uterus but not from those cultured *in vitro* (Edirisinghe and Wales, 1984). The difference is evidently attributable to the oxygen tension commonly maintained in the culture atmosphere (Khurana, 1987) – if held at not more than 5%, the difference between glycogen levels in cultured and recovered embryos disappeared. Evidently glycogen cannot be utilized by the egg before the eight-cell stage. Changes in the volume of lipid droplets in the cytoplasm may indicate a function as an alternative energy source (Dvorak *et al.*, 1985).

Attention has recently been directed increasingly to the question of the stage at which the embryonic genome takes over control of protein synthesis. In the mouse, this is evidently the two-cell stage (Flach *et al.*, 1982; Bolton *et al.*, 1984), but later in other species: in cattle, the four-cell stage (Barnes, 1988) or the eight- to 16-cell stage (Frei *et al.*, 1989); in man, the four- to eight-cell stage (Braude *et al.*, 1988); in sheep, the eight- to 16-cell stage (Crosby *et al.*, 1988). King *et al.* (1988) point out that activation of the embryonic genome coincides with the dispersal of the nucleolar precursor body in the cells of the embryo. They consider morphological changes in the nucleoli of embryonic cells to provide a useful indication of the activity of certain gene loci, and therefore of the onset of embryonic transcription.

The activities of various enzymes have been studied in the early developmental stages of the mouse, rat and rabbit (see Brinster, 1972). Major differences have been recorded between enzyme activities and also variations in the occurrence of enzymes at different stages, but little is known of the significance of these observations. Lactate dehydrogenase is conspicuous for its great abundance at the start of development in the mouse embryo; there was found to be about 10 times as much in the oocyte as in skeletal muscle, the amount later diminishing, and some 70 times as much in the cleaving eggs of the mouse as in those of the rabbit and man. The enzyme in the mouse eggs had an electrophoretic isozyme pattern of type H and at implantation additionally of type M. Again in the mouse, hexokinase was detected at low levels in the oocyte, increasing in activity about sevenfold at the time of implantation, and indications were that it is important in regulating glucose availability. Certain other enzymes present in the pre-implantation stages are known to have a genetic significance and will be discussed later under 'Protein synthesis and gene action' (section 2.2.10).

In the mouse blastocyst, the cavity remains small, about 0.4–0.45 nl; by contrast, the rabbit blastocoele enlarges from about 2 nl to 66 nl at implantation, almost entirely by the intake of water. Other substances are also passed into the cavity, some evidently originating in the bloodstream, though there are distinct differences between the two fluids. One day before implantation in the rabbit, the content of protein and glucose is lower and that of potassium and bicarbonate higher in the blastocoele fluid, but in the next 2 days the composition comes to resemble serum more closely, due to increasing passage to and from the maternal bloodstream. In addition, the phosphorus content doubles and that of chloride increases about threefold. (Further details are given by Brambell and Hemmings, 1949; Lutwak-Mann, 1954, 1959, 1960; Wiley, 1984; Pemble and Kaye, 1986.)

The mechanisms whereby water and ions are taken up into the blastocoele in the rabbit have engaged a good deal of research attention. Some of the first persuasive evidence that there was active transport of ions came when Cross and Brinster (1969) and Gamow and Daniel (1970) reported that a transtrophectoderm potential difference could be

demonstrated in 5½- to 6-day blastocysts, and that its persistence depended on a supply of energy and could be terminated by anoxia or treatment with certain metabolic inhibitors. There remained the question whether ion transport depended on electrical or chemical potential differences across the intervening membrane, or whether transport was effected by an active agent in the membrane. That the latter explanation was preferable was shown by Cross (1973), who applied the Ussing–Zerahn short-circuit technique to 6-day rabbit blastocysts; the results strongly supported active membrane transport of Na^+ and Cl^-, and Cross maintained that this movement of ions would adequately account for the fluid accumulation in the blastocoele. That the 'sodium pump' (Na^+, K^+-ATPase) is the agent in the membrane responsible for Na^+ and Cl^- transport emerges from the work of Borland *et al.* (1967), who used ouabain to inhibit the enzyme. Transport of bicarbonate, which exists in relatively high concentration in blastocoelic fluid, is evidently dependent on a similar mechanism. Hydrogen ions move freely across the membrane without assistance.

Robinson *et al.* (1990) claim to be the first to examine the mechanism of glucose transport across the trophectoderm of rabbit blastocysts; this they maintain is achieved by a sodium-independent system which is unaffected by progesterone, mifepristone, prostaglandins, insulin or cAMP.

Important questions relating to the role of the oviduct in the maintenance of embryos have been investigated by Gandolfi *et al.* (1989). Macrophages cultured with mouse blastocysts have been shown in ultrastructural studies to enter the cytoplasm of trophectoderm cells and to pass between ICM cells; there was no evidence that they exerted any cytotoxic effect (Tachi *et al.*, 1985).

Belling *et al.* (1985) have found that 5- to 6-day rabbit blastocysts can conjugate and actively metabolize diethylstilboestrol, and infer that there are at this stage specific enzyme activities, of which one, monooxygenase, is not expressed in the adult animal. Other aspects of metabolism in cleaving eggs and blastocysts are discussed under 'Recovery, culture, storage and transfer' in section 2.4.1.

2.2.10 PROTEIN SYNTHESIS AND GENE ACTION

The egg during fertilization has a high content of RNA, but this is inherited from the oocyte ('long-lived RNA') and there appears to be no RNA synthesis. Some synthesis occurs at the two-cell stage and then rapidly increases (in the mouse, rabbit and hamster). At the four-cell stage, preponderance of radiolabel over the nucleoli supports the idea that ribosomal RNA (rRNA) synthesis is occurring at this time. Messenger RNA (mRNA) and transfer RNA (tRNA) are also synthesized from the two-cell stage onwards. When development reaches the blastocyst stage, the rates of synthesis of rRNA, mRNA and tRNA have reached levels seen in adult cells (though uterine flushings have an inhibitory effect on RNA synthesis – Weitlauf, 1976).

Protein synthesis has been found to occur in the egg during fertilization (controlled solely by maternal genes), and from then onwards the incorporation of radiolabelled amino acids continues. Between the two-cell and eight-cell stages, the types of protein synthesized change greatly, though those synthesized at the two-cell stage can still be detected in the morula. Proteins specific to certain tissues are first seen at the morula stage. (Reviews on these topics have been published by: Epstein, 1975; Sherman, 1979; Magnuson and Epstein, 1981; Johnson, 1981; McLaren, 1982; Pratt *et al.*, 1983; Johnson *et al.*, 1984; Jackson, 1989.)

On the other hand, Norris *et al.* (1985), characterizing proteins in the cleaving eggs of four species (mouse, rat, hamster and gerbil), found great similarity in the later stages but

striking differences between the species at the one-cell stage. They surmised that the distinctive early protein synthesis on maternally derived templates has the function of maintaining species integrity. At later cleavage stages, the proportion of RNA synthesis controlled by the embryonic genome increases steeply throughout cleavage, so that at the eight-cell stage (or even the six-cell stage) it represents the total. From this point on, maternal genes no longer determine protein characters, and at the blastocyst stage the level of RNA synthesis is equal to that seen in the adult cell. Protein synthesis presents a more complex picture, actual patterns showing the greatest change between the one- and two-cell stages, but synthesis dependent at the two-cell stage on embryo mRNA templates seems to be limited to one protein, β_2-microglobulin. At the four-cell stage, β-glucuronidase appears, and between the eight- and 16-cell two more enzymes, hypoxanthine–guanine phosphoribosyl transferase (HPRT) and glucose phosphate isomerase, and two distinctive proteins, the H-Y antigen and non-H-2 alloantigens. HPRT deficiency causes the Lesch–Nyhan syndrome in the human subject, and the enzyme is also of special interest in that its determining gene is located on the X chromosome. The antigens are important because they are expressed on the surface of cells and are fairly readily detectable.

Evidence of zygote genome expression is also forthcoming from observations on the time of death attributable to lethal mutations carried by the paternal genetic complement. Thus mutants t^{12} and t^{w32} begin to show effects on development at the two-cell stage and cause death of the morula. Homozygotes for the albino locus deletion c^{25H} do not develop beyond a point between the two- and seven-cell stages. (For detailed reviews, see Mintz, 1974; McLaren, 1976a, 1982; Schultz and Tucker, 1977; Adamson and Gardner, 1979; Johnson, 1981; Magnuson and Epstein, 1981; Bolton *et al.*, 1984.) The question whether or not the paternal genome could be dispensed with altogether, in the development of the new individual, is dealt with later under 'Induction of parthenogenesis'(section 2.4.4).

Mitochondria in the developing egg are evidently all maternal in origin; in many animals, sperm mitochondria are released into the egg cytoplasm during early cleavage, but soon show signs of degeneration (Szollosi, 1965, 1976). The wholly maternal origin of these bodies makes it possible to relate individuals to one another by restriction enzyme mapping of the mitochondrial DNA, and study of mtDNAs from 147 individuals from African, Asian, Australian, Caucasian and New Guinea populations led to the conclusion that all could have been descended 200 000 years ago from a single progenitor, probably of African origin (Cann *et al.*, 1987).

Further information on the early effects of the paternal genome in development comes from investigations on experimental hybridization. Some hybrids are, of course, fully viable, but in other instances, though fertilization occurs, development fails before implantation. Insemination of the domestic rabbit with semen from the cottontail rabbits *Sylvilagus floridanus* and *S. transitionalis* resulted in apparently normal cleavage up to the morula stage but no further (Chang and McDonough, 1955; Chang, 1960). A similar experimental series with rabbits inseminated with semen from the hare *Lepus europaeus* yielded blastocysts but no implantation (Adams, 1957; Chang and Adams, 1962). When rabbits were inseminated with the semen of the hare *L. americanus*, there were essentially the same findings (Chang *et al.*, 1964; Chang, 1965). (See also the review by Chang and Hancock, 1967.) These losses of cleaving eggs and blastocysts could presumably have been due to some form of chromosomal imbalance, since in all instances the gametes came from animals with different chromosome number and constitution, but aneuploidy *per se* is not necessarily lethal.

One of the most successful hybrids is the mule [2n=63; *nombre fondamentale* (NF)=99], whose parents are the horse *Equus caballus* (2n=64; NF=94) and the donkey *E. asinus* (2n=62; NF=104), and other examples are listed by Gray (1954). Probably the most systematic enquiries into the effects of aneuploidy were those of Gropp *et al.* (1970, 1976), who crossed the house mouse with the tobacco mouse *Mus poschiavinus*. All house mouse chromosomes are acrocentric, while those of the tobacco mouse include seven metacentrics. The hybrid males had high rates of non-disjunction in spermatogenesis, and when these were back-crossed with female house mice the resulting conceptuses showed various forms of monosomy and trisomy. Monosomy was the more lethal, early development regularly failing to pass the blastocyst stage.

2.3 DEVELOPMENT IN MONOTREMES AND MARSUPIALS

2.3.1 MONOTREMES

In this order of mammals, the processes of egg maturation, fertilization and cleavage have many points of similarity with corresponding events in Sauropsida; original observations are not particularly numerous but a coherent picture is emerging, and the subject has been well reviewed by Boyd and Hamilton (1952), Tyndale-Biscoe (1973), Hughes (1977, 1984), Luckett (1977), Hughes and Carrick (1978) and Tyndale-Biscoe and Renfree (1987) (the last named is a major work with a great deal of useful information on monotremes, though the title names only marsupials).

During fertilization (which is still in progress when the egg reaches the uterus), the cytoplasmic component of the egg takes the form of a flat germinal disc lying upon a large yolk body (see Figure 14.6 in the third edition of *Marshall*), much as in the bird egg. After syngamy, the first cleavage furrow divides the germinal disc into two portions, which are commonly a little unequal in size, and the second furrow crosses the first approximately at right angles. The products are referred to as 'cells' despite the persistence of cytoplasmic continuity between them (the distinctive feature of meroblastic cleavage) as well as on the surface of the yolk body. The third cleavage involves the formation of two furrows, on either side of and roughly parallel to the first, thus dividing the disc into eight cells, regularly arranged but varying in size. The fourth and fifth series of furrows are less regularly oriented and produce groups of 16 and 32 cells with increasing disarray (see Figures 14.7 and 14.8 in the third edition of *Marshall*). Cleavage planes also divide cells into more central and more peripheral portions, thus forming two or three layers of cells, a group of which then become separated by a fluid-filled space from the layer of cytoplasm immediately covering the yolk body; this group forms the 'blastoderm'. The cytoplasmic layer on the yolk surface contains many nuclei and constitutes a syncytium, which spreads to enclose eventually the whole yolk body. The space beneath the blastoderm is termed the 'blastocoele' though not strictly homologous with the eutherian blastocoele. With further cell division, a superficial layer of cells of the blastoderm becomes identified as the embryonic ectoderm, the subjacent layer forming the endoderm. The cells at the periphery of the blastoderm multiply rapidly, spreading over the syncytial layer and forming the 'trophoblast' or 'epiblast'; and eventually, the two layers totally enclose the yolk body and thus the bilaminar blastocyst is established. The mural cells of the blastocyst develop tight junctional complexes and the blastocyst absorbs further fluid and so swells greatly. The ovulated egg was only some 3.5–4.0 mm in diameter, but the blastocyst soon achieves a diameter of 12 mm or more.

While the egg passes along the oviduct and into the uterus (a destination thought to be

[b]After formation of fluid-filled perivitelline space.

reached within 24 h of ovulation), it receives a thin layer of glycoprotein and a shell membrane; next a thick shell is deposited. The shell has been shown to be porous and allow passage of nutrients and gaseous exchange; this facility is important in view of the very limited reserves originally present in the yolk body, which is much smaller than the yolk of an egg of a bird of similar size. The fluids and essential metabolites that are absorbed by the late blastocyst and developing embryo derive from the uterine tissues, which are at this time in a congested and secretory state, under the control of progesterone (Hughes and Carrick, 1978). By contrast, some members of the Sauropsida, such as viviparous snakes and lizards, have well-developed chorioallantoic placentae (see Chapter 15 in the third edition of *Marshall*). Nevertheless, the monotreme embryo possesses a specialized membrane active in metabolic exchange, and there is a functional (though not tactile) relationship with the maternal tissues; on this basis, the monotreme can be said to possess a placenta (choriovitelline, in this case) during its intrauterine existence. The duration of intrauterine life is about a month.

Intrauterine development reaches approximately the 18-somite neurula stage in the platypus and the 19-somite stage in echidna. Up to this time, the only extraembryonic fetal membrane formed is the yolk sac, which is still non-vascularized. Vascularization occurs soon after laying, and then the allantois develops rapidly and in turn becomes vascularized. Eventually, choriovitelline and chorioallantoic composite membranes show about the same degree of development.

The platypus lays its eggs apparently directly into the nest, while the echidna seems to provide pouch accommodation until the young develop their sharp spines. Hatching occurs about 10 days after laying in the echidna (Griffiths *et al.*, 1969), but the period in the platypus is not yet known.

2.3.2 MARSUPIALS

The eggs are distinctly larger than those of eutherian mammals – figures available for four species are set out in Table 2.3. For comparison, the range of diameters of the vitellus alone in eutherians is about 60–180 μm, the largest being that in the sheep egg (Austin, 1961), the overall diameter including the zona pellucida being 200 μm.

The vitellus of the *Dasyurus* egg contains a distinctive body which has been termed a 'yolk mass'; it becomes separate after the first cleavage and is later enclosed within the cavity of the blastocyst. The relatively large size of marsupial eggs in general is commonly attributed to the presence of a plentiful supply of yolk, existing in the dispersed state, the *Dasyurus* egg being exceptional with its striking aggregate, but the deutoplasmic nature of this material is still only hypothetical. A similar 'yolk body' materia-

lizes after the second cleavage division in *Antechinus stuartii* and *Sminthopsis crassicaudatus* and *S. macroura* (Selwood and Young, 1983; Selwood, 1987). Unlike the eutherian egg, the marsupial egg at ovulation is not surrounded by a cumulus oophorus of follicle cells. Sperm entry occurs in the oviduct and fertilization is still in progress when the egg reaches the uterus, which it does within 24 h of ovulation. After sperm entry, the egg receives a thick coating of mucopolysaccharide, homologous with the mucin layer of the rabbit egg, and in addition a keratinous shell membrane which has no equivalent in eutherian eggs, but resembles the corresponding investment in monotreme eggs.

Cleavage results in the formation of increasing numbers of blastomeres, as in eutherians, but a clear difference soon appears in that in marsupials the blastomeres become separated, taking up positions around the periphery. In this manner, in due course, a unilaminar blastocyst is formed, without the intervention of a morula stage or the segregation of an inner cell mass. (Successive stages in the cleavage of the *Sarcophilus* and *Sminthopsis* eggs have been described and illustrated by Hughes, 1982, and Selwood, 1987.) The cells making up the wall of the blastocyst are attached to one another by tight junctional complexes, much as in the eutherian blastocyst, an arrangement permitting control over the passage of water and solutes (as discussed earlier in section 2.2.4). The cells at this stage of the unilaminar marsupial blastocyst are apparently identical, so that there is no obvious way of recognizing the presumptive embryonic area; collectively they constitute the 'protoderm'. At about the 60-cell stage, the blastocyst starts to expand, and indications are that, though development to this point can occur on endogenous resources, expansion and differentiation require the contributions provided by the uterine secretions.

The next step in differentiation involves the detachment of some of the cells in one hemisphere, which at first lie freely in the blastocoele but then come to constitute a layer of loosely connected cells under the protoderm; in this way the endoderm develops, conforming to a pattern like that in the avian egg, but unlike that in the eutherian. Part of the protoderm then differentiates into an oval plate of cuboidal cells which later becomes the medullary plate of the embryo. A primitive groove with Hensen's node then appears in the medullary plate, and it is from the primitive groove that mesoderm cells are generated and become distributed between protoderm and endoderm. Subsequent developmental stages include the formation of the notochord and neural tube, and later the spinal cord, brain vesicles and the somites. During the course of these events, the extraembryonic membranes are being formed, and large differences in pattern are discernible in different species. As in eutherians, two membrane structures can be important in the establishment of a system allowing uptake of nutrients by the embryo, gaseous exchange and elimination of wastes; these are the yolk sac and allantois, though in order to achieve close relations with the maternal environment some collaboration with the chorion is also needed, and thereby choriovitelline and chorioallantoic placentae are formed. These composites vary in their extent of vascularization, and this in turn depends upon the range of development of the mesoderm at an earlier stage. In marsupials, the mesoderm stops short of investing more than about half of the wall of the embryonic vesicle, so that the regions of placentae that become trilaminar and vascularized are rather limited. In *Didelphis* and *Dasyurus*, the only region to become thus developed is part of the choriovitelline membrane, whereas in *Phascolarctos* and *Perameles*, the honour is shared between the two composites. The prevailing view is that vascularized regions are mainly concerned with respiration and the non-vascularized with nutrition.

Differences also exist among marsupial species in the degree of intimacy that is achieved between embryonic and maternal tissues. The shell membrane may persist intact through much of intrauterine life in some species, as for example in *Trichosurus vulpecula* in which Hughes and Hall (1984) found that the membrane was not lost before the two-thirds point of the 17.5-day gestation period. But a placenta involving invasion of the maternal tissues by the fetal is formed in other species, as distinctively shown in *Perameles* (see Amoroso, 1952).

Both lactational and seasonal diapause are well known in marsupials. The former was demonstrated in the quokka *Setonyx brachyurus* and the tammar wallaby *Macropus eugenii* by Sharman (1955), the presence of pouch young inhibiting implantation of the uterine blastocyst that had arisen from a post-partum mating. Implantation followed removal of the pouch young; and the same mechanism appears to exist in the euro *M. robustus* and the red kangaroo *M. rufus*. Here, too, artificial control of photoperiod can produce the same result.

For further information on the pre-implantation development of marsupials, the reader is referred to reviews by Tyndale-Biscoe (1973), Hughes (1977, 1984), Renfree (1978,1982), Tyndale-Biscoe and Renfree (1987) and to Chapter 7 in this volume.

2.4 EXPERIMENTAL MANIPULATION

2.4.1 RECOVERY, CULTURE, STORAGE, TRANSFER

Recovery of cleaving eggs from the oviduct and blastocysts from the uterus is commonly achieved by flushing with a balanced salt solution or heat-treated homologous serum or a mixture of the two (Table 2.4). For this purpose, phosphate buffering is appropriate for maintaining a pH in the region of 7.0–7.5. In expendable animals, the oviduct is removed post mortem, straightened out if necessary by dissection, and then flushed by inserting a blunted hypodermic needle with syringe attached into the uterine ostium, the emerging fluid being collected in an embryological watchglass. This procedure is satisfactory for the rabbit; with the rat and mouse, flushing is easier done in the opposite direction, the needle being inserted into the infundibular end of the oviduct. In larger animals, and where the animal is to be preserved, laparotomy is performed and the ovarian end of the uterus is clamped off, the flushing medium being injected into this region and forced along the oviduct.

To obtain blastocysts from the uterus, dissection is usually depended on in expendable animals, but in others (generally farm animals, but rather similar methods are used in the human subject) a non-surgical procedure is employed. This involves the use of a long plastic catheter, of which two designs are about equally popular. In both, there is an inflatable bulb within a short distance of the end that is to be passed into the uterus; when the bulb is expanded with air, a region at the ovarian end of the uterus is closed off so that it will retain injected fluids. Accordingly, in one design of catheter, there are two lumina, through one of which air is forced for pumping up the bulb, and through the other flushing fluid is injected and later drained out, carrying the blastocysts with it. The other design of catheter has three lumina, one for bulb inflation as before, a second for fluid injection and the third for fluid return (which with this device can be simultaneous with injection). (Detailed descriptions of these techniques are given by Croxatto *et al.*, 1972; Hunter, 1980; Brackett *et al.*, 1981; Buster *et al.*, 1983; Trounson, 1983; Bavister *et al.*, 1984; Betteridge, 1986; Brambati and Tului, 1990.) Loskutoff *et al.* (1990) describe the non-surgical transcervical recovery of embryos from the uterus of the suni (*Neotragus moschatus zuluensis*), a small East African antelope, and give references to similar work on other African ungulates.

Culture of cleaving eggs, morulae and blastocysts has been carried out in several different kinds of receptacles, including small plastic Petri dishes, test tubes and agglutination tubes, but some prefer embryological watchglasses, Carrel flasks or capillary tubes. The composition of the culture medium is critical in respect of pH, osmolarity, metabolizable nitrogen and energy sources, certain ions and a macromolecular component such as serum albumin. Sometimes, additions of fetal calf serum or human umbilical cord serum appear necessary. Variations in the properties of the medium suit different species.

Rabbit cleaving eggs were the first to be cultured through to blastocysts (Lewis and Gregory, 1929), for which a mixture of 50% or more of serum in balanced salt solution is sufficient, though a uterine secretory component may be needed for full blastocyst expansion (see section 2.2, The cleaving eutherian egg and the blastocyst).

Most attention, however, has been given to determining the precise cultural requirements for mouse pre-implantation development. Hammond (1949) observed that mouse eggs would proceed to the blastocyst stage from the eight-cell (but not earlier) in a simple saline mixture containing hen egg-white. Whitten (1956), however, found this medium to be unstable in air, the pH rising rapidly owing to loss of CO_2 from the egg-white. He therefore used a Krebs–Ringer bicarbonate medium in stoppered tubes, but the addition of egg-white was still necessary, because of an essential but unidentified non-dialysable component. Bovine serum albumin came to be preferred to egg-white and, with this, eggs would consistently pass from the eight-cell to

the blastocyst. Development from the two-cell stage to the blastocyst would occur if the glucose in the medium were replaced by lactate and the space above flushed out with 5% CO_2 in air (Whitten, 1957; see also Whitten and Biggers, 1968, and Whitten, 1971). Development through from the one-cell zygote to the blastocyst, however, has been found unlikely to occur in chemically defined media, owing to the now well recognized two-cell block shown by many strains of mouse. The are also, however, non-blocking strains, which indicates that blocking could be attributable to a deficiency of some kind, an inference supported by the observation of Muggleton-Harris *et al.* (1982) and Pratt and Muggleton-Harris (1988) that the defect can be overcome by transfer of cytoplasm. Recent observations by Nasr-Esfahani *et al.* (1990) suggest that the cytoplasm in the non-blocking strains contains chelating agents that counter free radicle production by traces of iron responsible for the effect. More recently, Lawitts and Biggers (1991) have cultured pronuclear stage mouse eggs to the blastocyst stage in media whose composition was determined by 'simplex optimization', which examines a large number of variables simultaneously.

The importance of the composition of the atmosphere over the culture medium was pursued by Quinn and Harlow (1978), who noted that the proportion of mouse blastocysts developing, as well as the number of blastomeres per blastocyst, was increased if the oxygen content were reduced to between 2.5 and 5%. Later, Khurana (1987) reported that the turnover in acid-soluble glycogen in mouse morulas and blastocysts increased steadily as the oxygen concentration was reduced from 20% to 1%, the trend being accompanied by increase in rate of cell division.

That there were advantages in co-culturing eggs with other cells was reported by Cole and Paul (1965), who obtained enhanced development of mouse eggs if cultured with irradiated HeLa cells. Kuzan and Wright (1982) found that bovine blastocysts showed improved rates of hatching and attachment to the endometrium if previously incubated with a layer of 'feeder' cells. Wiley *et al.* (1986) obtained better development of mouse eggs when they were cultured in larger groups. Heyman *et al.* (1987) reported improved rates of development of cow and sheep eggs when cultured with trophoblastic vesicles and serum; the method also overcame the eight- to 12-cell stage development block, and cleavage proceeded to 16 cells or more. Benefit was also noted following co-culture with oviduct tissue (Eyestone and First, 1989; Eyestone *et al.*, 1991). Clearly there are components of a successful culture medium yet to be identified. An essential property would seem to be large molecular weight, as suggested by the earlier observations of Cholewa and Whitten (1970) that mouse eggs would develop normally from two-cell stage to blastocyst in the absence of any fixed nitrogen source, including albumin, provided the medium contained polyvinylpyrrolidone. Hamster embryos were found to differ greatly from mouse embryos in their energy substrate needs by McKiernan *et al.* (1991), who successfully cultured them from one-cell stage to blastocyst.

Rat eggs proved more difficult subjects for culture than mouse eggs, but rat blastocysts have nevertheless been maintained through to the mid-somite stage with beating 'heart' (Hsu, 1971), and even to the limb-bud stage of development (Chen and Hsu, 1982). Rabbit one-cell eggs have been grown in culture to the hatching blastocyst stage in a defined protein-free medium by Carney and Foote (1991), who claim this to be the first such success. Pig embryos could be grown in culture from the one- to two-cell stage to the morula or blastocyst in 45–60% of trials if glucose or glutamine (or the two together) were present in the medium (Petters *et al.*, 1990). The success with glutamine demon-

strates that an amino acid can be used as the sole source of energy for full preimplantation development. The metabolic availability of glutamine to early mouse embryos was confirmed by Chatot *et al.* (1990), who maintain that the amine plays an important role in sustaining the earliest stages of development. Bovine embryos have been grown from the one- to two-cell stage to morulae and blastocysts both in rabbit oviducts and in co-culture with bovine oviduct epithelial cells suspended in a simple medium (Ellington *et al.*, 1990), or epithelial cells suspended in TCM-199 medium (McCaffrey *et al.*, 1991); also in a mixture of synthetic oviduct fluid and fetal calf serum or human serum, under an atmosphere of 5% oxygen, by Fukui *et al.* (1991). Eggs from the rhesus monkey have been successfully cultured after fertilization *in vitro*, and viable young have been obtained after transfer to recipients (Figure 2.6) (Bavister *et al.*, 1983; Boatman, 1987). For the culture of human eggs from the one-cell stage through to the morula/blastocyst, good results have been obtained with Ham's F-12 medium (Muggleton-Harris *et al.*, 1990). More recently, improved blastulation and implantation rates after co-culture of embryos with tubal ampullary epithelial cells have been reported (Bongso *et al.*, 1992). The embryos of two dasyurid marsupials were cultured in cleavage and blastocyst formation by Selwood (1987). (Publications appearing up to 1958 on the culture of eggs and blastocysts were tabulated by Austin, 1961; for more recent reviews see Gwatkin, 1966; Bindon, 1971; Daniel, 1971, 1978; Brinster, 1972; Hunter, 1980; Edwards *et al.*, 1981; Bavister, 1986; Greve *et al.*, 1989.)

Storage of mammalian embryos at average refrigerator temperatures is of limited value because of loss of viability within a few days. By contrast, storage at temperatures well below freezing has proved highly successful. Striking results were obtained first with the low-temperature preservation of spermatozoa, blood cells and various tissues (see A.U. Smith, 1961, for a review of earlier work), and these greatly stimulated efforts to do the same with oocytes, cleaving eggs and blastocysts. It was, however, several years before Whittingham (1971) was able to report encouraging results in the mouse; he held 8-cell eggs and early blastocysts at −79°C for 30 min, with only polyvinylpyrrolidone as cryoprotectant. With the aid of dimethylsulphoxide (DMSO), it proved possible to store eggs at −196 and −269°C for several weeks and yet obtain the subsequent birth of a high proportion of normal young (Whittingham *et al.*, 1972). Some variables in egg survival were also studied by Wilmut (1972). Later, Whittingham (1974, 1975, 1976) reported that the freeze storage of eggs was a reliable and economical way of maintaining a large number of inbred mouse strains, and that oocytes could be fertilized *in vitro* after storage and, on transfer to recipients, would develop into normal young at birth. More recently, Rall and Fahy (1985) recommended a cryoprotectant mixture for mouse eggs consisting of

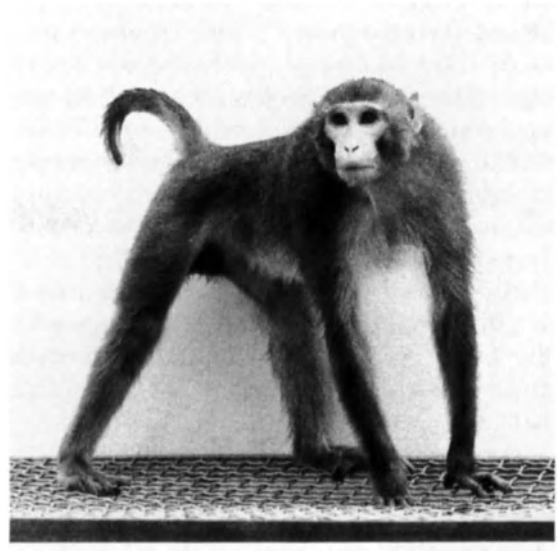

Figure 2.6 'Petri', a rhesus macaque, the first non-human primate to develop from *in vitro* fertilization and embryo transfer, at 3 years and 5 months (see Bavister *et al.*, 1984). (Courtesy of B.D. Bavister, Department of Veterinary Science, University of Wisconsin, Madison, USA.)

dimethylsulphoxide, acetamide, propylene glycol and polyethylene glycol. Kasai *et al.* (1990) obtained very high rates of survival of mouse embryos frozen after being equilibrated in a medium containing ethylene glycol or glycerol. Shaw *et al.* (1991) have recommended rapid freezing of two-cell mouse embryos in just DMSO, but at a concentration of 4.5 M, lower concentrations being associated with reduced embryonic viability and chromosome damage.

Sheep and cow embryos have also been cryopreserved and later transferred to recipients, those of the cow often on a very large scale (Wilmut and Rowson, 1973; Willadsen *et al.*, 1974, 1976, 1978; Betteridge, 1977, 1986; Polge, 1978; Hunter, 1980; Seidel *et al.*, 1983; Wright, 1985), but not very satisfactory results have yet been obtained with the pig. Even 'half' and 'quarter' cattle embryos have been preserved by freezing (Lehn-Jensen and Willadsen, 1983). The freezing of horse embryos has been reported by Yamamoto *et al.* (1982) and Czlonkowska *et al.* (1985). Human cleaving eggs and blastocysts can be cryopreserved (Whittingham, 1980a; Trounson and Mohr, 1983; Mohr *et al.*, 1985) and develop to birth after transfer (Cohen *et al.*, 1985); this field has been reviewed by Ashwood-Smith (1986), and see also the 'Symposium on Embryo Freezing' (mouse, baboon, man) in the *Journal of In Vitro Fertilization and Embryo Transfer* (1986), Vol. 3, pp. 1–61. More recently, Fugger *et al.* (1991) and Hartshorne *et al.* (1991) reported on their experiments with the freeze-preservation of human embryos and subsequent establishment of pregnancies.

Transfer of cleaving eggs probably began with Heape's (1891, 1897) classical experiment of inserting two four-cell eggs from an Angora rabbit into the oviduct of a mated Belgian hare; two young Angora rabbits were among the litter of six born later. Heape records how he made the transfer without the use of a fluid vehicle, picking up the eggs 'on the point of a spear-headed needle'. Since then a very large number of transfers has been made under a variety of circumstances. Literature surveys have been published by Adams and Abbott (1971) and Adams (1975, 1977), the subject has been reviewed by Austin (1961), Chang and Pickworth (1969), Dickmann (1971), Polge (1978), Hunter (1980) and Trounson (1983) and a symposium volume edited by Adams (1982) has been published. Animals used as donors and as recipients include the rabbit, hare, mouse, rat, hamster, guinea pig, ferret, mink, cow, sheep, goat, pig, horse, donkey, man, baboon, rhesus monkey, tammar wallaby and quokka (list compiled by Polge, 1978, and see also Oguri and Tsutsumi, 1982). To these can now be added: zebra (mare recipient: Betteridge, 1986), water buffalo (intraspecific: Drost *et al.*, 1983), rhesus monkey (IVF and transfer: Bavister *et al.*, 1984), squirrel monkey (IVF and transfer: Kuehl *et al.*, 1984), marmoset (intraspecific: Hearn, 1984), and embryos of Przewalski's horse and common zebra (*Equus burchelli*) transferred to domestic horse and donkey (Hearn and Summers, 1986; Summers *et al.*, 1987).

Oocytes and cleaving eggs are commonly inserted into the oviduct at laparotomy. In the human, however, less invasive techniques are preferred. Unfertilized, pronucleate and cleaving eggs are transferred to the outer fimbriated ends of the fallopian tubes translaparoscopically (Asch *et al.*, 1984; Yovich *et al.*, 1987; Balmaceda *et al.*, 1988). Several procedures have also been devised to visualize and access the tubes transvaginally using catheters, including radiography (Platia and Krudy, 1986), hysteroscopy (Confino *et al.*, 1986) and ultrasound (Jansen and Anderson, 1987). Pregnancies have been established in human subjects using transvaginal tubal transfer of gametes and embryos with (Bustillo *et al.*, 1988; Jansen *et al.*, 1988) and without (Bauer *et al.*, 1990) ultrasound guidance.

Embryos of various stages of development can also be transferred directly into the

uterus. Surprisingly, even uterine transfer of pronucleate eggs has resulted in pregnancies in the human (Ahuja *et al.*, 1985). Although embryos can be introduced surgically, most of the investigators (one of the earliest being Sugie, 1965) prefer non-surgical transfer involving the use of specialized equipment: a fine plastic catheter, outer sheath and instillation syringe, for human subjects (as described by Craft, 1984), or 'French straws' and a Cassou artificial insemination gun for cattle (as described by Betteridge, 1986). Table 2.4 summarizes the chronology of technical advances in the manipulation of oocytes and cleaving eggs.

Embryos have also been deposited in locations other than the genital tract ('ectopic transfer'). Some of the earliest successful transplants were of rat eggs to beneath the kidney capsule (Nicholas, 1942) and of mouse eggs to the anterior chamber of the eye (Fawcett *et al.*, 1947; Runner, 1947), where implantation on the iris often occurred and further development could be observed directly. Later, ectopic transfer was extensively used by Kirby (1960, 1963a,b, 1967), who found that cleaving mouse eggs would eventually develop some measure of placentation, not only in the kidney and spleen but even in the testis. Results showed the low antigenicity of the embryo, for grafts of more advanced tissues are very likely to be rejected. Then Stevens (1970) observed that mouse blastocysts injected under the testis capsule finally became disorganized and formed teratomas and teratocarcinomas, a finding that initiated a new line of research, which is discussed later in this chapter.

2.4.2 ATTEMPTED INDUCTION OF DEVELOPMENTAL ANOMALIES

With the successful induction of fertilization and cleavage *in vitro* of human eggs (Edwards *et al.*, 1969, 1970), and research then directed to obtaining pregnancies and full-term births, concern was widely expressed that the manipulations involved might interfere with normal development and produce birth defects, and so the literature was searched for any evidence to support these fears (Austin, 1973). This revealed that cleaving eggs and blastocysts of several different species had been subjected to wide variations in culture conditions, including large differences in pH and osmolarity, to storage for many weeks at −269°C, to incubation at temperatures up to 40°C, to metabolic inhibitors and stimulants, and to ionizing radiations, and in no instance had there been a significant increase in the incidence of developmental defect among the young eventually born. This remarkable imperturbility is probably attributable to the fact that the cells destined to form the future embryo are undifferentiated in the cleaving egg and blastocyst, so that while traumatic agents may cause the death of cells they cannot affect subsequent genome expression.

Later, Spielmann (1976) reviewed the field again and came to much the same conclusion, pointing out, however, that agents applied to the blastocyst just before implantation might remain in the blastocoele and interfere with morphogenetic processes at later stages. Such damaged embryos, however, almost certainly die before birth and do not contribute to the incidence of birth defects.

Essentially consistent findings were reported more recently by Fabro *et al.* (1984), who treated eight- and 16-cell mouse and rabbit eggs with different concentrations of alkylating agents. In the mouse, methylmethanesulphonate reduced the number of morulas and blastocysts developing in culture and the number of blastocysts 'hatching'. When treated eggs or blastocysts were transferred to recipients, implantation rate showed no reduction and the offspring at birth were free from major congenital defect, though mean birth weight was lower than in the controls. In the rabbit, following treatment with the same agent or with thalidomide or dichlorodiphenyltrichloroethane (DDT), there was a

reduction in birth weights but not in litter size and no congenital defects were observed. The authors inferred that damage was done to the developing conceptuses by the alkylating agents used, but that this was subject to compensatory repair during pregnancy in those that survived.

In human subjects, diabetic mothers have a two- to fourfold higher incidence of malformed infants than normal mothers, but observations in the Chinese hamster showed that spontaneously occurring maternal diabetes had no detectable influence on the cleavage rate of fertilized eggs or on the incidence of pre-implantation embryonic death, gross malformation or hypoplasia (Funaki and Mikamo, 1983).

2.4.3 NUCLEUS REMOVAL AND INSERTION

The pioneering work was that of Briggs and King (1952), following a suggestion made by Spemann (1938), who had observed that, when a fertilized newt egg was constricted by tying a hair about its equator, the cleaving nuclei were at first confined to one side of the knot; after some cleavage divisions, however, a nucleus sometimes migrated through the constricted region and initiated cleavage in the other half of the egg. Whether or not the two halves developed similarly or dissimilarly depended on the position of the constriction relative to the distinctive 'dorsal lip' region of egg cytoplasm, rather than upon the number of cleavages in the two halves. If the knot divided the dorsal lip cytoplasm equally, the two half eggs would produce identical embryos, even if the migrating nucleus had passed through when the cleaving half had reached the 16-cell or even the 32-cell stage. It was surmised that all these early nuclei were developmentally totipotent. Spemann argued that particular interest would attach to the injection of nuclei taken at later stages, after differentiation had occurred, into nucleated one-cell eggs, but in his day the necessary technology was lacking.

Briggs and King (1952) transferred nuclei from the animal hemisphere of frog blastulae to enucleated unfertilized eggs. Most of the treated eggs proceeded to develop normally into complete embryos, and many into normal tadpoles. With nuclei taken from blastulae, early gastrulae and late gastrulae, the proportion of recipient eggs proceeding to normal tadpoles declined correspondingly, suggesting a progressively limiting differentiation, though even nuclei taken from the tissues of adult animals could support extensive development. Best results were obtained with *Xenopus* (see Table 2.5) (Gurdon, 1962; Gurdon and Uehlinger, 1966; and see the review by Briggs, 1977).

Determined efforts have been made to repeat these observations in mammals, but largely in vain. Bromhall (1975), transferring nuclei from rabbit morulae to enucleated oocytes, was able to observe good nuclear development but very limited cleavage. Illmensee and Hoppe (1981) and Hoppe and Illmensee (1982) claimed that nuclei taken from the inner cell mass cells of fertilized or parthenogenetic mouse blastocysts and injected into fertilizing eggs from which the pronuclei had been removed would, in a few instances, permit development to term; but these findings have not been confirmed. On

Table 2.5 The developmental potential of nuclei from tadpole intestinal cells, as described by Gurdon (1968)

*Mono*nucleolated strain of frog	Intestinal epithelial cell nucleus injected into: V
*Bi*nucleated strain of frog	Oocyte, previously irradiated to destroy nucleus. Cultured. Result:
	No cleavage OR Abnormal embryo OR Mononucleolated adult frog

the contrary, McGrath and Solter (1983, 1984a) found that when nuclei from two-cell mouse eggs were injected into enucleated eggs undergoing fertilization, the products developed only to the blastocyst stage, and the use of nuclei from four-cell or eight-cell eggs, or from the inner cell mass cells of blastocysts, was not followed by significant development. Surani (1984) also reported that eight-cell and ICM nuclei were incapable of supporting more than two or three cleavage divisions.

More recently, Willadsen (1986), working with the sheep, found that if the nuclei for transfer were taken from embryos that were themselves the products of nuclear transfer, more extensive development ensued. Prather and First (1990) infer that when lack of significant development after nuclear transfer is repeated, this reflects the effects of asynchronies in donor and recipient cell cycles, and of deficiencies in genomic modification. In addition, however, Willadsen (1986) depended on blastomere transfer (from eight- and 16-cell embryos) as the means for nuclear transfer, achieving in this way development through to birth. Blastomere transfer avoids the problem that damage is done to naked nuclei by manipulative procedures. By these means, other investigators have succeeded in obtaining live-born calves from blastomeres removed from embryos up to approximately the 64-cell stage (see Massey, 1990). Prospects for the production of very much larger numbers of cloned calves are discussed by First (1990), who explains how the embryo developing from an oocyte implanted with a blastomere can in its turn serve as the source of up to about 64 transferrable blastomeres. Prior to such multiplication, embryos can be sexed by immunological methods.

2.4.4 INDUCTION OF PARTHENOGENESIS

Development by parthenogenesis is known in a wide range of organisms, in many of which it represents a normal reproductive process. Spontaneously occurring limited parthenogenetic development has been recorded in several mammalian species (see Kaufman, 1983) and is particularly notable in the ovaries of mice of the LT/Sv strain, in which egg cleavage frequently advances to the blastocyst stage and occasionally somewhat beyond (Stevens and Varnum, 1974). In no mammal, however, is there certain evidence of unaided parthenogenetic development (spontaneous or induced) leading to the birth of viable young (the literature has been reviewed by Suomalainen, 1950; Beatty, 1957, 1967; Austin and Walton, 1960; Tarkowski, 1971; C.F. Graham, 1974; Mittwoch, 1978; Whittingham, 1980a,b; Markert, 1982; Kaufman, 1983; Austin, 1987).

Parthenogenesis may be defined as development of the egg without the involvement of the male in any way. Gynogenesis occurs if a spermatozoon activates an egg but provides no genetic material to the future embryo. In androgenesis, the spermatozoon participates as in normal fertilization but the egg's genetic material is not involved. A few species of non-mammalian animals are known to reproduce by gynogenesis or by androgenesis, but we have very limited information on them. A major reason for continued research interest in this subject is that parthenogenetically and gynogenetically derived animals would possess only maternal genes and would be invaluable for the study of recessives. In addition, the fact that none of these alternatives to fertilization has yet been known to succeed demands an explanation.

Some observations were made on the tendency of unfertilized eggs to undergo apparently normal cleavage, with or without experimental stimulation (Austin, 1949, 1956). By contrast, human follicular oocytes are unusually resistant to parthenogenetic activation (Abramczuk and Lopata, 1990), although activation can occur after micromanipulation of oocytes (Kola *et al.*, 1990). The current phase of research on parthenogenesis may be said to have started with the

reports of C.F. Graham (1970) and Tarkowski *et al.* (1970) on their work in mice. C.F. Graham (1970) induced development simply by removing the cumulus oophorus with hyaluronidase, growing the eggs in culture for a short time and then transferring them to suitable recipients. Tarkowski *et al.* (1970) used electrical shock to stimulate eggs still in the oviduct, and recovered them at a later time or looked for any implantations. Both laboratories recorded a high incidence of activation and some implantation, and occasionally the presence of developmental stages further advanced than those previously described, namely the egg cylinder stage, with some embryos surviving for 9–10 days. Development appeared to be normal as far as it went and so the possibility presented itself that at least a small proportion of parthenogenones might survive to birth and beyond, but as yet and despite diligent efforts such an outcome has not been observed. Interesting possible explanations have been put forward. Recent findings may be summarized as follows:

1. Diploid parthenogenones have been united with cleaving fertilized eggs to make chimeras (entities that are discussed in the next section), and these, on being placed in recipient mice, have developed to term, further investigations revealing that the parthenogenetic line contributed to all tissue classes (Stevens *et al.*, 1977; Surani *et al.*, 1977), and even to fertile germ cells (Stevens, 1978; Anderegg and Markert, 1986).
2. Gynogenetic and androgenetic development has been produced by removing the male or the female pronucleus, respectively, from eggs undergoing fertilization, and restoring diploidy by inhibiting the first cleavage division with cytochalasin B. A few of these embryos of both kinds were claimed to be capable of developing to term (Hoppe and Illmensee, 1977). This report was later said to have been based on technical error (see Newmark, 1983, 1984).
3. After removal of the cumulus and zona pellucida, fusion was induced between oocytes and first polar bodies by treatment with 40% polyethylene glycol or UV-inactivated HVJ virus. The latter treatment yielded two blastocysts developing from 45 oocytes successfully fused with polar bodies (Tachi and Tachi, 1980a).
4. Fusion between paris of denuded oocytes was induced by treatment with inactivated Sendai virus (Soupart, 1980, 1982) or with phytohaemagglutinin followed by polyethylene glycol (Gulyas *et al.*, 1984), and then by a brief treatment with ethanol to increase the frequency of activation. Development in subsequent culture sometimes went as far as the blastocyst stage. When Gulyas *et al.* (1984) transferred blastocysts to suitable recipients, about half implanted and one embryo proceeded to the 14-somite stage.
5. Nuclei were removed from the inner cell mass of blastocysts developing from either fertilized or parthenogenetically activated eggs and injected into enucleated fertilized eggs, and some of the products were said to have developed to term (Hoppe and Illmensee, 1982). This paper was subject to the same qualification as that mentioned in paragraph 2 above.
6. Fertilized eggs were treated so as to induce suppression of the second polar division, and diploidy was restored by removal of one of the female pronuclei or of the male pronucleus. Eggs retaining the male pronucleus often developed to term but all others failed (Surani and Barton, 1983).
7. The two pronuclei of eggs undergoing fertilization were introduced into enucleated parthenogenetic eggs; development then often continued to term (Mann and Lovell-Badge, 1984). Replacing the male and female pronuclei with nuclei from

parthenogenetic eggs, however, did not have this effect.

8. The introduction of a male pronucleus into a haploid parthenogenetic egg was often followed by development to term, but this did not happen when a female pronucleus was inserted (Surani *et al.*, 1984).
9. Eggs undergoing fertilization were treated in two ways: (a) the male pronucleus was removed and replaced by either a male or a female pronucleus or (b) the female pronucleus was removed and replaced by a male or a female pronucleus; development to term only occurred when a male and a female pronucleus were present (Barton *et al.*, 1984).
10. Mouse blastocysts were reconstituted in two different ways: the inner cell mass from a parthenogenetic or a gynogenetic blastocyst was used to replace the ICM in a fertilized blastocyst, or the ICM from a fertilized blastocyst replaced that in a parthenogenetic or a gynogenetic blastocyst. In no instance did development go to term, nor did ICM or trophectoderm cells contribute to the deficient partner. Best results came from blastocysts in which parthenogenetic or gynogenetic ICMs existed within normal trophectoderms – development was rarely less than equivalent to 25 somites and in many instances proceeded to 30 or 40 somites (Barton *et al.*, 1985).
11. Gynogenesis and androgenesis were induced by removal of the male or female pronucleus, respectively, from mouse eggs undergoing fertilization and development was found generally to proceed to two- to 16-cell stages with gynogenesis and two- to four-cell stages with androgenesis. Nuclei from cleaving gynogenetic eggs could replace female pronuclei (but not male pronuclei) in eggs undergoing fertilization, and the product would develop to term; the same outcome would ensue with the replacement of male pronuclei (but not female pronuclei) by nuclei from cleaving androgenetic eggs (Surani *et al.*, 1986).

From these observations (summarized in Tables 2.6 and 2.7) it is inferred that failure of parthenogenones is not attributable to homozygosity and the expression of recessive lethal genes, as has often been suggested, or to a possible 'essential' extranuclear contribution by the spermatozoon, but specifically to some influence conveyed by the male pronucleus.

Surani *et al.* (1984) proposed that the male genome must undergo a distinctive 'imprinting' as to its paternal origin during gameto-

Table 2.6 Parthogenetic eggs have limited developmental potential unless appropriately modifed (Various sources)

genesis, and that this influence is essential for the proper development of extraembryonic membranes and trophoblast, since these structures are notably underdeveloped in parthenogenones. Eggs with one or two male pronuclei and no female pronucleus also fail to develop to term, the female contribution evidently being essential for some phase of embryogenesis, and again the suggestion is that genomic imprinting may take place during gametogenesis, this time in the ovary (Barton *et al.*, 1984; McGrath and Solter, 1984b; Solter, 1987). The observations support the idea that the cytoplasm of parthenogenetic and fertilized eggs is similar and that it is some deficiency in the genotype of the former that is the reason for failure to achieve full development (Surani *et al.*, 1987). The role of genomic imprinting is discussed further by Jackson (1989).

A possible explanation for some of the observations lies in the need for X-inactivation in the late blastocyst. As first reported by Takagi and Sasaki (1975), X-inactivation in mice is random in embryonic cells but preferentially affects the male X chromosome in those of the extraembryonic tissues. If only female X chromosomes are present, there could be an imbalance affecting development, this state existing in diploid parthenogenones. Kaufman *et al.* (1978), however, found that X-inactivation did in fact occur in more than 50% of the cells, and Rastan *et al.* (1980) showed that a similar proportion existed in the yolk sacs. This explanation, therefore, appears inadequate.

The effects of certain mutations can also differ according to their transmission through maternal or paternal routes. Hairpin-tail (T^{hp}) in the mouse, for example, allows survival in the heterozygote when derived from the father but causes death of the embryo about half-way through pregnancy when derived from the mother. Then again, in the DDK strain of mouse, matings between males and females within the strain are much more fertile than outcrosses of the females with alien males, which result in frequent death of morulae and blastocysts, and again just before the egg cylinder stage. A suggestion is that embryonic death is attributable to maldevelopment of the trophoblast.

In summary, we still lack a working hypothesis for the limited viability of mammalian parthenogenones.

2.4.5 MICROSURGICAL FERTILIZATION

In classic experiments using non-mammalian eggs, Hiromoto (1962) described a system for the mechanical breaching of the zona pellucida using a micropipette which has become the standard for sperm microinjection techniques in mammals. This and subsequent sperm microinjection studies have helped to elucidate the nature of gamete interaction.

Several workers have demonstrated that the injection of motile and immotile spermatozoa, either directly into the cytoplasm of

the oocyte or into the perivitelline space, can lead to pronuclear formation and normal development in mammals (Uehara and Yanagimachi, 1976; Thadani, 1980; Markert, 1983; Mann, 1988). In addition, interspecies fertilization, which would not otherwise have been possible, has been shown to occur after injection of foreign sperm directly into the ooplasm (Thadani, 1980). From these studies, it can be concluded that normal surface interactions between the spermatozoon and the egg are not essential to initiate development.

The ability of the oocyte to decondense sperm is acquired gradually by the egg cytoplasm. Sperm which are injected into immature eggs at the germinal vesicle stage do not decondense until the germinal vesicle breaks down and even then are unable to form pronuclei (Usui and Yanagimachi, 1976; Thadani, 1979). Conversely, unfertilized mature mammalian oocytes will cause premature chromosome condensation when fused with interphase blastomeres (Balakier, 1979). Thus, the capacity of the oocyte to support pronucleus formation develops towards the end of its meiotic maturation. Pronucleus formation is also dependent on egg activation. Mechanical stimulation of the oocyte plasma membrane or cytoplasm by the micropipette induces egg activation (Uehara and Yanagimachi, 1976). Therefore, injected sperm are deposited into an activated environment and respond as if the egg had been activated by the sperm during the course of normal fertilization.

Induction of the sperm acrosome reaction prior to subzonal insemination has led to higher rates of fertilization in the mouse (Yamada *et al.*, 1988) and increased human sperm penetration of hamster (Mortimer *et al.*, 1986; Lassalle and Testart, 1988) and human (Laws-King *et al.*, 1987) oocytes. Fertilization also occurs in the absence of acrosome reaction inducers (Ng *et al.*, 1988; Yang *et al.*, 1990), although normal physiological capacitation and partial acrosome reaction is likely to have occurred during the preparation of spermatozoa for injection. Pronucleus formation, however, does occur after direct injection of uncapacitated sperm heads (Thadani, 1980) and thus it may be argued that sperm capacitation and the acrosome reaction are relevant only to zona pellucida penetration and sperm–egg fusion and not to pronucleus formation.

The demonstration by Aitken *et al.* (1983) that spermatozoa from men with immotile cilia (Kartagener's) syndrome could fuse with hamster eggs when injected under the zona pellucida and that normal homospecific fertilization could occur after subzonal insertion of spermatozoa into human oocytes (Laws-King *et al.*, 1987; Lazendorf *et al.*, 1988) had exciting ramifications for the alleviation of infertility in man. Shortly thereafter, the first human pregnancy (Ng *et al.*, 1988) and live birth (Fishel *et al.*, 1990) was reported as a result of subzonal insertion of multiple sperm from subfertile men. In addition, microsurgical injection may also be applied to facilitate sperm–egg interaction where there are apparent structural defects in the zona pellucida, i.e. non-functional sperm receptors or zona matrix components which inhibit the passage of sperm.

Modifications of the technique have also been used as alternatives to subzonal insertion. The procedure of zona drilling developed in a mouse model (J.W. Gordon and Talansky, 1986) involves the exposure of a small section of the zona pellucida to a minute volume of acid Tyrode's solution slowly delivered from a microneedle until the zona is breached. Subsequent *in vitro* insemination allows sperm to utilize the artificially created gap (Conover and Gwatkin, 1988; Talansky *et al.*, 1991) and results in increased rates of fertilization in the mouse. Zona drilling has been applied clinically, but the acid Tyrode's solution was found to interfere with normal embryonic development (J.W. Gordon *et al.*, 1988). A mechanical version of the technique, partial zona dissection, which employs a microneedle to form a slit in the

zona pellucida, has, however, been a successfully applied microfertilization technique in the human with normal births resulting (Cohen *et al.*, 1989; Malter and Cohen, 1989). Several other variations on the zona drilling procedure have been attempted, including zona cutting and tearing (Depypere *et al.*, 1988; Odawara and Lopata, 1989) and the novel use of lasers (Godke *et al.*, 1990; Tadir *et al.*, 1991).

2.4.6 PRODUCTION OF CHIMAERAS

Mouse eight-cell eggs were first united in pairs by Tarkowski (1961, 1963), who removed the zona pellucida by drawing the egg into a pipette a bit narrower than the diameter of the egg, and by Mintz (1962, 1964), who digested the zona with the enzyme pronase. The resulting chimaeras revealed random intermingling of cells from the two sources and, on transfer to a recipient, generally developed to birth and functional adulthood. From early days, the need for appropriate cell markers was appreciated. Pigmentation, especially when it was expressed in the iris, was an early favourite; other markers have included enzyme variants (β-glucuronidase, glucose phosphate isomerase, isocitrate dehydrogenase), chromosome variations (T6 translocation in which the homozygote has two small 'marker' chromosomes, differing amounts of pericentric Giemsa-stainable heterochromatin, and for XX/XY chimaeras the presence of the Y chromosome), immunological features (cell-specific antigens detected by haemagglutinin tests or immunofluorescent methods, and skin grafting) and isotope labelling of one component of the chimaera (see McLaren, 1976b, 1981, for full discussion). Use of these methods clearly showed the lack of any pattern in the distribution of the cells from the two sources, unless contrived experimentally, as in the work of Hillman *et al.* (1972) in their investigation of cell determination during blastocyst development (discussed earlier in section 2.2.4). As expected, some chimaeras grew up as hermaphrodites, but most often the male cells assumed dominance and determined the functional sex. More than two cleaving eggs, from the two-cell stage to the late morula, can be induced to form a chimaera, and as many as 16 have been found capable of organizing *in vitro* into a single giant blastocyst of normal proportions.

The work described so far involved the mouse as an experimental animal, but Mayer and Fritz (1974) used the rat, and Moustafa (1974) the rabbit. Other investigators have explored the potential for development of interspecific chimaeras by pairing the zona-free cleaving eggs of mouse and rat (Mulnard, 1973; Stern, 1973; Zeilmaker, 1973; Tachi and Tachi, 1980b) or of mouse and bank vole (Mystkowska, 1975). Well formed expanded rat-mouse blastocysts were obtained, the cells of both species contributing to both SCM and trophectoderm, but implantation after transfer was not observed.

Willadsen and Fehilly (1983), working with sheep eggs, also employed the 'aggregation technique' (as initiated by Tarkowski and by Mintz) to improve the chances of survival of separated blastomeres. Thus, when each of the blastomeres from an eight-cell egg was placed in an empty zona pellucida along with a blastomere from another eight-cell egg, the chances of survival and development were much improved. In one experiment, the blastomeres from an eight-cell Finn–Jacob egg were paired up with blastomeres from an eight-cell Suffolk egg, and five lambs were subsequently born (Figure 2.7).

These were all of the Finn–Jacob phenotype, and this result was attributed to the Finn–Jacob egg being developmentally somewhat in advance of the Suffolk egg. By contrast, when single blastomeres from two two-cell eggs were paired up, the resulting lambs were regularly visibly chimaeric. More recently, interspecific bovine chimaeras have

Figure 2.7 Quintuplet lambs, each arising from a blastomere from an eight-cell Suffolk egg. (Photo by courtesy of S.M. Willadsen.)

been produced by Munro *et al.* (1986) (Figure 2.8).

Composite proembryos can also be constructed by Gardner's method (1968, 1971, 1978, 1982) and are distinguished as 'injection chimaeras'. This procedure involves the introduction of a whole or parts of an inner cell mass from one blastocyst into the cavity of another, the inner cell mass of which may have been partially or wholly removed. Gardner generally used the mouse as experimental animal, but occasionally also the rat (Gardner and Johnson, 1973; Gardner, 1975) and the rabbit (Gardner and Munro, 1974); and other workers have also used the sheep (Tucker *et al.*, 1974, 1978). As with aggregation chimaeras, the introduced cells mingle with those of the other proembryo (though only with the inner cell mass cells in this case), with no detectable pattern in their distribution. The recognizable contribution to the eventual adult animal varies a good deal – one introduced cell sometimes becomes the forerunner of half the final product, as judged by physical characteristics. (Chimaeras can also be produced by aggregating embryonal carcinoma or teratocarcinoma cells with cleaving eggs, or by injecting them into blastocysts – this is discussed later under 'Teratocarcinomas' in section 2.4.8.)

The rare spontaneous chimaeras recorded in clinical studies on the human subject are thought to arise by eggs adhering to each other during cleavage. They should be dis-

tinguished from 'mosaics', which can be very similar in physical characters; mosaics are generally caused by some chromosomal aberration during development, such as loss of a chromosome in mitosis, non-disjunction, somatic mutation or somatic crossing over. (The normal female mammal is, of course, a mosaic with cells differing through X chromosome inactivation.) By definition, mosaics necessarily derive from the fertilization of an egg by a single spermatozoon; if double fertilization occurs (of oocyte and polar body separately), or if cleaving eggs unite, the result is a chimaera.

The study of experimental chimaeras can yield useful information on a variety of developmental problems. One of the first to be investigated was the long-debated origin of skeletal muscle fibres (cells), which contain a central bundle of contractile elements as well as numerous nuclei. In culture *in vitro*, similar cells are formed by fusion of several precursor cells, rather than through multiple karyokinesis without cytokinesis. That this was also the manner of development *in vivo* was demonstrated by Mintz and Baker (1967), who aggregated pairs of mouse morulae that were each homozygous for an electrophoretically different form of the enzyme isocitrate dehydrogenase, and found that in the resulting mice skeletal muscle tissues alone displayed an intermediate form of the enzyme (otherwise found only in F1 hybrids) in addition to the two original forms.

As mentioned under 'Induction of parthenogenesis' (section 2.4.4), chimaeras have been used to test the viability of the cells of parthenogenones: fusion products of fertilized cleaving eggs and parthenogenones have been found to develop through to fertile adulthood, with the parthenogenetic cells contributing to the formation of fertile gametes (Stevens *et al.*, 1977; Surani *et al.*, 1977; Stevens, 1978). Other examples of such 'rescue' also exist. In T^{fm} male mice, spermatogenesis is arrested in meiosis, but chimaeras formed between XY cleaving eggs and those with $X^{Tfm}Y$ yield adults with normal spermatogenesis, for they sire both XY and $X^{Tfm}Y$ males. The sterility of T^{fm} males is thought to be due to supporting cells (e.g. Sertoli cells) failing to respond to androgen (Lyon *et al.*, 1975). For further details, see McLaren (1981).

Cross-insemination between *Mus musculus* and *M. caroli* rarely yields living young, but when chimaeras were made by injecting ICMs from *M. caroli* into *M. musculus* blastocysts, and transferred to *M. musculus* recipients, the majority developed to adulthood and showed contributions from both sources (Rossant and Frels, 1980, 1981).

Several attempts were made to produce intergeneric aggregation chimaeras between rat and mouse, but development went no further than the blastocyst stage (Mulnard, 1973; Stern, 1973; Zeilmaker, 1973); the injec-

tion chimaeras of Gardner and Johnson (1973) and Gardner (1975) fared somewhat better, developing to the 33-somite stage. The most advanced stages reported so far are those obtained with sheep–goat aggregation chimaeras, some of which survived to adulthood (Fehilly *et al.*, 1984) (Figure 2.9).

2.4.7 DISAGGREGATION, REAGGREGATION AND SECTION OF PROEMBRYOS

Some of the earliest attempts to investigate the developmental potential of separated blastomeres were those of Nicholas and Hall (1942) and Nicholas (1947) in the rat, but a more definitive phase of research began with Seidel's (1952) success in obtaining development to birth of two-cell rabbit eggs in which one blastomere had been destroyed by needle puncture; four-cell eggs with three blastomeres destroyed developed to somite-stage embryos. Then Tarkowski (1959) separated blastomeres of two- and four-cell mouse eggs and found that cleavage would often continue after transfer to recipients; in one test, six normal young were born (see also Rossant, 1976, 1986). Later, Moore *et al.* (1968) isolated blastomeres from early-cleaving rabbit eggs and found it necessary to replace these in their own zona pellucidas if cleavage were to proceed normally. By this means, full development to birth was obtained at frequencies of 38% for blastomeres from two-cell eggs, 19% for those from four-cell and 11% from eight-cell. In the pig, the survival rate to the blastocyst stage was 35% for single blastomeres from both four- and six-cell eggs (Moore *et al.*, 1969).

Further technical improvements were introduced by Willadsen (1979), who worked with sheep, cow and horse eggs. After transfer of isolated blastomeres to new zonas, he embedded them in small agar cylinders which were lodged in a recipient sheep until blastocyst expansion had begun. The blastocysts were then released and placed in the uterus of a second recipient of the appropriate species (sheep, cow or horse) in which implantation could occur. By these means it proved possible to obtain normal monozygotic twins. Allen and Pashen (1984) produced twin foals by similar means (Figure 2.10).

The blastomeres of later stages were found increasingly less likely to survive the rigours of transfer, presumably because of their progressively smaller nuclear and cytoplasmic volumes; accordingly, several blastomeres were transferred together, and full development was frequently found to be obtainable. When pairs of blastomeres from four-cell eggs, or quartets from eight-cell eggs, were handled together, the probability of normal birth was 70% or better. When a quarter of the blastomere population was used, namely single cells from four-cell eggs or pairs of cells

from eight-cell eggs, the success rate was about 50% or better (Figure 2.11).

Transferring single cells from eight-cell eggs yielded about 10% success. For further details, see Willadsen (1980, 1981), Willadsen and Fehilly (1983) and Fehilly and Willadsen (1986). (The technique of combining blastomeres from different donors was discussed in the previous section on 'Production of chimaeras'.)

Success in obtaining full development with only one or two blastomeres from two-, four- or eight-cell eggs means, of course, that the 'spare' blastomeres could be used for special studies, such as sex determination, karyotyping for chromosomal anomalies, determination of enzyme activity or identification of enzyme variants (see McLaren, 1985). Hardy *et al.* (1990) found that removal of one or two blastomeres from human eight-cell embryos, while reducing the numbers of cells in ICM and trophectoderm at the blastocyst stage, did not affect pre-implantation development. To overcome the handicap of small cell number for analytical work, blastocysts have been cultivated *in vitro* to yield embryonic stem cell lines (Axelrod, 1984); alternatively, growing EK cells *in vitro* as described by Evans and Kaufman (1981) could provide ample material for analysis (as discussed further in the next two sections). Blastocyst biopsy in the rabbit was demonstrated by Gardner and Edwards (1968), and could be applied to other large blastocysts such as those of sheep, cattle and horses. Trophectoderm biopsy of human blastocysts can provide sufficient material for genetic diagnosis without impairing hatching potential (Dokras *et al.*, 1990). With the aid of high-performance liquid chromatography, Leese *et al.* (1991) were able to assay the

enzyme HPRT in single cleavage-stage human blastomeres.

Monozygotic cattle twins have been obtained by transferring bisected morulas to recipients (Ozil *et al.*, 1982; Lambeth *et al.*, 1983; Baker *et al.*, 1984; Voekel *et al.*, 1984). Baker *et al.* (1984) obtained 79% of pregnancies with entire embryos and 68% with 'split' (bisected) specimens, the difference being insignificant, and Voekel *et al.* (1984) 42.6% with both. Tsunoda *et al.* (1985b) have reported the birth of twins in Japanese native goats following this procedure.

2.4.8 TERATOCARCINOMAS

These tumours can develop spontaneously from diploid spermatogonia in the testis or from oocytes after the first meiotic division (particularly in the LT/Sv mouse strain), but in the present context attention will be restricted essentially to teratocarcinomas arising from transplanted mouse embryos (a field reviewed by Stevens, 1981). Some of the earliest work involved the initiation of teratomas by inserting cleaving eggs or six-day egg cylinders from mice of the 129 strain under the testis capsule; after passing through some normal stages of development, the cells became disorganized and growth continued as a teratoma. Induced in this way, teratomas are, therefore, derived from somatic cells, in contrast to the germ cell origin of the spontaneous tumours. A minor proportion of the growths become teratocarcinomas, consisting of undifferentiated em-

bryonal carcinomic cells which can be maintained by reinsertion. The cells have been shown to be pluripotent or even totipotent, but after several transfers some lose their ability to produce some or any kind of differentiated cell.

Disaggregated teratocarcinomas injected into the peritoneal cavity can give rise to retransplantable ascites tumours, the ascitic fluid suspending many 'embryoid bodies'. These resemble the egg cylinder stage of development, with organized layers of embryonic ectoderm and endoderm (Stevens, 1958, 1964; Pierce and Dixon, 1959), or else a core of EC cells surrounded by a rind of cells resembling endoderm.

EC cells from a mouse of a black strain, when injected into the cavity of blastocysts from a white strain, became integrated with the inner cell mass cells and later contributed to parts of normal adult mice, as shown by the pigmented patches of fur (Brinster, 1974).

These two lines of enquiry were drawn together when Mintz and Illmensee (1975) took embryoid bodies from mice with ascites tumours that had been passaged between recipients about 200 times, dissected off the rind and disaggregated the core cells (Figure 2.12).

These cells were injected into the cavity of blastocysts which later developed into mice exhibiting coat colour mosaicism, testifying to a contribution from the embryoid bodies. More than that, when these mice were mated with untreated animals, some of the resulting young had coat colours indicating that the core cells from embryoid bodies had given rise to normal functioning gametes. The fact that the properties shown by the embryoid bodies could be matched by those of EC cells maintained in culture was shown by Papaioannou *et al.* (1978).

A few years later, Evans and Kaufman (1981) found that, if experimentally delayed mouse blastocysts were held in culture, they became attached to the dish and trophoblast cells grew out, the inner cell mass differentiating into an egg cylinder-like structure (Figure 2.13).

This could be removed, disaggregated and grown in culture over a feeder layer of inactivated fibroblasts. Soon, colonies of EC cells could be discerned and subcultured; they were found to have a normal karyotype and often displayed a Y chromosome, both features distinguishing them from corresponding cells produced by other investigators. These cells were accordingly identified as EK cells; they behaved in much the same way as EC cells, giving rise to teratocarcinomas on subcutaneous injection. When cultured without feeder cells, they formed embryoid bodies. When introduced into the cavity of blastocysts, the resulting adult mice showed visible evidence of the chimaeric origin (Figure 2.14), and mating studies revealed that several animals were functional germ cell chimaeras (Bradley *et al.*, 1984).

More recently, EK cells have come to be known as ES (embryonic stem) cells (see Robertson, 1987, and Jackson, 1989). Notarianni *et al.* (1990) have described the establishment in culture of cell lines from pig blastocysts that resemble mouse ES lines.

In the meantime, Fujii and Martin (1980) and C.L. Stewart (1982) reported that viable chimaeras consisting of normal cells and carcinoma cells could be produced not only by injection but also by aggregation of the carcinoma cells with those of eight-cell embryos. Subsequent development, however, was often abnormal, the degree of anomaly correlating with the proportion of carcinoma cells composing the fetus – when the proportion was large, the fetus was unlikely to reach term. The possibility existed that the ES cell lines tested (NG-2, PSA-1 and LT1-2D) failed because of chromosomal abnormalities. Rossant and McBurney (1982), however, found that major developmental errors were often associated with carcinoma cells that had normal karyotypes.

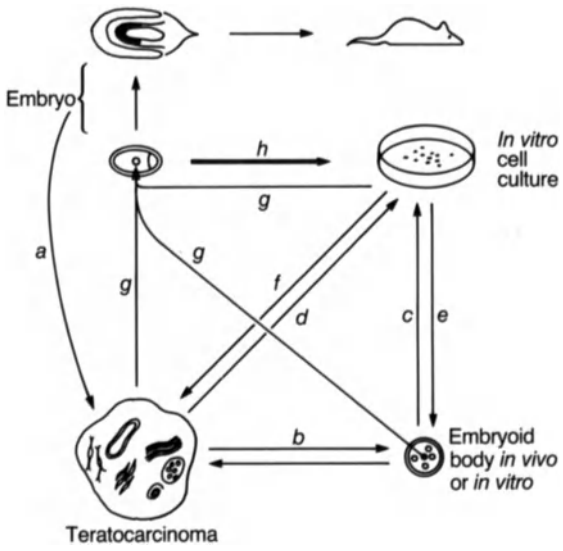

Figure 2.13 The potentials of mouse inner cell mass cells when cultured under different conditions. The arrow marked 'h' represents the accomplishment of Evans and Kaufman (1981) in obtaining clones of pluripotential 'EK' cells of normal karyotype directly from blastocysts.

2.4.9 RECOMBINANT DNA RESEARCH

Probably the first indication that a subcellular substance could transmit a heritable character between individuals came with the observations of Griffith (1928) on the exchange of colony characters between S and R strains of *Streptococcus pneumoniae*; the active agent became known as the 'transforming principle'. Some years later, Avery *et al.* (1944) demonstrated that this was, in fact, DNA. So our understanding of transformation as a means of gene shift between individuals preceded recognition of 'conjugation' – the normal mode of sexual reproduction in bacteria, seen first in *Escherichia coli*, whereby lengths of chromosome are passed from one cell to another (Lederberg and Tatum, 1946). Shortly afterwards, Zinder and Lederberg (1952) observed 'transduction' of genes between strains of *Salmonella*, effected by a temperate bacteriophage. In this process, a fragment of bacterial chromosome becomes incorporated into the virus particle and is carried to the next host cell.

Exploitation of viruses for the transfer of genetic information between mammalian cells would appear to flow logically from these observations, yet it was about 20 years before F.L. Graham and Van Der Eb (1973), interested in the infectivity of viral DNA, obtained transformation of cultured rat cells by the DNA of adenovirus. A year later, Jaenisch and Mintz (1974) announced that, when intact DNA from SV40 (a simian retrovirus) was injected into the cavity of mouse blastocysts, viral DNA sequences were later found incorporated into the adult mouse somatic tissues. A much higher success rate was obtained when J.W. Gordon *et al.* (1980) inserted into the plasmid pBR322 the herpes simplex thymidine kinase gene together with the SV40 virus origin of replication and injected the product into pronuclei of mouse eggs, which were immediately placed in recipient oviducts. Among the mice that developed to birth, some exhibited sequences in somatic tissues that were homologous with the injected plasmid, but there was no evidence of incorporation into the germ line. This step was achieved by Jähner and Jaenisch (1980) by viral infection of early mouse proembryos, and also by Costantini and Lacy (1981) by injection of a cloned rabbit DNA fragment containing the adult β-globin gene into the pronucleus in mouse eggs; in both instances, transmission to subsequent progeny was demonstrated. T.A. Stewart *et al.* (1982) were able to transfer human β-globin gene sequences to mice by pronuclear injection, and there was evidence of transmission to progeny by one animal.

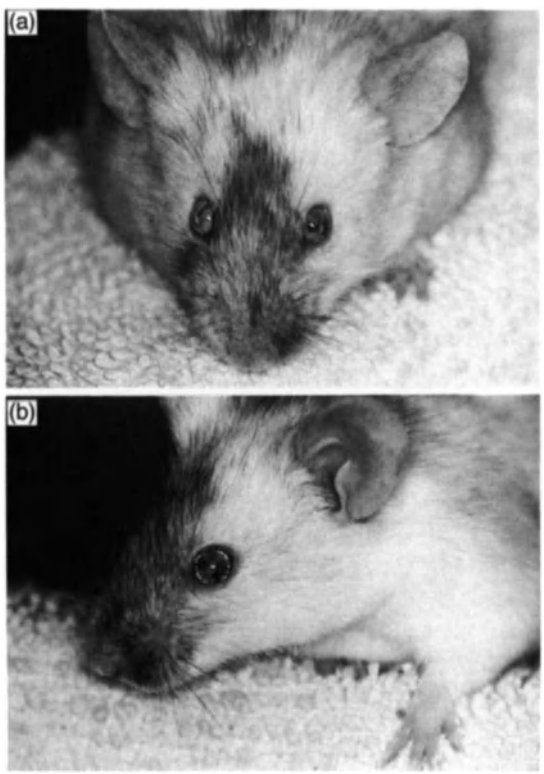

Figure 2.14 Chimaerism shown by the pigmentation of fur and iris in an adult mouse, which developed from a 'white' blastocyst into which EK cells from a black strain had been injected. (Figure 5.7 from Kaufman, 1983.)

But the striking advance in this phase of research was the production of larger-than-normal mice, in some instances nearly twice the body weight of controls and maintaining approximately a fourfold elevation of circulating growth hormone levels (Palmiter *et al.*, 1982). This was achieved by injecting into pronuclei of mouse eggs a DNA fragment containing the structural gene of rat growth hormone fused to the promoter of the mouse metallothionein I (MT-I) gene. Administration of zinc to the resulting animals stimulated the MT-I gene, which in turn evoked expression of the growth hormone gene. The possibility that the introduced rat growth hormone genes were integrated into a single chromosome of the mouse genome was supported by the pattern of inheritance through two successive generations (Palmiter and Brinster, 1984). The transfer of human growth hormone genes to mice by a similar means also resulted in growth promotion (Palmiter *et al.*, 1983), and similar results were obtained by transfer of the human gene for growth hormone-releasing hormone (Hammer *et al.*, 1985). The development of

gene transfer methods in cattle is described by Roschlau *et al.* (1989). More recently, Pursel *et al.* (1990) have reported functional integration and inheritance of growth-related genes introduced into pigs, and Rexroad *et al.* (1990) have commented on the need for better control of inserted genes in ruminants. Other genes are also worthy of attention (Ward *et al.*, 1984; Land and Wilmut, 1987; First, 1990).

Prospects for the advantageous application of recombinant DNA technology to human problems depend firstly on reliable diagnosis of genetic diseases (see Gosden and Gosden, 1985; Weatherall, 1985; and Akhurst, 1986, for reviews). Sometimes, diagnosis can be made by relatively simple biochemical means; for example, determination of the normality or otherwise of the gene for hypoxanthine phosphoribosyl transferase can be based on analyses for the presence or absence of the enzyme in single blastomeres from 8-cell mouse eggs.

More often, however, dependence must be placed on diagnosis much later, as in the examination of DNA in amniotic fluid cells collected usually in the sixteenth week of gestation, though adequate material can commonly be obtained by chorionic villus biopsy in the eighth to twelfth week of gestation (Rhine and Milunsky, 1979; Williamson *et al.*, 1981; Maxwell *et al.*, 1985; Brambati, 1986; Brambati *et al.*, 1986; and see also abstracts in Human Reproduction, 1, pp. Al 1-A13, A29-A30, 1986). For direct chromosome studies, at least 5mg of villous tissue is necessary for the preparation of useful karyotypes (Dalpra *et al.*, 1986). Satisfactory genomic analysis, however, can be made on 10 g of tissue, based on 'restriction endonuclease mapping'. Endonucleases cleave the DNA molecule at different highly specific points, and the normal length of the fragments and their localizations relative to particular genes are known, so that it is possible to detect mutations that produce new sites of enzyme action, or remove sites, or cause the addition or loss of one or more genes. This technique has been used successfully for the early recognition of sickle cell anaemia, some forms of β-thalassaemia and phenylketonuria, and a marker has also been discovered for Huntington's chorea, but there are at present difficulties in the wider application.

That sex determination at an early stage is of undeniable value has led to important advances in the development of DNA probes for the detection of X- and Y-specific DNA sequences in the pre-implantation embryo. The sensitivity of DNA analyses permits genetic diagnoses to be made utilizing a single cell. At present, it is possible to determine the sex of an embryo by analysing a single extracted blastomere using either *in situ* hybridization or the polymerase chain reaction.

In situ hybridization is a technique that allows direct visualization of specific DNA sequences. Initially, the procedure utilized radiolabelled probes coupled with autoradiography, and was used to detect Y chromosome-specific repeated nucleotide sequences in the human male embryo (Jones *et al.*, 1987) and in domestic species (Leonard *et al.*, 1987; Matthews *et al.*, 1987). More recently, rapid non-isotopic methods have been used for the detection of both X- and Y-chromosome sequences in human pre-implantation embryos (Penketh *et al.*, 1989; Griffin *et al.*, 1992). Since signals are visualized directly under the microsope, localization of the signal is more precise. Multiple signals using different reporter molecules such as fluorescein isothiocyanate (FITC) and rhodamine give different colour signals. Using different fluorochromes, it is possible to detect a number of autosomes as well as the sex chromosomes simultaneously, which opens up the possibility of using this technique for the detection of inherited disorders.

The polymerase chain reaction is a method which amplifies specific sequences of DNA for analysis. The sequence may be specific to a sex chromosome or may include a site of

deletion or mutation. The technique has been applied successfully for the screening of human pre-implantation embryos prior to transfer by determining the gender using Y-specific DNA amplification (Handyside *et al.*, 1990) and by the diagnosis of single-gene defects such as cystic fibrosis (Hardy and Handyside, 1992).

Although these techniques open up new frontiers in genetic diagnosis, the technology is currently limited. Analysis of a single blastomere from an eight-cell embryo may not detect mosaicism or genetic modification at a later stage, and the methodology itself can have problems such as loss or inactivation of DNA, amplification failure and contamination.

The problems of gene therapy are even more forbidding. The haploid human genome is considered to contain 3×10^9 base pairs, and some 50 000 to 100 000 structural genes. Many human genes have been isolated, along with their flanking regions, where regulatory sequences are likely to be found, and gene insertion into foreign cells has been widely achieved – for example, the recent transfer, with the aid of a mouse retrovirus, of a human gene for HPRT from a normal cell to a deficient cell, with transfer of appropriate function – but here there is great lack of tissue specificity. Some functions, such as the production of growth hormone, can evidently be performed by a wide range of cells with physiologically consistent consequences, but other functions, such as haemoglobin production, must be the prerogative of particular cells at particular stages of development. The problem is how to insert genes into selected target cells, and this is discussed by Weatherall (1985), with special reference to the haemoglobinopathies. Leads for future research may be derived from study of the so-called 'hotspots' or preferred sites for gene insertion, which could represent sites of DNAase hypersensitivity (Storb *et al.*, 1979). More recently, Smithies *et al.* (1985) described the insertion of DNA sequences into the human β-globin locus by homologous recombination, a procedure that could be applicable to the treatment of conditions such as thalassaemia and sickle cell anaemia.

Another and highly productive line of research in laboratory animals concerns the use of retroviruses and other foreign DNA forms to identify genes important in embryonic development. This has been exploited by Jähner and Jaenisch (1980) and more recently by Jaenisch *et al.* (1983), Schnieke *et al.* (1983), Wagner *et al.* (1983) and Jaenisch (1984). The introduced material either enhances the host gene transcription by the action of a strong promoter, or more commonly disrupts the host gene, both actions usually leading to a lethal mutation. The foreign DNA is generally capable of becoming inserted at many points in the host genome, apparently at random, so that the function of virtually any gene can be affected. The consequences of these changes can be studied by genetic analysis, recognition of significant effects depending on the inviability of homozygotes.

The following books are suggested as further reading: Connor and Ferguson-Smith (1984, 1987), Emery (1984), Glover (1984), Nossal (1985), Warr (1984); Jackson, (1989); Hansel and Weir (1990).

ACKNOWLEDGEMENT

Dr Karen Shelton, Deputy Scientific Director of Park Hospital Fertility Services Unit, Nottingham, kindly contributed the section on Microsurgical fertilization (section 2.4.5) and sex determination in section 2.4.9.

3.1 INTRODUCTION

In the two or three decades prior to the first edition of this book much of the basic morphological analysis of implantation and placentation took place so that Marshall (1910) was able to give a fairly detailed account of the early stages of placentation in several species. His account now provides a very interesting historical survey of the subject. Marshall did not separate implantation from placentation, in fact he only used the word implantation when talking of the implantation chamber which had been described by other workers. He mainly refers to attachment and embedding of the blastocyst.

The fact that embedding was accompanied by decidualization and only occurred in some species had been known for some time (section 3.4.5). Huxley (1869) divided species into deciduate and non-deciduate.

Nowadays the word embedding has been largely replaced by implantation. However, currently implantation usually refers to the initial stage of placentation in all species regardless of whether the blastocyst is embedded in the wall of the uterus or remains in the lumen. The word nidation is sometimes used, usually with regard to those species which undergo decidualization. The large decidual cells are likened to a nest or nidus. The use of this word implies that the uterine response is a passive protective structure, whereas the cells are now known to be actively secretory (section 3.5.4).

3.2 SPECIES VARIATION

In evolutionary terms the attachment of the ovum to the wall of the uterus is a fairly recent event. Sexual reproduction started with the joining of gametes in the external environment and has gradually evolved through an intermediate stage in which there is internal fertilization of the ovum with external development of the embryo, to the final stage where the embryo develops inside the wall of the uterus. The evolution of viviparity can be traced through non-mammalian species (Amoroso, 1981; Heyner, 1981), but it is in mammals that implantation has achieved its most complex form.

It is difficult, especially in the simplest forms of attachment between the mother and offspring, where there is little uterine reaction to the blastocyst, to separate implantation from the later stages of placentation. In order to avoid too much overlap, detailed descriptions of the early stages of placentation in species without much uterine response will be dealt with in Chapter 4 on placentation.

The simplest form of viviparity is where the embryo develops inside the mother but, isolated from her by a membrane, uses nutrients contained within the egg. The next stage is the development of the egg inside the mother but utilizing nutrients supplied by the mother, mainly by glandular secretions. In this there is no attachment of the fetal membranes and it is doubtful if the term implantation should be applied.

The simplest form of implantation is where the trophoblast of the embryo becomes closely applied to the surface of maternal cells so that nutrients can pass from the mother to the embryo directly across cell membranes. Among domestic animals this is found in the pig (Perry and Rowlands, 1962) and horse (Amoroso, 1952). In this form of implantation nutrients have to pass through several tissues from the maternal bloodstream to the embryo. To compensate for this the blastocyst, or at least the non-embryonic part of it, expands massively before implantation, so that the area of contact between mother and fetus increases dramatically. At the same time the surface of the trophoblast cells develops microvilli which interdigitate with similar microvilli on the luminal surface of the uterine epithelial cells. The result is that a very large area of close contact between maternal and fetal

tissues is established to produce a very efficient organ of exchange. A newborn foal is testimony to this.

Once this stage has been reached, the blastocyst cannot be easily washed from the uterus and the embryo is said to be attached to the uterine lumen. It is thought that the close contact between trophoblast and luminal epithelial surface is an active process brought about by changes in the cell surfaces (discussed in section 3.4.5). Most implanting blastocysts go through this stage which is called the 'attachment phase'. Enders and Schlafke (1967) distinguish it from the apposition stage which precedes it and during which the blastocyst can be easily removed from the uterus, implying lack of adhesive forces.

In spite of the effectiveness of the simple placenta, changes have taken place during evolution to bring the fetal and maternal blood system into closer contact, and one of the most fascinating facets of implantation is the variety of methods developed to ensure this (Finn, 1980). It is not proposed to give details of all the variations among species, as there are already several detailed accounts (Marshall, 1910; Amoroso, 1952; Boyd and Hamilton, 1952; Wimsatt, 1975), but it may be useful to highlight the main lines of development.

As long ago as 1882, Bonnet divided implantation into central, eccentric and interstitial. These terms are still used today. They refer, of course, to the position of the blastocyst in the uterus. In the first, the blastocyst remains in the centre of the uterine lumen and usually expands considerably just before implantation. In eccentric implantation the blastocyst remains small and comes to lie at one side of the uterine lumen as seen in transverse section, whilst in interstitial implantation the blastocyst burrows through the luminal epithelial cells.

Once settled in position the blastocyst and endometrium adopt various stratagems to 'improve' intimacy between fetal and maternal tissues. In the cow the uterine epithelial cells are initially columnar in shape. At implantation binucleate cells from the trophoblast pass into the uterine epithelium where they fuse with the columnar cells to form giant cells (Wooding and Wathes, 1980). For a short period most of the uterine epithelium consists of these giant cells. Subsequently, these cells die off and the remaining uterine columnar epithelial cells proliferate so that the maternal luminal epithelium is re-established (Wathes and Wooding, 1980).

Similarly, in the goat multinucleate cells are formed in the uterine epithelium, although there is, at present, no evidence that cells from the trophoblast contribute to these. These cells form a syncytium which later degenerates and is replaced by uterine columnar epithelial cells (Dent, 1973). In the ewe, like the cow, a syncytium replaces the columnar uterine epithelial cells (Boshier, 1969; Guillomot *et al.*, 1981; Wooding *et al.*, 1982), but this appears to be largely derived from the trophoblastic binucleate cells. Unlike in the cow and goat however, this syncytium is continuously replaced from binucleate trophoblast cells and remains throughout pregnancy.

These examples from domestic ungulates demonstrate the tendency of the uterine epithelium firstly to form a syncytium and then to degenerate, although in each case the epithelial layer is re-established either from the uterine epithelial cells or from trophoblast cells. It has been suggested that the purpose of this manoeuvre is to transfer a prolactin-like substance in the trophoblast binucleate cells into the uterine epithelium. The importance to the blastocyst of ensuring that the secretion of progesterone is maintained will be discussed in section 3.4.3.

In other species the uterine epithelium undergoes degeneration without subsequent re-epithelization. However, the mechanisms evolved to achieve this differ between species. For example, the rabbit undergoes a

process whereby, during the preparation of the uterus for implantation, the uterine epithelium becomes a syncytium whilst a similar reaction occurs in the trophoblast. At the time of implantation the two syncytia (maternal and fetal) fuse to form a single tissue originally containing nuclei from both animals. Eventually the maternal nuclei disappear so that the syncytium can now be considered fetal. This very novel way of getting rid of the maternal epithelium has only so far been reported in the rabbit (Larsen, 1970; Steer, 1970, 1971). In other animals it appears that the epithelial cells die by a process of programmed cell death in response to the presence of the trophoblast in contact with the uterine epithelial cells (discussed in section 3.4.6).

It appears that in evolution the ability of cells to undergo self-destruction in a controlled manner in response to the turning on of information contained in the nucleus [a process commonly used in embryonic modelling (Saunders, 1966)] has been adapted to allow the more intimate contact of the embryo with its mother.

However, not all species have gone in this direction in which, at least initially, the uterus is controlling the entry of the blastocyst into the uterine tissue. It was mentioned earlier that in the ungulates which have been studied cells migrate from the trophoblast into the uterine epithelium. It should also be added that the horse conceptus, later in pregnancy, sends chorionic cells into the substance of the uterus (W.R. Allen *et al.*, 1973). In these cases it appears that the object is to get large molecular weight hormones from the embryo to the mother. This is one of the first signs of the fetus endeavouring to influence its own destiny. Cell migration is carried a stage further in women and some other animals (chimpanzee, Heuser, 1940; guinea pig, Samson and Hill, 1931): it is not just isolated cells which migrate – large areas of trophoblast insinuate between the uterine epithelial cells. In order to do this some of the trophoblast cells form into a syncytium. Enders and Schlafke (1971) consider that this improves the flow characteristics of the tissue. It would presumably decrease the likelihood of the tissue breaking up during migration and preserve the organization of the blastocyst. The process is very rapid and the embryo becomes established in the uterine tissues with little apparent degeneration of the uterine epithelium. In the case of the human, and probably other species, the chorion does produce hormones, however the chief aim of trophoblast migration is not the passage of these to the mother; in fact it seems probable that chorionic gonadotrophins can reach the maternal circulation before the blastocyst has passed into the uterine tissues.

It is clear that the human embryo takes a much more active role in implantation than, for example, the pig or horse. However, the final product, the newborn animal, does not appear to be developmentally inferior in those species with simple placenta, and it is interesting to enquire what evolutionary advantage has come from the deep implantation of the blastocyst into the wall of the uterus, especially in view of the immunological and other problems which have had to be overcome. It is difficult to find any pattern relating the degree of intimacy in the attachment of the blastocyst with taxonomic position or size. Among the primates, for instance, there are species like man in which the ovum is deeply embedded in the wall of the uterus, whilst in other species, such as the marmoset, implantation is much more superficial.

With the blastocyst remaining small and coming into closer contact with the maternal blood vessels it is presumably possible to get adequate fetal nutrition with the involvement of a smaller area of uterus. This might be thought to be a special advantage to polytocous species. However, the pig, which has large numbers of offspring, implants superficially and gets round the problem by having a

very large uterus. Similarly, man, a species certainly larger than many which implant superficially, implants interstitially.

One possible advantage to an animal of attaining a very close contact between maternal and fetal bloodstreams is that it allows easier transfer of antibodies from the mother to the fetus, thus conferring on the neonate a degree of ready-made immunity which has to be acquired post-natally through the colostrum in those animals with simple implantation. This occasionally leads to problems, for example, when rhesus negative mothers are carrying rhesus-positive offspring. Nevertheless, overall it is probably advantageous to the species.

A great deal of care is needed in extrapolating information about implantation from one species to another. Owing to their ready availability a great deal of the research on implantation has been carried out on rats and mice, and these species have been particularly useful in providing basic information of the cell biology of the uterus and blastocyst. While much of this information will be of general applicability some will not. This is especially important when extrapolating from experimental animals to man (Finn, 1983).

3.2.1 DELAYED IMPLANTATION

Apart from differences in their method of implantation, species vary in the timing of implantation. In all animals the fertilized ovum appears to spend a defined period in the oviduct, reaching the uterus after having completed the early stages of development, usually as far as the blastocyst stage. There is then a variable period of free life in the uterus before attachment starts. Usually this period is short. In some species however the period can be varied in such a way as to give a measure of control over the time of birth of the offspring. The most common method of controlling the season of birth is by regulating the incidence of the oestrous cycle and ovulation in response to changes in the external environment. An alternative method is to insert a period of delay between the arrival of the blastocyst in the uterus and its implantation. This process of delayed implantation has evolved in several species over several taxonomic groups. In many cases the delay is inserted to allow a variable gestation period so that the young are born when the external environment is clement (roe deer, Ziegler, 1843; Aitken, 1974; badger, Canivenc and Bonnin-Laffargue, 1963; red kangaroo, M.J. Clark, 1968; mink, Hansson, 1947; Concannon *et al.*, 1980; black bear, Wimsatt, 1963; spotted skunk, Enders *et al.*, 1986). In these cases the delay is obligatory and controlled by seasonal factors in the environment (Mead, 1968; Hinds, 1989), probably via the pineal gland (May and Mead, 1986).

An alternative form of delayed implantation is related to the reproductive needs of the mother. This was first demonstrated in mice (Lataste, 1891; Kirkham, 1916). In this facultative form of delayed implantation, blastocysts are held quiescent in the uterus so as to delay the time of parturition of the litter until the mother has finished weaning the previous litter. This is common in marsupials (see Chapter 8) and rodents (rats, mice, bank vole, Andersson and Gustafsson, 1979).

Of course if implantation is delayed then development of the embryo must be halted, or slowed down very considerably. This condition of embryonic diapause is discussed here and in Chapters 6 and 8.

3.3 PREPARATION OF THE UTERUS FOR IMPLANTATION

3.3.1 THE OESTROUS CYCLE

The oestrous cycle, although referring semantically to behavioural events, covers a whole cycle of changes in the hypothalamus, pituitary, ovary and female reproductive tract. The transport of the ovum through the oviduct has to be precisely timed so that it

arrives in the uterus at the correct stage of development and at a time when the uterus is in a fit condition to receive it. The cellular and biochemical composition of the endometrium varies according to the hormonal influences acting on it and, although it has evolved to contain the blastocyst, it is, under most hormonal conditions, hostile to it; more hostile in fact than some other areas of the body. For example, if a blastocyst is transferred to the kidney or testis it will grow and destroy maternal tissue. In the uterus however, if the hormonal conditions are not appropriate, it will not survive and will itself be destroyed. It seems that the lining epithelium of the uterine epithelium under most conditions is resistant to attachment and invasion by the trophoblast and only under very precise hormonal states can implantation and survival of blastocysts take place.

In most animals the uterine conditions necessary for reception of the blastocyst develop during the later part of the oestrous cycle and receptivity of the uterus is controlled by the sequential secretion of ovarian hormones. As the same hormones control the passage of the ova along the oviduct, the coincidence of the arrival of the blastocyst in the uterine lumen with receptivity of the endometrium is assured.

A few animals, for example rats and mice, do not have a full oestrous cycle unless mating has occurred. Unmated animals, therefore, do not maintain the corpus luteum over the period during which ovum transport and implantation would be taking place. By abbreviating their oestrous cycles these animals, who are mostly solitary scavengers, maximize their chances of becoming pregnant. If a female is mated but the mating is infertile then the corpus luteum is maintained for about 11 days and a cycle with a luteal phase is attained. This so-called pseudopregnancy or extended oestrous cycle is equivalent to the normal oestrous cycle of most other animals. It is possible to extend the oestrous cycle in rats and mice without pregnancy by mating with a vasectomized male or in rats by artificially stimulating the vagina and cervix. In order to distinguish this from the abbreviated oestrous cycle it will be referred to as the 'extended' or 'mated' oestrous cycle and where general reference to oestrous cycles is made it will refer to cycles with a full luteal phase. The use of the term 'pseudopregnancy' is best reserved for a clinical condition in carnivores in which the bitch shows signs and symptoms of pregnancy.

During the course of the oestrous cycle the uterus is required to perform two functions. After copulation it provides the tube through which sperm must pass and in which it is capacitated before reaching the oviduct, there to fertilize the ovum. Later, after arrival of the blastocyst in the uterine lumen it provides the tissue in which implantation takes place. These two functions require different environmental conditions in the uterine lumen. For sperm capacitation and transport the uterine lumen is dilated, to a lesser or greater extent, with a thin watery fluid. Following fertilization, excess spermatozoa are removed, which probably involves the participation of eosinophil leucocytes. After arrival of the blastocyst in the lumen, the uterus is adapted, first to provide secretions for blastocyst nutrition and then to allow attachment and implantation of the trophoblast. The former involves differentiation of the uterine glands, and the latter differentiation of the luminal epithelium and stroma.

The cellular and biochemical changes that take place in the endometrium throughout the oestrous cycle have been most carefully worked out in rodents. This account therefore will be largely based on work on the rat and mouse, but, wherever possible, reference will be given to findings in other species.

The endometrium is made up of three main tissues – luminal epithelium, glandular epithelium and stroma (Figure 3.1).

Each of these has a specific role to play in

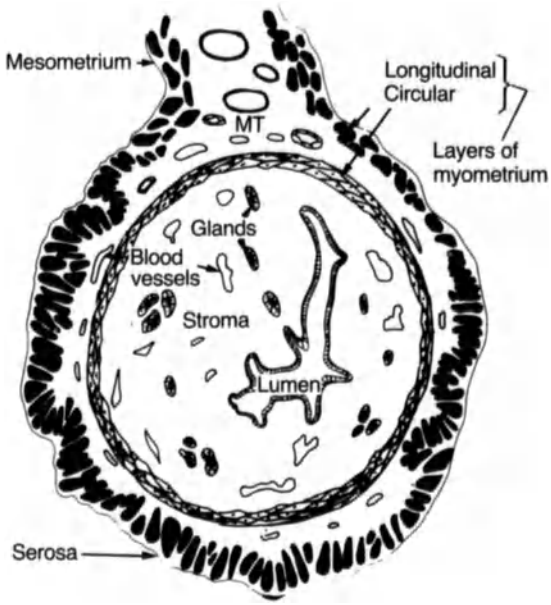

Figure 3.1 Diagrammatic cross-section of a uterus showing the main tissues (based on the mouse uterus).

implantation and each goes through a cycle of changes in preparation for this role. In addition to the resident cells making up the main tissues of the endometrium there are also cells which infiltrate from the bloodstream. Eosinophil leucocytes have already been mentioned, and during decidualization others become very important.

Each of the resident cell types undergoes three basic processes – cell proliferation, cell differentiation and cell death. Quantification of these processes is difficult although attempts have been made, especially with the first and last.

3.3.2 CELL PROLIFERATION

Cells which are undergoing mitosis can be seen in histological sections with the light microscope after normal staining. The condensation of the chromosomes during prophase and metaphase clearly distinguishes dividing from non-dividing cells. However, this stage of cell division is accomplished quickly so that even in an actively dividing tissue only a few cells will be visible. If, however, a drug is administered which destroys the activity of the microtubules, for example colchicine or vinblastine, then mitosis is halted in the metaphase stage. The animals can then be killed at a specific interval after the administration of the drug and all cells which have entered division during that period will be visible and can be counted. When dealing with the uterus it would be exceedingly tedious to completely section and count the whole organ, and normally a section is taken from each uterus of a group of animals and the mitoses counted in each tissue. Thus an estimate of the mean number of cells in mitosis is obtained with an estimation of the variability between animals. This provides useful data for comparisons between animals in various reproductive states or under different hormone regimens.

The results from such observations in the mouse (Finn and Martin, 1967) are demonstrated in Figure 3.2.

Cell division occurs at different times in the

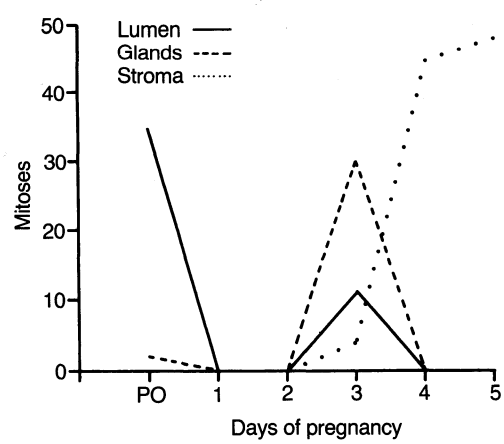

Figure 3.2 Graph showing the distribution of mitoses in the various tissues of the mouse uterus during early pregnancy. The animals were treated with colchicine 2 h before autopsy and the number of mitotic figures counted in one cross-section taken at random from each uterus. (Data from Finn and Martin, 1967.)

three uterine tissues. Luminal epithelial cells show maximum cell division at pro-oestrus with a second smaller increase on day 3 of pregnancy of the extended cycle. Glandular epithelial cells show a single peak of maximum cell division on day 3, whilst the stromal cells do not divide until day 4. There is thus an abrupt change in the pattern of cell division between days 3 and 4 of the mated cycle. A similar pattern has been shown in the rat (Leroy and Galand, 1969; Marcus, 1974a), guinea pig (Schmidt, 1943; Mehrotra and Finn, 1974; Marcus, 1974b) and hamster (Krueger and Craig-Maibenco, 1972). The situation in primates is not so well established. Human data come from biopsy material in which mitoses have not been pharmacologically arrested (Noyes *et al.*, 1950). It is difficult in this material to separate luminal from glandular cells. Nevertheless there appears to be a peak in epithelial mitosis during the follicular phase of the cycle with a peak in stromal mitosis in the luteal phase. Rhesus monkeys similarly show a peak in epithelial mitosis in the follicular phase (Bensley, 1951), but unfortunately no information seems to be available about stromal mitosis.

The animals for which information on cell division is available are those in which blastocysts pass into the endometrial stroma and the stroma decidualizes. It would be very interesting to know whether animals with superficial implantation, such as the pig, show stromal mitosis during the luteal phase. The situation with regard to mitosis in the rabbit, which, as mentioned earlier, has a very unusual method of blastocyst attachment, is unusual. There is a peak of mitosis on days 3 and 4 of pregnancy in the epithelial cells with very little mitosis in the stroma on any day up to day 10 (A.E. Lee and Dukelow, 1972; Davies and Hoffman, 1973).

An alternative method for assessing the rate of cell proliferation in tissues is to inject labelled thymidine into the animals at a determined interval before autopsy. All cells going into the S phase of the cell cycle will take up the nucleotide and they can be identified and counted in histological sections as before. On the whole, similar results have been obtained using this method as using colchicine (Leroy and Galand, 1969; Leroy *et al.*, 1969; Carter and McLaren, 1975). Another more recently developed method is to show the presence of proliferating nuclear antigen. Again, similar distribution of mitoses has been shown (Goodger and Rogers, 1993).

3.3.3 THE HORMONAL CONTROL OF PROLIFERATION

It has been known for many years that ovarian hormones influence cell division in the uterus (E. Allen *et al.*, 1937; Lloyd, 1937). E. Allen and his colleagues (1943) seem to have been the first to introduce the use of colchicine for the study of cell division in the uterus. During the following 30 years the effect of oestrogens, in particular, on the endometrial epithelium was confirmed (Perrota, 1962; Bertalanffy and Lau, 1963; Everett, 1963; Epifanova, 1966; Beato *et al.*, 1968; Leroy *et al.*, 1969). Most of the work was carried out on rats and mice, in which it was shown that oestrogen caused mitosis predominantly in the luminal epithelium. Work on rabbits demonstrated that progesterone stimulated proliferation of the glands (McPhail, 1934; Lloyd, 1937; A.E. Lee and Dukelow, 1972), whereas in the rat and mouse progesterone given alone had little effect on endometrial mitosis (luminal or glandular).

What was not apparent from the earlier work was the cause of change from predominantly luminal to predominantly glandular mitosis and then the abrupt change from epithelial to stromal during the extended oestrous cycle or early pregnancy in the rat and mouse. The answers became apparent when the effect of the ovarian hormones was studied, taking into account the fact that hormone secretion from the ovary occurs in a charac-

teristic temporal pattern. During the oestrous cycle there is secretion of high levels of oestradiol from the follicle during pro-oestrus followed by secretion of progesterone from the corpus luteum after ovulation. There is also in mice and rats a second small surge of oestrogen during the luteal phase of the cycle.

Using ovariectomized mice treated with exogenous ovarian hormones, Martin and Finn (1968) showed that the mitotic response of the endometrium to oestradiol was more complicated than originally thought. They demonstrated that the injection of a single dose of 100 ng of oestradiol into ovariectomized mice was followed 24 h later by division of the cells of the luminal epithelium. When daily injections were given and groups of animals killed every 24 h the luminal epithelial cells divided in response to the injections on the first 2 days but not to subsequent injections. However, animals killed after three daily injections showed large numbers of cells undergoing mitosis in the glandular epithelium (Finn and Martin, 1973). This rather surprising finding showed that the luminal and glandular epithelia respond differently to oestradiol. However, these results did not explain the rise in glandular mitosis on day 3 of the mated cycle. Oestrogen secretion is not high for longer than 2 days in late dioestrus and pro-oestrus in the mouse so continuous high levels of oestrogen could not explain the pattern of cell division during the oestrous cycle. Subsequent experiments showed that a differential effect on epithelial mitosis could be demonstrated if animals were given injections of 100 ng of oestradiol on only 2 days and killed at daily intervals for the following 5 days. The mitotic counts showed clearly that a level of oestradiol such as would be expected at pro-oestrus would, as before, have an immediate effect on mitosis in the luminal epithelium but a delayed one on the glandular, thus mimicking the situation observed during the mated cycle.

The next question concerns the cause of the switch from epithelial to stromal mitosis. Cell division is not seen in the endometrial stroma in the mouse in response to oestradiol. In view of the known presence of progesterone during the luteal phase it seemed likely that progesterone would be responsible for the switch from epithelial to stromal division between day 3 and day 4 of the mated cycle. However, the injection of progesterone into ovariectomized mice did not cause stromal mitosis, in fact after a single injection of the hormone cells undergoing division were found in the luminal epithelium. This unexpected result was explained when progesterone treatment was preceded by oestrogen, on a schedule to mimic the hormonal conditions of the mated cycle. Given at the appropriate time after oestrogen priming, a single injection of progesterone does stimulate stromal division. Combined with the previous results it was thus possible to reproduce the pattern of division characteristic of the mated cycle or early pregnancy by treating ovariectomized mice with two daily doses of 100 ng of oestradiol followed by 3 days rest then daily injections of 500 μg of progesterone. The numbers of stromal mitoses were not as high as expected. However, if a small dose of oestradiol is given in addition to the progesterone then a larger response is obtained. In fact, it is possible to get stromal proliferation without pro-oestrous oestrogen if progesterone is given for 3 or 4 days and a small quantity of oestradiol is added to the progesterone injections. Similar results have been obtained in rats (B.F. Clark, 1971). Recently the role of progesterone in inducing the switch from epithelial to stromal division has been confirmed using the antiprogestin, RU 486 (Cullingford and Pollard, 1988) and antibodies to progesterone (Heap *et al.*, 1988).

It is pertinent to ask what is the function of the cell division. As mentioned earlier, each uterine tissue, in preparation for implantation, differentiates to perform a specific function. It has been suggested that before

they can differentiate cells must perform a quantal mitosis, which in some way prepares them for differentiation. This was originally suggested for the mammary gland (Stockdale and Topper, 1966), but no concrete evidence has yet been found for such a role in the uterus.

An alternative, simpler explanation is that there is a need for an increased number of cells. Certainly the lumen has to increase very rapidly at oestrus, and increased cell division would be necessary. The glands, although not appearing to be as active in the mouse as in some animals, e.g. rabbit and man, presumably are brought up to full size by the cell division, whilst the number of stromal cells would need to increase to provide a stock of cells for decidualization.

3.3.4 INTRACELLULAR MECHANISMS IN CELL PROLIFERATION

Following the discovery of the importance of oncogenes and growth factors in cell proliferation, a considerable amount of effort has been expended in demonstrating their presence in the endometrium during pregnancy and after hormone treatment (Brigstock *et al.*, 1989; J.W. Pollard, 1990; Brigstock, 1991; Simmen and Simmen, 1991; Stancel *et al.*, 1993).

It appears that when oestradiol passes into a cell and attaches to its receptor (which is a transcription factor) several oncogenes are activated. The products of the nuclear oncogenes, c-*jun* and c-*fos* (which make up the transcription factor AP-1) increase within 2 h of oestradiol injection (Loose-Mitchell *et al.*, 1988; Weisz and Bresciani, 1988; Weisz *et al.*, 1990; P.J. Baker *et al.*, 1992). These genes are known as immediate early nuclear oncogenes. The presence of their products is short-lived and can be induced by oestrogenic compounds which are not able to initiate DNA synthesis and cell division (Persico *et al.*, 1990), indicating that some other factor is necessary for the completion of mitosis. This correlates well with the earlier finding that impeded oestrogens are not firmly bound in the nucleus and are not therefore able to induce an oestrogenic response (Martin, 1964). Progesterone inhibits their expression in the luminal epithelium (Kirkland *et al.*, 1992), which is consistent with the earlier finding that progesterone inhibits cell division in the luminal epithelium in response to oestradiol.

Other nuclear oncogene products found in the endometrium after oestrogen treatment include those from c-*myc* (Weisz and Bresciani, 1988; L.J. Murphy, 1991) and c-*ras* (Cheng and Pollard, 1986). The latter is analogous to a G protein and presumably plays an important role in the transmission of messages associated with mitosis.

Some of the products of other oncogenes stimulated by oestradiol are growth factors or growth factor receptors, for example that of c-*erb*-B is the receptor for both epidermal growth factor and transforming growth factor and its level is influenced by oestradiol (Lingham *et al.*, 1988). The product of c-*sis* is platelet-derived growth factor (see review Stancel *et al.*, 1993). Growth factors and their receptors play an important part in the reactions between the arrival of oestradiol in the cell and mitosis. Several have been demonstrated in the uterus. In most cases they are little in evidence in the uterus of the ovariectomized animal but increase after oestradiol treatment although basic fibroblast growth factor appears to be an exception to this (Wordinger *et al.*, 1992). In some cases their distribution is modified by progesterone in such a manner as would be expected from the hormonal control of mitosis. Growth factors and their receptors which are associated with hormone-induced mitosis in the uterus include epidermal growth factor (Mukku and Stancel, 1985a,b; DiAugustine *et al.*, 1988; Lin *et al.*, 1988; Huet-Hudson *et al.*, 1990), insulin-like growth factor (L.J. Murphy *et al.*, 1987; L.J. Murphy, 1991; Norstedt *et al.*, 1989; Kapur *et al.*, 1992), fibroblast growth factor

(Brigstock, 1988), platelet-derived growth factor (Stiles, 1985) and transforming growth factor (Tamada *et al.*, 1991). Other growth factors have been demonstrated in the uterus (colony stimulating factor 1, Bartocci *et al.*, 1986; transforming growth factor β Lea *et al.*, 1992) but their relationship with mitosis is less certain. They will be discussed in section 3.4.4 on cytokines and implantation.

The presence of growth factors and their receptors is by no means exclusive to the uterus. They are probably found in all cells which undergo division. The difference between endometrial cells and non-reproductive cells, such as those in the liver and skin, is that the prime stimulus for their synthesis comes from the ovary, whereas non-reproductive tissues are stimulated by other factors such as injury to the skin or removal of part of the liver. However, even in the uterus the presence of a blastocyst or a drop of oil or injury considerably increases cell division (section 3.5.3).

The intracellular mechanisms within the endometrial cells which bring about mitosis are similar to those within other cells and these have been studied in more detail, especially in cultured cells. The literature is very extensive but a good summary, relevant to reproduction, can be found in the review by Paton and Collins (1992) on the differentiation of ovarian granulosa cells.

3.3.5 CELL DIFFERENTIATION

(a) Luminal epithelium

In all animals the luminal surface of the epithelial lining to the uterus provides the first area of contact with the trophoblast. With the possible exception of animals undergoing interstitial implantation, the first stage of implantation involves adherence of the trophoblast to the luminal epithelium with very close contact between apposing surfaces. To attain this the surface of the epithelial cells has to undergo specialized changes. In many animals the changes can be seen at the appropriate stage of the extended oestrous cycle between apposing surfaces of the lumen even though blastocysts are not present. The changes can be followed in histological sections of uteri of animals killed at intervals during the cycle but for a full demonstration of the changes it is necessary to use the electron microscope.

After the burst of cell division, just before oestrus, the uterine lumen is dilated and irregular in cross-section; the epithelial cells are tall columnar with basophilic cytoplasm. Their luminal surface is active for alkaline phosphatase (Figure 3.3) (Arzac and Blanchet, 1948) and with the electron microscope can be shown to have numerous long microvilli, covered with a fuzzy material (glycocalyx).

During the first few days of the mated cycle the lumen is gradually reduced in size. This appears to be at least partly brought about by the death of many of the epithelial cells which follows the cessation of oestrogen action (section 3.3.7). With the formation of the corpus luteum a further loss of luminal fluid takes place by pinocytosis (Vokaer, 1952; Vokaer and Leroy, 1962; Enders and Nelson, 1973; M.B. Parr, 1980). In cross-section the uterine lumen now appears as a slit orientated in a mesometrial/antimesometrial axis (Figure 3.4).

The uptake of fluid from the lumen is accompanied by changes on the luminal surface of the epithelial cells. These can be seen when the cells are examined with the transmission electron microscope. Small blebs appear on the surface which have been shown to be absorbatent. With the scanning electron microscope they appear as 'small anemone-shaped structures' (Psychoyos and Mandon, 1971; Nilsson, 1972). These have been demonstrated in the uteri of rats (Enders and Nelson, 1973; M.B. Parr and Parr, 1974), ewes, cows (Guillomot and Guay, 1982) and women (Martel *et al.*, 1987). Endocytosis is probably also carried out by small coated vesicles (M.B. Parr and Parr, 1974, 1977). The cells are now regularly aligned and lipid droplets appear in the base of the cells (Alden, 1947). The tight junctions at the apical margins of the cells also change as differentiation proceeds (C.R. Murphy *et al.*, 1982a,b; Johnson *et al.*, 1988).

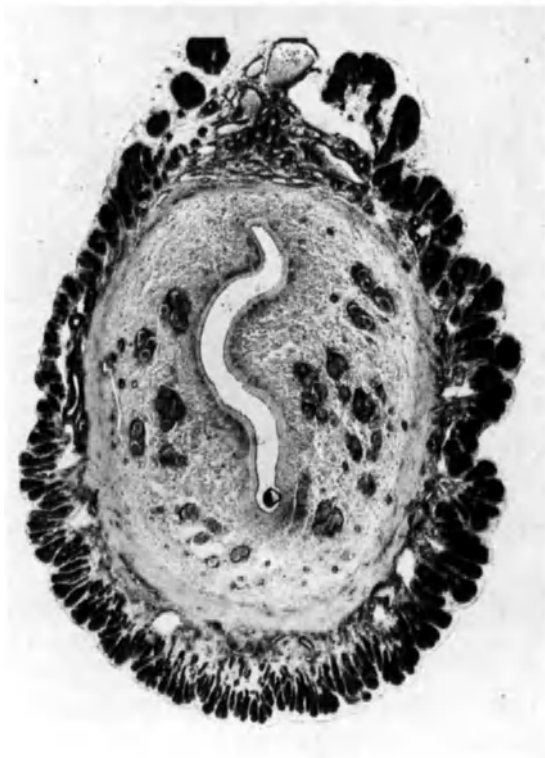

Figure 3.4 Cross-section of mouse uterus under the influence of progesterone. The lumen is slit shaped and orientated in the antimesometrial–mesometrial axis. The section is treated to demonstrate alkaline phosphatase which is present especially in the longitudinal muscle layer and the blastocyst. (From Finn and McLaren, 1967, by permission of the editor, *Journal of Reproduction and Fertility*.)

As a result of these and possibly other changes, the uterine lumen becomes almost obliterated with close interdigitation of the microvilli from apposing surfaces. This occurs at the time when the blastocysts have settled down to their determined position in the uterus and holds them firmly in place. It is called the first stage of closure (Figure 3.5) or the apposition stage of pregnancy.

With most fixatives used in light microscopy the apposing surfaces are pulled apart and have a scalloped or corrugated appearance in cross-section (Finn and McLaren, 1967). However, fixatives used for electron microscopy (glutaraldehyde) retain the closure (Nilsson, 1966).

During delayed implantation the uterus remains in this stage, but when implantation has been stimulated (section 3.4.3) a further change takes place in the lumen. On day 5 of the extended cycle in mice, the day on which implantation would be expected, the uterine lumen closes completely, so that the apposing surfaces now run together in a haphazard way with a small gap (about 150Å) between the apposing surfaces, 'the second stage of

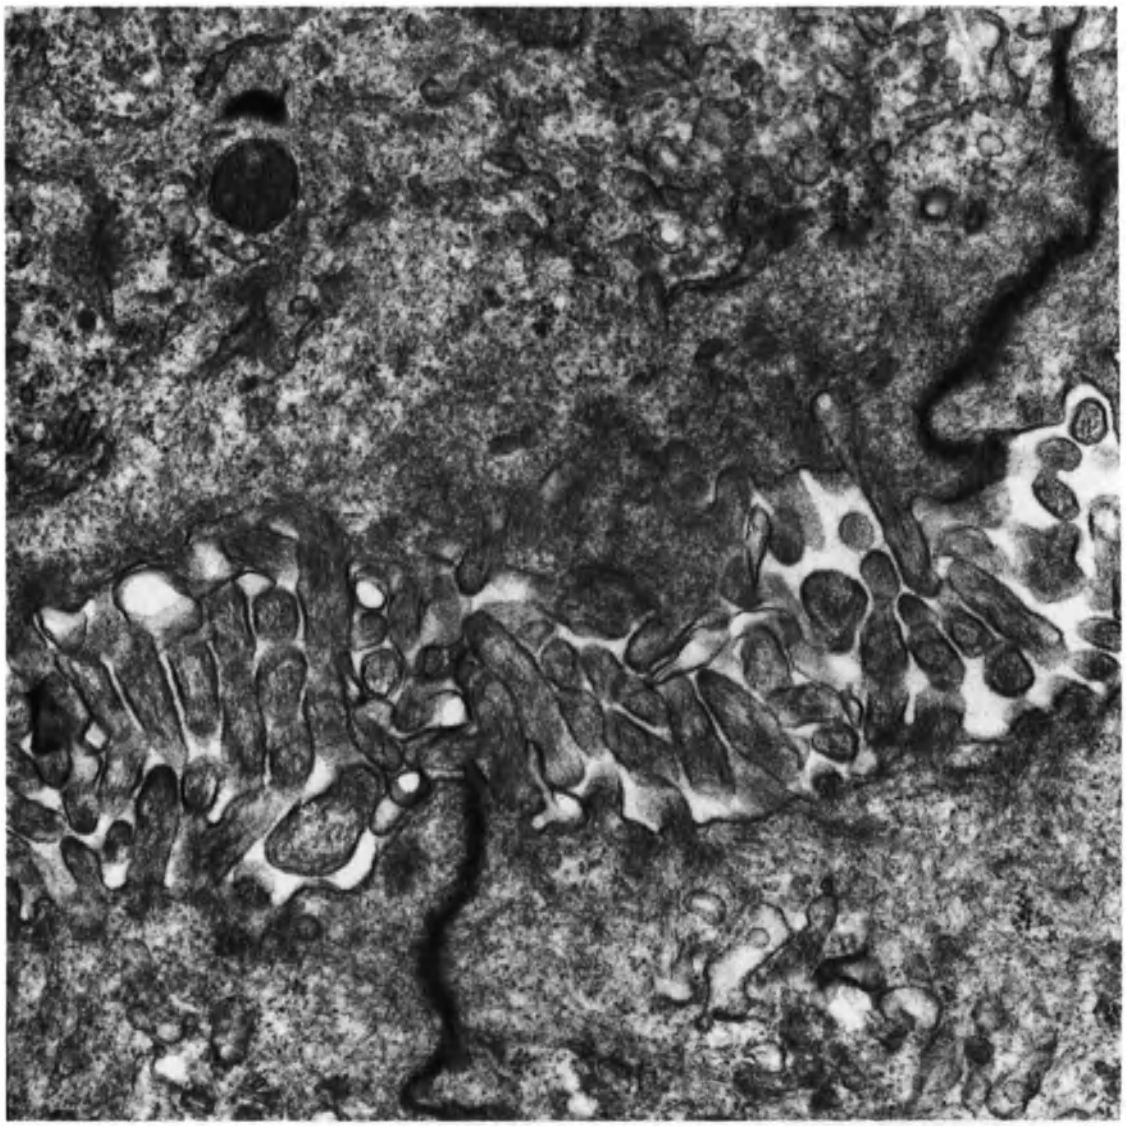

Figure 3.5 Electron micrograph of the lumen of a mouse uterus in the first stage of closure. The microvilli from opposing surfaces are interlocking. (Picture by Dr Rosemary Pollard.)

closure' (Figure 3.6) (Nilsson, 1966; R.M. Pollard and Finn, 1972).

Guinea pigs do not appear to undergo this second stage (Green, 1979), and no such stage has been reported in ruminants. The cause of the pronounced changes in the uterine luminal surface is probably the alterations to the cytoskeleton. It is suggested (Luxford and Murphy, 1989, 1992) that the ovarian hormones control the microfilaments underlying the apical plasma membrane (section 3.4.5 on attachment of blastocyst).

Rabbits undergo a very complicated process of preparation for implantation. Division of the epithelial cells occurs several days after ovulation (the rabbit is an induced ovulator

and does not have a cycle) following formation of the corpus luteum. Then, just before the expected time of blastocyst attachment, the luminal epithelial cells join together to form large multinucleated cells (syncytium) (Davies and Hoffman, 1973; Winterhager *et al.*, 1984). The fusion seems to be preceded by the formation of many gap junctions between the lateral surfaces of adjacent cells (Winterhager and Kuhnel, 1982).

(b) Glandular epithelium

Uterine glands are developed as downgrowths of the luminal epithelium. They are coiled structures and are, therefore, usually

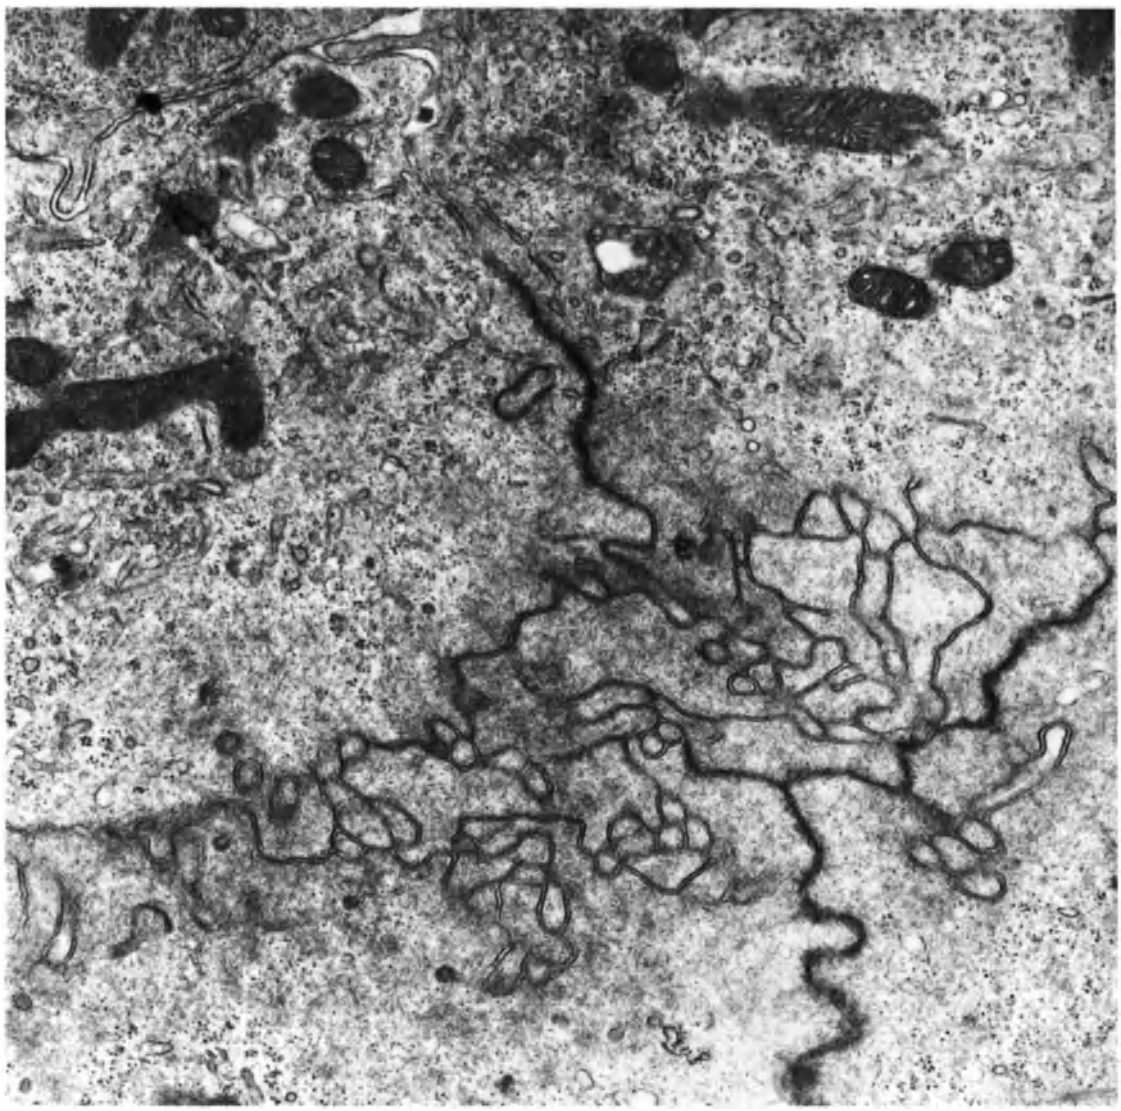

Figure 3.6 Electron micrograph of the lumen of a mouse uterus in the second stage of closure. The microvilli are no longer clearly defined and a very complex channel is formed between opposing surfaces. (Picture by Dr Rosemary Pollard.)

seen in histological sections as round follicles. After the peak of cell division on day 3 of the extended cycle (in the mouse) the cells differentiate to produce a periodic acid–Schiff (PAS)-positive secretion (Finn and Martin, 1971). This secretion is present in the glands in the later part of the luteal phase of the menstrual cycle in women and on day 6 of the extended cycle of mice, which would be after the blastocyst had attached but before chorioallantoic placentation had developed. It is interesting that the gland cells, although developed from the luminal cells, behave so differently in timing of mitosis and type of differentiation.

The secretions of these glands are probably important in animals in which there is a long period between arrival of the blastocyst in the uterus and permanent attachment. The secretion presumably contributes to the histiotrophe (Hoyes, 1972). The glands may also be important in the secretion of some of the specific polypeptides found at certain times in the uterus. An interesting recent finding is that leukaemia inhibitory factor (LIF) is found in the glands on day 4 of pregnancy in mice (Bhatt *et al.*, 1991). Mutant mice unable to synthesize LIF do not implant blastocysts (C.L. Stewart *et al.*, 1992), suggesting an important role in pregnancy. It had been suggested earlier (Aitken, 1976, 1977a) that gland secretions may be involved in activating the blastocyst during delayed implantation. Given and Enders (1980, 1981) have made an ultrastructural study of the glands of the mouse during the peri-implantation period, and have concluded that the mode of secretion is similar to that of other exocrine glands. The fine structure of the glands at various stages of the menstrual cycle has also been studied in women (Gompel, 1964).

(c) Stroma

The main stromal cells are the undifferentiated mesenchymal cells or fibroblasts. In rodents during the luteal phase of the mated cycle (and probably in man), these cells undergo division and are considerably influenced by the ovarian hormones. Their appearance after the burst of division on days 4 and 5 of the mated cycle in the rat has been examined with the electron microscope (Jollie and Benscosme, 1965). Endoplasmic reticulum is abundant and there are observable changes in the nucleoli. In view of the presence of large quantities of collagen, they are presumably actively secreting this substance (Figure 3.7).

However, in most animals, they do not differentiate further except during pregnancy and then only in areas where a blastocyst is present. There they differentiate into decidual cells. In man and a few other species decidualization takes place during the unmated cycle (section 3.5.8 on menstruation).

The stroma also contains blood vessels which undergo changes during the cycle. These are particularly prominent in the primate endometrium, where there is considerable development of the blood vessels. During the luteal part of the cycle the vessels grow towards the lumen and there is an increase in coiling (Daron, 1936; Phelps, 1946; Kaiser, 1948) and blood flow (Prill and Gotz, 1961).

The flow of blood through the uterus of other animals also varies during the cycle. In all animals studied the flow increases at prooestrus and oestrus. In some animals there is a second increase of blood just before the expected time of implantation. This has been shown in several rodents (guinea pig, Markee, 1929; Bacsich and Wyburn, 1940; Garris, 1984; rat, M.F. Williams, 1948; Einer-Jensen, 1977; Garris and Whitehead, 1981; and mouse, Bindon, 1969; Edwards and Milligan, 1987), although not in the ewe (Greiss and Anderson, 1969), rabbit (Krichesky, 1943) or sow (Ford and Christenson, 1979).

An interesting vascular change reported by Lunam and Rogers (1981) is an increase in the number of pericytes around the blood vessels

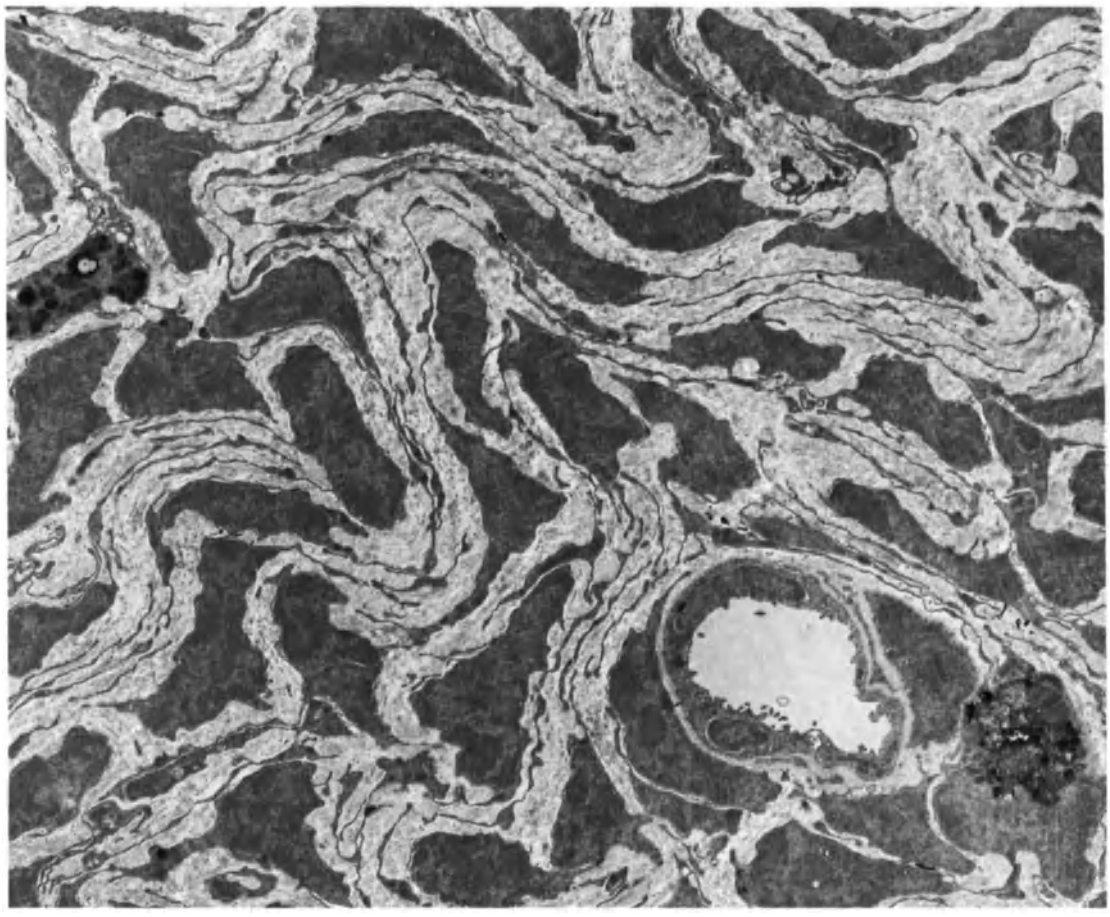

Figure 3.7 Low-power electron micrograph of an area of endometrial stroma of a mouse. Typical fibroblasts are shown.

of the endometrial stroma. These are flattened cells which have been reported in various situations and can be distinguished from the other connective tissue fibrocytes, although their origin or function is not known. It is, nevertheless, very interesting that they appear to increase markedly just before the expected time of implantation.

3.3.6 HORMONAL CONTROL OF DIFFERENTIATION

The same sequence of hormone secretion already shown to control cell division is responsible for directing the differentiation of the tissues. Hitschmann and Adler (1908) were probably the first workers to show that the cyclic changes in the endometrium were related to changes in the ovary. Since then many workers have studied the influence of oestrogen and progesterone on the morphology of the uterus, both with the light microscope (W.M. Allen, 1937; Loeb *et al.*, 1938; Burgos and Wislocki, 1958) and with the electron microscope (Nilsson, 1958; R.M. Pollard and Finn, 1972; Ljungkvist, 1971a–c). There is some variation between species and it is somewhat difficult to bring together all

the data into a coherent picture. The response to one of the ovarian hormones depends very much on the dose given, the period over which it is administered and the relationship to previous or concurrent injections of the other hormone (and possibly non-ovarian hormones). This was shown to be true of the effect of the hormones on mitosis, but is equally true of differentiation.

(a) Luminal epithelium

The uterus of any animal becomes atrophic after ovariectomy (Langston and Robinson, 1935), the epithelium becomes thinner and has an eosinophilic surface. The cytoplasm stains lightly and there are some fat droplets (triacylglycerols, Boshier *et al.*, 1981) in the base of the cells (Alden, 1947). The nuclei are small without prominent nucleoli. After a single dose of oestradiol (20–100 ng) the epithelium becomes thicker and, if appropriate staining methods are used, the luminal surface can be shown to contain alkaline phosphatase (Atkinson and Elftman, 1947; Atkinson and Engle, 1947; Aldeen, 1970). With higher doses, to give a level probably equivalent to pro-oestrus, the lumen fills with fluid (Astwood, 1938), which may escape during fixation and processing so that in cross-section, the lumen is very irregularly shaped and the cells bunched up. The amount of fluid in the uterus varies considerably between species and is particularly prominent in the mouse and rat. Associated with the passage of fluid is the appearance of gaps in the normally complete endothelial lining of capillaries and venues (Ham *et al.*, 1970). The lipid droplets in the base of the cells disappear after oestrogen treatment. Progesterone causes the epithelium to become thicker, with an extensive accumulation of subnuclear fat. After three or more daily injections of progesterone, the lumen closes with interdigitation of microvilli as seen on day 4 of the mated cycle in mice (Martin *et al.*, 1970). Using the electron microscope, it is found that to obtain the second stage of closure as seen on day 5 of the extended cycle it is necessary to administer a small quantity of oestrogen in addition to progesterone; progesterone alone can only induce the first stage of closure in mice. The second stage of closure can, however, only be maintained for a short period, after which the lumen reopens and an electron-dense substance appears in the uterus. At this time the uterine glands are actively secreting, and possibly it is their secretion which causes the morphological changes seen. Pinocytosis in the uterine epithelium is also under hormonal control and requires the same hormonal parameters as are required for implantation (Leroy *et al.*, 1976), as does the formation of pinopodes on the surface of the luminal epithelium (Martel *et al.*, 1991).

(b) Glandular epithelium

Although in the rabbit progesterone stimulates proliferation of the glands, its effect in most animals is to convert the glands into a secretory condition. This has been shown in women (Good and Moyer, 1968) and many other animals *in vivo* and in tissue culture (man, Kohorn and Tchao, 1969; guinea pig, Everett, 1962, 1963).

In the mouse daily injections of progesterone alone stimulate only a small amount of secretion by the glands even after 9 days' treatment. However, if a small quantity of oestradiol (10 ng) is added to the daily injections of progesterone, then the glands secrete, producing maximum secretion on the fifth day (Finn and Martin, 1976).

(c) Stroma

In women, stromal cells differentiate into decidual cells under the influence of progesterone or synthetic progestins (Ober *et al.*, 1964). However, in most animals differentiative changes in the stroma are more limited in response to hormones. The cells increase in

size somewhat and the nuclei (and nucleoli) get larger (Hooker, 1945; Tachi *et al.*, 1974). Under the influence of progesterone there is also evidence of increased activity in the cytoplasm (Greenwald and Everett, 1959; Brinsfield and Hawk, 1974) with an increase in rough endoplasmic reticulum and free ribosomes. Other changes in the organization and activity of the uterine stromal cells have been described (Wischik and Rogers, 1982; Rogers and Wischik, 1983). Blood vessels are also affected by the ovarian hormones so that blood flow is increased in preparation for implantation (Bacsich and Wyburn, 1941; Gilman, 1941; Salvatore, 1968; W.M. Dickson *et al.*, 1969; Ford *et al.*, 1977; Edwards and Milligan, 1987).

Clearly, the hormones secreted before implantation affect the stroma, however it is probably not correct to call these 'differentiated' changes, such as the decidual changes to be described later.

3.3.7 CELL DEATH

Cell death in a tissue is very difficult to measure quantitatively. Cells that are dying can be identified in histological sections from the shape and staining properties of the nuclei. However, dead cells are soon broken down and removed, probably at varying speeds, and therefore it is not possible to get a reasonably quantitative assessment of the number of cells dying over a period of time by simply counting the dead or dying cells. From histological studies in mice it is apparent that there is a significant amount of cell death in the endometrium during the mated cycle (Martin *et al.*, 1973). This is necessary to remodel the uterine lumen between oestrus and implantation. It is also obvious that the big increase in cell numbers in the stroma following the onset of progesterone secretion must be followed, if implantation does not take place, by a reduction in cell numbers before the start of the next cycle.

Several possible approaches to the assessment of the extent of cell death are possible. Each cell contains a characteristic quantity of DNA in the nucleus so that any change in total DNA in a tissue will represent a change in cell numbers. If cells are not proliferating, then a drop in DNA would represent cell removal and thus give some estimate of cell death. There is, however, the problem of the migration of cells from the blood. Under most conditions, this is not likely to be very great but it might complicate the picture. The problem with regard to this approach to the uterus is the difficulty of separating the various cells and tissues for biochemical analysis, although some success has been achieved at least in separating the endometrium from the myometrium and the luminal epithelium from the stroma (Fagg *et al.*, 1979; Glasser and Julian, 1986).

An alternative approach to the problem (Finn and Publicover, 1981) is to utilize the findings discussed earlier, that the different tissues of the endometrium undergo mitosis at different times and in response to different hormone treatments. Thus, the cells of each tissue will be synthesizing DNA and taking up thymidine at different times. When an injection of tritiated thymidine is given to an animal, cells in the S phase of mitosis take up the nucleotide and become radioactively labelled. This can be confirmed by making autoradiographs of the sections of the uterus after such an injection when the labelled cells show up clearly (Finn and Bredl, 1977). Thus, if an injection of tritiated thymidine is given to ovariectomized mice after two injections of 100 ng of oestradiol, then most of the luminal epithelial cells will be labelled and none of the stromal, whereas if the thymidine is given following treatment with oestrogen and progesterone to mimic the preparation for implantation then the label is found predominantly in the stromal cells.

With this technique, it is possible to identify a distinct population of cells and to follow their fate. It is assumed that any fall in the level of radioactivity in the uterus indicates

that cells from the tissue which was labelled have died and been removed. To estimate the number of labelled cells, it is easy to measure total radioactivity in the uterus by scintillation counting. As expected, it was found (Finn and Publicover, 1981) that the uteri of animals given tritiated thymidine after two daily injections of oestradiol had a very high level of radioactivity when killed soon after, but this had dropped to about 25% by the third day after injection, indicating that many of the luminal epithelial cells had been removed. If the oestrogen treatment was maintained, however, the level of radioactivity did not decrease, demonstrating that it is the decline in oestradiol levels which causes the cells to die.

When the thymidine is injected so as to label the stromal cells, i.e. after progesterone treatment, then the radioactivity is maintained for 2 days and then declines over the following 5 or 6 days. The reduction is less if the progesterone treatment is continued, but is still very significant. If, however, the uterus is stimulated to induce the decidual cell reaction (section 3.5) then the level of radioactivity is maintained. It was concluded that many of the stromal cells which are formed following mitosis in preparation for implantation are in an unstable condition in which they can either decidualize or die. Maintenance of a large population of undecidualized stromal cells does not occur.

In women decidualization occurs during the menstrual cycle, but if pregnancy does not follow there is overt breakdown of endometrial tissues causing menstruation (section 3.5.8). Whilst the extent of cell death has not been assessed quantitatively during menstruation it must be very high.

Clearly, there is no really satisfactory way of accurately measuring cell death at the moment. Nevertheless, it is clear that it is an important factor involved in the preparation of the uterus for implantation.

3.4 IMPLANTATION OF THE BLASTOCYST

3.4.1 LOCATION OF THE BLASTOCYST

Whether the blastocyst remains small and ultimately comes to lie in the wall of the uterus, or increases in size and fills the uterine lumen, the first stage of implantation is apposition of the trophoblast against the luminal surface of the uterine epithelium. Before this happens however, the blastocyst has to be positioned both with regard to its place along the length of the uterus, the orientation of the embryonic disc, and, in the case of the blastocysts which remain small, with regard to its position across the axis of the uterus. As discussed in the previous section, the uterus, even in the absence of a blastocyst, closes down during the mated cycle, and in the case of the mouse and rat the lumen appears as a slit orientated in a mesometrial–antimesometrial direction (Figure 3.4).

When blastocysts are present in mice and rats they locate themselves fairly evenly along the length of the uterus at the antimesometrial side of the lumen with the embryonic disc facing towards the mesometrium. In other species the location is different but characteristic for the species. This spacing and locating mechanism is also found in the uteri of animals undergoing delay of implantation (McLaren, 1968).

Three interesting questions present themselves:

(1) What forces operate on the blastocysts to space them along the length of the uterus?
(2) What causes the blastocyst to position on the antimesometrial side of the lumen?
(3) What is the mechanism causing the embryonic knob to face in a particular direction with regard to the mesometrium?

All of these problems have been investigated but no conclusive answers have been reached. (For a more detailed discussion of

the possible mechanisms see Mossman, 1971; Wimsatt, 1975)

When a small quantity of oil is injected into the uterine lumen to stimulate an implantation reaction (Finn and Keen, 1963), it breaks up into small droplets and a decidual response is always formed round the antimesometrial side of the lumen (Finn and Hinchliffe, 1964). The oil droplets are, however, found randomly along the uterine slit (Finn and Pope, 1989). However, pieces of muscle or tumour cells placed in the uterus become located antimesometrially (Wilson, 1960, 1963). There seem to be two factors operating: a locating mechanism and a preferential sensitivity for stimulation of the decidual cell reaction. Martin (1979) has studied the locating mechanisms in the mouse and has suggested that the circular muscle layers of the myometrium are active at the time of implantation under the influence of progesterone, and it is their contraction which forces the blastocyst towards the antimesometrial side. Martin points out that 'in transverse sections the antimesometrial extremity of the lumen is usually closer to the centre of a circle formed by the circular muscles than the mesometrial extremity. A body lying mesometrially would therefore receive asymmetric forces from the circular muscle and would tend to move to the centre of symmetry of the antimesometrial cleft.' An alternative hypothesis (Finn, 1989) suggests that the surface of the luminal epithelium on the antimesometrial side is preferentially organized both for reception of the decidual stimulus and for the attachment of the blastocyst. Myometrial activity would cause random movement of the blastocyst, which when it came in contact with the antimesometrial epithelium would not only stimulate a decidual reaction but become attached there. Oil droplets, whilst stimulating a decidual reaction, would not become attached and therefore are still free to move.

Spacing of blastocysts along the length of the uterus ensures that each blastocyst has sufficient space in which to develop. When there are many blastocysts this means more or less even spacing, although this is not necessarily so when there are only a few. Several suggestions have been proposed to account for the spacing. Mossman (1937) proposed that as each blastocyst starts to implant it sets up around itself an inhibitory zone which prevents other blastocysts implanting nearby. This hypothesis was challenged by Boving (1954) and McLaren and Michie (1959), who suggested that on arrival in the uterus the blastocysts are subjected to pressures exerted by muscular activity, which have the effect of distributing them along the length of the uterus. Evidence in favour of this view comes from the work of Pusey *et al.* (1980), who showed that relaxin, a hormone known to affect the activity of the myometrium, if given before implantation, upsets the normal distribution of blastocysts along the length of the uterus.

Whilst it seems very likely that muscular movement plays some role in the early distribution of the blastocysts, it may not by itself be sufficient to obtain the degree of even spacing attained when there are, for instance, 17 or more ova in the uterus of a mouse. A further mechanism has therefore been proposed in which, after an initial approximate distribution by muscular activity, more accurate spacing is achieved by growth of the uterus between implantation sites (Hammond, 1935; Reynolds, 1949; Finn, 1968). Certainly a very rapid increase in length of the uterus at the time of implantation has been noted, which might be due to increased cell proliferation (Finn, 1968) or to tissue hydration following a local increase in endometrial microvascular permeability at the implantation sites (Rogers *et al.* 1982a). However, Hamilton (1973) contests the view that there is growth of the uterus at the time of implantation.

The constant orientation of the embryonic knob with regard to the mesometrium and thus the entry point of the blood vessels is

associated with the final form of the placenta (Mossman, 1937). This is probably not so important in animals with placentae which involve the whole uterine surface (such as the pig and horse) or specialized areas over the whole surface (such as the cotyledenous placenta of the sheep, cow and goat). Consideration of the possible forces operating to fix the position of the embryonic disc led Kirby *et al.* (1967) to propose that once the blastocyst had been fixed in position the embryonic disc moved round the trophoblast shell to obtain its correct position. Gardner (1975) tested this hypothesis by growing blastocysts in culture medium and labelling the cells abutting the embryo with particles of melanin. He then transferred them to recipients (prepared hormonally to receive them). Once inserted, they orientated themselves correctly but the melanin-labelled cells were still in contact with the embryonic knob. It seems very unlikely therefore that the latter had migrated round the trophoblast and suggests that whatever causes the orientation acts on the whole blastocyst.

3.4.2 ACTIVATION OF THE BLASTOCYST

The arrival of the blastocyst in the lumen of the uterus is a crucial stage of pregnancy. For further growth of the embryo it is necessary for the blastocyst to become fixed against the wall of the uterus so as to tap the resources in the maternal bloodstream more directly. In most animals this happens at a predetermined time, soon after arrival of the blastocyst in the uterus, and if it does not the embryo will die. A few animals, however, can maintain the blastocysts in a condition of delayed implantation and embryonic diapause for extended periods (Lataste, 1891). During this time protein synthesis and metabolism of the blastocyst are reduced (Weitlauf, 1973, 1985). This latter can be shown by the very low level of carbon dioxide production (Menke and McLaren, 1970), the cessation of cell division (McLaren, 1968) and the reduction in RNA synthesis (Gulyas and Daniel, 1969). Some stimulus is necessary to bring the blastocyst out of this dormant condition. The ability of the blastocysts of some animals to stay in this state of suspended animation is very interesting. However, it is probably not a general property of blastocysts, and it is unlikely that activation is in general necessary for embryonic development. Findings about activation of rodent blastocysts should not therefore be extrapolated too freely to other species.

The mechanisms whereby the blastocyst is activated have been studied mainly in small rodents in which the condition of embryonic diapause occurs during lactation or can be easily induced artificially by removing the ovaries early in pregnancy and maintaining the animals on progesterone (Cochrane and Meyer, 1957). Implantation and activation of the blastocyst can be induced in such animals by the injection of small quantities of oestradiol – the same regimen required for the induction of the second stage of closure. Although there can be no doubt that this causes changes in the endometrium which lead to attachment of the blastocyst, it has been suggested that oestrogen also acts directly on the blastocyst to cause activation (D.M. Smith, 1968). This work has been criticized (Wu and Meyer, 1970; Weitlauf, 1973), and it is now generally thought that the oestrogen acts first on the endometrium, which then activates the blastocyst. There is less agreement concerning whether activation involves the turning off of an inhibitory influence of the uterus or the production of a stimulatory factor. It is also possible that the change in the surface of the luminal epithelium which allows attachment of the trophoblast is sufficient to activate the blastocyst.

If an unimplanted blastocyst is transferred from the uterus to another organ, for example the eye (Fawcett *et al.*, 1947), kidney (Fawcett, 1950; Kirby, 1960), testis (Kirby, 1963a; Mayer and Duluc, 1966) or spleen

(Kirby, 1963b), it continues its development, indicating that it is not reliant on a specific uterine factor. Similarly, if blastocysts from animals in delay are grown in tissue culture medium containing serum and amino acids they resume development (Gwatkin, 1966; Psychoyos and Bitton-Casimiri, 1969; Bitton-Casimiri *et al.*, 1976). It is clear from these and other findings that the uterus in delay either produces something inhibitory to development of the blastocyst or fails to provide it with necessary nutrients.

As the embryos of the majority of species develop continuously from fertilization to gestation, it seems likely that inhibition of blastocyst development, in those few species in which embryonic diapause is necessary for reproductive success, would have been superimposed during evolution as an active mechanism. Inhibitory substances have been demonstrated in washings from the uteri of animals in delay (Psychoyos and Bitton-Casimiri, 1969; Weitlauf, 1973; Aitken, 1977a,b; Weitlauf, 1978). Furthermore a finding which indirectly suggests that the uterus produces an inhibitory substance is that delayed blastocysts can be induced to implant by the injection into the mother of the drug actinomycin D (Finn, 1974; Camus *et al.*, 1979). It is suggested that this drug inhibits the synthesis of a newly synthesized protein of approximate molecular weight 7000 daltons (J.W. Pollard *et al.*, 1976), which is responsible for the dormant condition of the blastocyst. Recently, from a study of endometrial protein changes during sensitization for implantation, Mulholland and Leroy (1989) have also concluded that receptivity is effected by repression of certain proteins.

On the other hand, work on animals showing obligatory delay suggests that activation is brought about by increased nutrients in the uterus (protein, ferret, J.C. Daniel, 1970; hexoses, roe deer, Aitken, 1974). Probably the mechanisms for maintaining the blastocyst in diapause differ between those species in which it has evolved as a facultative response to lactation and those in which it is an obligatory part of the reproductive process.

Whether specific uterine secretions are necessary for normal blastocyst development in those species which do not undergo delay of implantation is undecided. Provided the correct nutrients are available, ova grow and develop normally in culture medium (McLaren and Biggers, 1958). However, a specific uterine protein called either 'blastokinin' (Krishnan and Daniel, 1967) or 'uteroglobin' (Beier, 1968) has been isolated in the rabbit, and it has been suggested that it regulates blastocyst development. No such regulator has been shown in other species (e.g. sheep, Staples *et al.*, 1976).

3.4.3 HORMONAL CONTROL OF IMPLANTATION

The necessity of the ovarian hormones for implantation has been known for a very long time (Corner, 1921). Ablation of the corpus luteum was shown to cause failure of implantation (Corner, 1928), which could be reversed by the administration of extracts of the corpus luteum (W.M. Allen and Corner, 1929), showing clearly the necessity for progesterone. This has been confirmed by the demonstration that antibodies to progesterone will block pregnancy (Rider *et al.*, 1985, 1986). Krehbiel's (1941) discovery that oestrogen could precipitate implantation of mouse blastocysts held in delay during lactation led to work indicating a role for oestrogen in implantation, at least in the mouse.

Two groups of workers showed that, whilst removal of the ovaries always prevented implantation in rats, the ability of exogenous progesterone alone to allow implantation when administered after ovariectomy depended on the time at which the ovariectomy was performed (Canivenc *et al.*, 1956; Cochrane and Meyer, 1957). If the ovaries were removed from mated rats or mice before a critical time then a small

amount of oestrogen had to be administered in addition to progesterone. However, the importance of this so-called nidatory oestrogen does not seem to be universal – many species require only progesterone during the luteal phase for implantation (ewe, Bindon, 1971; guinea pig, Deanesly, 1960; hamster, Orsini and Meyer, 1959; Harper *et al.*, 1966, rabbit, Kwun and Emmens, 1974; ferret, Wu and Chang, 1973; Mead and McRae, 1982; weasel, Shelden, 1973; skunk, Mead *et al.*, 1981). The situation in primates is equivocal. Some recent work suggests that there may be a need for luteal phase oestrogen in monkeys (Ravindranath and Moudgal, 1989).

It is also likely that the oestrogen secreted during pro-oestrus is important in preparing the uterus for implantation. Pro-oestrous oestrogen plays a role in controlling cell proliferation and differentiation in the endometrium and affects the timing of sensitivity to implantation in the mouse (Finn and Pollard, 1973). Possibly pro-oestrous oestrogen plays a more crucial role in species which implant following a set time interval after ovulation (Marcus and Shelesnyak, 1967; Finn and Martin, 1970; Moore and Miller, 1976), whereas in rats and mice, in which there is a variable timing of implantation associated with the presence of lactating pups, nidatory oestrogen has become important. (For a detailed review of the hormonal control of implantation see Psychoyos, 1974.)

The state of blastocyst acceptance or sensitivity is maintained for only a few hours (the so-called implantation window). At other times the uterus is hostile to the blastocyst. Such a condition of insensitivity was predictable from the early work on sensitivity to a decidual stimulus (Loeb, 1908a; W.M. Allen, 1931).

The critical timing of uterine sensitivity to the implantation of blastocysts was shown originally in mice by McLaren and Michie (1956), who transferred fertilized ova to pseudopregnant mice on succeeding days of pseudopregnancy and found that attachment of blastocysts would only occur over a very limited period. This was subsequently confirmed in rats (Noyes and Dickman, 1960).

During the oestrous cycles of animals which have a spontaneous luteal phase, the demise of the corpus luteum occurs very soon after the time when full sensitivity of the uterus had been attained and the fall in progesterone would be sufficient to render the uterus insensitive to the blastocyst. However, in animals with an induced luteal phase (pseudopregnancy) the progesterone levels remain high until well after the expected time of implantation, but the uterus nevertheless still becomes insensitive.

Most of the experimental work on the attainment of sensitivity and insensitivity has been carried out on species in which insensitivity occurs in spite of high progesterone levels, and it may not be valid to extrapolate results from these animals to species in which such a condition would not naturally exist (for example man).

Experimental work on ovariectomized mice has shown that if they are treated with hormones on a schedule of injections, which causes morphological changes in the endometrium similar to those found in pregnancy or the extended oestrous cycle, then the uterus will respond to a blastocyst or artificial decidual stimulus 4–6 Hafter the nidatory oestrogen injection but will then become refractory to such a stimulus even though progesterone treatment is continued (Finn, 1966a; Psychoyos, 1963; Finn and Martin, 1969a, 1972a; Finn *et al.*, 1991). Associated with the refractory state is the presence in the lumen of an electron-opaque substance which may be the result of secretion of the glands. The luminal surface of the epithelial cells loses its typical appearance of the second stage of closure. Whether such a refractory period with its associated morphological changes occurs in animals with a spontaneous luteal phase if progesterone is maintained artificially beyond the time of sensitivity is not known.

A similar condition of insensitivity to an implantation stimulus is produced if high doses of oestrogen are given during the luteal phase. It has been known for a long time that pregnancy can be interrupted by the administration of oestrogens before the time of implantation (Parkes *et al.*, 1938). Unlike progesterone, excess levels of which, provided the dosage is above the threshold, have no effect on uterine sensitivity, the response to nidatory oestrogen is critically dependent on the dose given (Finn and Martin, 1969b). Morphological examination of animals given high doses of nidatory oestrogen suggests that the onset of the closure reaction of the luminal surface is accelerated, which may be a factor causing insensitivity (R.M. Pollard and Finn, 1972).

3.4.4 CYTOKINES AND IMPLANTATION

Implantation involves a series of changes in the uterus and blastocyst involving endocrine, autocrine and paracrine control mechanisms. The role of growth factors and oncogenes in cell proliferation has been discussed earlier and the role of cytokines in the immune response will be discussed later. Although there may be redundancy in the system it is likely that removal of any of these would affect the course of implantation.

Some of these growth factors and other cytokines must also be involved in differentiation of the endometrium and attachment of the blastocyst. Two in particular have been implicated as playing a crucial role in implantation – leukaemia inhibitory factor (LIF) (C.L. Stewart *et al.*, 1992) and colony-stimulating factor 1 (CSF1) (J.W. Pollard *et al.*, 1991). Mice containing mutant genes rendering them unable to synthesize the cytokine have been developed, and in both cases pregnancy is compromised. It is suggested that CSF1 is necessary for placental development (Pollard *et al.*, 1987; Pampfer *et al.*, 1991, 1992), although the stage of placental development affected is not clear. The suggestion seems to be that endometrially produced CSF1 is essential for the growth of trophoblast cells. It is difficult to reconcile this with the fact that the trophoblast grows in animals in which transcription has been stopped by the administration of actinomycin D (Finn and Bredl, 1975).

The finding that blastocysts grow actively in other tissues (discussed earlier), although not ruling out the necessity for the presence of CSF1, suggests that it is not having a controlling influence. It would be interesting to know whether such ectopic blastocysts would grow in mutant mice devoid of CSF1. Further work is also needed to find the stage of implantation at which failure occurs. Actinomycin D, which presumably blocks the transcription of genes for CSF1, does not block attachment of the blastocyst or the pontamine blue reaction but does block apoptosis of the luminal epithelium and decidualization. Clearly, more biological information is needed before one can be sure that the uterus is producing cytokines which control the growth of the blastocyst.

Both LIF and CSF1 are cytokines originally discovered for their effects on the haemopoietic and immune systems. Colony-stimulating factor controls the recruitment of macrophages and other leucocytes to the uterus and is itself under the control of oestrogen and progesterone (G.W. Wood *et al.*, 1992). The role of bone marrow-derived cells in implantation is discussed in the section on the decidua, but whether there is any relationship between their presence and successful pregnancy is at present unknown.

3.4.5 ATTACHMENT OF THE BLASTOCYST TO THE UTERUS

On arrival in the uterus the blastocyst is normally still encased in the zona pellucida. In most animals this is removed before there is any contact between the trophoblast and endometrium. However, in the guinea pig, tongues of trophoblast penetrate through the

zona to make contact with the luminal epithelium whilst the zona is largely intact (Blandau, 1949). The rabbit also differs from the majority in secreting around the blastocyst additional coats of glycoprotein-like materials, which subsequently have to be removed before attachment, probably by proteases in the uterine secretions (Kirchner, 1975).

Removal of the zona appears to be largely brought about by enzymes in the uterine luminal fluid (McLaren, 1969, 1970; Rosenfeld and Joshi, 1981). There is some suggestion that the blastocyst contributes to the activation of this enzyme, and indeed blastocysts can hatch from the zona even in the absence of the proteolytic enzymes. This happens in delayed implantation (McLaren, 1968), when empty zonas can sometimes be seen in the uterus from which blastocysts have hatched without prior dissolution of the zona (Alloiteau and Psychoyos, 1966; McLaren, 1970). Similarly, if blastocysts are delayed in the oviducts, they will hatch, although at a later time than normal (Orsini and McLaren, 1967).

After emerging from the zona the blastocyst continues to have a surface coat of glycoprotein. This may be very thick, as found on the blastocysts of the rabbit and ferret, or only visible after the use of special stains, such as concanavalin A or ruthenium red (rodents; Enders and Schlafke, 1974; Nilsson, 1974; Wu and Chang, 1978).

The initial contact between the trophoblast and the luminal surface of the uterine epithelium has been studied in several animals (human, Aplin, 1991; rats, Nilsson, 1966; Enders and Schlafke, 1967, 1969; Schlafke and Enders, 1975; and mice, Mayer *et al.*, 1967; Reinius, 1967). Attachment involves changes in the chemical and physical nature of the contacting membranes of both the uterine epithelial cells (Murphy *et al.*, 1982b) and the trophoblast (although it only seems to be the mural trophoblast). The morphological change in the lumen of the mouse uterus which occurs at the expected time of implantation brings about closure of the uterine lumen and requires the intervention of a small quantity of oestrogen against a background of high levels of progesterone. It does not take place during delayed implantation in the mouse and is not dependent on the presence of a blastocyst, although there is some evidence that contact of the trophoblast may accelerate onset of the change (R.M. Pollard and Finn, 1974). When a blastocyst is present a similar condition of very close contact is formed between the trophoblast and uterine luminal surface (Figure 3.8) (Nilsson, 1967; Hedlund *et al.*, 1972; Ljungkvist, 1972).

Because it is not possible to wash the blastocysts out at this stage, it is called the adhesion stage.

The chemical and physical basis of this adhesion between the blastocyst and uterus is still being actively investigated (Anderson, 1989). It is assumed that there must be some sort of adhesive force holding the cell membranes together. Cells are held apart by the negative charge on their surfaces, and reduction of this is thought to be a necessary step in attachment. Attempts have been made to assess changes in negativity, both at the surface of the luminal epithelium and the blastocyst, using electron-dense probes, for example ruthenium red, alcian blue, colloidal iron hydroxide and polycationic ferritin (Holmes and Dickson, 1973; Nilsson *et al.*, 1974; Jenkinson and Searle, 1977; Hewitt *et al.*, 1979; Guillomot *et al.*, 1982; Anderson and Hoffman, 1984). In some animals a change has been demonstrated, but not in others.

The cause of the change in charge on the cell membranes is probably associated with the complex carbohydrate moieties of the glycoprotein, glycolipids and glycosoaminoglycans located at the cell surface in the glycocalyx (Wordinger and Amsler, 1980; C.R. Murphy and Rogers, 1981; Chavez and Anderson, 1985; Whyte and Allen, 1985; Chavez, 1986; Aplin, 1991). It has been suggested that the reduced negativity may be

caused by decreased amount of sialic acid residues (Nilsson *et al.*, 1974; Jenkinson and Searle, 1977).

Some authors have reported a thinning of surface coat material before attachment (Salizar-Rubio *et al.*, 1980), while others have been unable to show such an effect (Enders *et al.*, 1980; Guillomot *et al.*, 1982). Changes in the chemical nature of the surface carbohydrates have been studied by assessing the binding of various lectins and antibodies (human, M.C. Lee and Damjanov, 1985; Duncan

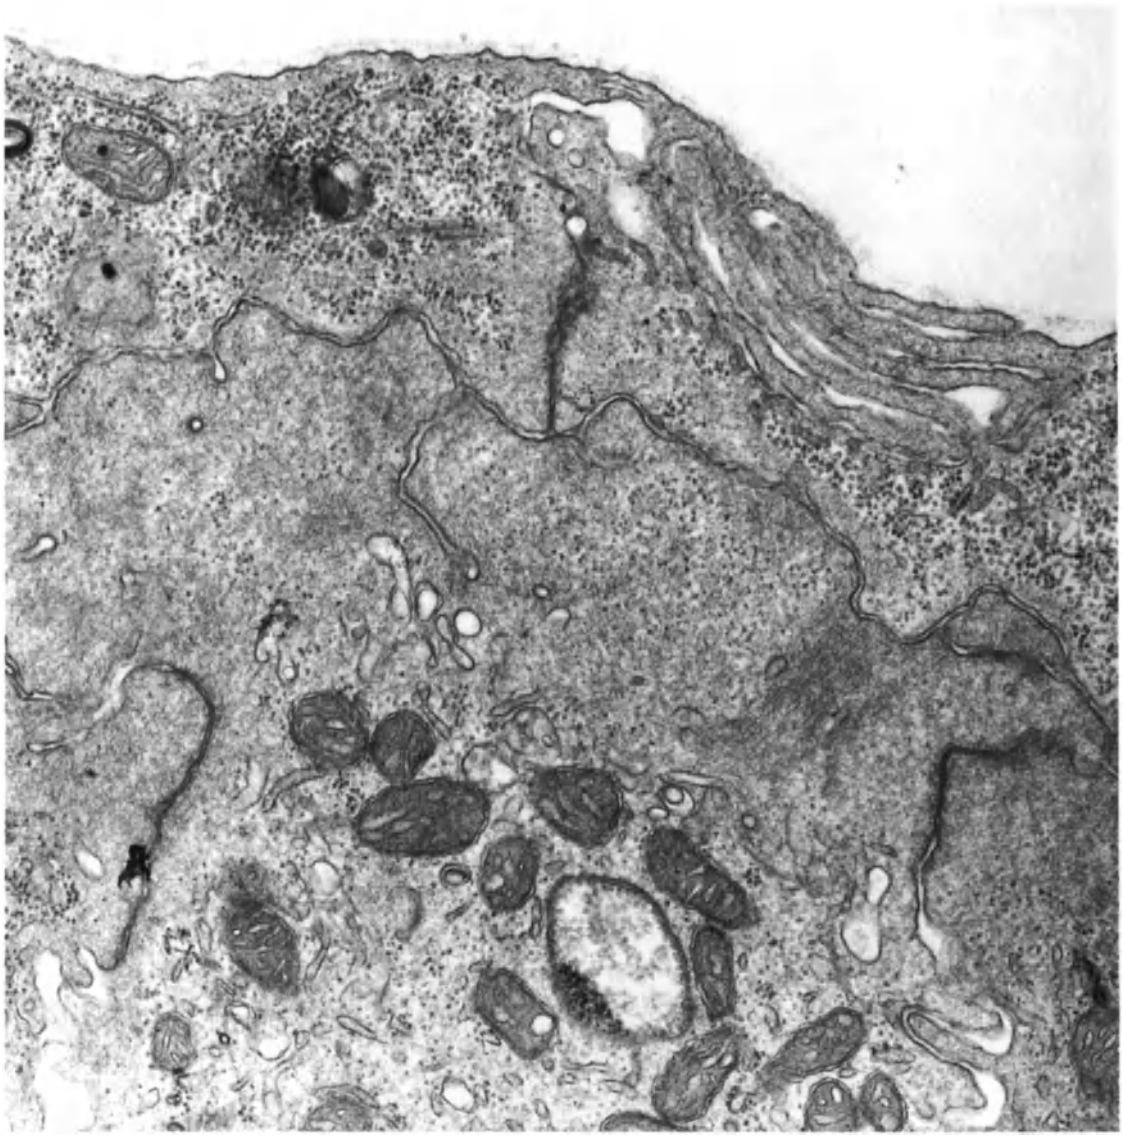

Figure 3.8 Electron micrograph of the junction of a trophoblast cell (top) with the uterine epithelium at the adhesion stage of implantation in the mouse. The interlocking microvilli have flattened out and very close contact has been established between the surfaces of the apposing cells. (Picture by Dr Rosemary Pollard.)

et al., 1988; cow, Wordinger and Amsler, 1980; rat, C.R. Murphy and Rogers, 1981; C.R. Murphy and Turner, 1991; and mouse, Wu and Chang, 1978; M.C. Lee *et al.*, 1983). Chavez (1986) tested the binding of several lectins to both surfaces and showed changes at the time of adhesion in only one lectin, succinylated wheat germ agglutinin. From these studies he suggests that at the time of attachment there is a change in *N*-acetylglucosamine on the cell surfaces.

Changes in cell-surface molecules in response to ovarian hormones have also been demonstrated. The cell adhesion molecule (CAM 105) is controlled by oestrogen and progesterone (Svalander *et al.*, 1987, 1990) in rats as are lacto-*N*-fucopentose (Kimber and Lindenberg, 1990) and lactosaminoglycans (Barbiarz and Hathaway, 1988) in mice. Recently, Potter and Morris (1992) have demonstrated changes in the distribution of heparin sulphate proteoglycan in response to oestradiol (they were unable to show any response to progesterone, but as they used an extremely low dose, 1.25 μg per mouse, this is not surprising).

Attempts have been made to isolate and purify the plasma membranes from the luminal epithelial cells and investigate their protein content (rabbit, Lampelo *et al.*, 1985; pig, Mullins *et al.*, 1980). This has shown that at the time of acquisition of receptivity to a blastocyst there is a change in protein composition of the endometrial plasma membranes. It is suggested (Lampelo *et al.*, 1985) that this may involve a shift in the number, distribution or configuration of some of the molecules on the surface. Similarly, Anderson *et al.* (1986) have shown that three new polypeptides can be identified in endometrial epithelial cells from rabbit uteri at the time of sensitivity to implantation. C.R. Murphy and Martin (1985) have suggested a different organization of cholesterol in the apical plasma membrane at the time of implantation.

It is clear that the adhesion between trophoblast and uterine luminal epithelial cell surface (and the second stage of closure) involves complex molecular changes. These changes do not occur in all species, and have indeed been studied in relatively few. It is nevertheless very relevant that the uterine changes in those animals in which they do occur take place during the extended oestrous cycle and produce adhesion between apposing surfaces along the length of the uterus. In pregnancy, it is only in those areas where a trophoblast is in contact with the epithelial surface that decidualization is triggered in the stroma, indicating that the cellular contact between trophoblast and epithelial surface must be different from that between apposing epithelial surfaces. The nature of the triggering stimulus is discussed later in section 3.4.6.

3.4.6 EPITHELIAL RESPONSE TO THE BLASTOCYST

In many species the close attachment of the trophoblast to the luminal epithelium is the final stage in the joining together of the fetal and maternal tissues (e.g. pig and horse). However, in some species there are further developments in the epithelium which bring about a closer fetal–maternal union. The changes in the domestic ungulates are described briefly in section 3.2 on species variation, and details will be found in Chapter 4. In this section the changes associated with implantation in species in which penetration of the trophoblast into the uterine stroma takes place will be described.

Deep implantation of the blastocyst into the wall of the uterus can come about either by degeneration and removal of the uterine epithelium which lies between the stroma and the blastocyst, with the trophoblast taking a passive role, or by the trophoblast actively invading through a healthy epithelium. The former appears to take place in rats and mice (Finn and Lawn, 1968) while the latter occurs in guinea pigs (Green, 1979),

ferrets and probably women (Knoth and Larsen, 1972; Lala and Graham, 1990).

It has been known for a long time that the uterine luminal epithelium, which in the rat and mouse is in contact with the blastocyst, undergoes degeneration, and that the cells of the trophoblast phagocytose the dead cells (Galassi, 1967; Mulnard, 1967; Finn and Lawn, 1968). However, there was dispute as to whether the trophoblast actively brought about the death of the epithelial cells or whether death was due to activity within the epithelial cells which was simply triggered by the attachment of the trophoblast. Such programmed cell death plays an important part in the modelling of tissues during embryogenesis (Saunders, 1966).

Most of the evidence points to the latter. If the drug actinomycin D is given to mice just before implantation the epithelial cells surrounding the blastocyst do not die (Finn and Bredl, 1973, 1975). This suggests that the drug, which stops transcription of DNA in the nucleus, is preventing the release of information which would bring about epithelial cell death. The blastocyst, on the other hand, does not appear to be affected by the drug and both the trophoblast and embryonic knob develop surrounded by intact uterine epithelium. At a later stage the trophoblast may send out processes between the luminal epithelial cells (Finn and Bredl, 1973). Another relevant finding is that when a decidual cell reaction is initiated by the instillation of a droplet of oil in the uterine lumen, the epithelial cells on the antimesometrial side of the lumen, but not those on the mesometrial side, degenerate, again indicating that the breakdown of the cells is spontaneous and only requires the stimulus to trigger it off. The instillation of oil into the uterine lumen of a mouse which has not been prepared hormonally for implantation does not cause the cells to die, indicating that the death of the cells is not due to any trauma caused by the oil but is part of the implantation reaction triggered off by it (Finn and Hinchliffe, 1965).

The rabbit blastocyst demonstrates a very unusual method of transit to the endometrial stroma. At the time of implantation areas of the trophoblast become syncytial and pegs of tissue pass through the blastocyst coverings to make contact with the uterine epithelial cells. Here the apposing surfaces of the two tissues fuse to form a single syncytium. As discussed earlier, the luminal epithelial cells, as part of their hormonal preparation for implantation, form a syncytium, so that there is now a combined maternal–fetal syncytium; with nuclei from both tissues. Soon the fetal nuclei become predominant and the maternal nuclei disappear so that the blastocyst has in effect penetrated the uterine epithelium (Larsen, 1961; Enders and Schlafke, 1971; Steer, 1971).

The other method of trophoblast penetration, which Schlafke and Enders (1975) refer to as intrusive implantation, can be seen in several species, but has been mainly studied in the ferret and guinea pig (von Spee, 1893; Samson and Hill, 1931; Blandau, 1949; Enders and Schlafke, 1972). In this method, processes from the trophoblast penetrate between the uterine epithelial cells with no apparent damage to the cells, beyond the breaking down of the apical junctions between them. The process is very rapid and few studies have been made of blastocysts in the process of passage through the epithelium (Schlafke and Enders, 1975; Green, 1979). Subsequently, the trophoblast, which is largely syncytial, penetrates deeply into the stroma and surrounds blood vessels and glands (Enders and Schlafke, 1971).

It is likely that women and some of the other primates undergo intrusive implantation. Unfortunately, however, the few descriptions of human implantation are of a fairly late stage, and intrusion can only be inferred (Knoth and Larsen, 1972; Hertig and Rock, 1941; 1945). Recent *in vitro* studies also point in this direction (Lindenberg *et al.*, 1986). Similarly the few detailed studies of other primates provide suggestive but not

decisive evidence for intrusive implantation (chimpanzee, Heuser, 1940; rhesus monkey, Reinius *et al.*, 1973; Heuser and Streeter, 1941).

Following the breakdown of the luminal epithelial cells surrounding the blastocyst, the trophoblast cells become very active, first penetrating the epithelial basement membrane (Schlafke *et al.*, 1985; Blankenship and Given, 1992) and then invading and ingesting the stromal cells (Bevilacqua and Abrahamsohn, 1989). Protease enzymes are probably involved (Kubo *et al.*, 1981; Lala and Graham, 1990), especially matrix metalloproteinase (collagenase, gelatinase and stromelysin) (Salamonsen *et al.*, 1991). *In vitro* studies suggest that fibronectin and laminin (Armant *et al.*, 1986; Sutherland *et al.*, 1988; Romagnano and Barbiarz, 1990) or heparin/heparin sulphate (Farach *et al.*, 1987) are involved in the attachment and invasion. The adhesion molecule CAM 105 has also been implicated (Julian *et al.*, 1992; Svalander *et al.*, 1990).

However, there is good evidence that apart from trophoblast invasion the stromal cells, which by now are decidualized, are very active in modelling of the implantation chamber. They appear to have a greater capacity to degrade extracellular matrix *in vitro* than either rat or mouse trophoblast cells (Welsh and Enders, 1989). The fact that implantation chambers form in animals stimulated with oil (Finn and Hinchliffe, 1965) also indicates that much of the apoptosis and remodelling of the stroma is independent of the trophoblast.

3.5 THE DECIDUAL CELL REACTION

In those species in which the blastocyst comes to lie within the stroma, the cells and blood vessels of the stroma undergo a marked transformation into a specialized tissue called the decidua.

3.5.1 HISTORICAL SURVEY

Interest in the decidua as part of the human placenta probably precedes interest in implantation of the ova. More than 200 years ago Hunter (1794) in his treatise on human gestation described the decidua as follows:

> This is a membrane of a very peculiar nature, the knowledge of which throws great light upon the contents of the pregnant uterus, and upon the connection between the mother and child. It is the outer membrane of the uterus.

By this description of the human decidua and the earlier pictures (Figure 3.9) he published of the gravid uterus (Hunter, 1777), Hunter first showed the maternal origin of the decidua and can be said to be the father of over 200 years of research on this fascinating tissue.

Although primitive microscopes were available in the eighteenth century, the study of the histology of tissues did not get under way until the nineteenth century. What Hunter described was a tissue or membrane, clearly visible macroscopically, and it needs to be stressed even today that the decidua is a tissue, consisting of several cell types and specialized blood vessels.

Like much scientific progress, advance in knowledge of the decidua has gone hand in hand with advances in technology. The advent of the compound microscope and techniques for the sectioning of tissues, originally using hand-held razors and subsequently using the microtome, allowed the cellular nature of the tissue to be investigated. The demonstration of the specialized decidual cells and their very large size must have come in the second half of the nineteenth century. In his review of anatomy in 1873, Sir William Turner refers to the 'well known colossal decidual cells'. In fact the cells seem to have been widely studied during the later part of the nineteenth century, and it was during this time that they were

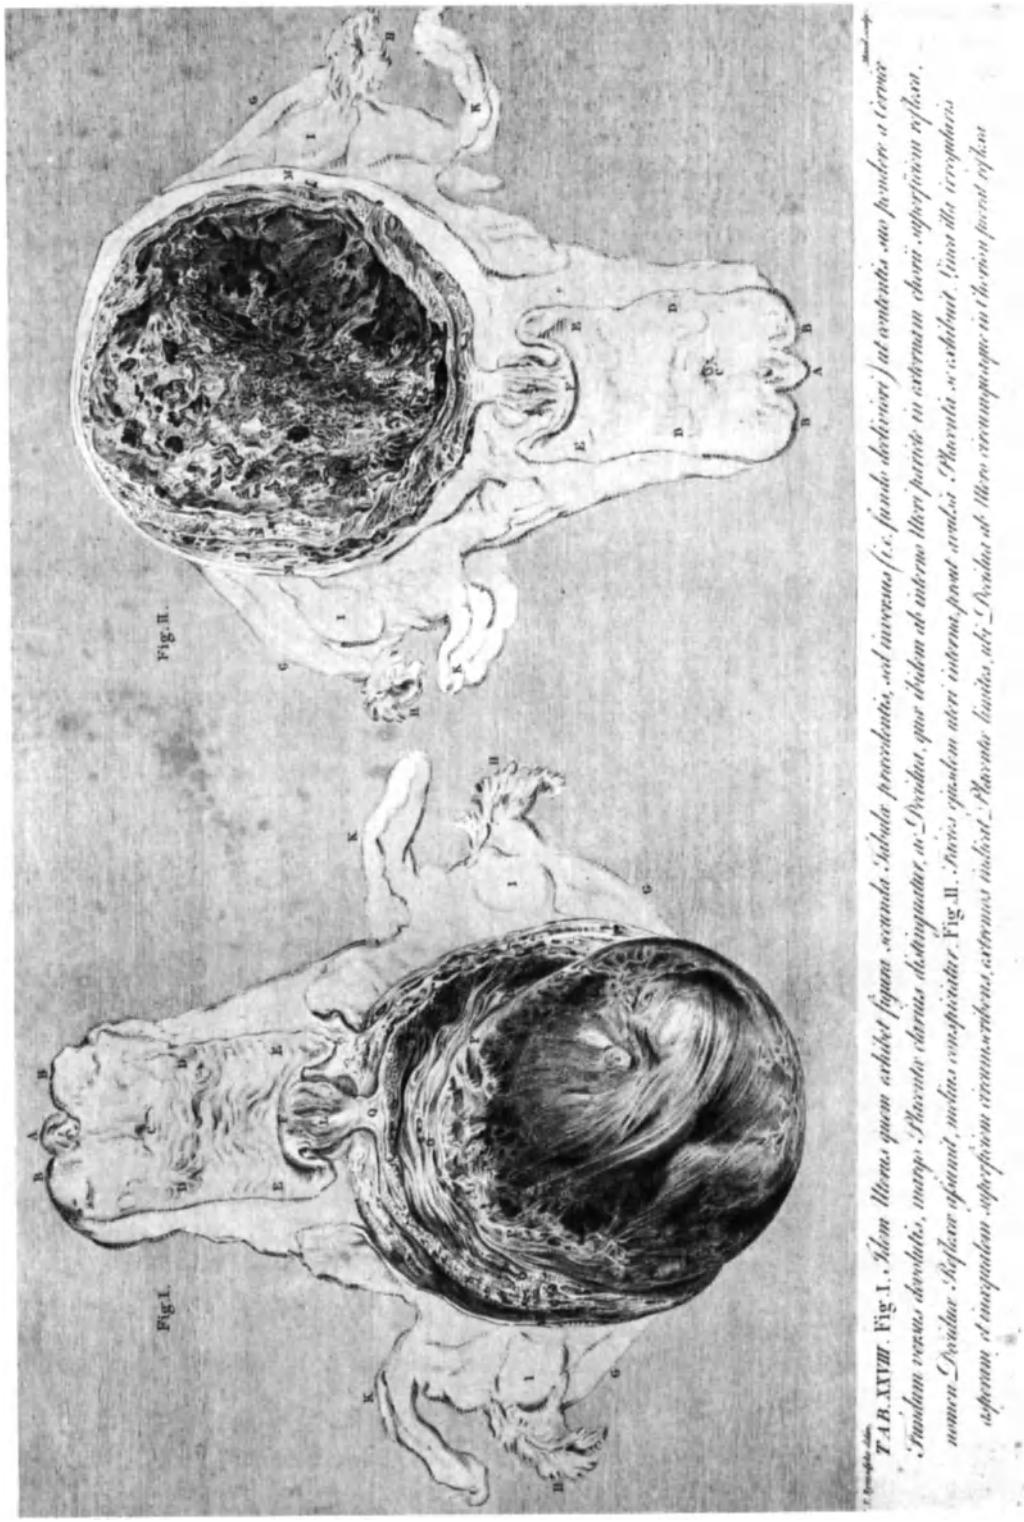

Figure 3.9 A plate from *Hunter's Anatomy of the Human Gravid Uterus* published in 1777 showing the decidual membrane.

shown not to be the sole preserve of the human placenta. In 1878 Creighton demonstrated their presence in the guinea pig placenta, and this was soon followed by their demonstration in other rodents (mouse, Tafani, 1886; rat, Duval, 1891), although we now know that they are an exclusive type of cell – most species manage without them. Apart from their size, another very characteristic feature of decidual cells, the presence of glycogen, was demonstrated before the end of the nineteenth century (Langhans, 1890).

As the cells appeared to be very unusual, there was obviously a lot of interest in their origin. Henning (1872) considered them to be enlarged and modified leucocytes, whilst Overlach (1885) and Frommel (1883) described them as modified glandular cells. However, their true origin from stromal fibroblasts was first suggested by Creighton (1878) from studies on the guinea pig placenta. The resemblance of the decidua to granulation tissue had been noted by Turner in 1876, who thought that it might have a similar defensive function. This theme was expanded by Fothergill (1899).

> The fertilized ovum, in arranging for its own nutrition, is known to make an attack on the maternal structures. The decidual cell, it is suggested, has been evolved as a protection, its function being to prevent injurious invasion of the uterine wall by the fetal elements of the placenta.

In the same paper Fothergill also makes the important statement 'the formation of a decidual membrane is now thought by some to be possible apart from pregnancy either uterine or ectopic'. The observation that a decidual reaction takes place in the uterus in cases of ectopic pregnancy had been noted earlier and had been commented upon by Turner in 1873. It was in fact a very interesting observation as it could only have been made in women. Apart from the fact that other animals rarely, if ever, have ectopic pregnancies it is only in women that decidual transformation occurs in the absence of a stimulus to the wall of the endometrium, which is normally of course an implanting blastocyst. This was apparently puzzling Marshall (1910) when he wrote the first edition of this book. Discussing decidual cells in the text he says 'the first appearance in the superficial layers of the mucosa has suggested a stimulus for their formation arising from the products of conception' but he adds a footnote:

> Under abnormal conditions the formation of decidual cells occurs even though no ovum is present in the uterus, e.g. in tubal pregnancy in the human female. Whether this indicates a chemical stimulus from the ovum, or perhaps from the corpus luteum, effected through the blood stream, is not yet known.

Here, before the isolation of the hormones of the ovary, we see one of the first suggestions that there might be hormonal control of decidual transformation and the first indication of the difference between the stimulus for the formation of the decidua in rodents and women.

At about the same time that Marshall was writing his book two very important discoveries were made by Leo Loeb (1907, 1908a), a pathologist working in America. He, like earlier workers, had been impressed by the similarity of the decidual response in rodents to the granulation tissue response following injury in other connective tissues. He therefore investigated the reaction of the guinea pig uterus to injury. However, he had the foresight, presumably influenced by the work on oestrous cycles by Walter Heape (1900), to injure the uterus on various days of the oestrous cycle. He obtained a decidual response to the trauma, but only when the uterus was injured at certain times. Thus, in one series of experiments he made two very important discoveries: first that the rodent uterus would respond to trauma with the formation of a decidual cell reaction and sec-

ondly that the responsiveness of the uterus varied during the cycle. This was later confirmed by W.M. Allen (1931) in the rat and Courrier and Kehl (1930) in the rabbit. [As Loeb (1923) was also the first to demonstrate the influence of the uterus on the corpus luteum he must surely rank as one of the greatest uterine physiologists.]

Loeb likened his trauma-induced deciduomata to tumours of decidual tissue which had already been reported in women (Ladinski, 1902) and which were known as **deciduomas malignum**. The name deciduoma has stuck for artificially induced decidual tissue although they are the antithesis of tumours, showing highly organized and controlled growth and programmed cell death. They are sometimes referred to as **placentomas**.

Loeb's discovery of the traumatic decidual cell reaction in guinea pigs was soon followed by its demonstration in other rodents (rat, rabbit, and dog, Loeb, 1908b; Frank, 1911; Gasbarrini, 1911; Kranz, 1914), and in 1922 Long and Evans introduced what they considered to be a more physiological method of decidual induction – a silk thread placed in the uterine lumen.

The end of the nineteenth and first third of the twentieth century saw the beginnings of reproductive endocrinology starting with the discovery of the endocrine functions of the ovarian follicle (Lataste, 1887) and corpus luteum (Beard, 1897; Prenant, 1898; Fraenkel and Cohn, 1901; W.B. Bell and Hicks, 1909) and the demonstration of the correlation of the menstrual cycle with ovarian activity (Schroder, 1915). This culminated in the isolation of oestradiol (E. Allen and Doisy, 1923) and progesterone (W.M. Allen and Wintersteiner, 1934; Slotta *et al.*, 1934; Butenandt and Westphal, 1934). The role of the anterior pituitary in the control of the ovary and the importance of copulation for the maintenance of the corpus luteum in rats was also discovered during this period (Brouha, 1928). A useful technological advance at the end of this period was the discovery by Shelesnyak (1931) that pseudopregnancy could be induced in rats by electrical stimulation of the cervix. This is not possible in the mouse.

By the end of this period it had been established that both ovarian hormones in succession are required for decidualization (Corner and Warren, 1919; Weichert, 1928). This was summed up by Nelson and Pfiffner (1930):

> The conditions essential for placentoma formation are (1) the uterus must be prepared for the luteal stimulus by the action of the follicular hormone upon the endometrium – a priming action, (2) the uterus must be sensitized by progesterone for several days prior to stimulation and must be under its influence throughout the life of the decidua.

Soon after the elucidation of the hormonal involvement in the regulation of the decidual cell reaction two classic descriptions of the histology of the decidual cell reaction were published (Selye and McKeown, 1935; Krehbiel, 1937). These publications showed clearly that the decidua is a complex structure which forms during several days following implantation (Figure 3.10).

In their descriptions the authors showed that the decidua contained three primary cell types:

1. the antimesometrial cells which form first, in close association with the implanting blastocyst,
2. the mesometrial decidual cells, which form later around the lateral and mesometrial aspects of the lumen and
3. granulated cells which form in the mesometrium, the metrial gland cells.

Antimesometrial decidual cells are large basophilic cells containing two or more nuclei with many mitochondria, abundant rough endoplasmic reticulum and Golgi complexes, while the mesometrial cells are smaller, irregular in shape, close packed, and usually

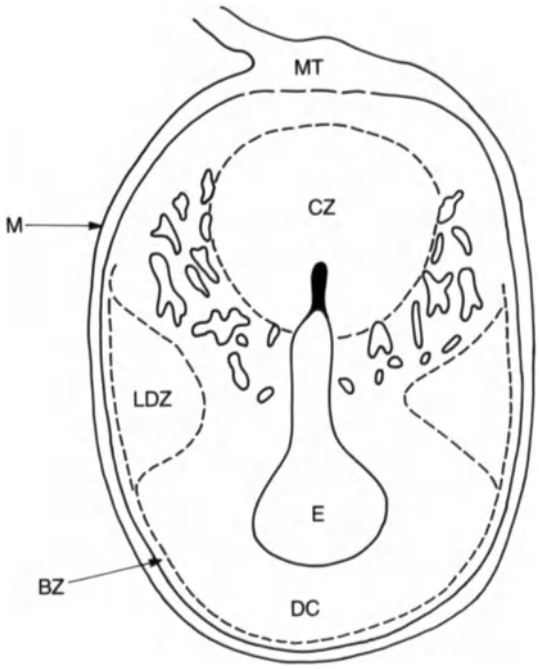

Figure 3.10 Diagrammatic representation of transverse sections of implantation sites on day 8½ of pregnancy in the mouse. Implantation of the embryo (E) occurs in the antimesometrial side of the lumen. The antimesometrial decidua forms the decidua capsularis (DC). The untransformed region of the stroma is termed the basal zone (BZ). The mesometrial decidua is composed of the central zone (CZ) and the lateral sinusoids (LS). The lateral decidual zone (LDZ) is formed between the major decidual ones. The metrial gland develops in a restricted region of the myometrium (M), the mesometrial triangle (MT) through which maternal blood vessels gain access to the uterus. (From S.C. Bell, 1983a, by permission of the editor, *Oxford Reviews of Reproductive Biology*.)

have a single nucleus and much glycogen. The third type of cell, the granulated metrial gland cell, was clearly described by Selye and McKeown (1935). The major development of these cells does not occur until later than the first two types of cell. Similar granulated cells had already been described in the human uterus during pregnancy (Weill, 1921), although the relationship of metrial gland cells to these was not appreciated at the time. These early workers also described the formation of large vascular sinuses laterally to the implanting blastocyst, indicating the importance of vascular changes.

It is apparent that by about 50 years ago many of the fundamental facts about the decidua were known. Progress since then has been partly in response to advances in technology, for example the development of the electron microscope, autoradiography, histochemistry and the availability of drugs affecting cellular metabolism, and partly due to the conceptual advances in other aspects of cell biology, especially concepts about local hormones and cell control mechanisms. Whereas the emphasis for the first hundred years after Hunter's death had centred on the human decidua, most of the emphasis over the last 50 years had centred on the decidua of experimental animals, especially rats and mice.

3.5.2 THE ORIGIN OF DECIDUAL CELLS

The problem of the origin of decidual cells, which had caused much controversy in the later nineteenth century, was settled beyond reasonable doubt with respect to the antimesometrial and mesometrial decidual cells using the technique of autoradiography. Galassi (1968) labelled stromal cells during the S phase of mitosis with radioactive thymidine and found that the label appeared in the nuclei of the decidual cells which formed subsequently, thus confirming Creighton's original suggestion. The suggestion of Kearns and Lala (1982) that the decidual cells derive from the bone marrow has been challenged by several workers (Gambel *et al.*, 1985; S.C. Bell, 1983a).

(a) Metrial gland

The origin of the metrial gland cells was not so easily settled. The early workers considered they formed from mesometrial mesenchymal cells (Selye and McKeown, 1935;

Baker, 1948), from the trophoblast (A.D. Dickson and Bulmer, 1961) or stromal fibroblasts (Larkin and Schultz, 1968; Larkin and Cardell, 1971). The first suggestion of what is now considered to be their true origin was by L.J. Smith (1966), who proposed that they were transformed from lymphocyte-like precursor cells. This suggestion was based on light microscope studies but supported later from examination with the electron microscope (I. Stewart and Peel, 1977, 1978). More recent work using bone marrow chimeras between rats and mice has confirmed that the metrial gland cells are derived from cells originating in the bone marrow (Peel *et al.*, 1983). A similar origin for endometrial granulocytes in the human uterus has been demonstrated (J.N. Bulmer and Sunderland, 1983; J.N. Bulmer *et al.*, 1987). The presence of immunoglobulin in the cytoplasm of metrial gland cells (D. Bulmer and Peel, 1977; Mitchell *et al.*, 1980) adds further weight to a lymphocyte origin.

3.5.3 THE MORPHOLOGY OF THE DECIDUA

(a) Resident decidual cell

There have been many detailed histological descriptions of the decidua (both natural and artificial) in several species (Finn and Hinchliffe, 1965; DeFeo, 1967; S.C. Bell, 1983a) since the classic papers by Selye and McKeown (1935) and Krehbiel (1937). The use of Feulgen straining and the realization of the importance of DNA in the nucleus of the antimesometrial decidual cell led to the finding that the decidual cell, described by Turner as being colossal, is polyploid (Sachs and Shelesnyak, 1955) and very often binucleate. Using autoradiography, it has been shown that the nucleus of the antimesometrial decidual cell can have up to 64 times the haploid DNA content and arises by a process of endoreduplication, whilst multinucleate cells arise from mitoses without subsequent cell division (Zybina and Grishenko, 1972; Leroy *et al.*, 1974a; Ansell *et al.*, 1974). The mesometrial decidual cells are somewhat smaller but still polyploid.

The decidual cell has also been shown to acquire the ability to synthesize specific enzymes, such as alkaline phosphatase (Finn and Hinchliffe, 1964) and ornithine decarboxylase (Collawn *et al.*, 1981).

With the electron microscope a characteristic relationship between the decidual cells has been demonstrated (Finn and Lawn, 1967; Kleinfeld *et al.*, 1976). The cells send out processes which make contact with adjacent cells and very often send finger-like processes into the cell. The area of contact between cells is characterized by gap junctions. Similar gap junctions have been shown between the predecidual cells which are formed during the menstrual cycle in women, although in later pregnancy the decidual cells are separated from each other by a connective tissue matrix (Lawn *et al.*, 1971). Gap junctions are now known to be formed of connexins, and high expression of these is found in developing decidual cells (Winterhager *et al.*, 1991). Intercellular junctions are thought to be important in the flow of material from one cell to another, especially in tissue growth and differentiation (Lowenstein and Penn, 1967). Decidual cells have also been shown to contain large quantities of intermediate fibres, made of two different proteins – vimentin and desmin. The former is also present in non-decidualized stromal cells, whereas the latter accumulates predominantly after decidualization (Glasser and Julian, 1986).

In the early stages of decidualization the stromal cells around the periphery of the decidua are undergoing active division (Finn and Martin, 1967). This is in response to the decidual stimulus.

(b) Extracellular matrix

The extracellular matrix surrounding the developing decidual cells changes, especially

with regard to hyaluronic acid (Brown and Papaioannou, 1992), collagen (Kisalus *et al.*, 1987; Karkavelas *et al.*, 1988), laminin (Wewer *et al.*, 1986) and fibronectin (Grinnell *et al.*, 1982).

Hyaluronic acid disappears from the extracellular matrix as decidualization progresses (Brown and Papaioannou, 1992), and the amount of collagen is reduced considerably (Myers *et al.*, 1990), with a change to predominantly non-fibrillar type IV collagen (Aplin *et al.*, 1988) and loss of collagen type VI (Mulholland *et al.*, 1992).

Decidual cells, however, retain their ability to synthesize collagen (Oliveira *et al.*, 1991), and the diameter of collagen fibres increases with decidualization (Alberto-Rincon *et al.*, 1989). At the same time decidual cells take up collagen (Zorn *et al.*, 1989), thus contributing to the remodelling of the stroma.

(c) Vascular changes

An important early response to a blastocyst noted by the earlier workers was oedema of the stroma. Extravasation of fluid into the tissues is an early response to an inflammatory stimulus and is caused by increased permeability of the blood vessels supplying the area. This can be demonstrated by injecting pontamine sky blue or some other dye into the bloodstream. The dye binds to albumin and normally therefore remains in the vessels. Blue staining of the tissues indicates increased vascular permeability. By injecting the dye into rats over the first few days of pregnancy Psychoyos (1960, 1961) showed that an increase in vascular permeability was a very early response of the uterine stroma to a blastocyst. The injection of ^{125}I-labelled human serum has since been used to give a more accurate picture of changes in vascular permeability (Milligan and Mirembe, 1984). The dye reaction has proved to be a very important finding, not only for its inherent interest but also because it makes it possible to delineate areas of the uterus which are responding to a decidualizing stimulus (for example an implanting blastocyst) well before any change in the uterus can be seen macroscopically. It is interesting to quote the comments of Emrys-Roberts (1909), one of the earliest investigators of implantation in the guinea pig:

> serial sections were cut from one end to another. This was necessarily a laborious and trying undertaking; each individual section had to be examined since there was no macroscopic indication as to the site of the embryo. Indeed it happened that many thousands of sections have been examined fruitlessly.

(By marking out areas with the dye much fruitless work is avoided!).

Several other species also undergo the dye reaction, and it is likely that it is of general applicability (rabbit, Hoos and Hoffman, 1980; mouse, Finn and McLaren, 1967; Milligan, 1987; guinea pig, Orsini and Donovan, 1971; ewe, Boshier, 1970; sow, Keys and King, 1985, 1988; ferret, Mead *et al.*, 1988). [The dye reaction to injected oil will, however, occur in the uteri of animals which have not been sensitized for decidualization (Milligan and Mirembe, 1985), indicating that although it is a prerequisite for decidualization it is not exclusive to it.] Abrahamsohn *et al.* (1983) and Hoffman and Hoos (1984) have shown ultrastructural changes in the relevant blood vessels, including fenestrations in the endothelial cells and gaps between them.

Oedema occurs in the stroma of the human and monkey endometrium during the menstrual cycle, probably associated with a change in the permeability of the blood vessels. This does not depend on a stimulus from the blastocyst. Further increase in vascularity does however occur in the human following implantation (Bouda, 1969).

Another interesting vascular effect is the absence of a basement membrane around the large endothelial cells which form the large sinusoids in the lateral decidua (Hall, 1968,

1969). Associated with this is the disappearance of the enzyme adenosine triphosphatase (Hall, 1968). The vascular changes in the rodent uterus during early pregnancy have been studied using the transmission electron microscope (Christofferson and Nilsson, 1988) and scanning electron microscope examination of corrosion casts (Takemori *et al.*, 1984). It has been shown that the area around the implanting blastocyst (the primary decidual zone) is free of blood vessels (Rogers *et al.*, 1982a,b) and may provide a partial permeability barrier (M.B. Parr and Parr, 1989). This has been confirmed by later work (Tawia and Rogers, 1992) using an *in vivo* microscopy technique in rats. At the time of implantation an avascular area surrounded by large-diameter vessels in which the flow was sluggish was demonstrated. Leucocyte rolling and adhesion was also a feature of these vessels, which fits well with the finding of increased numbers of leucocytes in the stroma at that time (Finn and Pope, 1991).

(d) Metrial gland

The granulated cells of the metrial gland which form in the metrial triangle in rodents have been extensively studied over the last 50 years (B.L. Baker, 1948; Wislocki *et al.*, 1957; A.D. Dickson and Bulmer, 1961; L.J. Smith, 1966; Larkin and Schultz, 1968; Larkin and Flickinger, 1969; Peel and Bulmer, 1977; I. Stewart and Peel, 1977; Bulmer *et al.*, 1983; Peel, 1989) as have the similar granulated cells in the uterine stroma of the human and rhesus monkey (Cleveland, 1941; Hamper, 1955; Dallenbach-Hellweg, 1967; Cardell *et al.*, 1969; Asplund and Holmgren, 1974; J.N. Bulmer *et al.*, 1980). As with the formation of oedema and decidual cells, primate granulated cells appear in the endometrium towards the end of the menstrual cycle and are not dependent for their formation on the presence of a blastocyst. Furthermore, they are scattered throughout the stroma.

Metrial gland cells are characterized by having numerous diastase-resistant PAS-granules in the cytoplasm. By day 12 in the rat they form a mass of cells in the mesometrial triangle. The cells have only been studied in detail in the rat and mouse, where rather surprisingly they differ in size of cell and size of granule. The mouse cells and their granules are much larger (Peel and Bulmer, 1977), although the rat cells have more granules (I. Stewart and Peel, 1977). The granules have an electron-dense amorphous matrix enclosed by a close-fitting membrane, and it has been suggested they are lysosomes (Peach and Bulmer, 1965). This is supported by the localization of acid phosphatase, leucine aminopeptidase and nitrocatechol sulphatase in the granules (D. Bulmer, 1968).

In addition to the three main cell types described and the blood vessels, other cells have recently been delineated by the use of cell-surface markers (Bernard *et al.*, 1978; S.C. Bell, 1985). The best defined are the Fc receptor-bearing cells, which are probably macrophages (G.W. Wood, 1980; Kirkwood, 1981). They also bear Ia antigen (Searle *et al.*, 1983). These are also found in non-decidualized uteri (Kirkwood, 1981), but there is a higher number in the decidualized uterus (Rachman *et al.*, 1981). They are probably an infiltrating cell (S.C. Bell, 1985). Fc receptor-bearing cells have also been reported in the metrial gland (Bray *et al.*, 1978; Bray and Craggs, 1979).

3.5.4 BIOCHEMICAL CHANGES

Obviously the morphological changes in the stroma will be accompanied by biochemical changes. For a detailed account see S.C. Bell (1983a,b).

(a) Nucleic acids

Any tissue undergoing cell division will be increasing its content of DNA (Ledford *et al.*, 1978) and RNA (Miller *et al.*, 1968; Jayatilak *et al.*, 1989) and of course the reverse is true for

tissues undergoing cell death. Equally, tissues undergoing active differentiation will most likely register changes in RNA and protein content (Lejeune *et al.*, 1982). Actinomycin D halts decidualization in rats (Burin and Sartor, 1965; Sennanes and Psychoyos, 1970) and mice (Finn and Martin, 1972b), suggesting that transcription and translation are taking place. Changes in RNA content of the uterus during decidualization have been among the earliest changes recorded (Heald *et al.*, 1970; Glasser, 1972; Miller, 1973). Most of the change is due to increased ribosomal RNA synthesis (Heald *et al.*, 1972). More detailed analysis has revealed changes in the species of RNA synthesized (Heald and O'Hare, 1973; O'Grady *et al.*, 1975; Glasser and Clark, 1975). S.C. Bell (1983a) pointed out that as some of these changes occur very early in the decidual reaction they may represent the onset of rapid cell division following the initiation of decidualization. It would nevertheless be very surprising if the complex differentiative changes of decidualization were not controlled to a large extent by changes in types of RNA synthesized.

(b) Enzymes

Changes in the synthesis of several enzymes have been demonstrated. Associated with increased ribosomal RNA synthesis in the early stages of decidualization there is an increase in RNA polymerase I activity (Serra *et al.*, 1978). Another enzyme which is probably associated with RNA synthesis is ornithine decarboxylase. This is involved in the production of polyamines, which are thought to be involved in the stabilization of ribosomes, the stimulation of RNA synthesis and inhibition of RNA degradation (Tabor and Tabor, 1972). Increased activity of ornithine decarboxylase has been demonstrated in the uterus in the early stages of decidua formation either during pregnancy (Saunderson and Heald, 1974) or after the artificial induction of decidualization (Heald, 1979; Collawn *et al.*, 1981). However, Milligan *et al.* (1992) have found that the enzyme increases in the uterus in response to stimuli not causing a decidual reaction and they question an association with decidualization.

Amine oxidase has been demonstrated in the decidual portion of the human placenta, and it has been suggested that it may fulfil a maternal protective role in neutralizing high levels of polyamines derived from the feto-placental unit (see S.C. Bell, 1986).

Lysosomes contain several proteolytic enzymes. These are important in the breakdown and remodelling of tissues. During the stage when decidual tissue is growing there is a decrease in some lysosomal enzymes (acid cathepsin D: J.G. Wood and Barley, 1970; Moulton, 1974; Moulton and Ingle, 1981), with little change in others (β-glucuronidase, Moulton, 1974; Jelinek and Jelinkova, 1977; J.G. Wood and Barley, 1970). During decidual regression, mostly investigated using the artificially induced decidual reaction, there is a dramatic rise in lysosomal enzymes (Lobel *et al.*, 1965; J.G. Wood and Barley, 1970).

Whilst changes in the enzymes so far discussed can be fairly easily understood in terms of what is known to be happening during decidual growth and regression, the reason for the appearance of the enzyme alkaline phosphatase in the decidua is at present unknown. The presence of this enzyme was first shown histochemically during implantation and after oil induction of decidualization in mice (Finn and Hinchliffe, 1964). It first appears soon after the pont-amine sky blue reaction, coincidental with decidual transformation of the stromal cells (Finn and McLaren, 1967) and disappears when regression of the tissue has commenced (Hall, 1969). *In vitro* and *in vivo* the presence of the enzyme is enhanced by prostaglandin E_2 (S.A.J. Daniel and Kennedy 1987; Yee and Kennedy, 1988). It belongs to the bone–liver–kidney class of alkaline phosphatase (J.W. Pollard *et al.*, 1990).

Alkaline phosphatase has also been demonstrated biochemically in the decidua of rats and mice (Manning *et al.*, 1966) and histochemically in the predecidual cells in the human uterus (E.W. Wilson, 1969). The role, if any, played by the enzyme in the decidua is unknown, although there have been suggestions (R.N. Murdoch *et al.*, 1978). Alkaline phosphatase is also found in the embryo in association with differentiating tissues, and it has been suggested that it is in some way involved in the differentiation of cells.

Other enzymes which have been demonstrated in decidual cells but to which no function can be assigned are adenosine deaminase (Hong *et al.*, 1991; Knudson *et al.*, 1991) and renin (K.J. Shaw *et al.*, 1989). The latter is involved in salt and water balance when produced by the kidney but its functional significance in the decidua is unknown.

(c) Polypeptides and proteins

The possible functions of the decidua involve actions on tissues or organs remote from the implantation site. It is not surprising therefore to find that the secretion of proteins and smaller polypeptides by the decidua is an active area of study (see S.C. Bell, 1983a, 1985 for reviews).

For both the human and rodent, evidence is accumulating that decidual cells secrete a protein with prolactin-like properties (human, Riddick and Kusmik, 1977; Golander *et al.*, 1978; Tomita *et al.*, 1982; rat, Gibori *et al.*, 1974; Basuray and Gibori, 1980; Terranova, 1980). In women decidual tissue, whether obtained in the late luteal stage of the menstrual cycle or in pregnancy, contains prolactin. It is likely that the prolactin in amniotic fluid arises from the decidua and it has been suggested that it is related to osmoregulation across the amnion (Tomita *et al.*, 1982).

Rodents require an additional source of luteotrophin in the second part of pregnancy to maintain the corpus luteum, and it is likely that decidual prolactin supplies this. Pseudopregnancy is prolonged in the rat when deciduomata are present in the uterus (Peckham and Greene, 1948).

Many other polypeptides have been found to be secreted during the early stages of pregnancy. Some of these are associated with the differentiation of the stroma into the decidua, e.g. basement membrane materials, laminin, fibronectin, type IV collagen (Wewer *et al.*, 1986), whereas others appear to be a response of the uterus to the hormones of pregnancy (Adams *et al.*, 1981; Waites and Bell, 1984, 1989; Bell, 1985; Nieder and Macon, 1987). A particularly interesting recent finding is that the human decidualized endometrium secretes pregnancy associated endometrial α_1-globulin, which is an insulin-like growth factor binding protein. It is suggested that it may be involved in trophoblast invasion of the endometrium (S.C. Bell *et al.*, 1988).

An interesting protein which has been found in the plasma during the late secretory phase of the human menstrual cycle and early pregnancy (Bischof, 1981) is pregnancy-associated plasma protein A (PAPP-A). This is probably secreted by the decidua (Schindler *et al.*, 1984). It has been suggested that PAPP-A is a pregnancy-associated analogue of normal human α_2-macroglobulin. Bischof *et al.* (1984) speculate that PAPP-A, by its inhibitory effect on C3, reduces complement-mediated lysis and this contributes to survival of the fetal allograph. Similarly, a protein found in rat decidual tissue (decidualization-associated protein, DAP) is immunochemically identical to serum α_2-macroglobulin (S.C. Bell, 1979a,b). This protein is an acute-phase reactant (Koj, 1974) which is synthesized by the liver in response to inflammatory stimuli. Pregnancy-associated α_2-macroglobulin has been demonstrated in the serum of normal pregnant women (Stimson *et al.*, 1983) (see Waites and Bell, 1986, for a discussion of the pregnancy proteins and the acute-phase response).

There are many studies on decidual proteins being carried out at present, and with the continuing development of protein chemistry major advances can be expected in the next few years (Nieder, 1988; Weitlauf and Suda-Hartman, 1988; S.C. Bell *et al.*, 1989).

3.5.5 HORMONAL CONTROL OF DECIDUALIZATION

Decidualization is normally part of implantation, and in preparing the uterus for implantation the ovarian hormones also prepare the endometrium to respond to an artificial decidual stimulus. Changes in receptors for oestrogens and progesterone have been demonstrated in the uterus during decidualization (Martel *et al.*, 1984). Not surprisingly, animals which do not require nidatory oestrogen for implantation do not require it for decidualization (guinea pig, Deanesly, 1960). It is also found that more traumatic stimuli such as crushing can elicit a decidual cell reaction (DCR) in the rat (Rothchild and Meyer, 1942) and mouse prepared only with progesterone, although to obtain a response to intraluminal inducers, such as oil, nidatory oestrogen is necessary (Finn, 1965, 1966a). Once established, the decidual reaction including the metrial gland (Martel *et al.*, 1989) is dependent on a supply of progesterone. However, even with a continuous availability of progesterone, the decidua has a predetermined lifespan in the mouse and rat and regresses after 6 or 7 days.

The pituitary hormones of course control the secretion of the ovarian hormones and are thus critical in decidualization. There is some evidence that as well as the gonadotrophins, growth hormone and thyroxine are also involved directly in decidualization (Kennedy and Doktorcik, 1988).

In women the situation is different. Decidualization occurs during the menstrual cycle (Novak and Te Linde, 1924) and requires only ovarian hormones for its induction. Whether both progesterone and oestrogen are necessary is not known but once started, the decidua will continue to grow with progestin treatment only, and the decidual tissue is maintained as long as a source of progesterone is available (Durham, 1961; Eichner *et al.*, 1951).

3.5.6 MEDIATORS OF THE DECIDUAL RESPONSE

In spite of much work on the nature of the stimulus for the induction of decidualization (DeFeo, 1962) there is at present no understanding of the exact mechanism whereby the presence of a blastocyst triggers off the events leading to decidualization. The fact that several artificial stimuli can elicit the reaction possibly suggests that the triggering involves some fairly simple physical reaction between the contacting surfaces of the trophoblast and uterine epithelium, rather than the passage of a chemical substance from the blastocyst. Although Weitlauf (1989) has suggested that the mouse blastocyst may release factors which influence the uterus in the peri-implantation period, this has not been confirmed.

Stimuli which overtly damage the uterus, such as crushing, scratching or the insertion of a thread through the wall, are unlikely to mimic closely the presence of a blastocyst in the rat or mouse, which does not appear (from light or electron microscopic examination) to be associated with damage to the endometrium. This may not however be true for animals with interstitial implantation, such as the guinea pig, in which the blastocyst burrows actively into the endometrium. It is interesting that trauma but not oil or beads is an effective decidual stimulant in the guinea pig (Blandau, 1949) and baboon (Wheeler *et al.*, 1983). Furthermore, the endocrinological conditions necessary for the traumatic deciduoma in the rat and mouse are not identical to those necessary for implantation (Finn, 1965).

It would be expected that the instillation of

substances into the lumen of the uterus would mimic more closely the presence of a blastocyst. They are acting at the same site as the blastocyst, and require the same hormonal conditions as implantation to be effective. The chemical nature of the substances does not appear to be important. Among the most effective intraluminal inducers are various vegetable and mineral oils (including the non-toxic fluorocarbon oil, Flutec (Milligan, 1987), solutions of carrageenan and agar and air (Finn and Keen, 1962a; Orsini, 1963). It is also important to recognize that the injection of a substance into the lumen may not be mimicking the initial stimulus. The substance may pass through the surface membrane of the luminal epithelial cells and activate later stages in the message transmission process. For example, the injection of phorbol esters and calcium ionophores into the uterine lumen induces a decidual reaction (Kyd and Murdoch 1992), presumably indicating that the decidual stimulus activates the phosphatidylinositol pathway within the cell.

It is tempting to try to find a common factor associated with all the decidual stimuli. It has been suggested that the activation of Hageman factor (factor XII) may be a common attribute (Finn, 1986). This factor has a central role in the inflammatory response, blood clotting and the complement system. It is activated by the presence of negative ions, which in injury are provided by exposed collagen. Carrageenan is known to provide negatively charged particles (Warren and Kellermeyer, 1968) and the blastocyst has negative charge on its surface (Clemetson *et al.*, 1970; Nilsson *et al.*, 1974). Possibly oil also acts in a similar way.

Whatever the initial trigger, its effect will be transmitted by the luminal epithelium (Lejeune *et al.*, 1981) and will be followed by a chain of chemical changes in the epithelium and stroma leading to the various vascular and cellular events of decidualization. Possibly traumatization of the uterus activates the chain after the initial reaction at the luminal surface. As the traumatic decidual stimulus does not depend on luteal-phase oestrogen, it suggests that the changes induced by luteal-phase oestrogen on the luminal cell surface (causing the second stage of closure) in some way allows triggering of the decidual cell reaction by the blastocyst or oil.

Several substances reviewed here have been implicated in the propagation of the decidual reaction once triggered, and it is interesting that most of these are substances involved in inflammation (Solomkin and Simmons, 1983).

(a) Histamine

A possible role for histamine in the stimulation of the decidual cell reaction was put forward by Shelesnyak (1957). He and his coworkers published evidence that a decidual cell reaction could be stimulated by the intraluminal injection of solutions of histamine and prevented by the administration of antihistamines (Shelesnyak, 1960). The evidence, however, has been challenged by later workers, who were unable to confirm that intraluminal histamine caused a reaction (Finn and Keen, 1962; Banik and Ketchell, 1964) or that classical antihistamines blocked either implantation or the decidual reaction (Finn and Keen, 1962c) when injected systemically. When injected intraluminally antihistamines caused such profound disruption of cellular integrity that any effect on implantation may not be associated with an effect of histamine (Tachi *et al.*, 1970). Several workers have also shown a change in the mast cell population in the uterus at the time of implantation (Gibbons and Chang, 1972; Brandon and Bibby, 1979), and as these cells release histamine (Archer, 1959) this was taken as evidence for a role for histamine in implantation. However, the finding that the uteri of mast cell-deficient mice decidualize normally (Hatanaka *et al.*, 1982; Wordinger *et al.*, 1986) makes it unlikely that products of

these cells play an essential part in eliciting the decidual cell reaction, although it does not rule out a role for histamine from other cells.

Since the discovery of H_2 receptors and drugs which block them, interest has been renewed in a possible role for histamine, especially in the elicitation of the vascular response (Brandon and Wallis, 1977; Dey *et al.*, 1979) in association with other mediators. In support of this, it is suggested that the enzyme histamine decarboxylase may be present in the endothelium of small uterine blood vessels (Psychoyos and Martel, 1985).

(b) Prostaglandins

There is little doubt that prostaglandins and possibly leukotrienes (Cejic and Kennedy, 1991) are involved in the development of the decidual cell reaction, and many relevant studies have been published over the last two decades (Hoffman and Strong, 1976; Tobert, 1976). Their exact role in decidualization is not however settled. It is very likely that they play some role in vascular changes (T.J. Williams, 1979; Kennedy, 1979; Psychoyos and Martel, 1985) and may promote fibroblast proliferation (Hial *et al.*, 1977) and alkaline phosphatase activity (Daniel and Kennedy, 1987). Prostaglandin antagonists such as indomethacin and tranyccypromine prevent implantation and the artificially induced decidual cell reaction in several species (Castracane *et al.*, 1974; Tobert, 1976; Saksena *et al.*, 1976; Hoffman, 1978; Rankin *et al.*, 1979), as do leukotriene inhibitors in rats (Tawfik and Dey, 1988).

Concentrations of various prostaglandins increase in areas of the uterus which have been stimulated to decidualize, e.g. PGE_2 (Hoffman *et al.*, 1977; Kennedy, 1977; Evans and Kennedy, 1978; Jonsson *et al.*, 1979), PGF_2 (Saksena *et al.*, 1974; Milligan and Lytton, 1983), PGI_2 (Kennedy and Samecnik, 1978; Phillips and Poyser, 1981).

Decidual cells synthesize prostaglandins, principally PGE_2 (Anteby *et al.*, 1975; K.I. Williams and Downing, 1977; Tsang and Ooi, 1982), and the uterine stroma acquires receptor for PGE_2 when under the hormonal conditions which induce sensitivity for decidualization (Kennedy *et al.*, 1983; Psychoyos and Martel, 1985). It is suggested that the uterine epithelium releases prostaglandin, which passes to the stroma, causing decidualization; the decidual cells so produced then produce more prostaglandin to propagate the response. They are presumably involved in the signalling of decidual transformation throughout the process (Kennedy, 1985), but are probably not the initial stimulus.

(c) Cyclic AMP

Prostaglandins increase the concentration of cyclic AMP (cAMP) in many cells, so it is not surprising that there is a rapid rise in levels of the nucleotide after decidual induction (Leroy *et al.*, 1974b; Swift and O'Grady, 1976; Rankin *et al.*, 1977; Kennedy, 1983). Attempts to induce implantation in ovariectomized rats and mice with dibutyryl cAMP have given contradictory results, some workers claiming a positive effect (Webb, 1975; Holmes and Bergstrom, 1975) and others no effect (Wu and Chang, 1977). Fernandez-Noval and Leroy (1978) were able to induce implantation with non-cyclic AMP.

Adenylate cyclase, the enzyme responsible for the formation of cAMP, is activated after the application of a decidual stimulus in the rat (Sanders *et al.*, 1986; Yee and Kennedy, 1991), and alloxan, an inhibitor of adenylate cyclase, inhibits implantation. There is also alteration of adenylate cyclase activity in the rabbit endometrium during pseudopregnancy, suggesting an involvement of cAMP in the regulation of endometrial sensitivity (Fortier *et al.*, 1989).

Whilst the results from these experiments must be considered inconclusive, it is likely that cAMP is a component of the transfer of

information from the decidual stimulus to the differentiated cell.

(d) Platelet-activating factor (PAF)

PAF is a potent vasoactive agent which is involved in inflammation. In early pregnancy it is produced by mouse embryos and causes thrombocytopenia (O'Neill, 1985). It has also been demonstrated in the rabbit uterus during early pregnancy (Angle *et al.*, 1985). It has been suggested that it is involved in the signalling of the decidual cell reaction (Spinks and O'Neill, 1988). In view of the relationship of the decidual reaction to inflammation, this is a very attractive idea. However, whilst some workers have been able to obtain a decidual reaction with synthetic PAF (Acker *et al.*, 1989), others have not (Milligan and Finn, 1990). The latter authors were also not able to block implantation with PAF antagonists. At present therefore, it is not possible to be sure whether it is involved or not.

Other mediators which are involved in inflammation, such as bradykinin (DeFeo, 1962; Humphrey and Martin, 1968) and plasminogen activator (Rybo, 1966; Strickland *et al.*, 1976), have also been studied during decidualization and implantation, but at present a role for them has not been proved.

3.5.7 DECIDUAL RESPONSE OF AGED ANIMALS

As rodent females get older the size of their litters gets smaller until breeding ceases (Biggers *et al.*, 1962). This usually occurs well before the death of the mother. One of the main causes of this declining fecundity is failure of the uterus to maintain the embryos to term. This situation is different from that found in women, in whom the principal cause of reproductive senescence lies in the ovarian depletion of oocytes.

In the mouse, rat and bank vole the decidual response of the uterus to an artificial stimulus declines as the mother gets older (Finn 1966b; Shapiro and Talbert 1969; Nerquaye-Tetteh and Clarke, 1987), and this is correlated in mice with failure of the luminal closure reaction which occurs in young animals in response to ovarian hormones (Finn and Martin, 1969b). The importance of failure of decidualization in causing reduced reproductive output in aged females is discussed by Finn (1970).

3.5.8 DECIDUALIZATION AND MENSTRUATION

Menstruation is one of the most obvious signs of reproductive activity in women, and must have puzzled primitive man, long before its role in relation to pregnancy was known. The relationship of the monthly sanguinous discharge to childbearing was suggested as early as the seventh century when Isodore of Seville (see Grant, 1978) wrote:

> After many menstrual days, however, the semen is no longer germiable because there is no menstrual blood by which the ejaculate can be irrigated. Thus semen does not adhere to the female parts; lacking this power to adhere it is lost. Likewise thick semen also lacks the power of growth, being unable to mix with the female blood because of its own excessive thickness. This is why men or women become sterile; from excessive thickness of semen or blood, or from excessive thinness.

Isodore had also noted that 'women are the only menstrual animal'. Considering that the bitch, the animal closest to man in his habitat, does show occasional vaginal discharges of blood, this observation, although correct, is rather surprising. In fact, in Victorian times there was strong support for the idea that menstruation was analogous to pro-oestrous bleeding in dogs.

The loss of blood at menstruation was assumed by the early medical writers to serve

some useful function. They would have had no way of knowing the cellular make-up of the discharge but Isodore, nevertheless, appreciated that it was not ordinary blood:

> On contact with this gore, crops do not generate, wine goes sour, trees lose their fruit, iron is corrupted by rust, copper is blackened. Should dogs eat any of it they go mad. Even bituminous glue which is dissolved neither by rain nor by [strong] water, polluted by this gore, falls apart by itself.

Because of the occasional putrefying appearance, smell and pain it was assumed that the period was a method of detoxification of the blood poisoning encountered by women (Medvei, 1982). It was considered to be a way of ridding the body of excessive blood ('the menstrual flow is woman's superfluous blood, it is termed 'menstrual' menstrua, because of the phase of the light of the moon by which this flow comes about' – Isodore) and if women failed to menstruate then bleeding was thought to be necessary. Trotula of Salerno, in her eleventh-century book *The Diseases of Women*, gives precise details of the necessary procedure, apparently quoting the work of Galen:

> If the menses are lacking and the woman is thin, the vein under the inner arch of her foot, the internal saphenous, should be lanced. On the first day from one foot, on the following day the other foot – the blood to be drawn as the case demands.

For hundreds of years the correct relationship of menstruation to reproduction was not appreciated. In the middle of the nineteenth century the study of reproductive processes in animals was well under way. Man was now aware of his descent from other animals, and there was a strong move to extrapolate from other mammals to man. Pouchet in 1842 suggested that menstruation corresponded to the period of sexual excitement in other animals. This view seems to have been held by many of the Victorian biologists (Heape, 1900; Bryce and Teacher, 1908; Marshall, 1910), with a certainty characteristic of the age. Heape (1900) stated 'the homology of the process in the bitch with that already described for the monkey is absolutely certain'. Marshall (1910) in the first edition of this work was equally certain and wrote at length on the similarity of the period of menstruation in women to the period of heightened sexual activity in other mammals and concluded that it demonstrated the remains of a primitive oestrous cycle.

Medical writers of the time, however, were putting forward an alternative view, that menstruation 'is only a secondary process, a degeneration of the mucous membrane which from a failure of pregnancy has not been able to fulfil its purpose' (Grosser, 1910). Gynaecologists held that menstruation was unique to some primates and occurred between successive oestrous cycles, not in association with them (Hartman, 1932). This view, that menstruation is associated with failure of implantation, is now accepted.

Disorders of menstruation are common, and the process has been studied in considerable depth from the medical point of view (reviewed by Shaw and Roche, 1980). The problem of why women should bleed at the end of the cycle if implantation has not taken place, whereas most other animals do not, has however received less attention. Corner in 1923 conjectured that:

> In order to provide for the highly specialized embryonic implantation of primates with its opening of maternal blood vessels into the intervillous space the endometrial process is carried so far as even to cause bleeding into the tissues during the last days of the interval at the time during which the early embryo is to be implanted. The action of the embryo alters the latter part of the process so as to inhibit or limit the haemorrhage, but if no embryo be present to utilize the extravasation, then

> the blood escapes into the uterine lumen and visible bleeding occurs.

He goes on to suggest that this is the reason for the total absence of menstruation in species which have a less specialized form of implantation. More recently, Fox (1985) concluded that the reason women menstruate is 'the very rapid rate at which oestrogen and progesterone levels fall as the corpus luteum degenerate, in some species oestrogen and progesterone values decline at a much slower rate and menstruation is avoided although only at the cost of lengthening the menstrual cycle'. In his view 'menstruation is the price that women pay for shortening of their menstrual cycle which allows for a greater number of possible conceptions during their limited years of fertility'.

The latter very teleological view is not in accordance with most of the known facts; many non-menstruating animals have shorter cycles than women, including some non-menstruating primates; and many animals have more limited years of fertility than women. There is in any case little evidence that progesterone levels fall faster in women than in other animals at the end of the cycle. Whilst it is possible to induce menstruation in the cycle in some primates by ovariectomy (van Wagenen and Aberle, 1931; Cleveland, 1941), it is not possible in other cycling animals. Corner's suggestion is likely to be nearer the truth because it takes account of a fundamental difference between the methods of implantation found in different species. However, his view that the blood vessels open into the tissues in preparation for bleeding into the intervillous spaces, and the suggestion that it is the direct presence of the embryo which prevents the bleeding, could not take account of the later finding that menstruation can be prevented by the administration of extracts of the corpus luteum or exogenous progesterone (P.E. Smith and Engle, 1932; Corner, 1935). From this we now know that the blastocyst prevents menstruation indirectly by maintaining the corpus luteum and that opening of the vessels is the result of degenerative processes in the stroma. The problem is why the fall in progesterone at the end of the cycle causes bleeding in women and not in other animals. Recently, it has been suggested that this is due to a fundamental difference between the species in the processes taking place in the endometrium during the earlier part of the oestrous or menstrual cycle (Finn, 1986, 1987). It was noted earlier that during this time the tissues of the endometrium are prepared for implantation by cell proliferation and differentiation. However, complete differentiation of the stroma into the decidua does not take place in non-menstruating animals in the absence of a blastocyst and decidualization is not, therefore, part of the infertile cycle. In women, on the other hand, the blood vessels and stromal cells differentiate, even in the absence of a blastocyst, at the end of every cycle (Bartelmez, 1933).

All species require progesterone for stromal differentiation, and if the level of the hormone drops (as it does at the end of the menstrual cycle) then the decidualized tissue breaks down. It has been known for a considerable time that removal of the ovaries from pregnant animals causes degeneration of the placenta (Deanesly, 1972, 1973). Similarly, removal of the source of progesterone from animals in which a decidual reaction has been induced artificially causes decidual breakdown.

The cellular and vascular changes in the decidualized endometrium of mice following a fall in progesterone levels has been studied in detail to determine whether the changes can provide a clue to menstruation (Finn and Pope, 1984). Ovariectomized mice were prepared with oestrogen and progesterone and oil injected into the uterine lumen. No further hormone was given and animals were killed at intervals and their uteri examined histologically. The first change was a massive influx of leucocytes into the stroma. This is

the first observable change in the uterus of primates before menstruation (Novak and Te Linde, 1924). Leucocyte infiltration was followed by congestion of blood vessels with swollen erythrocytes, and then breakdown of the walls and extravasation of red blood corpuscles into the tissues. At the same time the decidual cells underwent typical degenerative changes and eventually a mass of blood and tissue debris was extruded into the lumen. In about 50% of cases a sanguinous discharge was clearly visible in the vagina, but the bleeding into the tissues was less than in menstruation. Nevertheless, the early invasion by leucocytes (Novak and Te Linde, 1924) and the extravasation of blood is reasonable evidence for the hypothesis of menstruation discussed above.

Further evidence comes from three non-primate animals which menstruate, the elephant shrew (*Elephantulus myurus jamesoni*) (van der Horst and Gilman, 1941) and the bats; *Glossophaga soricina* (Hamlett, 1934; Rasweiler, 1979) and *Molossus ater* (Rasweiler, 1991). The elephant shrew is a member of the family *Macroscelididae* and is closely related to primates (some authorities classify the *Macroscedididae* with the primates). It has a very interesting cellular reaction in the endometrial stroma during the late luteal phase of the cycle. A small area of each uterine horn forms a swollen polyp which is well vascularized and oedematous and contains large stromal cells with big nuclei which resemble decidual cells. At the end of the cycle the polyp breaks down and bleeding occurs from it. This naturally occurring phenomenon is very similar to the breakdown of the artificial deciduoma in mice. In the bat, *Molossus ater*, decidualization has been demonstrated to occur spontaneously (Rasweiler, 1991), whilst in *Glossophaga soricina* Hamlett (1934) found that the endometrium thickens greatly in preparation for implantation and then in the absence of a fertile egg the hypertrophied endometrium disintegrates and sloughs off with marked extravasation of leucocytes and blood cells. Further information on this species is needed.

The main non-human animal in which menstruation has been studied is probably the rhesus monkey (Hisaw, 1935), an Old World primate which menstruates as part of the cycle. These animals have a very unusual uterine response to the implanting blastocyst with the formation of a plaque of epithelial cells and very little if any decidual cell transformation of the stromal cells. However, the endometrium does undergo the early stages of the decidual reaction with intense development of the blood vessels (Phelps, 1946) and oedema of the stroma. These occur at the end of the cycle and are hormone dependent. Furthermore, there are changes during the cycle in the occurrence of the granulated K cells. In view of this it seems likely that transformation of stromal fibroblasts into decidual cells may not be the essential factor in menstruation but rather that the changes in the endometrial blood vessels and maybe in the extracellular matrix which precede implantation, or possibly factors originating in the granulated cells, are of greater importance.

It has been suggested that the presence of spiral arteries is the crucial factor in menstruation (Reynolds, 1947; S.T. Shaw and Roche, 1980), although this has been challenged on the basis that New World primates, which do not have spiral arteries, do menstruate. Furthermore, with a corrosion vascular casting/scanning electron microscope method, spiral arteries have been demonstrated in the rat endometrium (Rogers and Gannon, 1981), suggesting that too much significance should not be placed on the tortuosity of the arteries. This may simply be a reflection of growth of vessels relative to other stromal tissue, and not represent a fundamental difference in the vasculature of the two species.

3.6 EVOLUTION OF THE ENDOMETRIAL RESPONSE TO IMPLANTATION

From the brief introductory discussion of the various methods of implantation found in different species and the more detailed description of implantation changes, it is apparent that there is a gradually increasing complexity in the cellular response of the uterus to the blastocyst, culminating in the complex vascular and cellular changes of the decidual cell reaction. It is interesting to enquire what has caused this evolution and what advantage it has meant for the animal.

The evolution from the simplest forms of viviparity to deep embedding of the ovum in the wall of the uterus, whilst presumably conferring advantages on the species, will have presented considerable problems to the defence mechanisms of the animal. Very early in evolution animals had developed methods to combat and prevent the ingress into the tissues of foreign organisms (viruses, bacteria and parasites) and to counteract the trauma inflicted by them or by other means. Two interrelated mechanisms are involved – the inflammatory reaction and the immune response. Inflammation is the first to be encountered and is phylogenetically the more primitive response. Ryan and Majno (1977) describe it as an all-purpose defence system. Unless the animal could negate or overcome the inflammatory response of the endometrium internal development of embryos could not have progressed to deep implantation of the blastocyst in the uterine stroma.

3.6.1 INFLAMMATION AND DECIDUALIZATION

Many workers over the years have noted the similarity of the uterine response to an implanting blastocyst to that of inflammation, especially the similarity of the decidual reaction to the inflammatory granulation tissue reaction (Turner, 1873; Creighton, 1878). Fothergill (1899) suggested that the decidual cell had been evolved as a protection against the injurious invasion of the uterine wall by the fetal elements of the placenta, and Wade and Watson (1908) described the decidual cells as being similar to 'young fibroblasts such as are seen in the process of repair'. Loeb's classic discovery that trauma of the endometrium will stimulate a decidual reaction added credence to this view (Loeb, 1907). Several workers have reiterated this idea (Huggett and Hammond, 1952; Finn and Keen, 1963; Finn, 1986).

The fact that myofibroblasts in granulation tissue have gap junctions (Gabbiani *et al.*, 1971), similar to decidual cells, has also been noted (Finn, 1986). Psychoyos's (1960) finding that the endometrial blood vessels were more permeable in areas of the uterus in which blastocysts were implanting followed similar findings for tissues in which inflammation is taking place. Increased blood flow and vascular permeability are early signs of inflammation. Apart from the decidual cells, some of the other cells which are found in the endometrium at the time of decidualization are thought to be derived from the bone marrow, indicating a kinship between inflammation and the immune response. De *et al.* (1993) have shown expression of interleukin 1, interleukin 6 and tumour necrosis factor α in the mouse uterus during the peri-implantation period. These are normally associated with the inflammatory reaction.

Many of the mediators of the decidual response discussed earlier are involved in inflammation, for example histamine and prostaglandins, and at least one of the proteins produced by the decidua is similar to an acute-phase protein of inflammation.

The incidence of polymorphonuclear leucocytes is interesting. During the early stages of implantation in the mouse and rat or during the early stages of the oil decidual cell reaction there is an increase in the incidence of leucocytes in the stroma (Finn and Pope, 1991) preceded by leucocyte adhesion to the

endothelium (Tawia and Rogers, 1992). Once the decidual reaction is developed, however, polymorphs are rare. However, if the supply of progesterone is removed they appear in large numbers (Deanesly, 1972, 1973; Staples *et al.*, 1983; Finn and Pope, 1986), which of course happens in menstruation (Novak and Te Linde, 1924). Under these circumstances the course of events in the uterus follows fairly closely the acute inflammation response. It is suggested (Clemens *et al.*, 1977) that progesterone has an effect on the inflammatory reaction by altering cell motility and thus inhibiting ingress of leucocytes. In this way an acute inflammatory response to a foreign body is converted into a mechanism for protection of the embryo and possibly the uterus (Finn, 1986). In women this has evolved to the stage where the whole reaction proceeds without the presence of the blastocyst but in anticipation of it.

3.6.2 IMMUNE RESPONSE AND DECIDUALIZATION

Having converted the inflammatory response to the blastocyst into a protective rather than a destructive mechanism, there is still the problem of the immune response. The embryo and associated membranes will carry antigens foreign to the mother and it would be expected that the mother's immune mechanisms would mount an attack on them. The reason this does not happen has been the subject of intensive investigation (see Carter, 1984, for review). The main relevant point in the present context is the extent to which the cellular reaction at implantation is involved in preventing immunological rejection. Several workers (Tekelioglu-Uysal *et al.*, 1975; S.C. Bell, 1983b) have put forward the hypothesis that the decidual cell reaction protects the embryo from any immune reaction mounted by the mother.

Various lines of evidence point to such a immunological role. Some studies have shown variations in the infiltrating cells (bone marrow origin) around the time of implantation (Bernard *et al.*, 1981; Parr and Parr, 1986), and some cells in the mouse uterus have been shown to be immunosuppressive (Hunt *et al.*, 1984; Daya *et al.*, 1985; Clark and Chaouat, 1989). Extract of decidual tissue from rats suppresses primary antibody response *in vitro* (Kouttab *et al.*, 1976), and supernatants from short-lived cultures of mouse decidual cells have immunoregulatory activity (Badet *et al.*, 1983). Recently, D.A. Clark *et al.* (1990) have demonstrated an immunosuppressive molecule related to transforming growth factor β in decidua and various cytokines including interleukins, and colony-stimulating factors have been implicated (see D.A. Clark, 1993, for review). Type 1 interferon has also been demonstrated in the decidua (Yamamoto *et al.*, 1992).

The presence of immunoglobulins in metrial gland cells is well documented (D. Bulmer and Peel, 1977; Mitchell *et al.*, 1980, 1981; Matthews *et al.*, 1985), and their probable bone marrow origin was discussed earlier. It has been suggested that they are natural killer-like cells (E.L. Parr *et al.*, 1987, 1990; Ginsburg *et al.*, 1989; Linnemeyer and Pollack, 1991), which would indicate a role in the immunological response, as would the finding that they produce the cytokine interleukin 1 (Croy *et al.*, 1991).

3.6.3 OTHER POSSIBLE FUNCTIONS OF THE DECIDUA

If the decidua has evolved in response to the need to overcome problems associated with entry of the blastocyst into the stroma of the uterus then its primary function would be associated with this need for protection. The presence of tight junctions and immune competent cells would certainly point in this direction.

However, other functions have been suggested, and there is no reason to rule out the possibility that, having evolved in response to a protective need, other functions

have appeared later. Prolactin-like proteins synthesized by the decidua may have a role in maintaining the corpus luteum or in preparing the mammary gland for lactation, or they may be important in the control of water transport across fetal membranes.

The presence of large amounts of glycogen in decidua led some workers to suggest a nutrient role. Possibly the decidua acts as a reservoir of carbohydrate (glucose) for the developing embryo. Small molecules could easily pass through the gap junctions between decidual cells and into the blood vessels supplying the embryo or pass directly to the trophoblast.

DeFeo (1967) suggested that one of the functions of the decidua may be to ensure separation of developing placentae, especially of their blood vessels. If this were correct one would expect decidualization to be associated with polytocous species. This is clearly not the case. Sows give birth to litters containing many young but do not decidualize, whereas women usually have only one baby at a time but the uterine stroma undergoes considerable decidualization. Of course this does not mean that when decidualization occurs in polytocous species it does not have this desirable effect but, as discussed earlier, spacing of the blastocysts along the length of the uterus has occurred well before decidualization takes place, so it is unlikely that decidualization has evolved in response to the need for separation of the embryos.

It is difficult to explain several of the main features of decidual tissue with any of the suggested functions. Why do decidual cells have two nuclei which are mostly polyploid? What is the function of alkaline phosphatase? At present we do not have the answers to these and many other questions about this fascinating tissue.

ACKNOWLEDGEMENT

I am very grateful for the valuable assistance of Mrs Audrey Meade in the preparation of this manuscript.

4.1 INTRODUCTION

This review of vertebrate placental structure attempts to integrate some of the considerable body of work done using electron microscopic and other techniques since Amoroso's classic 1952 chapter. The reference list concentrates on the most recent work. Mossman (1987) provides the best comprehensive list of placental references. This chapter is mainly concerned with providing data to facilitate broad comparisons of structures and secretions both during development and in their final form with a view to relating them to the functional activity of the placenta. The remarkably wide variety of structures in the mature placenta develops from a basically similar repertoire of extraembryonic membranes as typified in the amniote egg, and the diversity can be further simplified by use of straightforward structural criteria. The major problem is to relate those criteria to the wide range of functions served by the placenta. A few non-amniotes have developed analogous structures which serve similar functions to the extraembryonic membranes, and these offer further insights into the requirements for successful fetal development (Hagan, 1951; Woollacott and Zimmer, 1975; Amoroso *et al.*, 1979; Bone *et al.*, 1985).

The placenta developed as an organ of physiological exchange to take advantage of the protection and egg economy provided by the adoption of viviparity. The initially small area of fetomaternal apposition is usually enormously increased by folding and refolding as it proliferates in parallel with the growth of the fetus. The main functions of the placenta are to act as a surrogate fetal lung, gut and kidney and to camouflage the usually allogeneic fetus from the mother's immune system (Lala *et al.*, 1983; Gill and Wegmann, 1987).

The surrogacy requires efficient exchange of a necessarily wide range of metabolites and hormones using many different types of transport processes (passive diffusion, active transport, pinocytosis and phagocytosis), all favoured by a reduction in the separation of fetal and maternal blood flows (Moll, 1985; Munro, 1986).

The immunological camouflage is vital to avoid recognition by the multifactorial array of cellular and hormonal mechanisms mediating sensitization and immune rejection and is best served by the provision of a barrier between the two circulations (Amoroso and Perry, 1975).

Since the surrogacy and camouflage requirements are so complex and mutually antagonistic (it being very difficult to adequately conceal and feed an invading cellular army) it is perhaps not surprising that such a wide variety of structures has evolved as solutions to these two multifaceted major problems. In addition, a system for rapid disposal of the placenta with minimum trauma is essential and there are constraints of gross size, habitat (arboreal gliding versus aquatic diving) and lifestyle (secure den versus run-as-soon-as-born) further modifying the requirements defining a successful placenta.

Perhaps because of these various and usually conflicting pressures, there seems to be no straightforward progression to a unique 'best', most efficient placenta in parallel with the generally accepted course(s) of evolution of placental animals. Different groups of mammals have evolved different structural solutions, all originally from a common pattern of membranes modified by a general trend to a reduction in separation between fetal and maternal circulations. The greater the understanding of these structural solutions the easier it should be to design experiments to elucidate the manifold functions of the placenta, to establish how best to judge the 'efficiency' of a placenta and to plan strategies to reduce the considerable prenatal embryo losses (Wilmut *et al.*, 1986). Many of these functions are modified by hormones and their role

is discussed in section 4.4 on placental endocrinology.

4.2 GENERAL CHARACTERISTICS AND DEFINITIONS

4.2.1 PLACENTA

The most comprehensive definition is that of Mossman (1937): 'an apposition of parental, (usually maternal) and fetal tissue for the purposes of physiological exchange'. However, Steven's suggestion of 'an arrangement of one or more transporting epithelia between fetal and maternal circulations' more vividly encapsulates the functional aspects.

Mossman's definition is wide enough to cover the situations found in a variety of non-amniotes: tunicates, seahorses, some insects, fishes and amphibians as well as the amniotes (reptiles and mammals). The degree of apposition *in vivo* is sometimes difficult to establish because of technical problems of fixation and tissue preparation. There is good reason to believe that it is very close, often including microvillar interdigitation between fetal and maternal epithelia in the amniotes, but a shell or shell membrane remnant may persist in most reptiles and some fish (sections 4.3.1 and 4.3.4).

The tissue on the maternal side of the apposition is usually a derivative of either ovarian, oviductal or uterine epithelium or connective tissue.

The fetal component is invariably a derivative of the cellular ectodermal epithelium (trophoblast) which formed the blastocyst surface. This epithelium together with internal membranes of the conceptus eventually forms the choriovitelline and chorioallantoic placental structures.

Physiological exchange covers a range of transport processes from simple diffusion of O_2 and CO_2 to the uptake of uterine secretions and maternal red blood cells. There is increasing evidence that mature placentas have different regions for the different forms of uptake (section 4.2.5a) and also that different types of placenta have evolved different methods for the uptake of particular nutrients (e.g. iron, see section 4.2.3f).

4.2.2 EMBRYONIC MEMBRANES

The extraembryonic membranes of the vertebrate conceptus form from, and are in continuity with, the three germ layers (ectoderm, mesoderm and endoderm) of the embryo. They provide the basis for the placental structures essential for the physiological maintenance and protection of embryos within the egg or uterus (Figure 4.1; Mossman, 1937, 1987; Steven, 1975a).

(a) Yolk sac

This is formed by the enclosure of the yolk initially by cells from the embryonic disc which form a single cellular layer of ectoderm (unilaminar yolk sac, vitelline sac or omphalopleur) (Figure 4.1). Subsequent migration of a layer of endoderm internal to the ectoderm forms a bilaminar yolk sac, and finally growth of mesoderm between the first two produces a trilaminar yolk sac. If no yolk is present the last two membranes develop in the same way after a hollow unilaminar blastocyst is produced from the solid ball of cells forming the morula.

In the fishes and amphibians the mesoderm of the trilaminar yolk sac forms the blood vessels which vascularize the yolk sac and transport its contents to the growing embryo. This vascularized yolk sac persists in some fishes after the release of the embryo from the investments of the egg. Retention of the developing embryo within the mother allows the possibility of modifying the vascularized yolk sac into an organ for direct fetomaternal exchange. Several of the cartilaginous fishes (elasmobranchs – skates and rays) have developed such a placental system whereas bony fishes (Osteichthyes) and amphibia have modified other parts of their

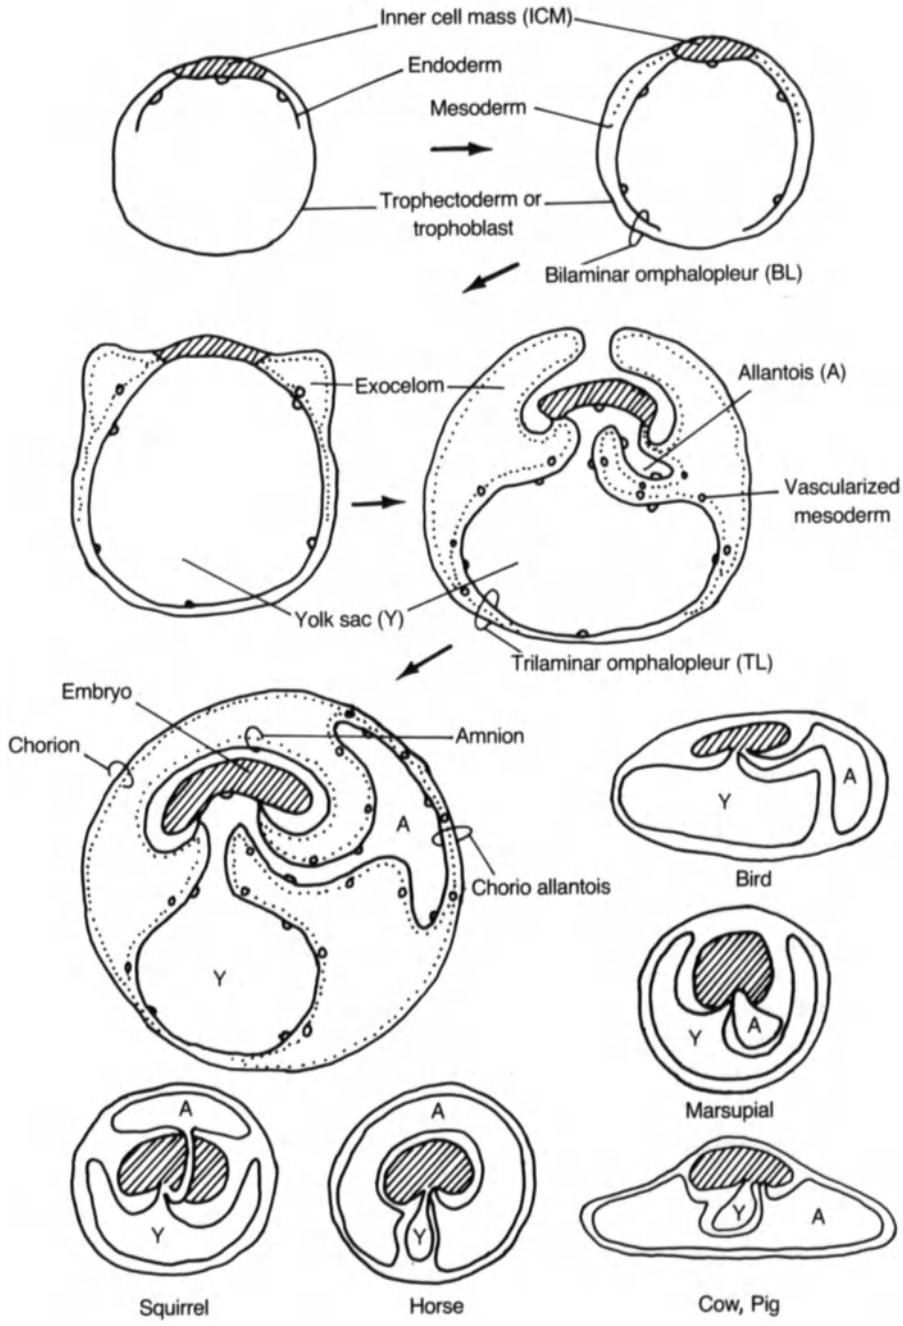

Figure 4.1 Development of the basic extraembryonic membranes with diagrams of the definitive disposition of yolk sac and allantois in various animals.

body surfaces for the same purpose (section 4.3.2).

In reptiles and mammals the initial spread of the mesoderm converts only the top part of the bilaminar yolk sac into the vascular trilaminar form. This is the basis for the development of the other extraembryonic membranes typical of the amniotes: chorion, amnion and allantois (Figure 4.1).

(b) Chorion, amnion and allantois

Growth of these membranes starts when the mesoderm of the partly trilaminar yolk sac splits to form the exocoelom in continuity with the embryonic coelom (Figure 4.1). The subsequent development of the mesoderm depends on whether it is associated with ectoderm or endoderm. Mesoderm plus endoderm (gut wall, splanchnopleur = definitive yolk sac wall) vascularizes very readily, whereas mesoderm plus ectoderm (body wall, somatopleur = chorion) only rarely produces blood vessels.

This chorion (ectoderm plus nonvascular mesoderm) produces folds which enclose the embryo to form the fluid-filled amniotic sac (Figure 4.1). Inside this the embryo can develop free of asymmetric constraints, in a shock-absorbing and compression-resistant environment. The amniotic membrane is thus derived directly from the chorion. In a few animals the amnion forms by cavitation (see Figure 4.2, rat and mouse).

As the amniotic folds fuse an endodermal vesicle grows from the hind end of the embryonic gut to form the allantoic vesicle, covered from its inception by vascular splanchnopleuric mesoderm. The allantois is in close anatomical association with the developing urogenital system of the embryo and acts as a site for waste deposition. Its rich blood supply also allows it to develop as an organ of respiratory exchange when it grows through the exocoelom to fuse with the chorion which surrounds the embryo (Figures 4.1, 4.2 and 4.75).

(c) Variations on the basic system

These membrane developments provide the basic systems which are common to all amniotes and can usually be recognized at least at the earlier stages of placental growth. The band of vascularized yolk sac fused with the ectoderm forms the fetal basis for the choriovitelline placenta and the vascularized allantois plus chorion forms the fetal part of the chorioallantoic placenta. Both are functional through most of prenatal development in reptiles, monotremes and marsupials (Figures 4.16 and 4.17).

Choriovitelline placenta

In eutherian mammals the choriovitelline placenta functions only for a short time and varies considerably in extent in different orders. In carnivores and some ungulates it may form an extensive area in early pregnancy, but eventually the vascularized yolk sac is completely separated from the chorion by expansion of the exocoelom. In most rodents, lagomorphs and insectivores formation of the trilaminar choriovitelline placenta, if it occurs at all, is restricted by the persistence of a large bilaminar segment forming the lower half of yolk sac and conceptus. A very different sort of yolk sac placenta is formed subsequently when expansion of the exocoelom invaginates the vascularized embryonic (top) half of the yolk sac into the bilaminar abembryonic (bottom) half to provide a multilayered cup apposed to the endometrium. The yolk sac cavity is reduced to a mere slit and the resultant layers referred to as an 'incompletely inverted yolk sac placenta' (Figures 4.2 and 4.3).

Loss of the non-vascularized bilaminar yolk sac layers adjacent to the endometrium produces complete inversion (Figures 4.2 and 4.3). What is 'inverted' is the sequence of tissues at the maternofetal interface. The choriovitelline placenta has maternal tissue: fetal ectoderm, mesoderm, endoderm; the

inverted yolk sac placenta has maternal tissue: fetal endoderm, mesoderm.

The choriovitelline placenta is usually transitory, but the inverted yolk sac type may persist to term and form part of the wide range of mature placental structures developed from the extraembryonic membranes. For example, the ungulates have a mere relic of a yolk sac but an enormous chorioallantois; the marsupials retain a large functional trilaminar choriovitelline placenta with a persistent bilaminar area and an allantois that does not usually reach the chorion; some insectivores and rodents have both inverted yolk sac and chorioallantoic placentas which function up to parturition (Figures 4.1, 4.2 and 4.3). The type of implantation can also greatly affect extraembryonic membrane development.

Implantation and membrane development

Implantation of the blastocyst, the initial apposition of fetal and maternal surfaces, usually occurs over the entire uterine luminal surface. However, some animals have very small blastocysts which develop in a narrow endometrial cleft (mouse, rat) or actively invade the endometrium (guinea pig, man: referred to as interstitial implantation) (section 4.2.9).

Presumably, because of lack of space around the conceptus, the development of the embryonic membranes is considerably modified in species with interstitial implantation although the basic pattern described above can be recognized if sufficient stages are available. The major differences are that part of the original outer ectodermal layer may be lost at a very early stage; the amniotic sac forms by cavitation in a solid mass of cells rather than by folding; and the allantoic endodermal vesicle may be very small or absent so that the allantois is replaced by a solid rod of mesoderm. Development of the placental membranes is compressed in both time and space and the homologies of the membranes can be appreciated best from comparative diagrams (Figure 4.2).

4.2.3 TYPES OF CHORIOALLANTOIC PLACENTATION

(a) Introduction

The great diversity among chorioallantoic placental structures has led to many attempts to devise a classification which would categorize only those common structural features which may be used as a valid basis for evolutionary comparisons and experimental investigations of function. No classification scheme based on a single criterion has proved adequate and the current practice is to use several in parallel, which produces convenient and possibly instructive groupings rather than necessarily exclusive categories.

The simplest criterion is the shape of the term placenta, but potentially more relevant to physiological exchange is the histological structure and organization of the layers separating fetal and maternal blood circulations at the fetomaternal interface (Grosser classification, Amoroso, 1952; Steven, 1975a). The structure of areas outside or bordering the main placenta (accessory or paraplacental regions) and the amount of maternal tissue shed at parturition are also characteristic. These criteria all refer to the structure at term but the developmental history of the placental membranes may also provide important clues to functional relationships.

(b) Classification by shape

The fetomaternal exchange area is enormously increased by elaboration of villi or folds. The distribution of the chorionic villi is characteristic among families and has four main categories (Figure 4.4).

1. Diffuse: villi over entire surface, e.g. pig, horse.

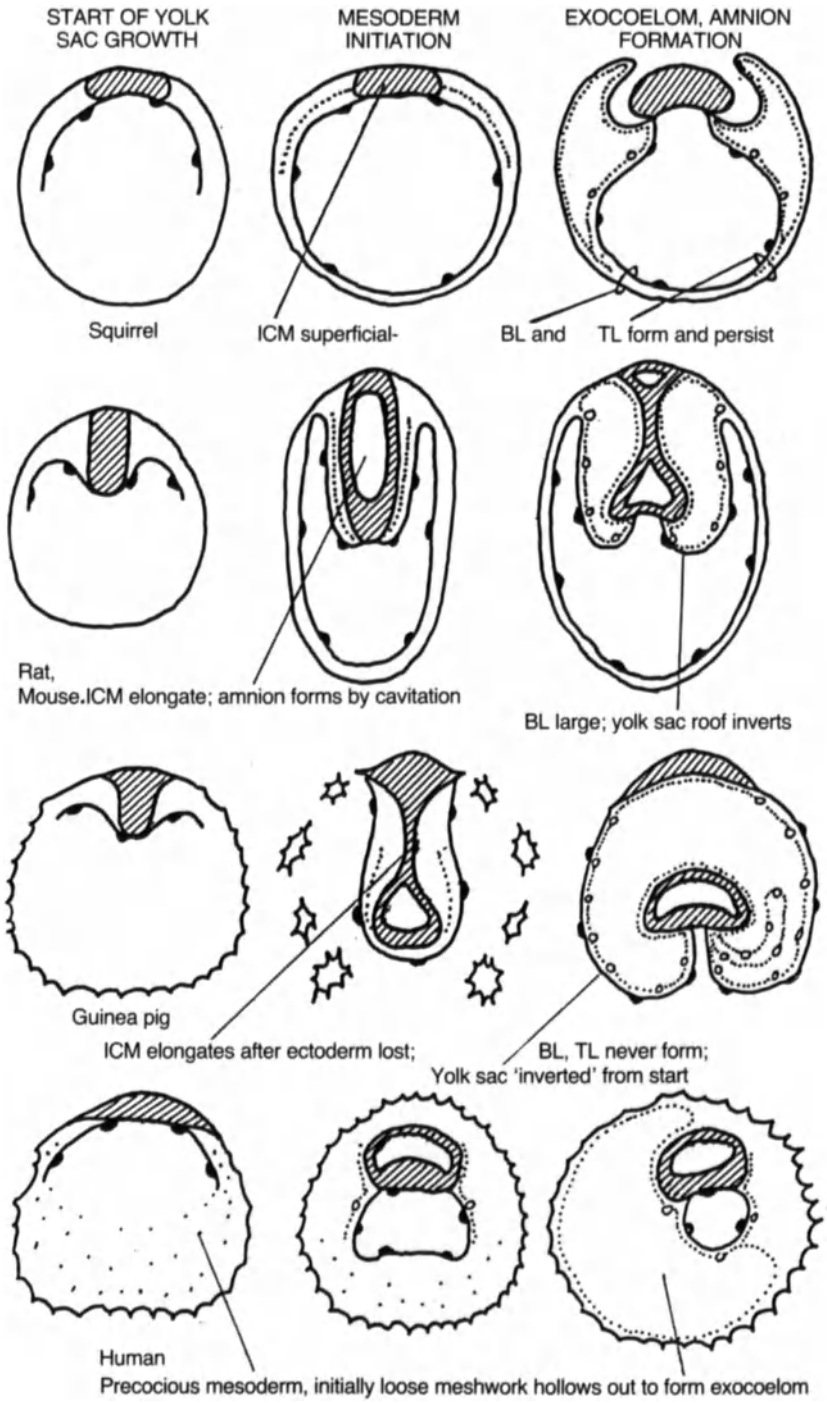

Figure 4.2 Development of placental membranes in squirrels, rat and mouse, guinea pig and human. For identification of individual membranes see Figure 4.1.

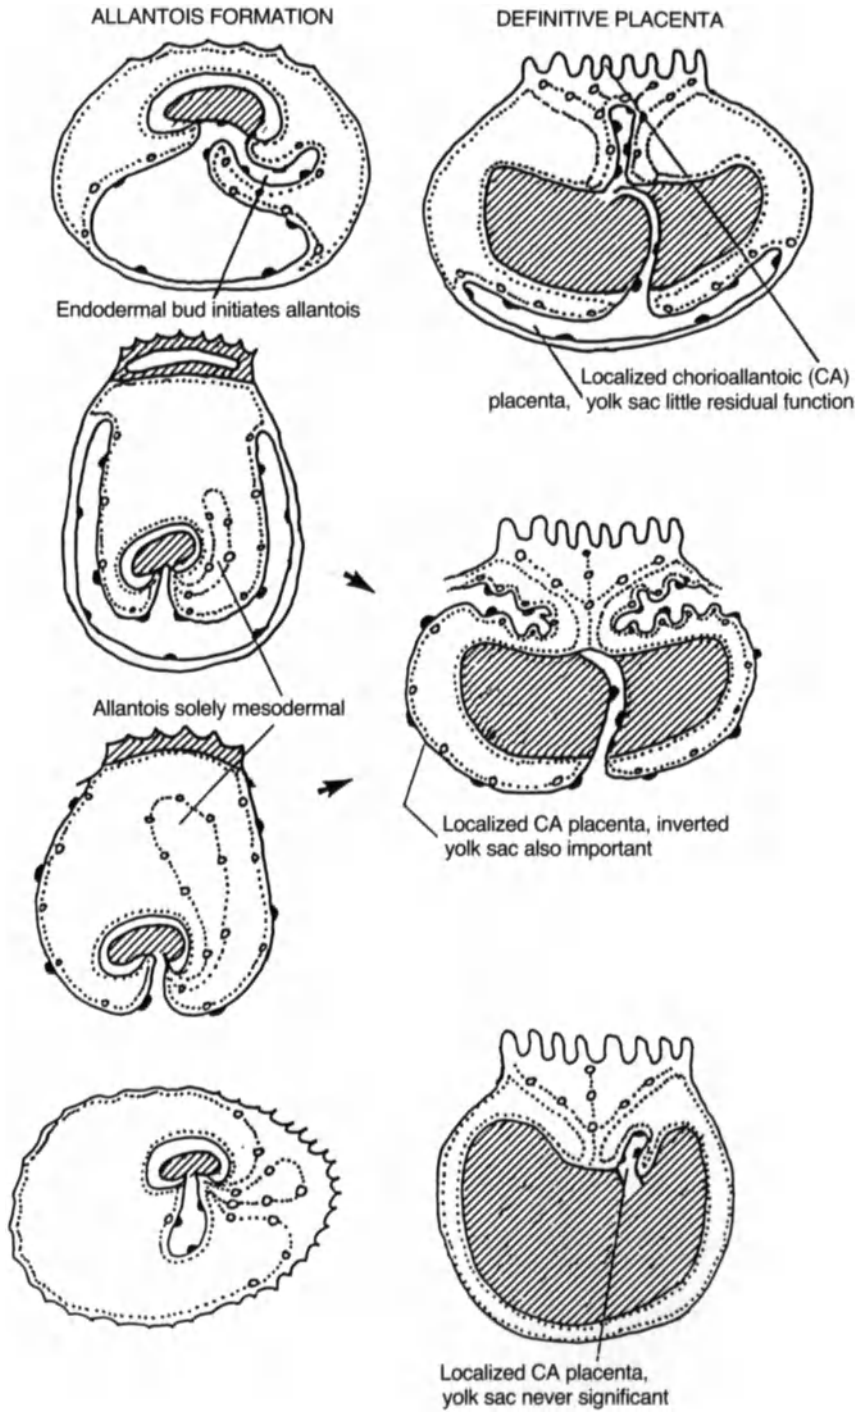

ALLANTOIS FORMATION
DEFINITIVE PLACENTA
Endodermal bud initiates allantois
Localized chorioallantoic (CA)
placenta, yolk sac little residual function
Allantois solely mesodermal
Localized CA placenta, inverted
yolk sac also important
Localized CA placenta,
yolk sac never significant

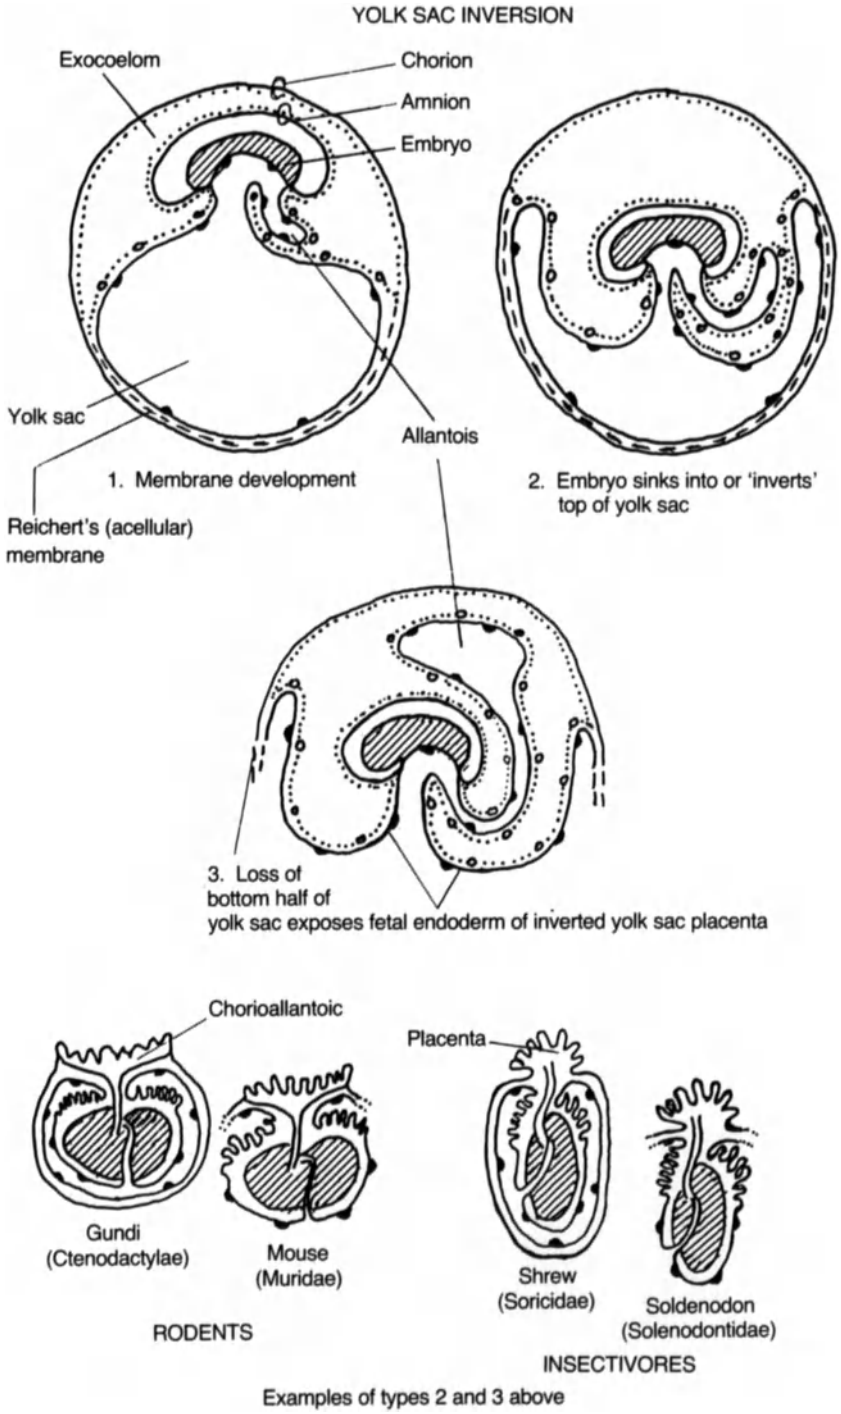

Figure 4.3 Development of the inverted yolk sac, with examples of definitive yolk sac placentation in rodents and insectivores.

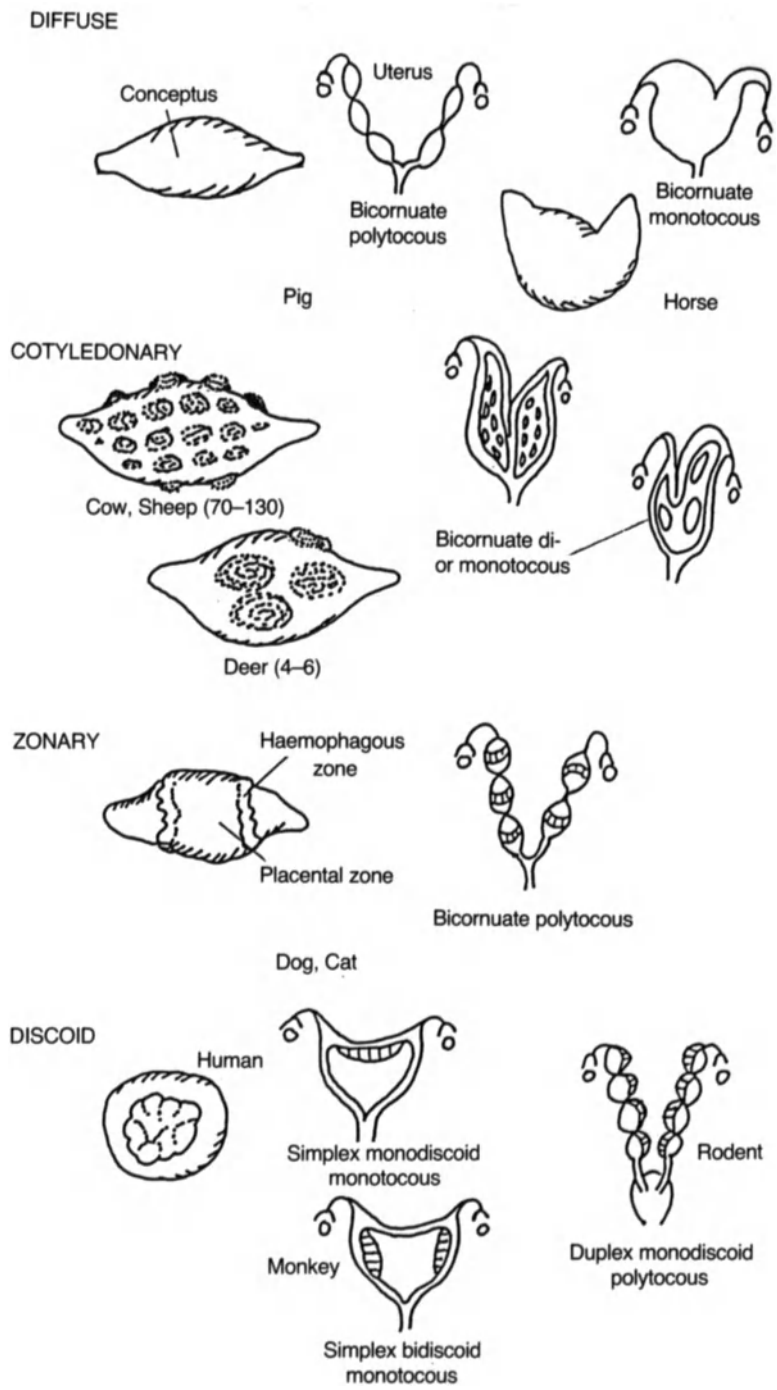

Figure 4.4 Schematic placental classification based on external form of the placenta and uterus.

2. Cotyledonary: chorionic villi grouped into a characteristic number of discrete tufts which can vary from 5 (deer) to 150 (giraffe), e.g. ruminants.
3. Zonary: villi restricted to an equatorial band or patch, e.g. carnivores.
4. Discoid: villi restricted to a single or double disc, e.g. rodents, insectivores, anthropoids.

This provides a useful simplification but within orders there are invariably exceptions outside the 'usual' category. Most insectivores have a discoid, but the American mole has a diffuse placenta; most of the ruminant placentas are cotyledonary, but that of the musk deer is diffuse; carnivore placentas vary from the usual zonary to rare discoid (brown bear) and non-carnivores are found with a zonary placenta (hyrax, dugong); a few placentas start diffuse and are discoid when mature (man, hyrax). These facts indicate that the four categories are convenient rather than functionally distinct.

Placentas with villi concentrated in limited areas (compact placentas) do have a 5–10 times greater fetomaternal exchange surface per gram weight of fetus at term than diffuse placentas (Baur, 1977), but whether this represents a higher transfer efficiency or lower safety margin in diffuse placentas remains to be established.

The uterine shape and number of conceptuses are also characteristics of a species. The uterus is based embryologically on (partial) fusion of the two Mullerian ducts to form a Y-shaped structure (Figure 4.4). The degree of fusion varies. Rats and rabbits have completely separate 'cornua' or 'horns' and this is defined as a 'duplex' uterus. Ruminants have partial fusion into common uterine body ('bicornuate'). In man and monkeys the horns are very small and the uterine body forms a 'simplex' uterus. Species producing a single offspring are designated monotocous, two ditocous, many polytocous (see Figure 4.4).

(c) Classification by histological structure

In 1909 Grosser pointed out that mammalian placentas could be grouped according to how many layers of maternal tissue were removed by the persistent chorion during development (cited in Amoroso, 1952) (Figure 4.5).

The number of tissue layers between fetal and maternal blood stabilizes after implantation and early differentiation of organ systems, and would directly affect the physiological exchange between the circulations. Grosser classified the placentas by defining first the maternal layer which was in apposition to the chorion in the definitive placenta, producing four categories (Figure 4.5):

1. Epitheliochorial: No layers removed; uterine epithelium in contact with the chorion, e.g. pig, horse.
2. Syndesmochorial: uterine epithelium removed, maternal connective tissue in contact with the chorion, e.g. ruminants.
3. Endotheliochorial: maternal uterine epithelium and connective tissue removed, maternal endothelial basement membrane in contact with the chorion, e.g. carnivores.
4. Haemochorial: all maternal tissue layers removed, chorion bathed directly in circulating maternal blood, e.g. rodents, insectivores, anthropoids.

Mossman (1937) and Owers (1960) added further categories in which the chorion was lost either from an endotheliochorial placenta (producing an endothelioendothelial) or from the haemochorial placenta (producing a 'hemoendothelial'). However, electron microscope investigations have since established unequivocally that in all chorioallantoic placentas so far examined the chorion persists to term even though it may be so thin as to be invisible at the light microscope level. The suggestion of 'vasochorial' for an endotheliochorial placenta with an especially thick interstitial membrane (Wislocki and

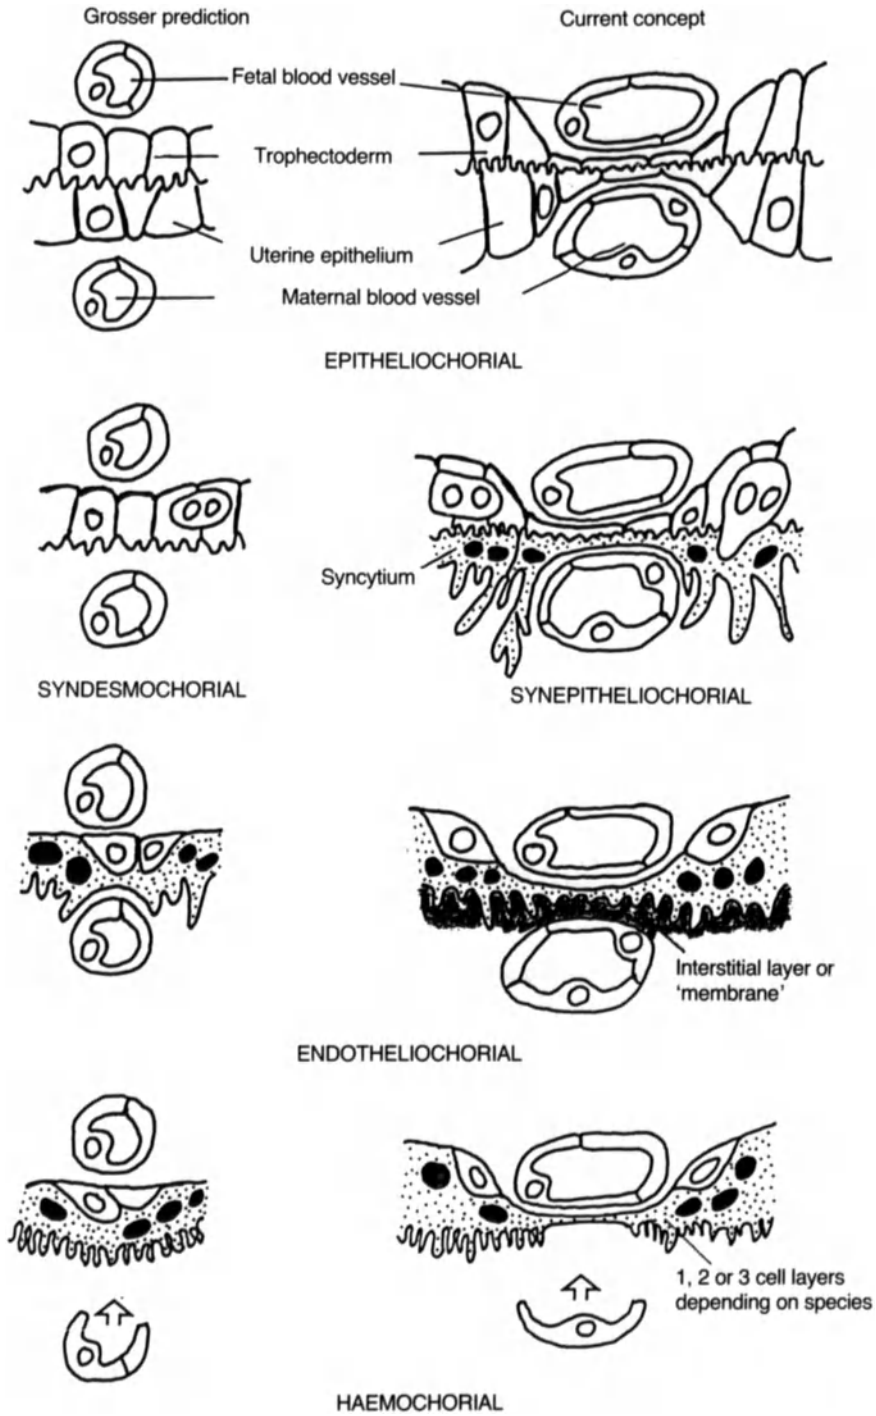

Figure 4.5 Placental classification suggested by Grosser on the left, revised to take account of recent research on the right.

Amoroso, 1956) seems an unnecessary complication of obscure derivation.

(d) Updating Grosser

Grosser initially suggested (see Amoroso, 1952) that the epitheliochorial to haemochorial series represented an evolutionary, anatomical and functional progression and proposed that, as the number of layers in what was regarded as a homogeneous semipermeable membrane decreased, the permeability and efficiency of the placenta increased. Subsequent work on capillary position, regional specialization and ultrastructure has shown that this is a considerable oversimplification (Figure 4.5).

Capillary position

By differential growth during development fetal capillaries sink into the chorionic epithelium. It is as if the capillary net expanded and pushed hard against a soft and yielding cellular layer. The capillaries always remain outside the basement membrane of the epithelium so that they are not anatomically 'intraepithelial' as usually described. They do, however, come much closer to the maternal blood, and in epithelio- and syndesmochorial placentas the maternal capillaries often indent the uterine epithelium [the analogy here would be tight string (the capillaries) around a soft parcel (the fetal villus)]. The extent to which the indentation occurs varies both within and between placental categories but generally increases toward term. There is no electron microscopic evidence that the process ever reduces the number of tissue membrane layers but the diffusion distance between the fetal and maternal circulations can be considerably reduced. This may explain why although the sodium ion permeability follows the Grosser prediction with the haemochorial (few layered) much higher than the epitheliochorial (multilayered) placentas, the gas-diffusing capacities of the two types of placenta are not significantly different (Moll, 1985). The sodium ion requires a transport system across each membrane, whereas gas diffusion depends solely on path length and concentration gradient.

Regional specialization

Biochemical, histochemical and fine structural studies have all combined to demonstrate that the placental layers can have very different characteristics in different areas of the same placenta or in equivalent layers within the same placental category. The placenta has been shown to be a very active organ metabolically and contains a wide range of selective transport systems and thus cannot be considered a homogeneous semipermeable membrane (Munro, 1986; Mossman, 1987).

Validity of the categories: EM evidence

Syndesmochorial/synepitheliochorial

Grosser defined the mature syndesmochorial placenta as having lost the maternal uterine epithelium, thereby bringing the fetal chorion into contact with the maternal endometrial connective tissue. This was based on light microscope studies which indicated that the characteristic chorionic binucleate cell of ruminants was directly involved in erosion of the uterine epithelium. Subsequent electron microscope studies could not confirm this but did demonstrate that a microvillar junction was present in all ruminants investigated, with either a syncytium (sheep, goat) or a cellular epithelium (cow, deer) on its maternal side interdigitating with the fetal chorion. This was taken as evidence that the uterine epithelium persisted (Ludwig, 1962), albeit in syncytial form in some species, and that the syndesmochorial category was therefore more accurately described as epitheliochorial with the microvillar junction being also the fetomaternal junction.

However, Wooding (1982a,b, 1984) and

C.S. Lee *et al.* (1985) have demonstrated that the sheep and goat syncytia are formed largely from the fetal chorionic binucleate cells which migrate across the microvillar junction to fuse into and form the syncytium. The layer in contact with the uterine connective tissue is therefore a fetal chorionic derivative and the placenta is legitimately described as syndesmochorial. At implantation, however, the syncytium originates from the fusion of a fetal chorionic binucleate cell with a uterine epithelial cell and the relative contributions of fetal and maternal tissue to the mature sheep or goat syncytium is still uncertain.

In cow and deer a fetomaternal syncytium is formed in the same way at implantation, but is subsequently displaced by regrowth of the residual cellular uterine epithelium. Continued binucleate cell migration across the microvillar junction produces fetomaternal trinucleate cells throughout pregnancy. These minisyncytia do not spread further but die and are resorbed after releasing their fetally produced granules to the maternal connective tissue (Wooding, 1982a,b).

All ruminants so far studied have binucleate cells and/or mini- or more extensive syncytial formations throughout pregnancy. Production of fetomaternal hybrid tissue in contact with the maternal connective tissue thus appears to be characteristic of ruminants. It is so unlike anything that is found in the other placental categories that it seems useful to maintain the distinction between epitheliochorial and syndesmochorial placentas.

The prefix 'syndesmo' was used by Grosser as a rather obscure synonym for connective tissue (*Borland's Medical Dictionary*: syndesmo, a continuing form denoting a relationship to connective tissue). It is now clear that the uterine epithelium is not removed by the chorion but more or less extensively modified by fusion with binucleate cells from implantation to term. The chorion is thus in contact with a fetomaternal syncytium and not with connective tissue. A usefully descriptive term for this situation which retains a reference to the older usage would be 'synepitheliochorial' (Wooding, 1992) (section 4.3.6b).

Haemochorial

Enders (1965), in an elegant comparative study, demonstrated that the haemochorial placenta does not always have a single layer of chorion. Different species show a constant pattern of one, two or even three separate layers between maternal blood and fetal endothelium. The terms haemomonochorial, -dichorial and -trichorial were introduced to accommodate this (Figure 4.76, section 4.3.6d). Further complexity was evident in that any layer could be either cellular or syncytial and some layers had macroscopic pores through their entire thickness. Most layers were thin, but this varied considerably. Thus, again the Grosser category covered a much wider range of structure than originally realized. There is an equivalent variation in functional capacity; the gas-exchange values for haemochorial placentas cover such a range that they include the values for epitheliochorial placentas (Moll, 1985).

Although many of the initial assumptions and predictions of the functional significance of the Grosser classification have been shown to be incorrect, the basic categories are still easily recognisable and nothing more convenient has yet been found to replace it (Figure 4.5).

Grosser also separated placentas into villous or labyrinthine types depending on the way in which the continuous increase in the fetomaternal junctional area throughout pregnancy was organized. In villous placentas the chorion initially forms simple finger-like projections which subsequently may become profusely branched but remain separate. Conventionally 'primary' villi are formed by a solid mass of ectoderm. These are said to

be 'secondary' villi when mesoderm grows into their core and 'tertiary' villi when this core vascularizes (Steven, 1975a).

In labyrinthine placentas the fetomaternal junction forms a network. This can be produced by fusion between the branches of an initially villous placenta, by a hollowing out of spaces in solid trophoblast or by the engulfment of a meshwork of maternal capillaries by the invasive chorion which replaces the maternal connective tissue. Although the structural development is usually villous to labyrinthine there are instances, such as man, where the initially labyrinthine placenta becomes villous secondarily.

(e) Classification by tissue lost at parturition

In the 'deciduate' type (see section 4.2.8) a variable amount of maternal tissue is lost with the fetal membranes at birth. The non-deciduate (or adeciduate) placenta separates at the fetomaternal junction. There is a reasonable correlation with the Grosser classification in that if there is any erosion of the maternal layers during placental development then the placenta is shed together with maternal tissue at term, which is defined as decidua. Since the data are relatively easy to collect, this classification can serve as an initial indication of structure. In contradeciduate placentas some fetal tissue is retained and resorbed after parturition. This has been reported in only a very few epitheliochorial placentas (European mole, lemurs; Amoroso, 1952).

It was originally thought that the specialized tissue (decidua) formed early in pregnancy from stromal cells in the endometrium of species with haemochorial placentation was related to the eventual placental separation zone. However, the extent of its production is variable, it frequently disappears before parturition and is completely absent in 'deciduate' endotheliochorial placentas. It therefore seems very unlikely that decidual tissue only plays a major role at parturition. For a more detailed discussion of decidua see section 4.2.8.

(f) Classification by accessory placental structures

These do not form a comprehensive scheme but are consistent features and provide a basis for further characterizing categories in the other schemes such as Grosser's. These structures are normally outside or at the edge of the main placental region and may be very different in structure.

Haemophagous zones/organs

These structures are also known as haematomas, but this term is already used in other less specific contexts and is best avoided; they occur in many endotheliochorial and some epitheliochorial placentas, normally around the margin of the main placenta but occasionally centrally (see review by Ulysses *et al.*, 1972, and Burton, 1982).

The haemophagous zone is a specialized area where the chorion and maternal tissue are widely separated by stagnant, but not necessarily clotted, maternal blood. There is no circulation of blood, the supply is by intermittent leakage and the control not understood. The chorionic trophoblast cells are typically very tall and columnar and full of large vacuoles containing phagocytosed red blood cells in various stages of digestion. It is assumed that by breakdown of maternal haemoglobin these zones provide a principal source of fetal iron.

Haemophagous zones are characteristically found at the edge or centre of the zonary endotheliochorial labyrinthine placentas of carnivores, but also occur in some endotheliochorial placentas in insectivores and bats. Some synepitheliochorial placentas also show haemophagous zones at the base of the fetal villi in the cotyledons (sheep and goat), but none has been reported in epitheliochor-

ial and only two in haemochorial placentas (shrew, B.F. King *et al.*, 1978; tenrec, Mossman, 1987).

Areolae

Areolae consist of small areas of the chorion overlying the mouths of the uterine glands whose secretion separates the two epithelia. The chorionic surface is normally elaborated in small folds carrying tall columnar cells showing evidence of active phagocytotic uptake of uterine secretions (Figures 4.20, 4.21 and 4.35). There is evidence of both merocrine and holocrine secretory modes from the uterine glands and epithelium. In the pig there is ultrastructural evidence for secretion of the iron transport protein uteroferrin from the glands and uptake by the chorionic areolar epithelium (Raub *et al.*, 1985). Enzymes related to sodium transport processes have also been localized to the areolar chorion (Firth *et al.*, 1986a,b).

Areolae are characteristic of epitheliochorial placentas and occur in large numbers over the entire surface of the placentas of pigs and horses (8000–9000 in pig, Amoroso, 1952). They are also common in the intercotyledonary areas of synepitheliochorial placentas (ruminants). In both groups large amounts of uterine gland secretion (also known as uterine milk) are produced and the areolae represent a localization and concentration of the uptake function common to all chorions. Their prominence in epithelio- and synepitheliochorial placentas may be correlated with the relative impermeability of such multilayer structures to non-diffusible substances; they are much simpler and less frequent in paraplacental regions in the cat and dog (endotheliochorial) placentas.

Chorionic vesicles

These may be derivatives of the chorionic roof of an areola invaginated into the allantoic sac (Figure 4.21). They range from vesicles lined with well-preserved chorionic epithelium containing material identical to that present between the epithelia in an areola, to sacs with no discernible internal structure (Amoroso, 1952; Mossman, 1987). These possibly represent the initial and final stages of such structures. They occur in placentas with areolae but are so infrequent and sporadic in their distribution that it seems unlikely that they have any specific function other than removal of excess secretion from between the fetomaternal layers. This is corroborated by the observation that in the horse the remnants of the endometrial cup (see below) are removed from the uterine surface and stored in a very similar structure (Figure 4.26b).

Chorionic girdle and endometrial cups

In equids before implantation, a girdle of binucleate cells develops in the trophectoderm surrounding the conceptus (Figures 4.26 to 4.30). These fetal cells migrate across the uterine epithelium to form a ring of solid structures in the uterine subepithelial connective tissue known as endometrial cups (Figures 4.26 and 4.32). These aggregates of fetal cells produce large amounts of equine chorionic gonadotrophin (eCG), previously known as pregnant mare serum gonadotrophin (PMSG), during the second quarter of pregnancy. The cells subsequently are killed by maternal leucocytes and the remnants are encapsulated by the chorion and invaginated into the allantoic cavity. This remarkable system (Figures 4.26a and b) is found only in the Equidae, but the binucleate nature, migration and hormone production of these cells are very reminiscent of the binucleate cells in the ruminants. (For further details and references, see section 4.3.6a.)

Yolk sac structures

As discussed above, the yolk sac membranes display a wide range of structural organization throughout gestation in eutherian

mammals. In the present context it is the usually transient presence of the choriovitelline placenta and the structure and position of the yolk sac at term which are used as diagnostic features.

The choriovitelline placenta (vascularized trilaminar yolk sac apposed to uterine tissue) forms the definitive placental structure in metatheria (marsupials) and is temporarily present in some families of nearly all eutherian orders whatever their eventual chorioallantoic placental type. It is important at implantation in subsequently endotheliochorial carnivores but much more transient in ungulates. In both, the vascularized yolk sac is soon separated from the chorion by expanding exocoelom, and by mid-gestation it is regressing in size. It soon becomes vestigial in ungulates but may retain some (unknown) function in carnivores and some bats (Figures 4.1 and 4.2).

In the largely haemochorial rodents, insectivores and lagomorphs the choriovitelline placenta may be present during development, but these orders are characterized from an early stage until term by the presence of an inverted yolk sac placenta which may be complete or incomplete (Figure 4.3). The incompletely inverted type has many layers but is still reported to be active in absorption in some sciurid rodents (squirrels) (Mossman, 1987). The completely inverted type has fewer layers and several studies have demonstrated its active role in macromolecular uptake including specific transport of immunoglobulins, in mouse, rat and guinea pig. Typically the relationship with the maternal tissues is far less intimate than in the choriovitelline placenta, the yolk sac tissue absorbing secretions like a fetal areolar epithelium by endocytosis from the uterine lumen (Bainter, 1986).

Subplacenta

Unique to hystricomorph rodents, a subplacenta is found on the maternal side in the central area of the placenta (Davies *et al.*, 1961a,b) (Figure 4.6 and 4.72).

It consists of trophoblast villi lacking a fetal blood supply which penetrate into the decidualised area of what becomes the placental stalk. The villi are covered by cytotrophoblast underlying a syncytial trophoblast layer of characteristic ultrastructure which proliferates to form closed lacunae not perfused by maternal blood (Figures 4.6 and 4.7).

This absence of circulating blood and the ultrastructure make the subplacental syncytium quite unlike that in the rest of the placenta. A secretory rather than absorptive function has been suggested (Davies *et al.*, 1961a,b).

4.2.4 DEFINITIVE PLACENTATION

The 'mature' or 'definitive' placenta may be characterized as the one whose structure shows no significant differences in number or type of layers between fetal and maternal blood when compared with the term placenta. If two types coexist (synepitheliochorial and epitheliochorial in sheep; haemochorial and inverted yolk sac in rodents) then usually one of them has a considerably larger fetomaternal exchange area and is quoted as the definitive form.

Often a functional yolk sac precedes the development of the chorioallantoic placenta. The growth of the fetus also has two phases: an initial implantation and differentiation of the organ systems and a subsequent exponential growth phase. A prerequisite for this rapid growth is a vast increase in the placental capacity for nutritive and gas exchange. It is to meet this demand that the chorioallantoic placenta has attained its characteristic or definitive structure usually by the second half of pregnancy and frequently much earlier, but always by the time that the maximum rate of fetal growth occurs. Baur (1977) has shown for a variety of placental structures that the absolute area of the fetomaternal junction increases continuously

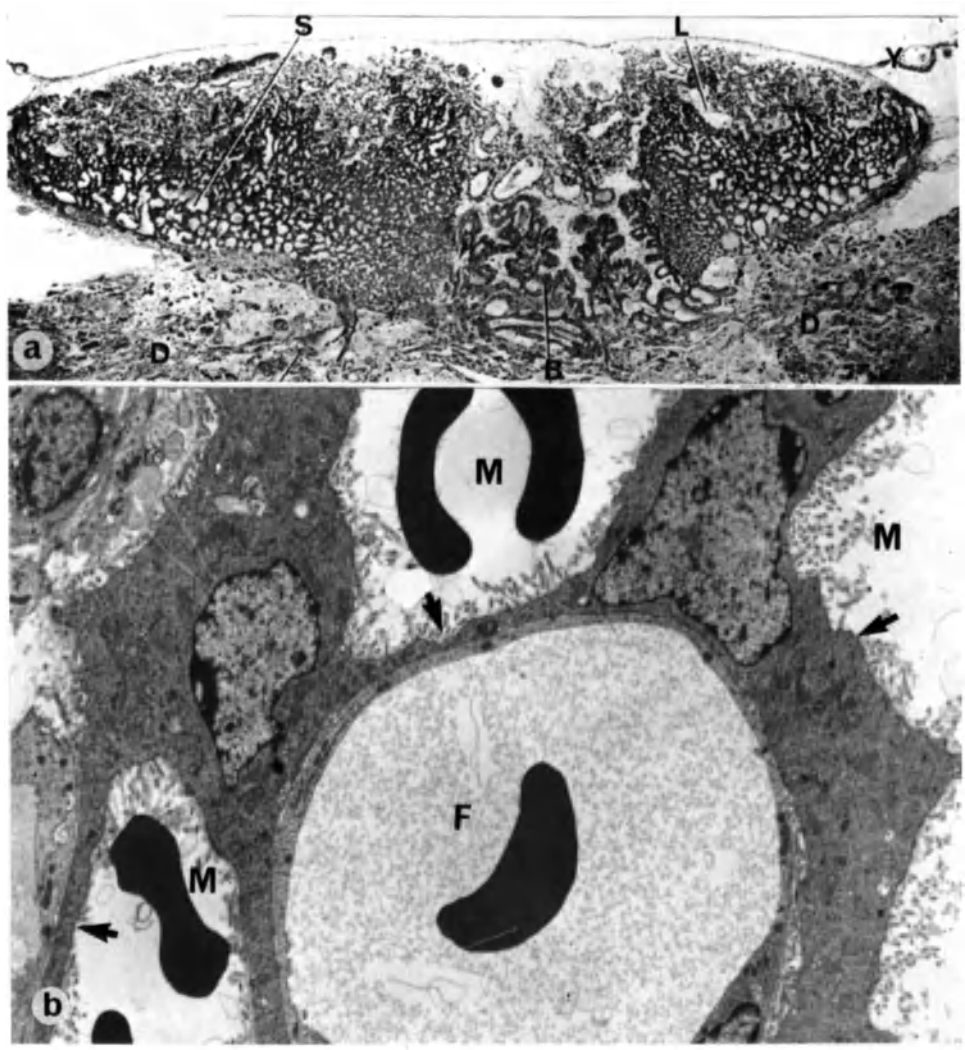

Figure 4.6 Haemomonochorial guinea pig placenta. (a) Light micrograph of a transverse section through the whole placental disc illustrating the different regions of the placenta. B, subplacenta; D, decidua; L, labyrinth; S, spongiotrophoblast; Y (inverted), yolk sac. (b) Electron micrograph showing the labyrinth structure. Note the variation in thickness (arrows) of the single syncytial trophectodermal layer. F, fetal capillary; M, maternal blood spaces. (a) 23 dpc, × 20. (b) 39 dpc, × 5200.

throughout pregnancy although the area per unit weight of fetus usually decreases significantly just before term. This indicates that the existing area of the placenta needs to be used with ever-increasing efficiency, and in most placentas the layers between the fetal and maternal circulations do get progressively thinner, which would be one way of achieving this. The fetal and maternal capillaries approach more closely by indentation of the layers and may also increase in width and frequency. The type and number of layers remain, however, unchanged, the modification being merely a refinement of a pre-existing structure (Figure 4.25).

It has been suggested that, ontogenetically,

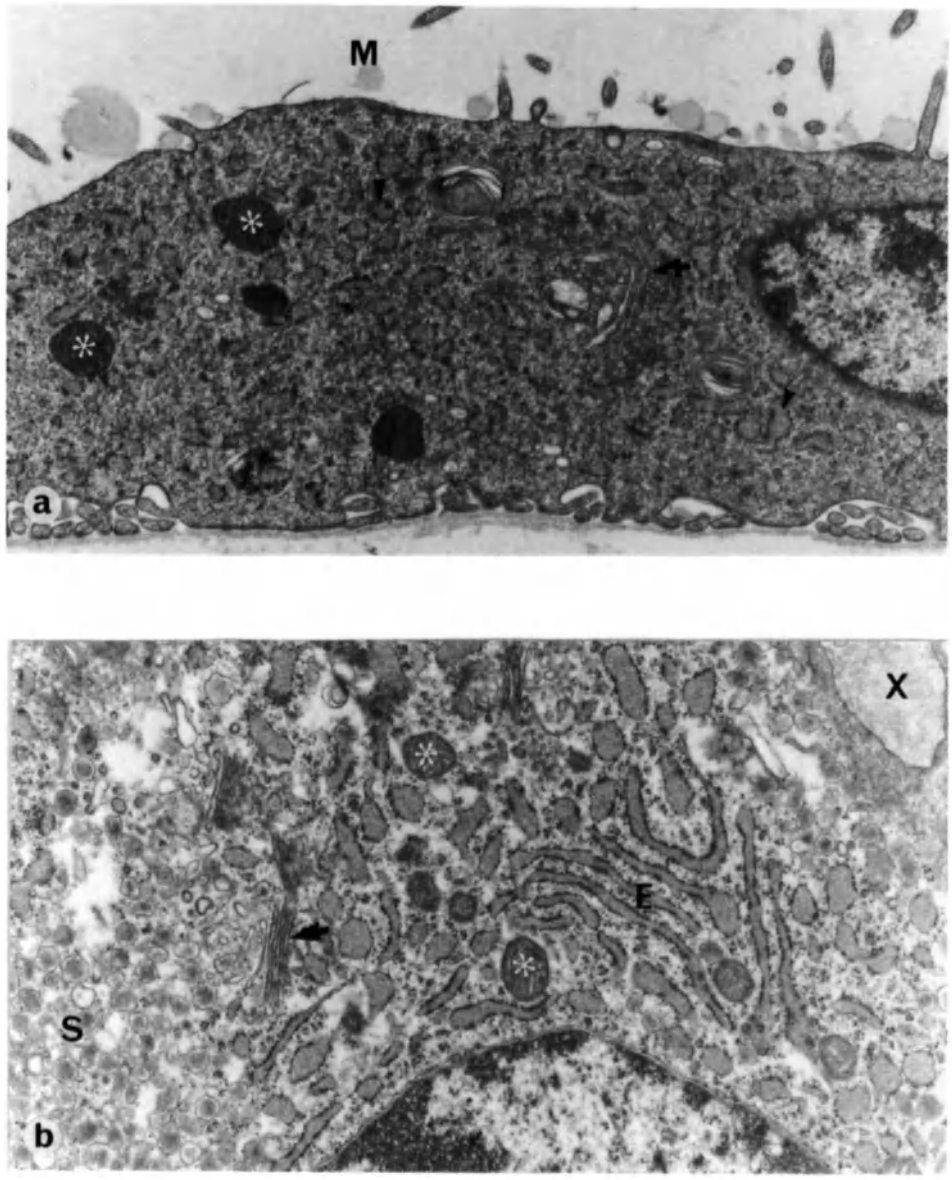

Figure 4.7 Haemomonochorial guinea pig placenta. (a) The spongiotrophoblast fine structure is very similar to, and continuous with, the trophectodermal syncytium of the labyrinth. Note the large mitochondria (asterisks), vesicular rough endoplasmic reticulum (arrowheads) and Golgi body (arrow); M, maternal blood space. (b) The ultrastructure of the subplacental syncytium is markedly different from other placental syncytium. It has arrays of endoplasmic reticulum (E) and numerous characteristic small secretory granules (S) produced from the Golgi body (arrow). X, intrasyncytial lacuna which usually is edged with microvilli. (a) 39 dpc, × 13 400. (b) 39 dpc, × 14 000.

haemochorial placentation is developed via epitheliochorial and endotheliochorial stages (Amoroso, 1952). However, this is only approximately true even at the invading front of the (usually syncytial) trophoblast because of the speed and lack of any synchrony in the development. There is no stage at which there is a significant area of (for instance) endotheliochorial placental structure in human or rodent haemochorial development. Behind the invading 'front' the definitive placental structure is immediately established and apart from 'fine tuning' in respect of diffusion distances no change in basic or definitive structure subsequently occurs, merely an increase in area. This again emphasizes that the different placental types are equally successful solutions to a particular cluster of environmental pressures. If one type of chorioallantoic placenta was more efficient, as the demands of the fetus increased it might be expected that this type would predominate since the placental area is growing continuously after establishment until term and thus is susceptible to continuous modification.

The definitive placental structures may thus be defined as those found in the main placenta close to term. Accessory placental structures should also be considered although they do not normally constitute a significant proportion of the total area. In the bovine cotyledonary placenta for example the intercotyledonary area represents less than 2% of the total area available for exchange at term (Baur, 1972) but it may have an essential functional role.

4.2.5 MATERNOFETAL EXCHANGE

(a) Histotroph and haemotroph

Conventionally there are two sources of fetal nutrition: histotroph, extracellular material including cellular debris secreted into the space between maternal and fetal surfaces in direct contact with the fetal trophectoderm, and haemotroph, materials carried in the maternal blood.

Histotroph

Since maternal blood can supply all of the needs of the mother and those fetuses with haemochorial placentation, the persistence of histotroph presumably reflects the inability of nonhaemochorial placentas to extract and transfer sufficient materials from maternal blood at a lower energy cost than absorbing a specific secretion. Phagocytosis of histotroph is considered to be a characteristic of both cellular and syncytial trophoblast. Uptake by this means is usually concentrated in specific regions such as areolae (pig, ruminants) or haemophagous zones (carnivores, sheep).

Haemotroph

Haemotrophic nutrients cross the interhaemal barrier by three major mechanisms: diffusion, endocytosis and the carrier-based systems facilitated diffusion and active transport (for a good general review of transport mechanisms, see Schaerer *et al.*, 1991). Small lipid-soluble molecules (such as oxygen, carbon dioxide and urea) cross by diffusion, a process involving no specificity of transport and only occurring down a concentration gradient. There are other devices, such as the differential affinities of fetal and maternal haemoglobin for oxygen, which serve to maximize the diffusion gradient.

Although increasing numbers of reports are appearing categorizing regional structural differentiation of the placental membrane (Ludwig, 1968; Enders, 1982; P. Kaufmann 1982), as yet only the simplest correlations of structure and function are possible. Reduction of the diffusion path length to facilitate respiratory exchange and modifications of cell structure to enhance endocytotic absorption are the two most easily recognized systems. Respiratory specializ-

ation manifests itself by attenuation of, and indentation by capillaries into, the respective fetal and maternal (if present) epithelia to bring both bloodstreams as close as possible. Absorptive specialization is recognized by membrane elaborations (microvilli, small folds), the presence of numerous coated pits, extensive apical tubulovesicular, endosomal and golgi systems plus a large lysosomal compartment. Tight junctions are also necessary in cellular epithelia to prevent passive return flow. Recent *in vitro* studies with tissue culture or isolated cells indicate that most fluid and macromolecular cellular uptake is via the coated vesicle system rather than macro or micropinocytosis (Rodewald and Kraehenbuhl, 1984; Willingham and Pastan, 1984). It occurs by non-specific fluid phase uptake (endocytosis) into the lumen of the coated vesicle and specific receptor-mediated binding by molecules in the same coated vesicle membrane. All material is then internalized via a receptosome/endosome compartment to the apical tubulovesicular system, which in some cells may be closely related to the Golgi body. Here it is sorted and dispatched either to lysosomes in coated vesicles for degradation, or to the basolateral cell membranes in smooth vesicles for release unchanged. The total fluid uptake can be enormous – up to the entire volume of a fibroblast or macrophage in 6–12 h (Steinman *et al.*, 1983). The few placental systems investigated so far with ultrastructural tracer techniques indicate the general validity of the model in this context (bat: Enders and Wimsatt, 1971; guinea pig: King and Enders, 1971; Moxon *et al.*, 1976; Kimberley and Thornburg, 1989).

Hydrophilic solutes with a low permeability coefficient in lipid membranes (such as glucose) are frequently transported by facilitated diffusion, that is by a process involving a membrane-bound carrier molecule which displays a substrate specificity and can be saturated, but again only down a concentration gradient. Where energy is utilized to drive the process of facilitated diffusion against a concentration or charge gradient, the mechanism is named active transport; amino acids are transported in this way. Here the relevant carrier molecule is located in the plasmalemma and has a receptor and transfer function. Usually the import of one molecule such as an amino acid is coupled to the export of another (in this case sodium ions). The imported molecule then has to utilize a similar system to cross the basolateral plasmalemma before it can pass right across the epithelium. Breakdown products from the lysosome may also cross lysosomal and cellular membranes by carrier systems. There is no good ultrastructural evidence for release of lysosomal content by exocytosis. Morphological evidence for carrier-mediated transport can only be obtained if the carrier protein can be localized by histochemical or immunocytochemical methods. So far for the placenta this has been limited to broad categories of enzymes – acid or alkaline phosphatases for example – the precise roles of which are unknown. However, recent work on Na/K-ATPase (Skolek-Winnisch *et al.*, 1985; Firth *et al.*, 1986a,b) and the steroid interconversion enzymes (Farkash *et al.* 1986) does show the potential of the technique. Carrier-mediated transport will be enhanced by short diffusion path lengths between membranes given an equal number of membrane barriers to cross. Thus, the capillary indentation and attenuation of the fetomaternal interface epithelia will facilitate this type of transport as well as respiratory exchange.

The structural criteria described for the various fetomaternal transfer systems can be used to identify potential regional specializations in many different types of placenta. Evidence that such areas function as proposed requires detailed tracer and physiological studies.

(b) Transport processes: quantitative aspects

Clearly all of the substances required for the growth and metabolism of the fetus, including water, oxygen, carbohydrates, amino acids, non-esterified fatty acids, metal ions and trace elements enter the fetal from the maternal circulation. Products of metabolism such as carbon dioxide and urea, as well as certain other compounds, flow in the opposite direction. Placental intervascular transport (either chorioallantoic or vitelline, or both) is the principal route of fetomaternal exchange. (See Morriss and Boyd, 1988, and Sibley and Boyd, 1988, for recent comprehensive reviews.)

Some indication of the quantities of material transported can be obtained from the following: in the fetal lamb late in gestation 7.8 g of carbon/day per kg fetal weight enters the fetal circulation, of which 4.6 g/day per kg is returned as carbon dioxide and urea (Battaglia and Meschia, 1978). Estimates of amino acid uptake made in fetal lambs between 118 and 146 days' gestation show that approximately 11 g of amino acids enters the fetal circulation per kg fetal weight per day, of which approximately 4.5 g is accumulated as new tissue (Lemons *et al.*, 1976; Battaglia and Meschia, 1978). Oxygen consumption by the sheep fetus between 80 days' gestation and term is approximately 8 ml oxygen STP/min per kg fetal weight; the quantity of substrate oxidized by this oxygen (caloric equivalent) is 58 kcal/day/kg, and at 130 days' gestation an additional 32 kcal/day/kg is accumulated as new tissue (Rattray *et al.*, 1974; Battaglia and Meschia, 1978). The mean growth rate of lambs at 130 days' gestation is 36 g/day/kg (Rattray *et al.*, 1974). A.W. Bell (1991) provides an excellent review of the maternal metabolic adaptations to the demands of pregnancy and quantitative aspects of transport to and metabolism in the developing conceptus.

Rates at which substances enter the fetal circulation are most frequently estimated from direct measurements of umbilical arterial and venous concentrations (venoarterial differences) multiplied by umbilical blood flow (the Fick principle), and unless otherwise indicated the data described here were obtained in this way, usually in late gestation. However, this technique cannot be applied to solutes for which placental uptake or clearance represents only a small proportion of umbilical concentration, because of the difficulty of measuring small differences in concentrations between the two vessels, and it is difficult to apply in small animals because of the size of the vessels; in these cases only a more indirect estimate of transfer rates can be obtained from measurements of the differences in concentration of radioactively labelled solutes introduced into the maternal or fetal circulations. Reliable data can only be obtained in chronically catheterized animals which have been allowed sufficient time to stabilize following surgery. Data for the human fetus are predictably scarce, although umbilical arteriovenous concentration differences can be obtained at Caesarean section. Methods used have been reviewed in detail in Nathanielsz (1980), Battaglia and Meschia (1986) and Molina *et al.* (1991).

Oxygen, carbon dioxide and urea cross the placenta, as they do other epithelia, by diffusion. The rates of gaseous diffusion across the placenta depend on the diffusion distance and are independent of the number of tissue layers involved. It must be remembered that the placenta itself consumes up to 40% of the total oxygen uptake by the uterus in late pregnancy (see discussion in A.W. Bell 1991). Fetal oxygen consumption does not appear to be limited by the rate at which it diffuses across the placenta since acidbase balance studies show that under normal conditions there is no metabolic acidosis in the fetus of the sheep, calf, horse or man; furthermore raising fetal Po_2 by transiently administering 100% oxygen to the mother does not alter

fetal oxygen consumption (see Battaglia and Meschia, 1978).

However, this leaves unexplained the results in the horse, which seem exceptional in this respect (Silver *et al.*, 1973; Silver and Steven, 1975); differences between the oxygen tensions in umbilical venous and uterine venous blood (Table 4.1) show that transfer in the mare is clearly more efficient than that in sheep (Wilkening and Meschia, 1992).

Uptake of oxygen by uterine tissues, or by the interhaemal tissues constituting the barrier between maternal and fetal blood, is a minor factor contributing to this difference; the major factor has been suggested to be the countercurrent relationship between fetal and maternal microcirculations in the microcotyledons in the mare compared with the less efficient cross-current flow in the sheep (Figures 4.8 and 4.9). This is dealt with in more detail in section 4.2.5(c).

Glucose is the most important single source of fetal energy (Molina *et al.*, 1991). It is transported by facilitated diffusion (sheep, guinea pig, Folkart *et al.*, 1960; Bissonnette, 1981; man, Carstensen *et al.*, 1977; Ingermann, 1987). This is shown by the dependence of the transfer on fetal and maternal glucose concentrations, which are in turn controlled principally by glucose ingestion and circulating insulin levels. Injection of insulin into the fetus decreases fetal blood glucose concentration by increasing utilisation and increases the flux from the mother. Maternal starvation reduces the flux and lowers fetal insulin (Boyd *et al.*, 1973). However, fetal oxygen consumption does not drop as much on maternal starvation as would be predicted, on the basis of reduced glucose transport, indicating an alternative fetal energy source, probably lactate and amino acids. Lactate, which is produced in the placenta (Burd *et al.*, 1975), is transported from mother to fetus by facilitated diffusion but its use has attendant dangers since a high circulating level can damage the fetal brain. A lack of glucokinase in most fetal livers ensures that glucose is delivered preferentially to the brain and nervous system. The fetal liver can efficiently utilize a variety of other substrates including lactate and galactose (Sparks *et al.*, 1976) but fructose is not metabolized despite its rapid synthesis in and transfer from the placenta and its high concentration in the fetuses of several species (Tsoulos *et al.*, 1971).

There are only limited differences between placentas of different structures in the characteristics of amino acid transport. Concentrations of amino acids in the fetal circulation are in general higher than those in maternal blood and this, together with a good deal of other evidence, indicates that most amino acids are transported across the placenta by active transport (Battaglia and Meschia, 1978; Young, 1981, 1988; Battaglia, 1992). The transport process involves the accumulation of amino acids to high levels in placental tissue, from where they diffuse into the fetal circulation; in addition there is some placental amino acid metabolism. Since they have different carriers, groups of amino acids differ in the rates at which they are transported: branched-chain amino acids such as valine, leucine and isoleucine are readily transferred from mother to fetus in the sheep, guinea pig and monkey, but basic amino acids cross relatively slowly in the sheep (see Young, 1981, 1988; Edwards *et al.*, 1993). Acidic amino acids such as aspartate and glutamate do not cross the placenta readily, in keeping with their behaviour in other transport systems such as those of the small intestine and blood–brain barrier. On infusion of ^{14}C-labelled aspartate and glutamate into the pregnant rhesus monkey, Stegink *et al.* (1975, 1979) observed labelled catabolic products such as glucose and lactate in fetal blood, but none of the parent compounds. The fetus is, in fact, capable of the synthesis of these amino acids, and there is a concentration gradient for glutamate across the placenta from fetus to mother, indicating that glutamate may be secreted by the fetus;

in the fetal lamb this flux may reach 5 mmol/day per kg of fetus (Lemons *et al.*, 1976). The glutamate is produced by glucose/lactate catabolism in fetal liver and converted to glutamine in the placenta. This utilizes the considerable ammonia production by the placenta, which has low urea cycle activity. The newly synthesized glutamine is then passed back to the fetus for use in protein synthesis (A.W. Bell, 1991).

Estimates of amino acid uptake made by measuring the nitrogen content of the fetus at various stages of gestation indicate that the fetal lamb accumulates approximately 0.65 g of nitrogen/kg/day (Battaglia and Meschia, 1973); estimates of amino acid uptake based on umbilical concentration differences in the same species are of the order of 1.5 g of nitrogen/kg/day (Lemons *et al.*, 1976). The disparity can be accounted for by deposition and metabolism in the placenta and nitrogen loss as urea from the fetus and placenta. Arteriovenous concentration differences for urea are too small to allow a comparable calculation, but infusion of labelled urea has shown the mean placental clearance rate to be 0.36 g of nitrogen/kg/day (Gresham *et al.*, 1972). This is consistent with the high fetal to maternal concentration gradient for urea across the placenta observed in a number of species, including man and sheep (see Battaglia and Meschia, 1978), and it is thought that almost half of the amino acids transferred are oxidised by the fetus with production of urea.

There are considerable species differences with respect to placental transfer of fatty acids. In ruminants, the placenta is relatively impermeable to long-chain fatty acids (Van Duyne *et al.*, 1960); although there may be uptake of acetate by the fetus (Comline and Silver, 1976), fetal circulating concentrations of fatty acids are low, and fat represents only a small proportion of fetal body weight at term (Rattray *et al.*, 1974). A.W. Bell (1991) provides an excellent review of the maternal metabolic adaptations to the demands of pregnancy and quantitative aspects of transport to, and metabolism in, the developing conceptus. However, some fatty acids do enter the fetal circulation from the mother, for example, essential fatty acids such as linolenic and linoleic acids. These are substrates for synthesis of prostaglandins, leukotrienes and thromboxanes, which are obligatory requirements for the fetus, and they are taken up via the placenta in all species. In contrast to the ruminants, fatty acid transport is much more rapid in some other species (mare, guinea pig, rabbit, rat, rhesus monkey and man, for example) and circulating levels of fatty acids are higher; in the rabbit fetal fatty acid uptake is so avid that starvation, which leads to an increase in maternal circulating non-esterified fatty acid level, results in increased fatty acid deposition in the fetuses (Edson *et al.*, 1975; Elphick *et al.*, 1979).

Most ions (sodium, potassium, calcium, chloride, phosphate, etc.) are transported across placentas by carrier-mediated processes at each membrane barrier, although paracellular routes ('pores') allowing passive diffusion are also considered probable, for example for sodium and potassium (Sibley and Boyd, 1988; Edwards *et al.*, 1993). However, it should be remembered that such 'pores' are merely postulates to explain physiological results (for a recent review, see Stulc, 1989): they have no convincing ultrastructural correlates in the fetal and maternal placental compartments. Each placenta relies on a variety of 'pores', carriers and cytoplasmic binding proteins, but the localization and quantitative efficiency of each system is not yet known in any detail (reviews: Shennan and Boyd, 1987; Brunette, 1988; Morriss and Boyd, 1988; Sibley and Boyd, 1988). Large molecules, for example proteins and vitamin B_{12} bound to a carrier protein, are taken into the cell by pinocytosis, but this process is by no means non-selective, since the trophoblast membranes express on their surface specific receptors. These are involved in recognition and uptake of the proteins and loaded carrier

Table 4.1 Comparative physiological data (approximate means) for term or near term placentas

Species	*Placental type*	*Relationship of maternal/fetal blood microflows from the literature***	*Fetal wt at term (g)*	*Placental wt at term (g)*	*Percentage placental/ fetal wt*	*Conceptus growth rate (slope of cube root of total volume vs age, wks)*	*Relative villous surface area (cm^2/g placenta)*

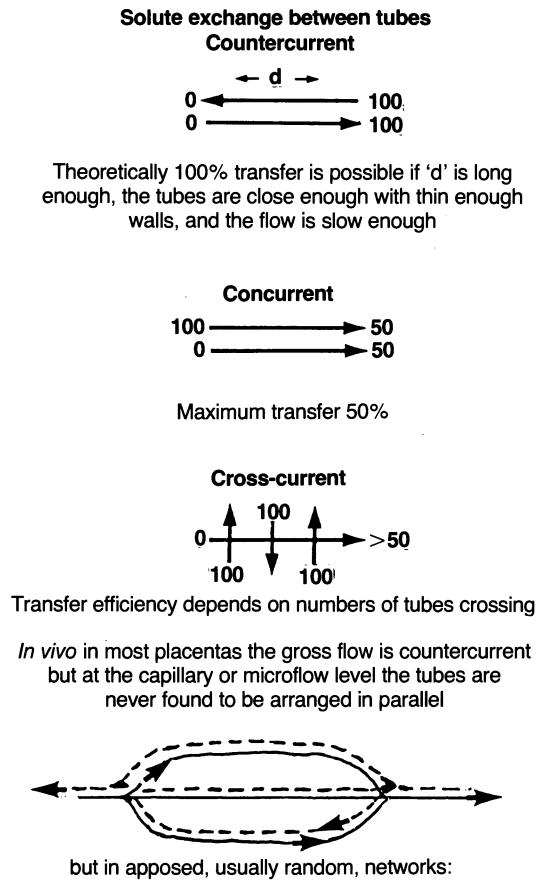

Figure 4.8 Theoretical considerations of solute exchange between capillaries.

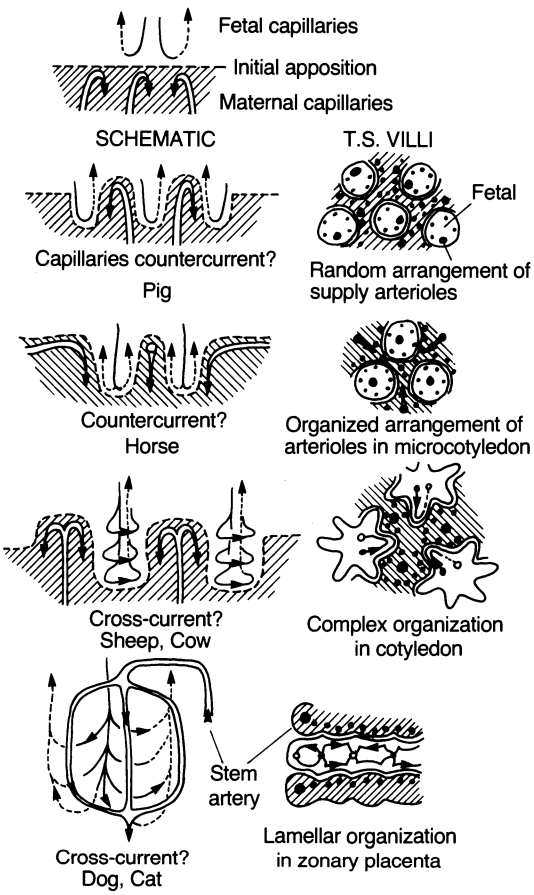

Figure 4.9 Schematic illustration of the relationship between the direction of capillary blood flows in the fetal and maternal placental circulations in various animals. See also Figures 4.8, 4.72 and 4.88.

proteins. The discussion is complicated by the fact that the transport of these molecules is not limited to one mechanism or to a single component of the placenta; the transport of large molecules can occur via the phagocytosis of uterine secretions (histotroph; see below), or of extravasated maternal blood by the trophoblast in a haemophagous zone of the placenta, or via the vitelline placenta (if present) and/or via the chorioallantoic placenta. The proportion of solutes transported

by each of these routes varies according to the type of placentation employed.

The principal evidence for pinocytotic uptake and microvesicular transfer of intact specific proteins across the placenta comes from studies with the electron microscope of the transfer of substances such as ferritin and peroxidase, and these studies emphasize the importance of the yolk sac (vitelline) placenta, particularly in the guinea pig and rabbit and to a lesser extent in rodents (Bainter, 1986). In primates this process occurs at the chorioallantoic placenta, and in animals with epitheliochorial placentas in the areolae. Other evidence for this form of transport comes from studies on the uptake of fluorescein-labelled immunoglobulin antibody proteins by the rabbit yolk sac *in vivo*. Labelled rabbit IgG introduced into the uterine lumen in 24-day pregnant rabbits was transferred across the endodermal cells of the inverted yolk sac placenta to the fetal circulation, but bovine IgG was degraded to amino acids and did not enter the fetal compartment (Hemmings, 1957). This is now known to be due to the existence of two routes for protein uptake (Bainter, 1986). Rabbit IgG is bound to specific receptors in the endocytotic (coated) vesicle membrane while bovine IgG is taken into the cell nonselectively in the fluid bulk phase within the vesicle. Proteins recognized by receptors are destined for transport to specific sites – the basolateral plasmalemma for transcellular transport or the Golgi body for modification; bulk phase proteins are transferred to the lysosomal system for breakdown. Brambell's (1966, 1970) suggestion that lysosomes are involved in selective transport of immunoglobulins has now been superseded.

Transport of specific immunoglobulins has been demonstrated in the rabbit (Moxon *et al.*, 1976; Wild, 1981) and guinea pig (B.F. King, 1977) inverted yolk sac placentas and in the primate chorioallantoic haemochorial placenta (Bainter, 1986; Leach *et al.*, 1990; Sooranna and Contractor, 1991). No such selective transport of immunoglobulins has been detected across ungulate (pig, Matre *et al.*, 1975) placentas where maternal protective immunoglobulin antibodies are transferred post-natally in the milk. There are reports of immunoglobulin transfer prenatally in carnivores (Bainter, 1986) but the site and mechanism of transport are unknown.

From the discussion above it can be seen that the rate of placental transport of nutrients to the fetus can be influenced by many factors; inadequacies result in failure of normal fetal growth (fetal growth retardation). Of most importance in relation to fetal growth retardation are the concentrations of nutrients in the maternal circulation and the transfer ability of the placenta. For those substances crossing the placenta by facilitated diffusion down a concentration gradient there will clearly be no transport if the gradient is not maintained; thus undernourished mothers provide insufficient glucose to their fetuses. The insufficiency is exacerbated by the competition for use of glucose by the undernourished mother and the placenta, when it does become available. Under these conditions active transport in the placenta is also reduced, as it receives less substrate for oxidative metabolism. Similar constraints on fetal well-being are caused by placental disease, such as pregnancy toxaemia, probably due to reduced effective placental surface area. The relationship between placental size and fetal mass is fairly direct and has been studied in sheep with reduced cotyledon numbers following uterine carunclectomy (Alexander, 1964; Robinson *et al.*, 1979). For a review of the gross macroscopic relationships between placental size and fetal mass see A.W. Bell (1984). The ways in which the fetus uses endocrine mechanisms to alter maternal circulating levels of nutrients is dealt with below under the endocrinology of placentation.

(c) Vascular relationships

General considerations

There are two placental circulations, maternal and fetal, which are separated from each other by one or more layers of placental tissue. The maternal vessels in the placenta arise from the uterine vasculature, and are closely related to those vascularizing the rest of the uterus and the ovary; in some primate species, during late pregnancy, ovarian arterial blood may also reach the placenta via uteroovarian arterial anastomoses (Wehrenberg *et al.*, 1977). As a result it is not possible to isolate major arteries supplying only the placenta; this can readily be demonstrated by infusing X-ray opaque material into the uterine artery *in vivo*, when both myometrial and placental circulations fill with tracer concurrently. The fetal side of the chorioallantoic placenta, on the other hand, receives all the blood entering it through the umbilical arteries, and is drained exclusively by the umbilical veins. Thus, although direct measurements of blood flow in the umbilical vessels give an accurate indication of blood flow in the placenta and fetal membranes, measurements of uterine arterial blood flow always include uterine and placental components. The magnitude of these flows can be judged from Table 4.1. For reviews see Dawes (1968), Rankin and McLaughlin (1979), Wallenberg (1981), Martin (1981), Silver *et al.*, (1982), Battaglia and Meschia (1986) and Mossman (1987).

The first measurements of maternal uterine blood flow were made in the 1930s by collecting venous outflow in rabbits (Barcroft, 1933); nowadays uterine arterial blood flow can be determined directly with cuff electromagnetic or ultrasonic flowmeters which, once implanted, can be used to record flows over long periods in conscious animals. Alternatively, acute experiments can be carried out using labelled microspheres to determine flows to individual tissues at the time the animal is killed. Measurements of umbilical blood flow are most frequently made using flowmeters.

For substances diffusing across the placental barrier, such as blood gases, factors influencing transfer rates include the spatial relationships between maternal and fetal blood capillaries; the fetal villous exchange area; concentration gradients across the areas of exchange; blood flow rates on either side of the barrier; the distance the gases have to diffuse between blood systems; and the rate of gas utilization or production by the placenta itself.

Probably the most important factors governing placental gaseous exchange are the vascular architecture, which determines the directions of the maternal and fetal blood flows, and the distance separating those flows. There appear to be at least four theoretical types of flow relationships: con-, cross- and countercurrent and mixtures of some or all of these together (Martin, 1981) (Figure 4.8). Of these, the countercurrent system is expected to be most efficient because blood leaving the exchange area on one side will tend to equilibrate with that entering it on the other, and a maximum solute transfer of 100% is theoretically possible. For concurrent flow such equilibration can only result in a maximum solute transfer of 50%.

It must be remembered that there are two levels to be considered, gross flow and what may be termed microflow. Gross flow is the overall direction which in all placentas so far investigated, with the possible exception of Old World monkeys and anthropoids, appears to be countercurrent. Fetal stem arteries run directly to the maternal side and maternal arteries to the fetal side before dividing up into capillaries which conduct the blood back to the veins. The microflow is at capillary level, and this is where the haemotrophic exchange takes place, most efficiently with the least practicable separation between the flows.

In all cases so far examined in sufficient

detail, the architecture of both fetal and maternal capillaries or blood spaces is a network, sometimes but not always with a predominant direction (Figure 4.8). There is no evidence for significant lengths of parallel apposed tubes of the networks which would allow sufficient equilibration of, for example, oxygen concentration as usually figured in model systems (Moll, 1972; Martin, 1981). It may be more realistic to consider that all placental capillary exchange takes place between microflows in networks which vary continuously between cross-, counter- and even concurrent and are best described as 'network current' (Figures 4.8 and 4.88).

The vascular morphology of the placental exchange region may be investigated histologically or by injection and subsequent hardening of plastic or latex followed by removal of the soft tissues and light (Figure 4.23) or scanning electron microscopic (SEM) (Figure 4.24) examination of the resulting 'corrosion casts'. Injection of visually detectable or X radio-opaque dyes (angiography) is also useful, but the latter technique is of no value at the microflow level at which exchange occurs. Of prime importance to the nature of the relationship between the gross flows of maternal and fetal blood are the positions of the arteries and veins supplying and draining the primary villi, and this can be determined by the methods described above. SEM studies of corrosion casts give exquisite detail of either maternal or fetal plumbing (Figures 4.40 and 4.47) but it is very difficult to elucidate the intimate relationship between them, since it is not yet possible to distinguish fetal from maternal capillaries unequivocally on the same preparation.

As more SEM microcorrosion cast studies are published (e.g. Leiser and Kohler 1983, 1984; Burton, 1987; Leiser, 1987; Christofferson and Nillson, 1988; Leiser and Dantzer, 1988; Ogura *et al.*, 1991), it becomes increasingly obvious that a placenta consists essentially of two bloodstreams separated by a minimum of tissue. Most conventional EM and LM sections overemphasize the tissue component. Better perfusion fixation shows that probably more than 50% of the *in vivo* placental volume is occupied by blood channels (Figure 4.44), a figure supported by measurements of the total blood volume using tracers in placentas clamped *in vivo*.

The progression (in morphological but not necessarily evolutionary terms) from epitheliochorial to haemochorial placentation occurs with increasing loss of uterine tissue, with important consequences for vascular organization (Figure 4.9). Epitheliochorial placentas are formed by a mutual growth of short fetal and maternal villi to form a structure consisting principally of two complex and extensive capillary beds. Synepitheliochorial and endotheliochorial placentas develop similarly but have much longer villi with great modification or elimination of the uterine epithelium. The maternal connective tissue remains an important constituent of maternal placental structure. Haemochorial placentas have no residual uterine epithelium blood capillaries or connective tissue, but need to deliver maternal blood up to the fetal side of the placenta from where it drains back through entirely fetal tissue. To accomplish this the main maternal arteries persist, usually passing through the full depth of the fetal villi or labyrinth (Figure 4.9). The endothelium of such arteries is usually replaced by invading fetal trophectoderm early in gestation, but the initial maternal blood conduits are retained and even greatly enlarged throughout pregnancy (Figure 4.72). The only exceptions to this are the Old World monkeys and anthropoids (section 4.3.6d and Figure 4.88). Thus, in late pregnancy there is virtually no maternal tissue left in a haemochorial placenta above the decidual layer or myometrium.

Different placental types

The following descriptions of placental vascular anatomy will be limited to the mature placentas of late pregnancy. It should be noted that placental vasculature develops throughout gestation as the fetal nutrient and blood gas requirements increase, and that total placental blood flows and chorionic villous areas increase with increasing fetal mass (Baur, 1977). In the pig's definitive placenta blunt fetal villi (length 150 μm, width 30 μm, Tsutsumi, 1962; Crombie, 1972) are inserted into maternal crypts. Each fetal villus has a peripheral meshwork of non-fenestrated capillaries usually supplied by an arteriole running up one side to the top of the villus before branching significantly into capillaries draining down to the base. The maternal crypts have a very similar arrangement, but of fenestrated capillaries, with arterial supply to the top and draining around the base (Figures 4.9, 4.23 and 4.24). The predominant capillary flow is therefore down both fetal villous and maternal crypt, in opposite directions. As can be seen from the diagram (Figure 4.9), this produces a gross countercurrent flow between the capillaries, which indent their epithelia deeply (Goldstein, 1926; Steven, 1983; Figures 4.22 and 4.25) and are presumably the main site of haemotrophic fetomaternal exchange. The corrosion cast evidence (Tsutsumi, 1962; MacDonald, 1975, 1981; Leiser and Dantzer, 1988) indicates that the microflow is between two capillary networks with no predominant direction. Microflow is therefore the mixture of cross and countercurrent, here called network flow (Figure 4.8).

In contrast to the pig, the vascular structure of the diffuse epitheliochorial placenta of the horse is more complex (Tsutsumi, 1962; Silver and Steven, 1975; Steven and Samuel, 1975) because of the formation of longer fetal villi and their organization into microcotyledons. These appear to arise by villous growth between the pre-existing pattern of endometrial arteries. In these fetal villi, fetal arterioles run centrally to the tips before branching into a peripheral capillary network 75–125 μm in length (Tsutsumi, 1962), which carries blood back to veins at the base. The capillary blood therefore flows from the tips to the bases of the villi. Maternal blood, entering each microcotyledon (section 4.3.6a) over the rim of the cup-like structure, flows into a capillary network vascularizing maternal septa which have their tips between the bases of the chorionic villi. The flow is from the tip to the base of the septa; venous blood is collected in veins running round the base of the microcotyledon. In this species, therefore, there are clear morphological grounds for considering the gross blood flow to be countercurrent (Tsutsumi, 1962), but the microflow seems to be the cross and countercurrent system characteristic of apposed networks (Tsutsumi, 1962).

In the ruminants the sheep and goat have 10- to 100-fold longer villi forming much larger cotyledons than in the horse. Both maternal septa and fetal stem villi have central supply arteries which give off some branches as they run in opposite directions to their tips. Fetal and maternal blood passes back via capillary meshworks about 250 μm long in grossly countercurrent flow (Tsutsumi, 1962; Steven, 1966; Makowski, 1968).

The microflow arrangement has been controversial. It was initially suggested to be countercurrent (Barcroft and Barron, 1946) but reports of axial venules in the fetal terminal villi and maternal septa indicated that a crosscurrent system was equally likely (Figure 4.9; Tsutsumi, 1962; Steven, 1966; Makowski, 1968). A recent corrosion cast study of the goat placental vasculature has clearly demonstrated that the maternal and fetal capillaries are arranged in mixed cross and countercurrent microflow systems, network flow again (Figure 4.48; Leiser, 1987). A functional test has been applied by Metcalfe *et al.* (1965), who reversed the direction of flow on the fetal side of the placenta,

and found no major change in the rate of exchange of nitrous oxide from fetal to maternal blood; they concluded therefore that the flow must be cross-current. However, it is possible that flow reversal damaged the vascular beds, leading to altered transfer of the gas: a higher perfusion pressure was required to reach normal flow rates, when flow was reversed, and returning flow direction to normal did not restore normal vascular resistance. Measurements of transport using the non-metabolizable, freely diffusing substance, antipyrine, in chronically catheterized preparations have confirmed that the relationship is not exclusively countercurrent (see Battaglia and Meschia, 1986; Wilkening and Meschia, 1992).

The placenta of the cow is, in many respects, similar to that of the sheep (Tsutsumi, 1962) except that the placentomes are convex instead of concave, because of the greater complexity of the branching of terminal fetal villi. Convex placentomes are in fact sometimes found in sheep, particularly in late gestation; their formation can be induced by maintaining pregnancy in ovariectomized animals with administered progestagens (Alexander and Williams, 1966, 1968; Ricketts and Flint, 1980). It is not known, however, when the change from concave to convex placentomes occurs or what controls it. As in the ovine placenta fetal villi are vascularized by central arterioles running to their tips, branching to form many small lateral capillary beds, length 150–300 μm (Tsutsumi, 1962), which are drained by central venules. In cross-section these branches, which are longer and more prominent than those in sheep, resemble the arms of a starfish (Figures 4.9 and 4.49; Tsutsumi, 1962). The peripheral capillary bed in the maternal villi is supplied with blood from central arterioles and drained into venules at either the base of the villus or its centre. The relationship between maternal and fetal blood flows in the cow is therefore similar to that in the sheep and goat, with the exception that some maternal blood drains via central venules, whereas in the sheep the maternal capillary cascade (Silver and Steven, 1975) is said to be the only continuous channel back to the basal veins.

A detailed study of the endotheliochorial labyrinthine zonary placenta of the cat (Leiser and Kohler, 1983,1984) using scanning electron microscopy of corrosion casts shows that the fetal and maternal arterial systems deliver blood to opposite sides of the placenta before it drains back in what seems to be a grossly countercurrent arrangement. However, it is claimed that the capillary dispositions at the microflow level show that capillaries carry blood not in a direction opposite to maternal flow, but across it (Figures 4.9, 4.66 and 4.67). If this can be substantiated this labyrinthine placenta would have blood microflows which are principally cross-current (Leiser and Kohler,1984).

Vascularization of the haemodichorial rabbit placenta has been studied by dye dilution and angiography by Mossman (1926) and Carter *et al.* (1971), and has been reviewed by Carter (1975). The labyrinth (or zona intima) of the mature placenta is composed of a meshwork of trophoblastic tubules permeated by maternal blood. Fetal arteries penetrate directly to the maternal limit of this fetal tissue labyrinth before breaking up into capillaries which lead blood back towards the fetal side of the placenta to the fetal veins (Figure 4.72). Maternal spiral arteries pass through narrow sphincter-like regions in the myometrium before dilating to form large arterial sinuses located in the decidua; blood flows from these via four or five wide arteries to the fetal side of the labyrinth before draining back towards the decidua through the trophoblastic tubules of the placental labyrinth. From the tubules maternal blood enters large venous sinuses in the decidua which subsequently drain into the uterine veins. Countercurrent (gross) flow of maternal and fetal blood results from the fact that both arterial flows pass directly to the furthest

opposite sides of the labyrinth before draining back through the exchange area. As far as the maternal vasculature is concerned, this arrangement is consistent with the results of angiography (Carter *et al.* 1971). The maternal arterial sphincters are thought to represent the point just above which placental separation occurs at parturition, their purpose being to reduce maternal blood loss.

In the haemomonochorial villous placentas of man and Old World monkeys, as in the synepithelio- or endotheliochorial systems, the fetal arteries run to the tips of the fetal villi, here anchored in the maternal decidua, before draining back through a capillary network. However, unlike all the other placental arrangements, there are in man no channels to carry the maternal blood to the fetal surface, the maternal spiral arteries end abruptly at the maternal surface (Figure 4.88). A plausible explanation of how such a system works is as follows. The fetal villi are organized into groups called lobules or cotyledons, each of which has a hollow centre where villi are less densely packed. The lobules are situated over the openings of the maternal spiral arteries, which deliver blood into the hollow centre; in order to leave the intralobular spaces the blood flows radially over the villi into spaces between lobules (Wigglesworth, 1969). From these spaces venous blood leaves the placenta through venous openings in the decidual plate and interlobular septa (Figure 4.88). By angiography, puffs of maternal blood can be seen entering the intervillous space from the spiral arteries (Ramsey, 1967); pressure of blood may lead to a hollow-centred lobule by pushing villi outwards. Growth of the villi is thought to occur from the centre of the lobule towards the periphery, in the direction of blood flow; the most peripheral villi are reported to be more highly differentiated (Schuhmann, 1982). Solutes are removed from the maternal blood as it passes from the spiral arteries to the endometrial veins, thereby establishing a concentration gradient from the point of entry into the lobule to the exit. The diffusion barrier thickness of the human vasculosyncytial membrane does appear to be significantly reduced in regions where solute concentrations would be predicted to be lowest (Critchley and Burton, 1987; Burton and Tham, 1992). Arteriovenous shunting and blood stasis in the intervillous space are prevented by the velocity and momentum with which maternal blood enters this space and the villus architecture, which ensures mixing of highly oxygenated blood with that already present (Ramsey and Donner, 1980).

It has been suggested that the human placental villi represent a mop passively suspended in a bucket, but this does not explain the movement of maternal blood around the fetal villi in each lobule. It would be more realistic to imagine a brief separation to capillary dimension of the villi caused by each spurt of maternal blood, followed by closure of the intervillus 'capillary' spaces as the pressure drops – rather like water flow through fish gills. This system would prevent significant backflow towards the arterial orifices.

The structure of the fetal vessels in each villus is such that the terminal villi which protrude from the intermediate villi at random are vascularized by a network of peripherally located anastomosing capillaries arising from the central primary arteriole and draining into the central primary vein (Habashi *et al.* 1983). There is no evidence that the capillaries in the terminal villi have any consistent spatial relationship to the mean direction of blood flow in the intervillous space, so the maternal and fetal blood microflows presumably have a mixed or random directional relationship to one another (Figure 4.88).

Placental vascular architecture and placental function

Various functional parameters measured in different types of term placenta are summar-

ized in Table 4.1, in which placentas are arranged in order of the number of tissue layers separating maternal and fetal blood. Correlation of structure and function in the different placental morphological types should be simplest with diffusible gases and solutes where, given similar concentration gradients, the rate of transfer depends directly on the interhaemal diffusion distance and the area of the exchange surface.

The permeability of a placenta to blood gases can be determined directly by measuring the transfer of non-metabolizable carbon monoxide or estimated from morphological measurements (Mayhew *et al.*, 1984). The results show that the rate of fetal oxygen utilization is never limited by the oxygen diffusion capacity of the normal placenta. The range of values found in different species (7–45 ml/min/mmHg per kg of placenta) bears no simple relationship to the range of placental interhaemal structure. One problem here is that it is very difficult to determine the average interhaemal distance since the degree of indentation of fetal (or maternal if present) layers by the capillaries varies considerably both within the same placenta (Figures 4.25 and 4.44) and between placentas of different species. This indentation means that the minimum interhaemal distance in the epitheliochorial six-layered pig placenta may be very similar to that in the human haemomonochorial three-layered placenta, but the average interhaemal distance is much greater in pig than in man. Which value, minimum or average, is the more relevant is difficult to determine. It is possible that in the pig placenta there are enough closely adjacent lengths of maternal and fetal capillaries separated by the minimum distance to provide sufficient respiratory exchange for the fetus. The average interhaemal distance would not then be relevant. There are statistical treatments which are said to give more realistic estimates of the interhaemal barrier thickness (Critchley and Burton, 1987; Burton and Tham, 1992). There is some evidence for a local specialization of structure and function in the human placenta. Here the areas of minimum interhaemal separation, the vasculosyncytial membrane, are more extensive in regions where the oxygen concentration is plausibly suggested to be lower (Critchley and Burton, 1987). Whether such an arrangement is also found in other types of placenta remains to be demonstrated.

Differences in the transport capacity of various placental types clearly do not determine fetal growth rates, because as shown in Table 4.1 these are as high in the pig and the mare (epitheliochorial) as in primates or the guinea pig (haemomonochorial). Other factors that potentially influence placental efficiency are villous surface area, the size of the placenta relative to the fetus and placental blood flow rates. However, none of these parameters alone appears to correlate with fetal growth rate. Calculation of villous surface area at term per kg fetus from the data of Table 4.1, shows that this parameter varies widely, independently of fetal growth rate, from 300 cm^2/kg in the mare, to 10 400 cm^2/kg in the cat (Baur, 1977). Fetuses with compact placentas do not consistently grow faster than those with diffuse placentas, although compact placentas always have a higher villous surface area per gram of tissue.

Among the species in which fetal blood gases can be measured accurately, the mare has a markedly higher rate of transfer of oxygen into fetal blood, as judged by Po_2 (maternal vein minus fetal vein) than ruminants or the pig. This cannot be accounted for by a particularly high oxygen affinity of fetal haemoglobin compared with maternal, or to a high fetal haemoglobin concentration, or a high fetal arterial oxygen saturation, since these three parameters are similar in all species investigated. Unlike other species, neither the horse (Kitchen and Bunn, 1975) nor the pig has a special 'fetal' form of haemoglobin. It has been suggested (Silver and Steven, 1975; Steven and Samuel, 1975)

that the efficiency of gas exchange in the equine placenta reflects the countercurrent nature of the vascular architecture and the close proximity of the fetal and maternal capillaries.

The similar high gas-exchange efficiency of the guinea pig placenta may also be due to the suggested countercurrent flow (P. Kaufmann, 1981) plus the high fetal–maternal haemoglobin–oxygen affinity ratio. These are probably both adaptations to the lower oxygen availability at the high altitude at which these animals live in the wild in South America.

As the placenta grows the mother has to increase her blood volume and cardiac output in order to perfuse the new organ. The higher the blood flow through the maternal placenta in millilitres per minute per kg of fetus (see Table 4.1), the greater the demand on the maternal vasculature. Animals with haemochorial placentas have the advantage here since they consistently show lower maternal placental flow rates (100–160 ml/min/kg) than those with epithelio- or synepitheliochorial placentas (250–330 ml/min/kg). The last two types must also provide extra maternal energy to fuel active transport across the two maternal layers, endothelium and uterine epithelium, which are absent in haemochorial placentas. In all placental types on the fetal side the blood flows in endothelium-lined channels. Since the range of umbilical flow rates in haemochorial placentas from guinea pig (64 ml/min/kg fetus) to man (208) (Table 4.1) spans nearly all of the synepithelio- and epitheliochorial values from pig (115) to cow (232) there would seem to be no simple relationship between structure and function in this respect.

As well as total blood flow, the rate of fetomaternal exchange will depend, at least to some extent, on the speed of the flow through the placenta. It has been suggested that the slower the rate the more efficient the transfer, and structures have been identified in haemochorial placentas which are said to be designed to produce **local** maternal blood stasis (Enders, 1965). There is no doubt that in many haemochorial placentas the total maternal blood in flow is slowed by the development of arterial sinuses (rabbit) or grossly widened arterial vessels (guinea pig, man). There is also some evidence for intermittent rather than continuous blood flow in primate placentas. How relevant these flow rate changes are to efficiency of maternofetal transfer and whether there is an optimal flow rate remains to be determined.

Transport of hydrophilic, non-diffusible compounds requires carrier systems to allow them to cross each membrane barrier. Rates of transfer have been shown to be inversely proportional to the number of interhaemal membranes, which would suggest a similar frequency or equivalent capacity of carriers in each membrane. Sodium, for example, is transported 300 times faster in human (four membranes) than in pig (eight membranes) with the cat (six membranes) in an intermediate position (Moll, 1985).

However, what direct evidence there is indicates local specialization rather than uniform distribution. In the pig, Firth *et al.* (1986a,b) have shown that the Na^+,K^+-ATPase-based sodium transport system appears to be concentrated in the apical trophectodermal membranes of the fetal areolae. In human there are differences in carrier systems between microvillar and basal membranes of the syncytiotrophoblast (Shennan and Boyd, 1987; Vanderpuye and Smith, 1987) and the latter shows considerable local elaboration (Figure 4.87). Thus, within the basic constraint of the number of barrier membranes, there may be considerable localized differentiation of transport functions which are only now becoming apparent.

Control of placental blood flow

Most organs are capable of regulating their blood flow (the process known as autoregula-

tion), so as to maintain a constant rate (ml/min) of perfusion during periods of altered blood pressure. This process which involves local control over dilatation or constriction of arterial precapillary sphincters, would not be expected to occur in haemochorial placentas, which lack post-myometrial vessels with such sphincters. However, the premyometrial uterine arteries are responsive to systemic agents acting on vascular beds (Greiss and Anderson, 1970; Ford *et al.*, 1977) and, since maternal placental flow accounts for a high proportion of uterine blood flow, maternal placental flow can be modulated through effects on these vessels. Thus, Venuto *et al.*, (1976) showed that maternal placental blood flow was maintained at approximately 25 ml/min in haemochorial rabbits when mean arterial pressure was reduced from 135 to 65 mmHg, and C. Bell (1972, 1974) has described uterine vasodilatation following uterine nerve stimulation in the pregnant haemochorial guinea pig. However, in the synepitheliochorial sheep placenta, which has both precapillary sphincters and systemic agents affecting premyometrial vessels, there is no evidence for maintenance of a constant rate of perfusion; Greiss (1966) showed that, during the last 30 days of gestation in the synepitheliochorial sheep, uterine blood flow is linearly related to central arterial pressure over the range 10–110 mmHg (arterial minus venous pressures), and Anderson and Faber (1982) showed that this is also true for fetal placental flow over the range 25–45 mmHg, in chronically catheterized fetal lambs.

Although uterine arterial blood flow may not change with changing maternal blood pressure in all species, there is evidence that local factors may control the ratio of maternal to fetal blood flows in the placenta. Rankin and his colleagues (see Rankin and McLaughlin, 1979) have drawn an analogy between the placenta and the lung in this respect; in the lung compensatory mechanisms exist to maintain a constant ventilation–perfusion ratio following local vascular embolism or hypoxic alveolus. It is clear that mechanisms serving a similar function exist to control blood flow in the placenta; when part of the umbilical blood supply is occluded in sheep and rabbits, maternal blood flow to that region (as measured with microspheres) eventually falls (Rankin and Phernetton, 1976); furthermore in the normal sheep placenta maternal–fetal perfusion ratios are similar throughout the organ although the gross flow to various parts of the placenta varies (Rankin *et al.*, 1970; Rankin and Schneider, 1975). Rankin (1978) and Rankin and McLaughlin (1979) have suggested that PGE_2, which is produced in large quantities by the fetal placenta in the sheep (Challis *et al.*, 1976; M.D. Mitchell and Flint, 1978a), may be involved in regulating the ratio of maternal to fetal flow, by exerting opposite effects on different sides of the placenta. Such a mechanism would not work in a haemochorial placenta with no arterial precapillary sphincters capable of responding to vasoactive compounds; in synepitheliochorial placentas, such as that of the sheep, it would depend on the PGE_2 diffusing very considerable distances from the fetal vasculature. An alternative function for fetal placental PGE_2 may be in maintaining the patency of the fetal ductus arteriosus (Coceani *et al.*, 1978). Other mechanisms by which placental blood flow may be altered over long periods of time must include angiogenesis and local necrosis; the latter could explain the effects of partial umbilical occlusion and the former the relatively constant maternal–fetal blood flow ratios referred to above.

Because of the proximity of the maternal and fetal placental vessels it is possible that a transient rise in pressure on one side might lead to occlusion of the other. This has been investigated experimentally in the near-term sheep placenta, in which it has been shown that, while an effect can be demonstrated in the isolated perfused placenta by applying

large changes in pressure (Bissonnette and Farrell, 1973; Power and Longo, 1973; Power and Gilbert, 1977), this cannot be confirmed in sheep with chronically implanted catheters (Thornburg *et al.*, 1976). A second form of mechanical control of placental blood flow, which has been investigated principally in man and rhesus monkeys, is that exerted by myometrial contractility; individual contractions of the kind associated with the early stages of labour lead to compression of the veins running through the myometrium so that flow of blood into the intervillous space is intermittently interrupted, with potentially dramatic effects on fetal well-being. The most usually monitored parameter which reflects this form of stress during labour is fetal heart rate, the transient fetal bradycardia associated with increased uterine pressure known as a type II dip (or late deceleration) being an indication of fetal distress (see Ramsey, 1967; Carter, 1975).

4.2.6 TYPES OF YOLK SAC ABSORPTION AND PLACENTATION

Four basic types can be characterized by reference to the origin of the fetal cellular layers they present to the maternal tissues. The association with the maternal tissues is rarely as close as in the chorioallantoic placenta, absorption being from the fluid (usually uterine) at the fetal surface. The fetal layers are different in each of the four categories and serve as important if usually transient sites of physiological exchange between mother and fetus.

(a) Bilaminar yolk sac or bilaminar omphalopleure

This is present in all species initially as the layers surrounding the yolk or forming the blastocyst (Figure 4.1). The trophoblast forms the outermost layer and there are ultrastructural indications of absorption by endocytosis. Delayed implantation blastocysts can survive up to 6 months at this stage in the uterine lumen. The trophoblast is usually cellular but may also form a syncytium and initiate implantation as in lagomorphs. The pole opposite the embryonic disc may persist as a functional yolk sac zone to term in marsupials and some insectivores (Figure 4.3).

(b) Trilaminar yolk sac (trilaminar omphalopleure or choriovitelline placenta)

The central mesoderm is richly vascularized and the external trophoblast usually forms an intimate apposition with uterine tissues so a true placenta is formed. This is found in certain fish (Figures 4.14 and 4.15), reptiles (Figure 4.16) and marsupials (Figure 4.17) as the major placental structure. Eutherians frequently develop an area of this structure which may be important at early stages of development following implantation but never persists as a functional structure to term (Figure 4.2). The external trophoblast is usually cellular, but occasionally this forms a syncytium also, for example at implantation in carnivores. Monotremes and marsupials (Metatheria) typically have exclusively cellular bilaminar and trilaminar areas which persist to release from the egg or term (Figure 4.17). The bilaminar areas show intracellular structures indicating endocytotic uptake, while the trilaminar areas are structured to minimize the diffusion distance between fetal and maternal circulations, thereby facilitating respiratory exchange (section 4.3.5c).

(c) Incomplete/partially inverted yolk sac

Invagination of the yolk sac sphere to form a cup brings the vascularized endodermal top (or embryonic) half of the sac against the outer non-vascularized bilaminar half, obliterating the yolk sac lumen (Figure 4.3). The bilaminar segment may persist up to term in some insectivores, bats and rodents but usually thins and degenerates before this. A characteristic of the bilaminar segment is the

presence of a robust acellular membrane – Reichert's membrane – between trophoblast and endoderm (Figure 4.3). In many cases this is the only continuous layer of the three. Recent evidence indicates that in the rat it is composed of basement membrane material produced by the endodermal layer (Fatemi, 1987; Mazariegos *et al.*, 1987). The trophoblast may transform into a discontinuous giant cell layer and invade the endometrium as in the rat and mouse or persist as a columnar epithelium as in the squirrels (Figure 4.2). There is no firm evidence that the bilaminar layer acts as anything other than a coarse filter between the mother and fetus. Large protein molecules pass across freely. The top segment of the yolk sac does function as a barrier with selective transport capability as described below.

(d) Completely inverted yolk sac

In many rodents, insectivores and bats the bilaminar segment of the yolk sac is either never formed or disappears at an early stage. This exposes the vascularized columnar endodermal cell layer ('inverted yolk sac', see Figure 4.3) to the uterine lumen or endometrium. A number of studies have demonstrated selective absorption and transmission of proteins across these cells (Bainter, 1986), which are sealed at their apices by tight junctions. This is the main route for transfer of intact maternal immunoglobulins for fetal immunoprotection in rodents, rabbits and guinea pig. There is no evidence that their coexistent chorioallantoic placentas have any similar function. Conversely, in primates with no functional yolk sac, the chorioallantoic trophectoderm is the immunoglobulin transporting epithelium.

There is a considerable range of elaboration of the 'inverted' endodermal layer in the various orders from a simple and loose association with a flat uterine epithelium (mouse, rat) to a profusely branched villous array very closely apposed to corresponding uterine projections – a true placental structure only found so far in one rodent, *Perognathus* (Mossman, 1987). Whether such placentas play a necessary or purely subsidiary role during gestation has yet to be established.

4.2.7 TYPES OF CHORIOALLANTOIC ABSORPTION AND PLACENTATION

In the chorioallantoic placenta throughout gestation the outermost fetal layer is invariably the trophoblast (trophectoderm, chorion if in association with somatopleuric mesoderm) or a trophoblast derivative. It is a remarkably versatile epithelium showing great capacity for invasion, cell fusion, hormone production, specific nutrient absorption, selective transport, active metabolism and ability to resist maternal immunological attack.

(a) Cyto- and syncytiotrophoblast

All trophoblast is initially cellular; in endotheliochorial and haemochorial placentas this cytotrophoblast provides a continuous mantle of syncytiotrophoblast by division and fusion of one of its daughter cells into the syncytium. In haemochorial placentas the daughter cells may develop into individual giant cells which can migrate into the maternal tissues; in synepitheliochorial placentas they form fetomaternal syncytia throughout pregnancy.

Evidence from *in vivo* and *in vitro* growth studies shows that syncytiotrophoblast can form only by fusion of cytotrophoblast cells. No nuclear division has ever been clearly demonstrated in placental syncytium in any species. In the human placenta all the syncytial nuclei investigated were shown to be diploid, whereas the cytotrophoblast nuclei ranged from diploid to tetraploid as would be expected of a dividing cell population (section 4.3.6d).

The formation of syncytiotrophoblast ex-

clusively from cytotrophoblast means the latter needs to be available throughout pregnancy to provide for the enormous increase in area found in all placentas examined. In most haemomonochorial placentas the cytotrophoblast (which lies between the syncytiotrophoblast and its basement membrane) is discontinuous from an early stage but is always available to support expansion. Where the cytotrophoblast itself forms the (cellular) haemomonochorial placenta growth in area is by simple division [in *Zapus* the jumping mouse (Figure 4.97), *Tadarida*, a bat (Figure 4.11), and hyrax (Figure 4.96)].

Haemodichorial placentas (rabbit; section 4.3.6d) can theoretically accommodate expansion once formed as long as one layer has some cellular constituents which can divide and fuse into either layer to support growth (Figures 4.76, 4.81 and 4.98). However, there is no experimental evidence for the production of one layer from the other and the relationship between the two is very different from that between cyto- and syncytiotrophoblast in the haemomonochorial placenta.

In the haemotrichorial placenta, of which all so far investigated have two inner syncytial layers and one outer cellular layer in contact with maternal blood (Figures 4.76 and 4.100) (Enders, 1965; King and Hastings, 1977), there is a similar growth problem. No evidence for any contribution from the cellular layer to the adjacent syncytial (middle) layer has been reported. There is good evidence that the three layers are formed at the very start of labyrinth development (Carpenter, 1972) and that there is an enormous increase in area of all three layers as this chorioallantoic placental labyrinth grows. To support this growth it seems likely that in both haemodi- and trichorial placentas each syncytial layer grows independently from occasional persistent cellular insertions or interruptions. In the absence of evidence for any nuclear division in the syncytium this is the simplest hypothesis but requires more definite confirmation than the occasional observations currently available (Davies and Glasser, 1968; Metz, 1980).

Once formed, the haemochorial placentas show increasing attenuation of their constituent layers as pregnancy progresses, as do all other types of placenta. Near term all show areas of trophoblast, syncytial or cellular or both, which are so thin that organelles are excluded (Figures 4.81 and 4.87). These areas usually overlie deeply indenting fetal capillaries and, presumably, greatly facilitate rapid fetomaternal exchange. The trophoblast also has a considerable capacity for endocytotic uptake of non-diffusible molecules, and the normal ultrastructural marker for this is coated vesicle formation from caveolae at the relevant plasmalemma. In di- and trichorial placentas caveolae are only found on layer II, and not on the loosely apposed fenestrated layer I, which is bathed in maternal blood. Layer I forms no barrier to serum or tracer molecules but does provide a baffle plate slowing down blood flow and producing relatively static regions immediately adjacent to layer II, which may, according to Enders (1965), facilitate endocytosis. Other regions of trophoblast past which maternal blood flow would be sluggish (judging by blood space architecture) also have a high incidence of coated vesicles. In many haemomonochorial placentas a lattice of narrow subsurface intrasyncytial channels is found, and this is in continuity with the maternal blood space (Figures 4.10 and 4.99; Enders, 1982).

Coated vesicles form from these channels, which may represent an alternative method of providing a static blood serum reservoir for efficient absorption. The channels are derived from the basement membrane of the maternal endothelium, which is displaced by syncytiotrophoblast invasion starting soon after implantation. The intrasyncytial channels with their fibrogranular content persist and grow in extent as the syncytium increases in area throughout gestation. In the bat, *Myotis*, autoradiographic studies indicate

that the structured glycoprotein/carbohydrate material in the channels (Figure 4.99) is synthesized by the syncytium (Cukierski, 1987). In all cases save one, the intrasyncytial channels form a closed system accessible only from the maternal blood space. The exception is the bat *Tadarida*, in which the channel content is clearly continuous with the basement membrane of the fetal syncytiotrophoblast (Figure 4.11).

Whether this forms a continuous conduit from maternal blood to fetal connective tissue remains to be determined.

The fibrillogranular material in the channels is analogous in origin and appearance to the interstitial layer ('membrane') found at the syncytial surface of the endotheliochorial (carnivore) placenta (Figures 4.68, 4.70 and 4.71). Although normally superficial, this interstitial layer is frequently penetrated by syncytiotrophoblast processes. A function exclusively as a fetomaternal barrier therefore seems unlikely and further functions relevant to transport seem feasible.

The continuity of a syncytial layer is considered to provide a better barrier to potentially harmful or toxic maternal cells and molecules than a cellular layer linked by tight junctions. The rarity of cellular haemomonochorial placentas supports this conclusion, but their existence again emphasizes the lack of any unique advantage of a syncytium.

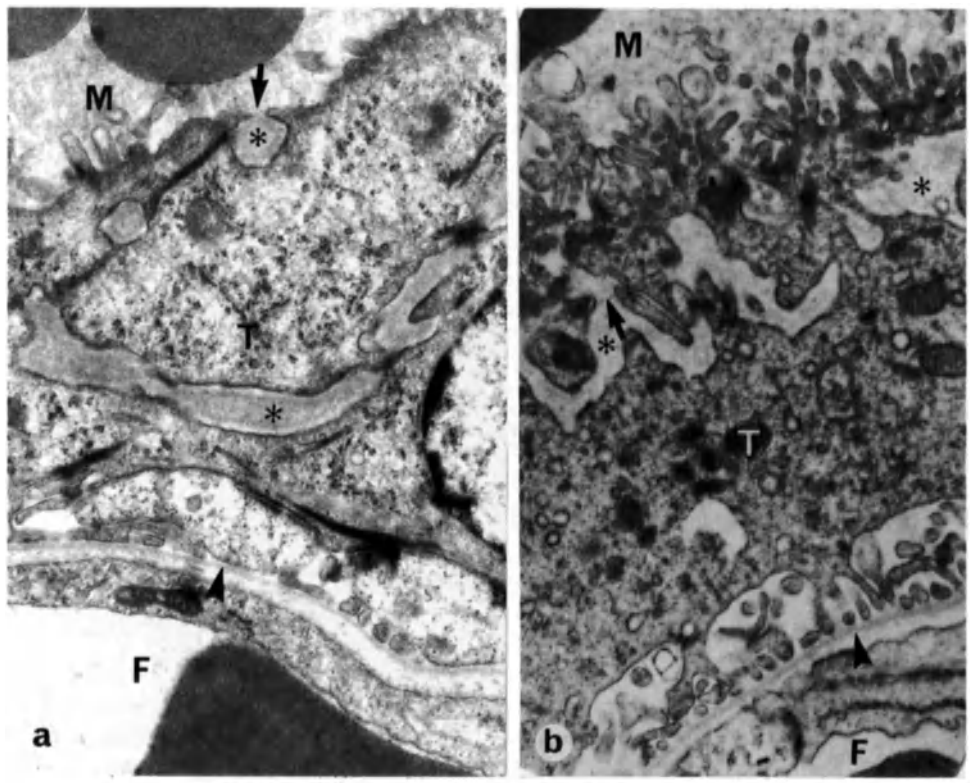

Figure 4.10 Haemomonochorial placentas with intrasyncytial lamellae (asterisks). In (a) the carnivore, hyena and in (b), the sciuromorph rodent, marmot, the lamellae (asterisks) are frequently open (arrows) to the maternal blood space (M) but no connection to the basement membrane (arrowheads) has been reported. (a) Hyena, mid-pregnancy; × 16 000. (b) Marmot, late pregnancy; × 15 200. (From Enders, 1965.)

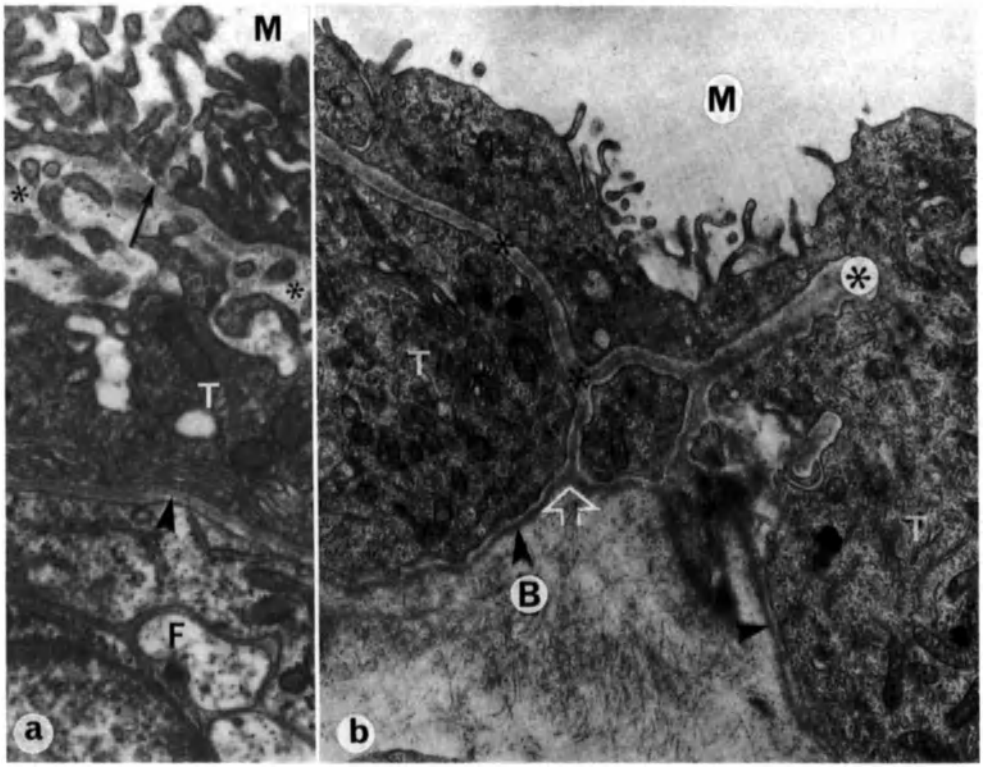

Figure 4.11 Haemomonochorial placentas with intrasyncytial lamellae (asterisks). In the sciuromorph chipmunk (a), the lamella is only open (arrow) to the maternal blood space (M) but not to the basement membrane (a, arrowhead) In (b) *Tadarida*, a molossid bat, the lamella and basement membrane (arrowhead, B) are continuous (open arrow) but here there is no evidence of any connection of the intrasyncytial lamella directly to the maternal blood space (M). F, fetal tissue. (a) Chipmunk, late pregnancy, × 21 500. (From Enders, 1982.) (b) *Tadarida*, late pregnancy, × 12 000. (From Stephens, 1969.)

In haemodi- and trichorial placentas the layers are linked by occasional tight junction remnants, frequent desmosomes and extensive gap junctions (Figure 4.81) (Metz *et al.*, 1976, 1978). The tight junctions may be remnants of those which linked the cells from which the syncytium formed and the desmosomes are needed to maintain the relationship between the layers. Gap junctions are normally considered to function by allowing the unimpeded passage of molecules below a certain size and thus to link cells biochemically for synchronous activity (uterine smooth muscle, for example). It has been suggested that in this placental context the gap junctions facilitate metabolite transfer across the layers. Tracer studies with lanthanum chloride and horseradish peroxidase clearly show that the healthy syncytial layers completely prevent transport in either direction of molecules of this larger size (Aoki *et al.*, 1978; Metz *et al.*, 1978) and any role of gap junctions in molecular transport from mother to fetus has yet to be demonstrated.

Although the syncytiotrophoblast shows no nuclear division it is very active in metabolism, synthesis and secretion. In man it has been shown to produce a wide variety of steroids and proteins including interferons (Bulmer *et al.*, 1990) and several hormones

(Figure 4.65), *in vivo* and *in vitro* (Patillo *et al.*, 1983). Syncytiotrophoblast in other groups contain an equivalent highly developed range of organelles and seems likely to play an equally important metabolic and endocrinological role.

Immunologically the syncytiotrophoblast surface facing the maternal blood in man and in mouse (the only two species investigated in detail so far) seems inert with no clear demonstration of any major histocompatibility complex (MHC) determinants. It has been suggested (Billington and Bell, 1983) that MHC antigen expression is obligately linked to cell division so that formation of a non-dividing layer would be one way of eliminating this expression with its attendant hazards.

Several advantages of a fetal syncytium in a placental context have been suggested: its plastic invasiveness, its synthetic versatility and capacity to secrete directly into the maternal compartment; its ability to form a continuous selective barrier which can include a considerable degree of regional differentiation or attenuation and; its immunological unresponsiveness and its inability to proliferate if fragments are released into maternal blood as human syncytiotrophoblast undoubtedly is (Covone *et al.*, 1984). However, there are examples of cellular trophoblasts which apparently perform just as well, so that syncytial change does not seem to be a prerequisite for successful placentation. Its widespread occurrence does argue that it may be better suited for carrying out the multifaceted requirements of a placenta than is a cellular system.

(b) Giant cells

Mononuclear giant cells are characteristic of rodent placentation and are formed from the surface cytotrophoblast of the conceptus during implantation and pregnancy. They are phagocytic and migratory and initially play an important role in enlarging the implantation chamber by eroding the superficial endometrial and decidual tissue including the capillary endothelium. Subsequent to implantation they form a loose sheath two to five cells thick around the conceptus through the interstices of which, on the antimesometrial side, maternal blood circulates. They are characteristically, though not exclusively, large (50–100 μm diameter) with large polyploid nuclei (16–32N, but 850N has been reported) (Barlow and Sherman, 1972; Ilgren, 1983). Visualization of individual chromosomes indicates that the giant cells usually only have the diploid number but each chromosome consists of multiple unseparated copies of its own DNA. This is polyteny rather than polyploidy and the distinction may have important functional consequences (Snow and Ansell, 1974; Bower, 1987; Varmuza *et al.*, 1988).

No evidence has been observed for cell division in giant cells with or without prior colchicine treatment. Incorporation of radioactive thymidine into giant cell nuclei is considered to be evidence of endomitosis, DNA replication without subsequent cell division.

Primary giant cells are defined as trophoblast cells which transform during and just after implantation on the antimesometrial and lateral (mural) aspects of the blastocyst external to Reichert's membrane. Secondary giant cells are formed a little later from the edge of the trophoblastic ectoplacental cone (M.H. Kaufmann, 1983). This is situated mesometrially and is a thickened cytotrophoblastic cellular plate which develops into the chorioallantoic placenta, producing from its growing edge secondary giant cells which are occasionally incorporated into the labyrinth.

There is great variation between rodent and lagomorph families in giant cell production, with murine rodents showing the largest and most characteristic forms. Their ultrastructure is unspecialized apart from the massive nucleus and quite different from the

adjacent spongiotrophoblast (Figure 4.82, rabbit). They frequently show evidence of phagocytosis, have little glycogen, contain both rough and smooth endoplasmic reticulum and a small Golgi apparatus. No cell junctions to other cells have been reported (Jollie, 1969; Kaufmann, 1983). The secondary giant cells form the boundary of the developing chorioallantoic placenta and play an important role together with the syncytiotrophoblast in the selective phagocytotic erosion of the maternal tissues essential for placental growth. They also form the only layer in one haemomonochorial placenta, that of *Zapus* (jumping mouse) (Figure 4.97). An endocrinological role is indicated by the finding that giant cells can produce steroids (Deane *et al.*, 1962) and placental lactogen *in vivo* and *in vitro* (Hall and Talamantes, 1984; Soares, 1987; Yamaguchi *et al.*, 1992). They share several characteristics with the endometrial cup cells in equids, and the ruminant binucleate cells, which have often been called giant cells in the past (Amoroso, 1952). All are transformed cells from the cytotrophoblast with specific secretions and capacity for migration (Hoffman and Wooding, 1993). There is one major difference in that ruminant and equid binucleate cells are diploid whereas rodent mononucleate giant cells are usually polyploid (Ilgren, 1983).

Rodent giant cells are immunologically specialized in expressing none of the MHC determinants on their plasma membranes (Lala *et al.*, 1983) and could therefore represent an immunologically neutral buffer zone when they form a continuous shell around the conceptus in early pregnancy. Most primary giant cells have degenerated by the time Reichert's membrane breaks down, and the majority of secondary giant cells also regress before the end of pregnancy. It has been reported that some giant cells which penetrate rather deeper than the others into the endometrium can survive parturition and persist until a subsequent pregnancy (Mossman, 1987). In humans all so-called 'giant cells' found in the maternofetal interface junction zone are syncytial, probably with diploid nuclei. They form part of the wide range of 'interstitial' trophoblast cells or syncytium scattered in the basal plate of the placenta (Hoffman and Wooding, 1993).

(c) Spongiotrophoblast

Rodent placentas usually have a definite zone between the giant cell layer and the base of the labyrinth referred to as the 'spongiotrophoblast', 'trophospongium' or 'junctional zone'. The tissue forms channels draining the maternal blood from the placenta but fetal capillaries do not penetrate this far (Figures 4.72, 4.77 and 4.82).

The spongiotrophoblast is derived from the outer layers of the original ectoplacental cone and is perfused by maternal blood from a very early stage of chorioallantoic placenta formation. It has been pointed out that it is in an excellent location to secrete fetal hormones or other effector molecules solely into the maternal circulation, and there is some evidence in the rat that it has a cytoplasmic structure significantly different from that in the contiguous labyrinth (Jollie and Craig, 1979). This does not seem to be true of the guinea pig (Figures 4.6 and 4.7) but in this case the uniquely structured subplacenta intervenes between spongiotrophoblast and maternal decidua (Figures 4.6 and 4.7). Its cellular form and extent vary considerably, ranging from a coarse mesh of syncytium in the guinea pig to a compact cellular layer in the mouse. Mossman (1987) suggests that it is homologous with the cytotrophoblastic shell at the base of the placental disc in primates. An immunological role has been postulated because in rat, mouse and man this trophoblast bears MHC antigens absent from the vast bulk of the haemochorial placental syncytiotrophoblast (Faulk and Hsi, 1983; Kanbour *et al.*, 1987), although there are dissenting voices (Chatterjee *et al.*, 1982).

(d) Endovascular trophoblast

In human (first trimester), hamster [10–11 days post conception (dpc)], rat and mouse placentas there is a considerable early invasion by the cytotrophoblast down maternal arteries supplying the placenta (Pijnenborg *et al.*, 1981). Migration proceeds almost to the myometrial level down those arteries which have already undergone decidual alteration, with an aggregation of pericytes around them and a swollen endothelium within. Migrating cytotrophoblasts then phagocytose and eliminate both the endothelium and the elastic lamina of the arteries, replacing them eventually with cytotrophoblast cells and their syncytial derivatives dispersed between tubular lamellae of fibrinoid. Slightly later (human, second trimester) there is a second cytotrophoblast migration even further, now into the (spiral) arteries of the myometrium. These successive migrations produce considerably widened tubes discontinuously lined with cyto- and syncytiotrophoblast which are permanently open, and unresponsive to vasoactive materials (Pijnenborg *et al.*, 1983; Hees *et al.*, 1987). These tubes can accommodate the vast increase in blood flow necessary to supply the exponentially growing fetus during the second half of pregnancy. Insufficient erosion and distension of the arteries has been shown to be correlated with failure of pregnancy in hamster and human (Faulk and McIntyre, 1983).

There is some evidence in man of an infiltration of lymphocytes and endometrial granulocytes around the distended arteries (Pijnenborg *et al.*, 1980). This may represent a maternal response to the invasion by the cytotrophoblast, which has been reported to bear MHC antigens (Faulk and Hsi, 1983).

(e) Fetomaternal hybrid syncytiotrophoblast

There is good evidence for fetomaternal cell fusion in three cases so far. Such hybrid tissue persists only briefly at rabbit implantation and in the chorioallantoic placenta of the marsupial *Perameles* (bandicoot) but is formed from implantation to term in all ruminants so far investigated.

In rabbit the blastocyst trophoblast forms a fetal syncytial 'peg' which fuses with a uterine epithelial cell or syncytium formed from the uterine epithelium (Figure 4.13) (Larsen, 1961; Enders and Schlafke, 1971a). By this means the blastocyst gains access to the endometrium to initiate formation of the chorioallantoic placenta. The maternal nuclei in this hybrid syncytium are said to disappear rapidly (although this aspect has not been closely studied) and the fetomaternal fusion is seen simply as a means of penetrating the uterine epithelial barrier.

Perameles is one of the few marsupials to develop a chorioallantoic placenta, and this forms only in the last 3 days of a 12 day gestation. At this stage the uterine epithelium consists of syncytia of limited extent (plaques), each containing several identical small nuclei. It is apposed to trophoblast cells each with a morphologically very different, large nucleus. Subsequently, the cellular trophoblast disappears and the syncytial plaques are found to contain both sizes and sorts of nuclei (Figures 4.17, 4.18 and 4.19) (Padykula and Taylor, 1976). No direct ultrastructural evidence for fusion of the apposed cellular and syncytial layers has been observed but this is the simplest explanation. The fusion allows the fetal and maternal blood capillaries to approach much more closely (see Figures 4.17, 4.18 and 4.19). The postulated fetomaternal tissue persists for the last 2 days of gestation when the fetus grows at a very rapid rate.

Fetomaternal fusion in ruminants is a much more persistent phenomenon (Wooding, 1982b). Binucleate cells develop in the predominantly uninucleate trophoblast just prior to implantation. They form 15–20% of this layer throughout gestation. When mature (i.e. with a full complement of their characteristic granules) they migrate out of the trophectoderm and fuse with the

apposed uterine epithelium to produce a persistent fetomaternal syncytium at the interface with the maternal endometrium (Figures 4.38, 4.42 and 4.43). This process continues throughout pregnancy (Figure 4.39), contributing to an integral layer of the placenta and/or delivering to the maternal tissue the granules which contain placental lactogen among other constituents (Figure 4.39). Further details and a discussion of the relevance of this system can be found in section 4.3.6(b) on synepitheliochorial placentation below and Wooding (1992). Other examples of fetomaternal fusion may well occur in other placentas, but without unequivocal markers it is difficult to recognize and verify such unexpected events.

4.2.8 DECIDUAL TISSUE, STRUCTURE AND FUNCTIONS

(a) Origins of decidua

Decidual tissue is usually restricted to those species with invasive, haemochorial placentation. It was initially defined as that part of the maternal endometrium which was shed at parturition. However, at partus little is left of this complex tissue which is now known to play a vital role from the start of successful conceptus development, and the definition has been widened considerably to take account of this (S.C. Bell, 1983; Kearns and Lala, 1983; Lala *et al.*, 1983; Glasser, 1990).

It is the non-glandular non-vascular cell populations of the endometrial connective tissue which form decidual cells, and this results in a considerable increase in the thickness of the gravid endometrium in early pregnancy. Decidual cell development is initiated either immediately below the uterine epithelium (rodents) or much deeper in the endometrium around the (spiral) arteries (lagomorphs, primates). The initial zones extend to produce a semicontinuous layer between the advancing trophectoderm and the myometrium.

By definition decidual cells are produced by steroid hormone-dependent division and differentiation of maternal uterine stromal cells (Glasser and McCormack, 1980; Tarachand, 1986). They form characteristic decidual cell areas found in significant extent only in orders with haemochorial placentation in which the trophoblast invades the maternal connective tissue: the insectivores, rodents, lagomorphs and anthropoids (Wynn, 1967). The areas are most prominent in early stages of pregnancy but vary considerably in extent in the different genera. In man there is a very extensive development, but in the closely related baboon the initial decidualization is morphologically much less obvious (Ramsey *et al.*, 1976), but all primates have extensive decidua by mid-pregnancy (Enders, 1991).

Decidual development is initiated by the arrival of a blastocyst or some artificial stimulus (oil drop, suture thread, electrical stimulation) in the hormonally primed (oestrogen plus progesterone) uterine lumen and follows a specific sequence (Figure 4.12).

In rodents the antimesometrial decidual cells develop first and form a very compact avascular zone which excludes most blood proteins from the uterine lumen containing the implanting conceptus (6–9 dpc) (M.B. Parr and Parr, 1986; M.B. Parr *et al.*, 1986; Christofferson and Nillson, 1988). Subsequently, the more loosely packed mesometrial decidual cells are closely involved in the fetomaternal interactions as the trophoblast invades to form the hemochorial placenta (8–12 dpc). Proliferation of the blood sinuses in the decidualizing mesometrial uterine stroma also facilitates placental growth (7–11 dpc). The areas of decidual cells rapidly increase from the uterine lumen outwards to the myometrium and can be conveniently visualized by the characteristic presence of alkaline phosphatase and periodic acid–Schiff (PAS) reactivity in the decidual cells (S.C. Bell, 1983).

Granulated decidual cells develop through-

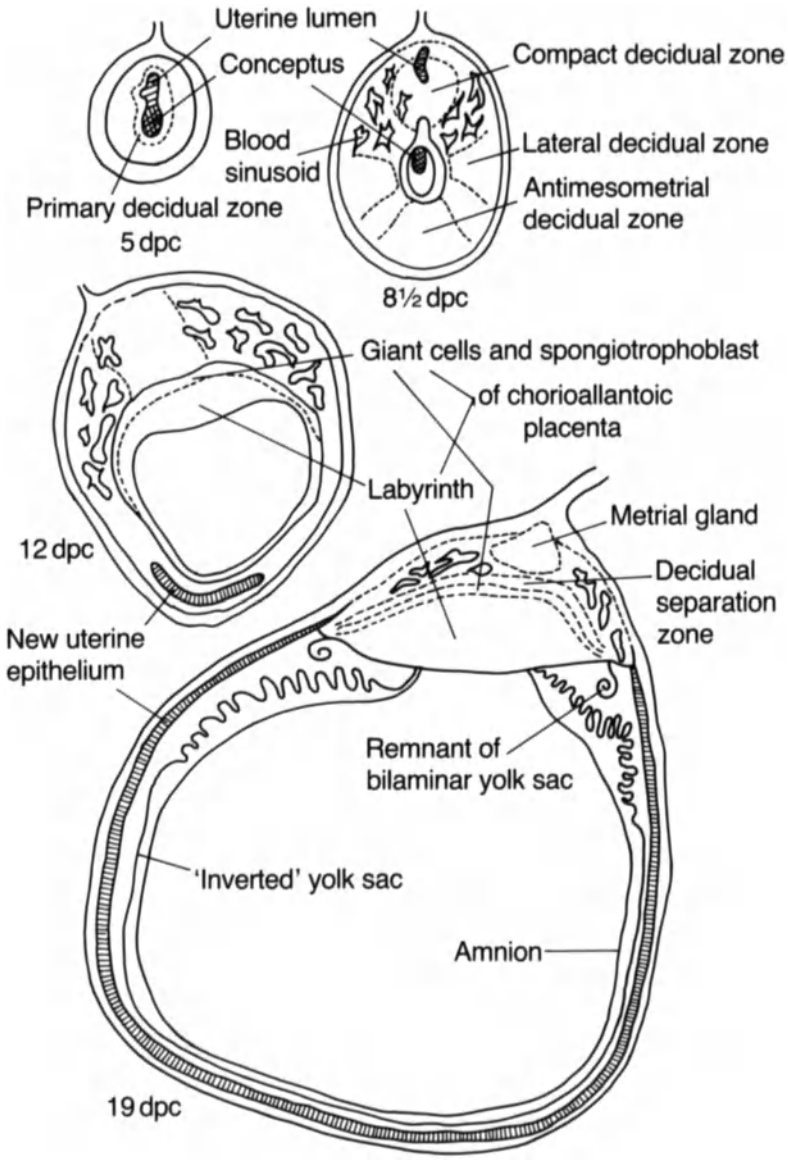

Figure 4.12 Scale drawings of the development of decidual and placental tissue in the mouse. (Based on S.C. Bell, 1983, and Rugh, 1975.)

out the mesometrial decidua but are initially concentrated around the blood vessels where they pass through the myometrium. This population eventually forms the metrial gland in rats and mice (section 4.2.8b). In man the conversion of stromal to decidual cells starts around the spiral arteries prior to implantation and spreads through the stroma to link up with the decidual area developing around the conceptus from 9 to 10 dpc (Figure 4.88).

Maximum development of the decidual cell populations occurs early in pregnancy, eventually occupying most of the uterine stroma and in mice and rats, completely surrounding the conceptus (Welsh and Enders, 1985). Cell division then largely ceases and the decidual cell layer is continually eroded by spontaneous necrosis and attenuated by growth of the placenta and fetus until at term it forms only a thin layer at the base of the placenta through which the placenta separates (Figure 4.12).

Deciduoma

The decidual tissue formed in response to an artificial stimulus is called a deciduoma, and is grossly similar to that induced by a blastocyst but has fewer regional specializations (Wadsworth *et al.*, 1980; O'Shea *et al.*, 1983). Deciduomas regress spontaneously in mice and rat (but not man) even if pregnancy is mimicked by maintaining the progesterone level artificially. This indicates that cells of the deciduoma have a predetermined lifespan and undergo programmed cell death, a process which is also seen to some extent later in pregnancy when sequential spontaneous death of the decidual cells facilitates the expansion of the conceptus and growth of the placenta. Decidualization therefore, does not produce a uniform population but a succession of coordinated differentiations of different cell types. There are also indications that specific lymphocytes and macrophages are recruited into the decidua from the circulation to perform functions related to pregnancy maintenance (Clark, 1985a). There is increasing evidence for a variety of functions for the decidua at different stages of haemochorial pregnancy: a physical and/or immunological barrier, a nutrient source, a hormone producer and a facilitator of placental growth and eventual release.

Decidualization and menstruation

The hormonal changes preceding ovulation produce correlated changes in the uterine stroma and epithelium. Usually such changes are restricted to tissue oedema and structural changes in the uterine epithelial cells (in ruminants and carnivores, for example). However, in humans and Old World monkeys the cyclic changes include considerable stromal to decidual cell development and proliferation of the spiral blood vessels. The subsequent cell necrosis and haemorrhage in this tissue as the progesterone level drops produces the menstrual discharge (Ramsey, 1982). The instructive similarities between menstruation, inflammation and decidualization have been pointed out in an excellent review by Finn (1986).

(b) Decidual cell structure

Stromal cells

The majority of decidual cells develop from the division in the endometrial stroma of irregularly shaped fibroblast-like cells with little cytoplasm and few organelles. Decidualization starts with the blood vessel pericytes in rabbits and humans and subepithelial stromal cells in rodents and characteristically involves a considerable increase in cell size (Amoroso, 1952; Mossman, 1987). The cytoplasm may develop meshworks of intermediate filaments, many free ribosomes, much glycogen and/or lipid droplets and numerous gap junctions with

adjacent decidual cells. Different areas (see Figure 4.12) also display their own characteristics. In rats and mice, antimesometrial decidua have very large closely packed cells, frequently binucleate or polyploid, with well-developed rough endoplasmic reticulum and Golgi apparatus and a low level of glycogen and/or lipid stores. Mesometrial decidual cells are smaller, more irregularly shaped and uninucleate, usually with rather more glycogen. Lateral decidual cells, among the rapidly expanding blood sinuses, have massive amounts of glycogen and are only occasionally binucleate (Welsh and Enders, 1985; M.B. Parr *et al.*, 1986).

In man there is a comprehensive decidualization throughout the uterine stroma but with less regional specialization than in rodents (Wynn, 1974; Schiebler and Kaufmann, 1981). There are three main types of human decidual cells. There are numerous 'small predecidual' swollen fibroblasts (50 μm × 5 μm) which have an equivalent low level of cytoplasmic organelle development and frequent 'large undifferentiated' decidual cells (100 μm × 25 μm). Scattered among these two predominant types are 'large differentiated' decidual cells (100 μm × 25 μm) with well-developed arrays of rough endoplasmic reticulum, many mitochondria, an extensive Golgi complex and large areas of glycogen and lipid. Human decidual cells are isolated from each other by an investment of fibrinoid and are linked by fewer gap junctions than are found in rodents (Boyd and Hamilton, 1970; Schiebler and Kaufman, 1981).

These cells form the basic structural matrix of the decidua. Other cells are invariably present (in pregnancy and deciduomata) which do not originate from stromal fibroblasts but are recruited instead from either the bone marrow (Gambel *et al.*, 1985; Krcek and Clark, 1985) (endometrial granulocytes equivalent to metrial gland cells), or the blood (decidual macrophages, Ia-antigen bearing cells, non-T suppressor lymphocytes) (Croy *et al.*, 1985). After the definitive placental structures have formed, the decidual area frequently also contains trophoblast derivatives: the occasional giant cell in rodents and large numbers of multinucleate trophoblast masses (known also as 'extravillous trophoblast') in humans as well as endovascular trophoblast in the blood vessel walls.

Non-fibroblast stromal cells

Endometrial granulocytes (metrial gland cells) Electron microscope and cell repopulation studies with irradiated mice and rats indicate that endometrial granulocytes develop from small round cells which originate from the bone marrow but divide and differentiate in the endometrial stroma (Peel *et al.*, 1983; Peel and Stewart, 1986). They can easily be distinguished on structural and staining criteria from blood eosinophils, basophils, neutrophils or mast cells. They are present in pregnant and pseudopregnant uteri (Peel *et al.*, 1979).

Mature granulocytes are the most frequent cell type after the fibroblast-derived decidual cells. They are often binucleate, and typically contain glycogen, rough endoplasmic reticulum and a large Golgi body which produces numerous membrane-bound granules. These are usually homogeneously electron dense, but some also have membranous inclusions (monkey, Cardell *et al.*, 1969; rat, Larkin and Flickinger, 1969; mouse, I. Stewart and Peel, 1977). In the light microscope the granules are eosinophilic and PAS positive and are said to contain lysosomal enzymes, IgG molecules synthesized in the granulocyte (B.S. Mitchell *et al.*, 1981), a protein, perforin, characteristic of killer and cytotoxic lymphocytes (E.L. Parr *et al.*, 1987), and the protein hormone relaxin, although this last localization has not been confirmed (Dallenbach-Hellweg, 1967, 1981). Human granulocytes show a weak natural killer activity which is enhanced by interleukin 2 (Ferry *et al.*, 1990)

and blocked by interferon-γ but not -α (A. King and Loke, 1993).

The granulocytes do not show phagocytosis, nor do they form intercellular gap, tight or desmosomal junctions with each other or with disparate cell types. In mice the cells average 50 μm in diameter and have a smaller number of larger (5 μm) granules compared with the rat (25 μm diameter, 2 μm granules) or man (12 μm diameter, 1 μm granules). The cells are found scattered in the mesometrial decidua from an early stage (mouse, 8 dpc) and in rat and mouse they collect around the myometrial blood vessels to form an accumulation in the mesometrial triangle between the myometrial layers which is referred to as the metrial gland (Figure 4.12) (For a comprehensive review see Peel, 1989.) Endometrial granulocytes are also found adhered to the walls of the placental labyrinth and decidual blood spaces. It has recently been suggested (I. Stewart, 1984) that such a granulocyte–trophoblast interaction may be relevant to their function, which may be related to non-specific immune suppression in the uterus and/or regulation of placental growth (Croy and Kassorf, 1989). Granulocytes have also been reported in the lungs of mice (I. Stewart, 1985).

The metrial gland reaches its peak size and placental vascular granulocytes their maximum numbers at 13–14 dpc in the rat. Between 15 and 21 dpc (term) there is a progressive loss of the cells by swelling and lysis and they release their cell contents including the granules into the connective tissue. This process has been referred to as holocrine secretion (Peel and Stewart, 1979) but seems more analogous to the 'programmed cell death' seen in other decidual cells, or cell regression in ovarian luteolysis. This would mean that the functional life of the cells is finished rather than that the release of the cell contents is the ultimate purpose of the process of granule development.

The cell debris is removed by macrophages, which are the probable precursors for the cells full of lipid droplets and phagolysosomes which progressively replace the granulocytes in the metrial gland region from 17 dpc. Some granulated cells may persist post term, but most regress long before parturition. There is no evidence for direct transformation of granulocytes to lipid-laden cells.

Decidual macrophages The evidence for this population comes from histological work and from tissue culture studies of mouse decidua (Hunt *et al.*, 1984). The cells have immunoglobulin (Fc) receptors, an ectoesterase enzyme on their plasma membranes and are phagocytic, suggesting an infiltrating macrophage type. This is corroborated by the absence of lymphocyte surface markers (IgG or Lyt antigens). The incidence of this cell type increases to a peak at 15 dpc in mouse, is strain dependent and low numbers seem to be correlated with poor fertility and a high conceptus resorption rate (S.C. Bell, 1983; Tawfik *et al.*, 1986).

Ia antigen-bearing cells Cells with a high level of Ia expression (MHC class II antigen) which lack lymphocyte or macrophage markers are typically involved in antigen presentation in the immune response sequence. Such cells have been identified in tissue cultures of mouse decidua from 14 dpc onwards (Elcock and Searle, 1985) and on sections of human decidua in early pregnancy (Oksenberg *et al.*, 1986).

Suppressor cells Characteristic cell populations have been isolated recently from mouse (mesometrial) (Brierley and Clark, 1987) and human (basalis) (Daya *et al.*, 1985) decidua which display suppressor activity against cytotoxic lymphocytes (CTLs) *in vitro*. Decidua lacking such cells cannot usually support a successful pregnancy. The cells are small and lymphocyte-like with eosinophilic granules and Fc receptors but lacking all lym-

phocyte surface markers (no Thyl, Lyt 1 or 2). They appear to produce a soluble factor capable of suppressing the interleukin 2 dependent expansion and subsequent attack by a CTL population directed against the fetal allograft. Fetal trophoblast is necessary for their recruitment (from about 7 dpc) into the decidua; they have not been found in deciduomata.

In the mouse, there is a population of larger cells showing similar suppressor activity found at implantation (4–6 dpc) which are also present in deciduomata. The detailed structures and localizations of these small and large 'suppressor' cells have yet to be clarified (Brierley and Clark, 1987).

'Decidual' structures in non-haemochorial placentation Extensive decidual cell development characterizes haemochorial placentation, but in some synepitheliochorial and endotheliochorial placentas specialized cells originating from uterine stromal cells are consistently incorporated throughout the definitive placental structure at the feto-maternal interface. The best example is the frequently binucleate giant cells in the cat placenta (Figure 4.68). Much smaller less obvious cells are also present in an equivalent position in the dog (Amoroso, 1952; Mossman, 1987). Cells of similar structure are found as giant pericytes around the maternal vasculature in the sheep and goat (Figure 4.69). These cells never form a coherent layer as in haemochorial placentas but their consistent presence suggests that they may play a role (producing a specific secretion?) in maintaining the delicate balance between fetal and maternal tissues. Decidual changes have also been reported in the pseudopregnant ferret, but the alterations are in the subepithelial uterine capillary endothelium rather than the stromal cells (Beck and Lowe, 1972).

Epithelial plaque Decidualization has been defined here as endometrial stromal cell differentiation. Epithelial plaque, which is always cellular, is formed by proliferation and development of uterine luminal and glandular epithelium dependent on the same hormonal regimen and enhanced in a similar way by contact with the blastocyst.

Plaque formation is characteristic of some monkeys whose implantation is superficial and whose early stromal decidualization is minimal (Rossman, 1940; Enders *et al.*, 1985; Owiti *et al.*, 1986). The epithelial proliferation is transient, starting at 6 dpc, and the plaque is engulfed and removed by the developing trophoblast by 20–22 dpc in the rhesus monkey for example (Figures 4.92 and 4.93) (Enders *et al.*, 1985). Prior to its obliteration it undergoes symplasmic degeneration. This life history is similar to that undergone by the surface epithelium in the uterus of carnivores and lagomorphs (Steer, 1971; Schlafke and Enders, 1975; Leiser, 1979). In these cases there is less initial proliferation but the symplasmic masses have to be absorbed in the same way by the trophoblast during the cellular remodelling involved in the trophoblast invasion of their maternal tissues. It seems probable that the symplasmic masses reported in the fetomaternal junctional zone of many placentas are derived from the epithelium of the glands rather than aggregated stromal decidual cells. Their production is the first stage in the reduction of the maternal tissue to merely a scaffolding of proliferating maternal blood vessels invested by a layer of vascular fetal trophoblast.

The extreme proliferation involved in plaque production can be seen as one of the ways of avoiding too rapid a penetration of the endometrium by the trophoblast (compare Figures 4.83 and 4.92). Plaque allows controlled access to the maternal circulation. Once this has been achieved superficial development of a purely fetal vascularized syncytium to form villi or a labyrinthine meshwork is all that is required to produce the haemochorial primate placenta. There is no need for deeper erosion of the endo-

metrium for in most Old World primates the maternal blood supply is restricted to orifices at the maternal face of the fetal tissue. Epithelial plaque formation is one way of achieving this controlled access to the maternal blood after superficial implantation: by contrast, interstitial implantation induces stromal decidual cell development (Ramsey, 1982). Both are systems for establishing a viable fetomaternal dialogue with a minimum of delay and stress to either party.

The variation in the balance between epithelial plaque and stromal decidual transformation (Ramsey *et al.*, 1976) is in sharp contrast to the similarity of the final placental structure. This may be taken as further evidence for the difficulty of rapidly establishing the fetomaternal dialogue: of balancing the nutritional needs of the embryo against the immunological sensitivities of the mother.

The same problems may be solved by what appear superficially to be very different morphological methods. In practice, small changes in mitotic rates of particular cell groups or phagocytotic capacity of the trophoblast might be sufficient to account for the differences.

(c) Functions of the decidual cells

Many functions have been proposed for decidua and it seems likely that there may be several roles it can play; which one is emphasized probably depends upon the specific demands of each particular animal group.

Isolation of the implanting blastocyst

In rodents with a small blastocyst there is a rapid initial decidual development of stromal cells immediately around the blastocyst (Figure 4.10). These cells become so closely packed, accentuated by both tight and gap junction formation, that maternal blood cells and proteins are prevented from reaching the blastocyst (M.B. Parr *et al.*, 1986). The effect is transient, lasting only from 6 to 9 dpc in the rat, and subsequently these early decidual cells die, to be displaced by the expanding conceptus. Reichert's membrane forms between the yolk sac ectoderm and endoderm coincidentally with the loss of this decidual barrier, and it has been suggested that this new acellular layer may take over the function of excluding harmful constituents of the maternal blood from the embryo (M.B. Parr and Parr, 1986).

Barriers to trophoblast invasion

Direct evidence that decidual cells act as barriers to trophoblast invasion comes from the observation that blastocysts transferred to subepithelial ectopic sites (kidney, testis, anterior chamber of the eye) penetrate into the non-decidualized connective tissue much more deeply than into uterine decidua (Kirby, 1963, 1965; Porter, 1967). Conversely, skin grafted onto decidualized uterine stroma is rejected much more slowly than skin in the non-decidualized uterus. The process of decidualization starts at the luminal surface, and the uterine epithelium, though rapidly lost, probably plays an essential role in mediating and amplifying the stimulus to decidualization (Kennedy, 1983). Uterine epithelium that is not receptive (i.e. that is not hormonally primed) is a much more complete barrier to blastocyst penetration.

A mechanical barrier results from the formation of a coherent decidualized cell layer by rapid division and expansion of the initially widely separated fibroblasts in the oedematous endometrial stroma (Glasser and McCormack, 1980; M.B. Parr *et al.*, 1986). The resulting decidual cells are often linked by gap junctions and are thus capable of concerted changes. It has been suggested that such a linked cellular barrier is so effective that expansion of the trophoblast is dependent on prior programmed cell death of the decidual tissue (Beaulaton and Lockshin, 1982). Certainly there seems to be a very close relationship between the two tissues in rodents (Welsh and Enders, 1985).

In man the decidualized cells are not so closely packed as in rodents and they frequently secrete a dense extracellular matrix consisting of collagen and glycosaminoglycans, which would also hinder trophoblast invasion (Boyd and Hamilton, 1970; Schiebler and Kaufmann, 1981). Such material is usually referred to as 'fibrinoid' and may form continuous sheets between fetal and maternal domains like Nitabuch's and Rohr's 'striae' at the base of the human placenta (Boyd and Hamilton, 1970).

However, such decidual cellular and extracellular barriers are rarely complete (Martinek, 1970) and elements of the trophoblast frequently penetrate well past the decidualized 'layer'. The interstitial and endovascular trophoblast of humans and rodents are examples of this breaching of the 'barrier'. The decidual layer may form an effective if partial barrier in some species (Bradbury *et al.*, 1965), but even then it is probably only part of an array of accommodations between mother and fetus to promote fetal survival.

A functional barrier may be provided by the secretion of specific proteins by decidual cells which either directly inhibit the protease activity of the trophoblast or compete locally for the growth factors such as insulin-like growth factor 1 (IGF-1) necessary for trophoblast growth. Bell and colleagues (S.C. Bell, 1979; S.C. Bell *et al.*, 1988) have published evidence for the production of decidual associated proteins and/or alkaline phosphatase which may serve such functions.

The loss of fibronectin from the surface of decidualizing cells may provide another functional barrier. As a result of the loss the trophoblast can no longer so readily form the close associations necessary for rapid and efficient killing or engulfment of the barrier cells (S.C. Bell, 1983).

Nutrient provision

One of the characteristics of decidualizing cells is the accumulation of glycogen and/or lipid stores, although this is not always found. It is generally assumed that this is produced for the eventual nutrition of the blastocyst. Amoroso (1952) noted that animals without decidual cells usually have many more uterine glands producing histotroph for blastocyst maintenance and growth.

Decidual cells phagocytosed by the trophectoderm would provide considerable readily convertible food stores very necessary to support the rapid growth of the conceptus. Presumably the barrier function of the decidua prevents the blood nutrients reaching the trophectoderm directly. Alternatively, the glycogen and lipid storage may be merely a measure of the senescence of the cells of the decidua which results in subsequent phagocytosis by the trophectoderm.

Hormone production

Prolactin There have been several reports of progesterone-dependent prolactin production by cultured decidual cells in man (Maslar *et al.*, 1986) and rodents, and histological studies indicate localization of prolactin to parietal decidual cells by immunofluorescence, (Braverman *et al.*, 1984; Al-Timimi and Fox, 1986; Bryant Greenwood *et al.*, 1987) and hybridization histochemistry (Xuan *et al.*, 1990; W.X. Wu *et al.*, 1991).

The amount of prolactin produced increases during pregnancy, and there is increasing evidence for a paracrine or autocrine role for this decidual prolactin in control of the osmotic balance at the fetomaternal interface (Meuris *et al.*, 1980; Gibori *et al.*, 1984). Control of decidual prolactin secretion is significantly different from pituitary prolactin because it is unaffected by bromocriptine (which blocks) or thyrotropin-releasing hormone (which stimulates) prolactin secretion from the pituitary (see Gibori *et al.*, 1984).

Prostaglandins and steroids Cultures of rodent and human decidual cells have been

shown to produce prostaglandins (Lala, 1989) and steroids, which have immunological potential as demonstrated by their effects on the mixed lymphocyte reaction (MLR) and cytotoxic lymphocyte (CTL) function. They are also implicated in the control of predecidual cell division, in the initiation and maintenance of decidual differentiation (Glasser and McCormack, 1980; Kennedy and Lukash, 1982; Clark, 1985b), and in the initiation and process of parturition.

Relaxin This hormone has been reported in human endometrial granulocytes and was suggested to be present in the rodent metrial gland (Dallenbach-Hellweg, 1967). Neither of these localizations has been confirmed. Sakbun *et al.* (1987) have reported an immunofluorescent localization to basal plate cells and the amniotic epithelium in human term placenta; and Bryant Greenwood *et al.* (1987) a localization to chorion laeve cytotrophoblasts and parietal decidua (see Sherwood, 1988, for an excellent review).

Immunological (functions) implications

1. Occlusion of lymphatics by adjacent decidual cell growth has been suggested to block the efferent immunological response to the foreign conceptus. However, there appear to be very few lymphatics in the uterine endometrial stroma of species which produce decidua so the importance of this effect is difficult to assess (Head and Seelig, 1984).
2. Soluble factors from cultured mouse decidual cells are said to have several local immunosuppressive functions (S.C. Bell, 1979). Such factors can recruit T and non-T suppressor cells, protect against natural killer (NK) and cytotoxic lymphocyte-mediated lysis and stimulate blocking antibodies rather than antibodies mediating rejection. The trophoblast is the primary source of these local immunosuppressive soluble factors, but the most recent informed opinion is that 'decidual factors can do almost all that trophoblast can' (Chaouat, 1987).
3. The decidual tissue forms a matrix in which immunologically active cells can modify the maternal response to the fetus (for a good review see Colbern and Main, 1991). There are reports of the presence of suppressor cells (mentioned in section 4.2.8c above) and macrophages and other Ia-positive cells which may process foreign antigens in such a way that the fragments induce tolerance rather than rejection (Clark *et al.*, 1984, 1986, 1987; Hunziker and Wegman, 1986). However, severe combined immunodeficient (scid) mice produce perfectly normal litters (Croy and Chapeau, 1990) although they lack B and T lymphocytes and have few NK cells, so such cells cannot be essential for normal pregnancy.

Release of the placenta

By definition the decidua is a hormone-dependent tissue layer at the fetomaternal interface autolysing on progesterone withdrawal to facilitate release of the placenta soon after birth of the young. Release of prostanoids by the autolysing cells may also play a part in the initiation and process of parturition (S.C. Bell, 1983). However, the wide variety of animals without decidua manage to separate their placentas successfully and in the European mole *Talpa* there is a well-developed decidua but the placenta remains *in situ* and is resorbed (Amoroso, 1952).

4.2.9 IMPLANTATION

Implantation is the mechanism by which the blastocyst establishes itself in the uterus, and the trophectoderm develops an intimate relationship with the uterine epithelium (M.B. Parr and Parr, 1989; Denker, 1993). This process is easily disrupted and most early preg-

nancy loss occurs during this time (Wilmut *et al.*, 1986). The process can also be suspended ('delay of implantation, embryonic diapause') at this stage, which serves to reduce the metabolic load on a lactating mother and to ensure that birth occurs at the most advantageous season (Enders and Given, 1977; Given and Enders, 1989).

The conceptus reaches the uterus in the morula stage surrounded by the acellular zona pellucida. It must then position itself correctly in the uterus, adhere to the uterine epithelium and possibly invade that epithelium in initiating the development of the characteristic placental structure. Recent studies have indicated that these structural changes are controlled by complex interactions between hormones, cytokines and their receptors (Ben Rafael and Orvieto, 1992; Mathialinagen *et al.*, 1992; C.L. Stewart *et al.*, 1992; Strickland and Richards, 1992; Wathes, 1992; De *et al.*, 1993).

(a) Position (spacing) in the uterus

In duplex uteri (rat, mouse, guinea pig, rabbit) the horns open separately into the cervix and blastocysts cannot pass from one horn to the other. Spacing in each horn is independent. In bicornuate uteri (pig, dog, cat, ruminants) the two horns are continuous and a conceptus ovulated on one side can pass to the other side prior to implantation (Figure 4.4).

In species with several conceptuses (polytocous), the blastocysts normally implant at evenly spaced sites along a uterine horn (Boving, 1971). How this spacing is achieved in the 2 or 3 days available is not clear. In the rabbit (duplex uterus) there appears to be no relationship to any pre-existing structure such as the scars of the previous pregnancy since conceptus number varies but the spacing is always even. If there is only one conceptus per horn it is always in the middle of the horn (Boving, 1971). In the pig and cat with bicornuate uteri, animals with a single ovary provide evenly spaced implantation sites in both horns and pig conceptuses of different phenotypes (colours) introduced in a set order randomize before implanting at an even spacing (Dziuk *et al.*, 1964).

These experimental observations indicate a considerable capacity for blastocyst migration along the uterine lumen and the most likely explanation is a passive movement propelled by the vigorous contractions of the uterine musculature. Inert beads of a similar size to a rabbit blastocyst are moved along if introduced into the uterine lumen at this time (4–6 dpc; Boving, 1971). However, the trauma of surgery makes this an unreliable experimental model. Presumably the conceptus would first need to be roughly spaced by vigorous muscular contractions instituted perhaps by substances present in the oviductal fluid entering with the conceptuses; and subsequently adjusted by local initiation of contractions and/or uterine growth by the individual conceptus.

This seems to fit with more of the observed facts than Mossman's ingenious 'leap-frog' concept. In this the first conceptus into the uterus attaches at the uterotubal end, modifying the surrounding uterine epithelium to inhibit further adhesion thus forcing the next conceptus to 'leap-frog' and pass further along to implant and so on.

However, all the above discussion refers to cat, pig or rabbit experiments, in which the blastocyst swells considerably (10–2000 × in the rabbit) during the positioning and adhesive phases. In the rat and guinea pig the blastocysts do not swell at this stage but are still evenly spaced in the uterus prior to adhesion. This may be achieved by muscular contraction since relaxin disrupts it (Pusey *et al.*, 1980), but there is no direct evidence for such movement of these tiny blastocysts (Boving, 1971).

In species with a single conceptus in the uterus (monotocous) or in each uterine horn (ditocous) there is also evidence for preferred sites of implantation. For example, multiple

ovulators such as the elephant shrew implant only a single conceptus in each horn, and some African antelopes ovulate on either side but implant predominantly in the right horn. No clearly identifiable receptive structures have yet been described (Mossman, 1987).

Most ruminants normally implant about halfway between the cervix and uterotubal junction but the caruncles at this site have no reported unique characteristics. It has been shown that cow and sheep blastocysts anchor themselves at their preferred site by trophectodermal outgrowths (papillae) into the mouths of the uterine glands (Figure 4.38) (Drieux and Thiery, 1951; Guillomot and Guay, 1982; Wooding *et al.*, 1982), but this does not explain how the site is initially selected.

There is now direct evidence for considerable conceptus movement in the uterus prior to implantation: the large horse blastocyst can be located *in vivo* with ultrasound, and it is reported that it moves freely between the two horns on 11–15 dpc but then implants caudally in one horn at 16–17 days (Ginther, 1979, 1983, 1984a,b).

There seems to be clear evidence for free conceptus movement, and also a consensus that positioning is complete before the zona pellucida is lost. Rupture of the zona then allows intimate adhesion between blastocyst and uterine epithelial surfaces.

(b) Adhesion

There are three main requirements for adhesion: loss of the zona pellucida, 'closure' of the uterine lumen, and development of trophectodermal pseudopodia (cellular or syncytial) which make membrane contact with the uterine epithelium.

The zona pellucida is ruptured and/or dissolved by a combination of blastocyst swelling plus the action of glycosidase and protease enzymes from uterine epithelium and blastocyst (Denker 1978; Denker *et al.*, 1978; Denker and Tyndale-Biscoe, 1986). The success of ectopic implantation demonstrates the non-specific nature of any uterine enzymes involved.

After rupture of the zona pellucida, closure of the uterus occurs by the resorption of fluid and development of muscular tone. These processes bring the uterine epithelium into an intimate relationship with the trophectoderm and this is accentuated in many species by swelling of the blastocyst.

Uterine closure brings the glycocalyces on the external surface of the trophectoderm and on uterine epithelial cells close together. Since both bear negative charges they will not readily adhere. Several cytochemical investigations have shown a generalized decrease in uterine epithelial surface change (measured by cationic probes) around the time of implantation (reviewed by M.B. Parr and Parr, 1989). There is also increasing evidence for change in the plasmalemma prior to the apposition between blastocyst and uterine epithelium. For example, erosion of the unusually thick glycocalyx can be demonstrated in the ferret (Enders and Schlafke, 1971b), changes in uterine epithelium luminal proteins have been shown in the rabbit (T.L. Anderson *et al.*, 1986; Hoffman *et al.*, 1990a) and alterations in the expression of carbohydrate epitopes demonstrated in the mouse (Kimber and Lindenberg, 1990). Specific lectins have been used to demonstrate pregnancy-dependent regional differences in binding to the blastocyst (Chavez and Enders, 1982) and to the uterine epithelium (Anderson and Hoffman, 1984; Anderson *et al.* 1986; Whyte and Allen, 1985; Anderson *et al.*, 1986).

However it is achieved, the fetal and maternal plasmalemmas characteristically finally adhere very closely at the implantation site. There is little clear evidence for fetomaternal tight or desmosomal junction formation despite several claims (Reinius, 1967; Potts, 1968; Schlafke and Enders, 1975; Tachi and Tachi, 1979). Evidence from freeze-fracture is required to adequately characterize the

nature of the adhesion. Examination of the blastocyst attachment to uterine epithelium *in vitro* may also provide useful information (Lindenberg *et al.*, 1989).

(c) Invasion and/or placental development

From the common start of flat apposition between maternal and fetal apical plasma membranes there are several different ways of initiating placental development. Schlafke and Enders (1975) categorized four basic types: simple interdigitation, displacement, fusion and intrusive implantation (Figure 4.13).

Interdigitation

In the pig (Dantzer, 1985) the flat apposition develops into an interdigitation of microvilli from trophectoderm and uterine epithelial surfaces. There is no loss of cells or any fetal or maternal syncytial transformation. Development of the placenta is essentially a vast increase in the area of fetomaternal apposed epithelia with their interdigitated microvilli.

Displacement

In the mouse, rat and hamster the apposition of the fetal and maternal cellular epithelia results in loss of integrity and subsequent delamination or sloughing of individual cells and sheets of the uterine epithelium which are then phagocytosed by the trophectoderm (M.H. Kaufman, 1983; Schlafke *et al.*, 1985; Bevilacqua and Abrahamsohn, 1989; Blankenship *et al.*, 1990).

This change in coherence of the uterine epithelial cell sheet may be induced either by contact with the trophectoderm or by isolation from the vascular supply by the coincident decidual cell development immediately below the uterine epithelial basement membrane. Whatever the cause it does not seem to be analogous to normal cell killing, since inhibition of RNA synthesis with actinomycin D completely blocks the uterine epithelial change (Finn and Bredl, 1973) and the trophectoderm then is reported to penetrate the uterine epithelium intrusively (see below). The results certainly suggest fetomaternal interaction rather than cytolysis and phagocytosis by an aggressive trophectoderm (M.H. Kaufmann, 1983).

This sort of concerted delamination of a large area of uterine epithelium has also been reported for the vespertilionid bats *Myotis* and *Glossophaga* (Enders and Wimsatt, 1968; Rasweiler, 1979; Kimura and Uchida, 1983, 1984).

Fusion

Evidence for fusion between trophectodermal syncytial protrusions and uterine epithelial cells in rabbits has been presented by Larsen (1961) and Enders and Schlafke (1971a). Fusion of cytotrophoblast cells produces a trophectodermal syncytium which forms numerous processes. These penetrate the zona pellucida and indent the apex of the uterine epithelial cells forming initially a flat apposition. Subsequently, the apposed membranes fuse to form a fetomaternal hybrid tissue. Evidence of fusion comes from the observation of chains of vesicles in regions where one would expect flat apposition. Also, cells linked to the adjacent uterine epithelium by the usual apical tight junction complex demonstrate cytoplasmic continuity with the overlying trophectodermal syncytium (Figure 4.13). Since at the same time the uterine epithelium itself is producing plaques of symplasm by loss of lateral membranes, it is difficult to follow the detailed outcome of the initial fetomaternal fusion. Fusion seems to be necessary to initiate trophectodermal invasion, but it is considered likely that the maternal nuclei and cytoplasm make only a transient contribution to the invasive trophectodermal syncytium (Enders and Schlafke, 1971a).

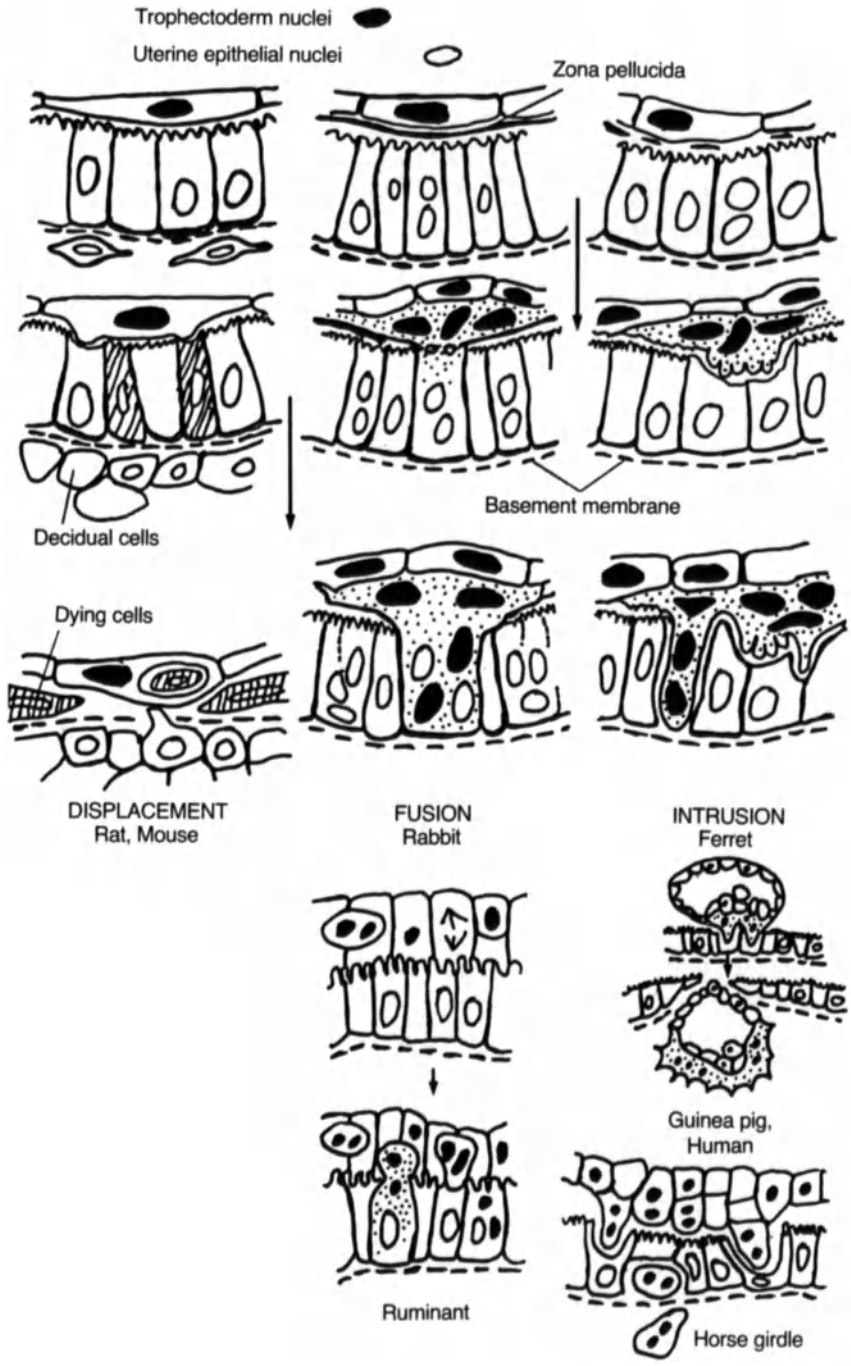

Figure 4.13 Classification of the different fetomaternal cellular interactions at implantation. (Based on Schlafke and Enders, 1975.)

In the ruminant trophectoderm, characteristic granulated binucleate cells (BNCs) are first produced just before implantation (Wimsatt, 1951; Wooding, 1982b, 1983). BNCs migrate to form a flat apposition with a uterine epithelial cell, and then fuse apically, finally providing a trinucleate cell within the uterine epithelium (Figures 4.13 and 4.38) (Wooding, 1982b). Evidence for the fusion comes from images of the two cells cytoplasmically continuous across the fetomaternal microvillar junction but linked by tight junctions to their epithelia (Figure 4.42) and the presence of BNC-derived granules containing placental lactogen hormone only in trinucleate cells in the uterine epithelium (Morgan *et al.*, 1987) (see section 4.3.6b for further details).

The final example of fusion comes from the marsupial *Perameles* (Padykula and Taylor, 1976). On about the ninth day of the 12-day gestation a limited area of trophectoderm cells, each with a characteristically large nucleus, comes into close apposition to the uterine epithelium which consists at this stage of plaques of syncytium containing numerous very small nuclei. Specimens a day or so later display no separate trophectodermal layer but the fetal and maternal blood capillaries are separated only by plaques of syncytium which contain a mixture of very small and characteristic large nuclei (Figures 4.17, 4.18 and 4.19). The simplest explanation for the apparent disappearance of the trophectoderm and two sizes of nuclei in the final syncytium is fetomaternal fusion but the details have yet to be investigated (see section 4.3.5c).

The advantages of fetomaternal hybrid tissue formation are obscure. It does offer rapid access through the uterine epithelium while maintaining its structural integrity; presumably some immunological camouflage is provided by the maternal component of the hybrid tissue. However, the problem of dual cytoplasmic control must be formidable, and the fact that the hybrids are produced by such dissimilar methods – fetal syncytium or cell fusing with maternal cell or syncytium – once again indicates that these cases are probably individual answers to specific problems rather than a general solution of the puzzle of fetomaternal accommodation.

Intrusion

This type is found in several families and is characterized by firm adhesion followed by penetration of trophectodermal processes through a healthy uterine epithelium without any signs of destruction of, or alteration in, the contiguous uterine cells (Figure 4.13). In the ferret syncytial processes pass between the cells, apparently forming tight junctions with them (Enders and Schlafke, 1971b). In contrast, in the horse individual binucleated trophectodermal cells are said to indent the cell apices away from the tight junctions and initially pass through the body of the uterine epithelial cell on their way to form the endometrial cups (Allen *et al.*, 1973). In both cases the uterine epithelial cells are subsequently surrounded and phagocytosed to allow a broader trophectodermal access to the endometrium.

The tiny blastocysts of the human and guinea pig form a trophectodermal syncytium at the site of apposition to the uterine epithelium (Enders and Schlafke, 1969; Boyd and Hamilton, 1970). This seems to facilitate rapid subsequent penetration of the entire conceptus into the endometrium, but the details of the process are unknown. The uterine epithelium subsequently closes over the implantation site.

Intrusion seems to require protrusions from syncytium or binucleate cells, but the means by which these negotiate the tight junction barrier remains to be elucidated. The ruminant BNC is the only cell so far demonstrated capable of passing through a tight junction while maintaining the junction intact, but the BNC is derived from that same epithelium (Morgan and Wooding, 1983).

Intrusion implantation suggests that the fetal trophectoderm can form tight junctions with the maternal tissue but there is no direct evidence for this in any system as yet.

As more EM studies are made it becomes clear that the categories above may not be exclusive. In the mouse, for example, there is an excellent electron micrograph which demonstrates that the first visible sign of implantation may be intrusion into or fusion with a healthy uterine epithelial cell (Figure 4.73) (M.H. Kaufman, 1983), and at the light microscope level similar penetration of the intact uterine epithelium has been reported after actinomycin D injection (Finn and Bredl, 1973).

In some marsupials there is a local penetration of an otherwise unchanged uterine epithelium by cellular trophoblast which could be by fusion or intrusion (Tyndale Biscoe and Renfree, 1987); a similar process has been reported in *Galago* (Butler, 1967). There are now three examples of fusion implantation; only one was known in 1975. This process may be more widespread than has been realized.

The problem is the transience of the initial cellular events and the lack of markers to distinguish fetomaternal fusion from intrusion. The ruminant BNC fusion with a uterine epithelial cell was recognized by several criteria. There are obvious BNC 'marker' granules; it is a cellular system so that the number of nuclei per hybrid cell can be counted; finally the tight junction between fetal and fetomaternal trinucleate cells (TNCs) can be logically explained by the migration and fusion hypothesis (Wooding 1982b, 1984).

Investigations of other systems are complicated by lack of markers and by considerable coincident syncytium formation so it is not practical to count nuclei. However, it should be remembered that tight junctions between fetal and maternal tissue [as reported, for example, by Leiser (1979) at cat implantation] may indicate fusion just as well as intrusion.

4.3 DEVELOPMENT OF EMBRYONIC MEMBRANES IN THE VARIOUS VERTEBRATE TAXA

4.3.1 FISHES

(a) Introduction

The fishes are non-amniotes which have evolved a wide variety of modifications for successful viviparity (Amoroso, 1960; Hogarth, 1976; Wourms, 1981; Mossman, 1987). The most widely used system is an increased secretion of nutrients into the ovarian or uterine cavity and absorption via the fetal gut or skin surface, but a number of genera have produced specialized structures, both embryonic and extraembryonic, some of which closely parallel amniote placentas.

(b) Classification

Fishes:

Class	Chondrichthyes (cartilaginous fish)
Subclass	Elasmobranchii, selachians

About half the 100 families have viviparous members; only two of these families (Carcharinidae and Syphonidae, including sharks, skates and rays) have either a yolk sac placenta (Figure 4.4) or trophonemata. The latter are long glandular extensions of the uterine epithelium producing abundant secretion (Wourms, 1981).

Class	Osteichthyes (bony fish)
Subclass	Actinopterygii

This includes more than 99% of all living bony fish. Fourteen out of the 425 families are viviparous, and five of these have structures ranging from fin elaborations, gut extensions (trophotaeniae) and expansions to extraembryonic pericardial sac elaborations analogous to the vertebrate amnion and chorion (Figure 4.15).

It is clear that fish viviparity has evolved many times in many different genera (Amor-

Table 4.2 Dryweight increases during gestation in fishes

Species	*Percentage change in dry weight of conceptus*	*Reproductive pattern*	*Uterine secretion*
CHONDRICHTHYES; Cartilaginous fish			
I OVIPAROUS			
Scyliorhinus caniculus	−20	oviparous	none
II VIVIPAROUS			
Squalus acanthias	−40	yolky egg	serous
Mustelus mustelus	370	yolky egg	mucous
Dasyatis violacea	1,600	trophonemata	lipid
Mustelus canis	1,050	placenta	mucous
Gymmura micrura	4,900	trophonemata	lipid
Odontaspis taurus	1,200,000	intrauterine cannibalism	
OSTEICHTHYES; Bony fish			
I OVIPAROUS			
Salmo vivideus	−40	oviparous	
II VIVIPAROUS			
Poeciliopsis monacha	−40	yolky egg	
Poecilia (lebistes) sp.	0	yolk, small pericardial sac	
Heterandria formosa	4,000	large smooth pericardial sac, simple	
Anableps dowei	800,000	follicular placenta large specialised pericardial sac	
Ameca splendens (Goodeidae)	15,000	villous follicular placenta	
Embiotoca lateralis	20,400	trophotaeniae	
Jennynsia sp.	24,000	fin extensions, gut expansion trophonemata	

oso, 1960, Wourms, 1981). A decrease in the amount of yolk after retention in the body of the mother necessitated an efficient system of nutrient transfer. In fishes, the placenta is only one, and not necessarily the most efficient, solution to the problem. In fish physiology a rough measure of the efficiency of viviparity is taken as the percentage increase or decrease in organic material between egg and neonate (Table 4.2).

(c) Chondrichthyes

In Table 4.2 it can be seen that retention in the uterus does not necessarily offer any nutrient transfer advantage (*Scyliorhinus* versus *Squalus*) unless the organic content of the uterine secretion is increased (*Squalus* versus *Mustelus mustelus*). Development of trophonemata, uterine glandular extensions which may be in close relationship with the fetal mouth or gills, further augments the percentage increase (*M. mustelus* versus *Dasyatis*) and a true trilaminar yolk sac closely apposed to an expanded semivillous uterine epithelium is almost as effective (Cate-Hoedemaker 1933; Schlernitzauer and Gilbert, 1966) (*M. canis* versus *Dasyatis*). However, a richer uterine secretion plus trophonemata can be three or four times as good as a yolk sac (*Gymmura*

versus *M. canis*), and a species in which the surviving uterine tenant has eaten all its originally numerous siblings (*Odontaspis*) has no rival measured on this criterion.

Yolk sac placenta

In several of the skates and rays after the yolk is exhausted the trilaminar vascularized yolk sac is then modified to serve a placental function. Such species have very lengthy gestation times. In *Mustelus canis* (*laevis*) which has been most closely investigated structurally (Cate-Hoedemaker, 1933), the placenta forms after a 3 month dependence on yolk and is functional for another 9–10 months (Figure 4.14).

The uterus develops shallow folds around each embryo and within the fold the yolk sac trophoblast forms with the uterine epithelium a localized intimate association which subsequently increases in area by folding. A shell membrane, or derivative thereof, persists between the maternal and fetal epithelia until term, but there is a considerable decrease during pregnancy in the thickness of the epithelia and the shell membrane. In addition, the blood capillaries eventually deeply indent the epithelia, reducing still further the separation of fetal and maternal blood (Figure 4.14). Cate-Hoedemaker (1933) suggested that there was a syncytial change in both epithelia, but this has yet to be verified electron microscopically. A more recent tracer and ultrastructural study of the yolk sac placenta of *Carcharhinus* (Hamlett and Wourms, 1984; Hamlett *et al.*, 1985) demonstrated the ability of the trophoblast to absorb proteins endocytotically and of the uterine epithelium to mediate transfer, but capillary indentation of the epithelia was not so marked as in *M. canis*. There is a complete range from the firmly adherent structurally modified yolk sac placenta of *Mustelus canis* to the transient non-specialized association of yolk sac trophectoderm and uterine epithelium (across a fairly thick shell membrane) reported in *Squalus acanthis* (Jollie and Jollie, 1967). In some cases (*Scoliodon*) very complex elaborations of the yolk sac stalk surface (appendiculae) are present as well as a placenta (Figure 4.14). These fetal appendiculae, like the glandular extensions of the maternal uterine epithelium (trophonemata), may also play an important role in fetomaternal nutritive exchange in other families but, since the tissue association is very loose, as far as it has been investigated, a placental relationship cannot be assumed (for a recent review see Hamlett, 1989; Hamlett *et al.*, 1993).

Thus, in the Chondricthyes a true yolk placenta with considerable specialization for haemotrophic exchange has been developed, but the vast majority of viviparous species rely on histotrophic nutrition with only a few structural adaptations to facilitate this.

(d) Osteichthyes

The bony fish do not have true uteri and viviparous development takes place either in the ovarian follicle or, after follicular rupture, in the ovarian cavity (Turner, 1947; Amoroso, 1960; Wourms, 1981). Table 4.2 demonstrates that again the level of maternal organic provision is greatest when facilitated by specialized fetal and/or maternal structures. Unlike the Chondricthyes the yolk sac is not developed further than its function as a yolk store; but in parallel with the Chondricthyes some species do have gland-rich trophonemata which reach from the uterine surface into the mouth or gill cleft of the embryo. The other structures, pericardial sac, trophotaeniae or fin extensions, are unique to a few families of the Osteichthyes (Figure 4.15) (Schindler and Hamlett, 1993).

Pericardial sac

In three families (Anablepidae, Poeciliidae and Goodeidae) gestation starts in the follicle. In early development the exocoelomic cavity around the heart extends to form an

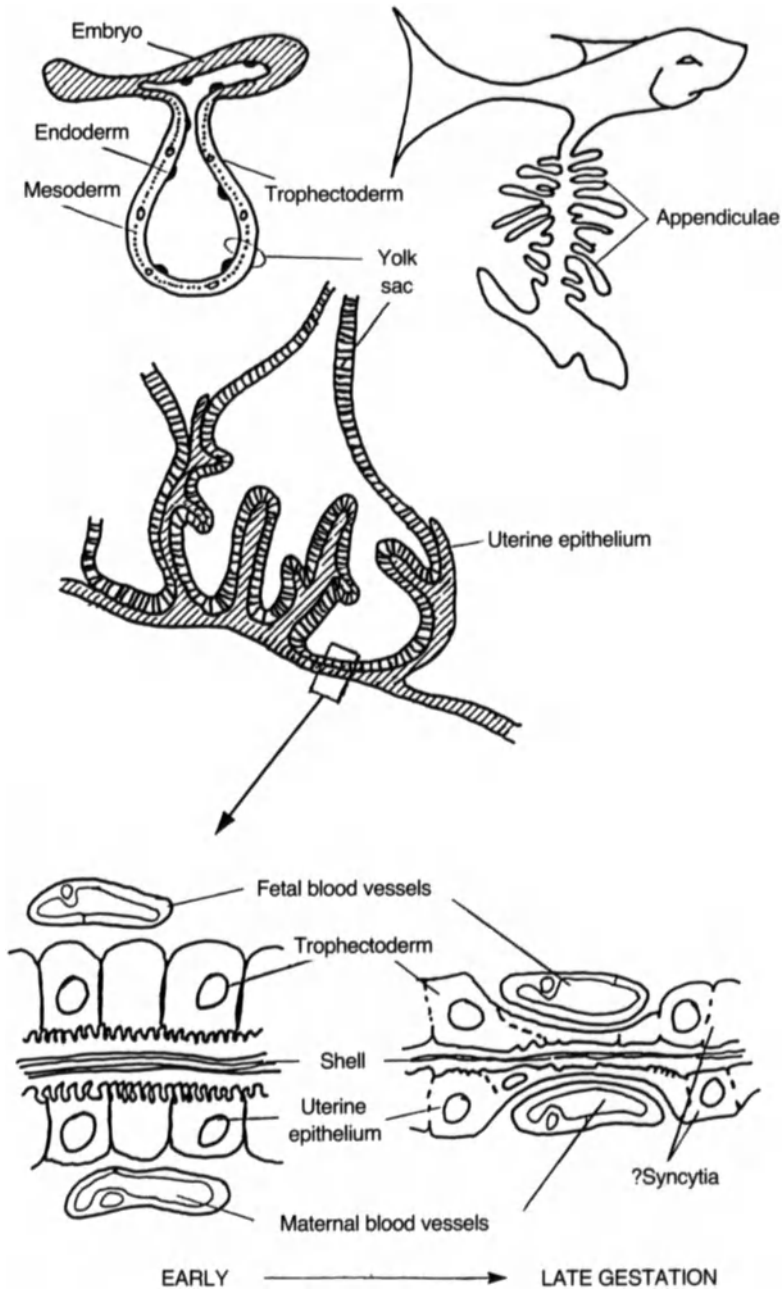

Figure 4.14 Placental development in the cartilaginous fishes; skates, rays and sharks (Chondrichthyes).

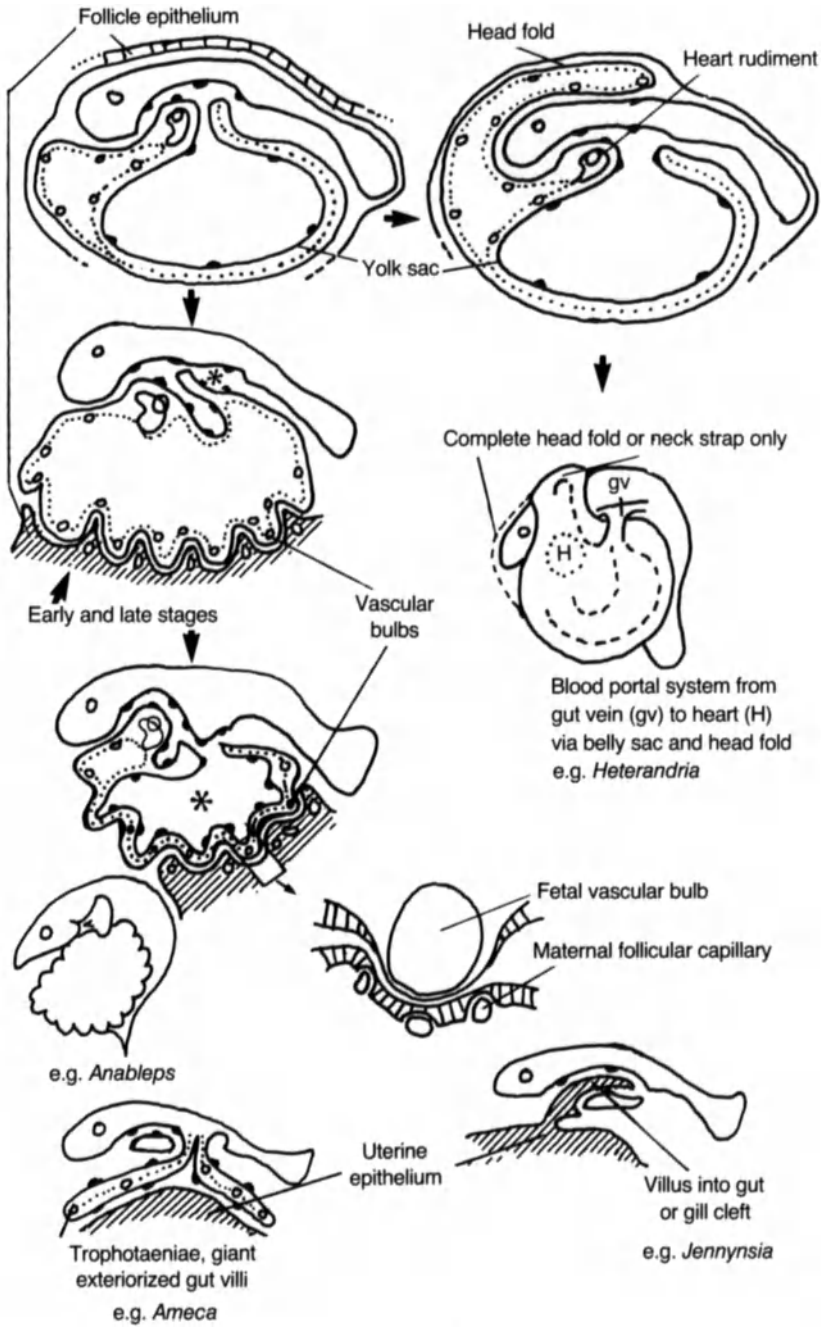

Figure 4.15 Placental membrane relationships in the bony fishes (Osteichthyes).

extraembryonic sac whose wall consists of somatopleuric mesoderm bounded by trophectoderm. This enlarges to a variable degree in different genera enclosing the entire head in some cases (Figure 4.15). The sac is richly vascularized and blood from the body flows through this portal system before returning to the heart. The trophectoderm is closely apposed to a well-vascularized follicular epithelium, and capillary indentation of fetal and maternal epithelial layers is observed in some species in later gestation. The degree of development of the pericardial sac varies considerably in different genera. *Lebistes* (Kunz, 1971) and *Poecilia* (Tavolga and Rugh, 1947) still retain a large yolk sac but the development of a small pericardial sac increases the efficiency of the organic transfer (Table 4.2). *Heterandria* has a much larger pericardial sac covering the entire head and most of the body at one stage with only a small yolk sac (Fraser and Renton, 1940; Grove and Wourms, 1991) and this combination produces a considerable increase (4 000%) in organic material during gestation. In Anableps the pericardial sac does not cover the head but expands ventrally into the area normally occupied by the yolk sac (vestigial in Anableps). The pericardial sac develops vascular swellings ('bulbs') under the trophoectoderm surface which is closely apposed to a proliferation of slender, richly vascularized villi developed from the follicular epithelium (Figure 4.15). Fetal and maternal epithelia are tightly adherent and the efficiency of this true placental structure is exemplified by the vast increase in organic transfer (800 000%) during intrafollicular development (Knight *et al.*, 1985).

The Anablepidae also show considerable embryonic gut expansion in the last third of pregnancy so that the gut wall comes to lie close to the pericardial sac with its placental function (Figure 4.15). The relevance of this juxtaposition to increased fetomaternal exchange is unknown. This association of a vascularized endodermal sac (the hind gut) with the trophectoderm of the pericardial sac is directly analogous to the formation of the allantochorion in other taxa. Many other viviparous genera show similar gut expansion and direct absorption of follicular or ovarian fluid via mouth or anus has been suggested (Wourms, 1981).

Trophotaeniae

These are extensions from the hind gut epithelium (endoderm) which are richly vascularized (by sphlanchnic mesoderm) (Figure 4.15). They range in size from small rosettes to groups of ribbon-like appendages as long as the embryo.

Trophotaeniae are present in several unrelated families, but are best developed in the Goodeidae, of which *Ameca splendens* has been best investigated (Lombardi and Wourms, 1985a,b,c; Wichtrup and Greven, 1985). Embryos are released early from the follicle into the ovarian lumen; there may be a brief pericardial sac and yolk sac stage before the development of the trophotaeniae. There is a close relationship between the trophotaeniae and the ovarian epithelium but never a permanent adherence. Ultrastructural and tracer studies indicate that the trophotaenial epithelial cells are greatly specialized for endocytotic absorption (Schindler and DeVries, 1987) and the ovarian epithelial cells for secretion. The efficiency of the system is indicated by the 15 000% increase in fetal organic material during gestation.

Other systems Two other families show large dry weight increases during gestation (Wourms, 1981). Embiotocidae (20 000% increase) have spatulate fin extensions, an enlarged hind gut and lie close to an actively secreting ovarian epithelium; and *Jennynsia* (24 000% increase) has ovarian trophonemata extending into the mouth and buccal cavity (Figure 4.15). Nothing is known of the functional cytology of these ostensibly efficient associations.

Homologies between fish and amniotic placentas

Based on embryological derivation and intimacy of apposition the chondricthyean yolk sac placenta is directly homologous to the trilaminar choriovitelline placenta of mammals. Functionally there may be differences since the most specialized fish placenta appears to have a considerable respiratory function, judging by the extensive capillary indentation and attenuation of the fetal and maternal epithelia (Cate-Hoedemaker, 1933; Schlernitzauer and Gilbert, 1966). Similar modifications are reported for the persistent trilaminar yolk sac of most marsupial families (Luckett, 1976; Tyndale-Biscoe and Renfree, 1987). This contrasts sharply with eutherians, which have tall columnar trophectodermal cells over the transient trilaminar yolk sac designed more for macromolecular uptake rather than for gas exchange.

Trophotaeniae are essentially exteriorized giant gut villi, with an endodermal epithelium vascularized by splanchnic (gut) mesoderm (Figure 4.15) (Lombardi and Wourms, 1985a,b,c). They are thus homologous to the inverted fetal yolk sacs of rodents and insectivores (Figure 4.3) and like them specialized for endocytotic uptake rather than gas exchange and with a similar loose association with the maternal epithelium.

The pericardial sac membrane of Poeciliidae and Anablepidae consists of somatopleuric mesoderm underlying trophectoderm. The extension and folding of the sac over the embryonic head (Grove and Wourms, 1991) indicates that it is functionally homologous with the chorionic headfold which produces the amniotic cavity in the amniotes. In amniotes the somatopleuric chorion would not normally be vascularized until reached by the allantoic mesoderm, but in the Poeciliidae vascularization spreads from the adjacent yolk sac portal circulation as this yolk sac is superseded by the pericardial sac (Turner, 1947; Knight *et al.* 1985). In Anablepidae the modified pericardial sac and villous elaborations of the maternal follicular epithelium are firmly adherent and Wourms (1981) seems entirely justified in defining this as a true follicular epitheliochorial placenta, not a 'pseudo' placenta (Turner, 1947). It is much more efficient than a yolk sac placenta in facilitating embryonic dry weight increase and possibly represents a parallel development to the replacement of the yolk sac by the chorioallantoic placenta in mammals. How specialized the apposed epithelia of the follicular placenta are with respect to gas exchange and macromolecular uptake remains to be determined.

Clearly the fish have evolved placental structures remarkably analogous to those in the amniotes. Apart from intrauterine cannibalism, proliferation of a non-yolk sac extraembryonic membrane in intimate association with maternal tissue seems to be the most efficient solution.

4.3.2 AMPHIBIA

(a) Introduction

Like the fish, the amphibia have evolved many viviparous forms. Most provide internal nutrition by secretions of the oviduct or ovary. There is little evidence of fetal modifications for fetomaternal transfer. Some species do show expansions of a highly vascularized tail or gill extensions, but how closely these are related to maternal tissues remains to be demonstrated.

(b) Classification

Class	Amphibia
Order	Anura

This order has some remarkable adaptations to viviparity (Hogarth, 1976). *Rheobatrachus* broods the young in its stomach, digestion being suspended for the duration. In *Rhinoderma* the male incubates the young in

its vocal chord pouch. The dorsal skin modifies into individual pouches in which the young develop in *Pipa* and *Gastrotheca*; the former has an expanded vascularized tail, the latter leaf-like gill extensions wrapped around the embryo (Del Pino *et al.*, 1975). Similar modifications are seen in many free-living juvenile forms and further investigation is necessary to establish if the association with the maternal tissue is close enough to be considered placental. *Nectophrynoides* is, more conventionally, retained in the oviduct and depends on the epithelial secretions for maintenance and growth (Xavier, 1976).

Order Urodela

Nearly all the salamanders have internal fertilization, but only one of the 400 species is obligately viviparous. It relies on ovarian secretions for growth.

Order Gymnophiona (Apoda)

Only 25 of the 170 species have been investigated; half of these are viviparous supported by lipid-rich ovarian secretions with no obvious fetal modification to facilitate absorption. Some have a long gestation period, depend on yolk for the first 3 months but then develop on ovarian secretions for a further 9 months. Viviparity is normally associated with extreme conditions of altitude or desiccation.

4.3.3 AVES

The only class with no viviparous forms. All birds have the full complement of embryonic membranes in the egg with very little variation despite enormous differences of habitat and size. The massive amount of yolk in the yolk sac is the initial and continuing source of nutrition; the allantois with deeply indented capillaries is the organ of respiration within the egg (see Mossman, 1987).

4.3.4 REPTILIA

(a) Introduction

The reptilia are mostly egg-laying amniotes with a full complement of extraembryonic membranes like the birds. The adoption of viviparity may be associated with extremes of habitat and has occurred many times (Panigel, 1956; R. Shine and Bull, 1979). Many genera today have ovoviparous and viviparous species in different climatic areas (Guillette, 1982).

The viviparous groups retain the egg in the oviduct or uterus for up to nine months; the shell is reduced to an acellular proteinaceous layer (almost to vanishing point) in some, and many ovulate eggs with very little yolk. The extraembryonic membranes have developed into structures facilitating fetomaternal exchange (J.R. Stewart and Blackburn, 1988; Blackburn, 1993; Stewart, 1993) (Figure 4.16).

The yolk sac, bi- or trilaminar, is loosely associated with the secretory uterine epithelium and the trophoblast is capable of considerable endocytotic absorption. The yolk sac placenta is present from an early stage of development and may persist to term or be reduced to a vestige by the growth of the chorioallantoic placenta. The association between trophoblast and uterine epithelium in the chorioallantoic placenta varies from a simple fetomaternal cellular apposition to those forms in which fetal and maternal capillaries deeply indent the attenuated layers (Figure 4.16). The development of this potential respiratory facility occurs just prior to the period of maximum fetal growth with its vastly increased requirement for gas exchange. Oviparous species lay their eggs just before this time (Guillette, 1982).

(b) Classification

Reptilia
Orders Chelonia (turtles), Crocodilia

All species oviparous.

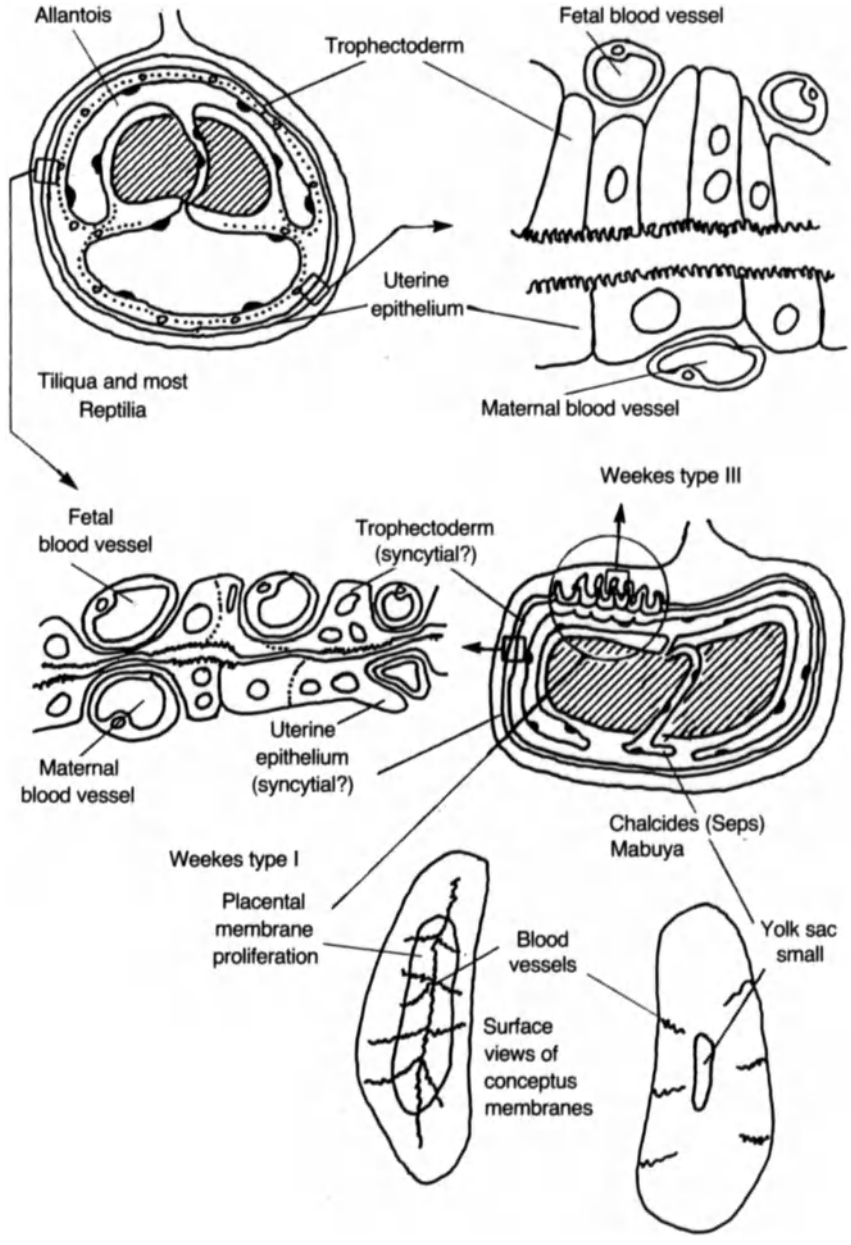

Figure 4.16 Placental membranes in reptiles. Not shown is the very thin acellular shell membrane which persists between the trophectoderm and uterine epithelium in many reptiles.

Order Squamata
Suborder Lacertiliformes (lizards)

Most families oviparous. Numerous viviparous forms (with some ovoviviparous), e.g. family Scincidae, *Lygosoma*, *Chalcides* (Seps) *Xantusia*, *Mabuya*, *Tiliqua*; Lacertidae, *Lacerta*.

Suborder Serpentiformes (snakes)

Most species viviparous.

Family Colubridae: *Thamnophis*, garter snake
Hydrophiidae: *Hydrophis*, seasnake
Viperidae: viper

(c) Suborder Lacertiliformes (lizards)

All viviparous lizards have yolk sac and chorioallantoic placentas (Bauchot, 1965: Luckett, 1977). The yolk sac is formed first and is largest in those orders with much yolk (*Tiliqua*) but may be reduced to small dimensions in those with very little (*Lygosoma*, *Chalcides*) (Figure 4.16). Initially the trophoblast is bilaminar, but it may be subsequently vascularized by yolk sac or allantoic capillaries. Both fetal and maternal layers are cuboidal, the uterine epithelium is said to be secretory, the trophoblast absorptive. Fetal yolk sac and maternal capillaries are numerous but do not indent the adjacent epithelia significantly. Fetomaternal exchange area may be increased by folding of one or both epithelia (Bauchot, 1965).

The chorioallantoic placenta is extensive in lizards, with highly vascularized fetal and maternal epithelia closely apposed in both ovoviviparous and viviparous forms. Weekes (1935) defined a range from type III with apposition of the unchanged columnar cell layers to type I in which the two epithelia are very attenuated and deeply indented by capillaries (Figure 4.16). Reports of degeneration of, or syncytial transformation in, one or both type I epithelia need to be reinvestigated with electron microscope techniques since the relevant layers may be too thin to be detected with the light microscope (Luckett, 1977). Whatever the detailed structure, the lizard chorioallantoic placenta is normally diffuse with flat apposition of fetal and maternal layers. This is the form found in the Yucca night lizard *Xantusia* in which Yaron (1977) has shown that the type I placenta is not only respiratory (with indenting capillaries) but also a major site of amino acid uptake, emphasizing the oversimplification of the respiratory as distinct from absorptive, functional classification.

However, some lizards (characteristically those with small eggs with little yolk, *Chalcides*, *Mabuya*) develop a specialized oval area in the middle of the diffuse placenta which consists of interdigitating villous folds of chorion and uterine epithelium referred to as a 'placentome' (Cate-Hoedemaker, 1933) (Figure 4.16). Unlike the remainder of the attentuated and indented (i.e. type I) fetomaternal layers the placentome in *Chalcides* has well-developed columnar epithelia (i.e. type III), presumably fulfilling the same secretory and absorptive functions as the yolk sac, which in these species is small and/or transient. A slightly different pattern is reported for *Mabuya* (Blackburn *et al.*, 1984; Blackburn, 1993), which is said to have the same 'absorptive' (type III) structural type in both placentome and at least part of the surrounding areas of the chorioallantoic placenta. Since *Mabuya* has the smallest egg and the biggest percentage increase in dry weight during gestation so far found in lizards (38 000%) it is possible that detailed investigation may yet demonstrate areas with the usual respiratory structural specialization (type I).

Fetal binucleate cells have been reported in the chorion of the placentome in both *Mabuya* and *Chalcides*. There is no evidence for migration or any significant differences in cytoplasmic structures with adjacent uninucleate cells. This is a further example of the variety of form shown by the trophoblast, but there is no evidence for any specialized role such as that demonstrated for the equid (Allen, 1982)

or the ruminant binucleate cell (Wooding, 1982b).

(d) Suborder Serpentiformes (snakes)

The placental structures of viviparous snakes are similar to those of lizards. However, several forms show the modification of an early absorptive yolk sac placenta into a unique, discoid chorio-omphaloallantoic placenta (Hoffman, 1970; J.R. Stewart and Blackburn, 1988; Stewart, 1993). This is complemented or replaced by a later chorioallantoic placenta frequently showing adaptations facilitating respiratory exchange. No specialized placentomal areas have been reported. Hoffman (1970) has produced autoradiographic evidence for the yolk sac chorion as a major site of nutrient uptake. In *Thamnophis* (Hoffman, 1970) and *Hydrophis* (Kasturirangan, 1952) chorionic binucleate cells are present in the yolk sac region instead of the chorioallantoic placenta as in lizards but with a similar absence of specialized structure.

(e) Homologies between reptile and amniotic placentas

The reptiles thus show many examples of the development of specialized fetomaternal extraembryonic membrane apposition as a result of reduction or loss of the shell membrane in eggs retained in the uterus.

The yolk sac is important in many species, providing both respiratory and nutrient uptake. It is never as specialized as in some elasmobranchs (*Mustelus canis*) for respiratory exchange because this function is provided by the chorioallantoic placenta and the two placentas coexist in snakes and many lizards.

In the most highly developed lizards with the smallest, least yolky eggs and earliest shell loss, the chorioallantoic placenta supersedes the early yolk sac and develops two structurally different areas. A central region is elaborately folded, increasing the surface area available for endocytotic uptake, and the remainder is specialized for respiratory exchange. This arrangement is functionally analogous, but structurally reversed, to that seen in the mammalian chorioallantoic placenta, in which the folded area provides for respiration.

In the reptiles this increase in extent and specialization correlates with the exponential growth phase of the embryo and seems to be essential to supply sufficient nutrient and gas exchange to ensure a successful uterine development.

4.3.5 CLASS MAMMALIA, SUBCLASSES PROTOTHERIA (MONOTREMATA, e.g. PLATYPUS) AND METATHERIA (MARSUPIALIA)

(a) Introduction

Prototheria lay eggs and Metatheria produce shelled eggs *in utero* with the same reliance as birds on a bi- or trilaminar yolk sac and allantois for mobilization of yolk and respiratory exchange. However, they all have far less yolk and a much earlier hatching or birth than the birds and require subsequent mammary nutrition and protection in a pouch in Metatheria (Luckett, 1976, 1977; Tyndale-Biscoe and Renfree, 1987). A few marsupials lose their shell and show localized invasion of the uterine epithelium by the yolk sac trophectoderm, and other families develop an area of chorioallantoic placentation in the last quarter of the typically very short 12–14 day gestation.

(b) Prototheria (Monotremata)

Two families only

Ornithorhyncus: Platypus
Tachyglossus: Echidna

The eggs are much smaller than those of equivalent sized reptiles or birds with a much greater increase in size by absorption of uterine secretions *in utero* prior to shell depo-

sition. The blastocyst forms precociously and has 19 somites when the egg is laid. The mesoderm has spread to produce a vascularized trilaminar yolk sac over two-thirds of the blastocyst with the remainder bilaminar and avascular (Luckett, 1977) (Figure 4.17).

The trophectoderm of the trilaminar region is thin, minimizing the gas diffusion distance to the yolk sac capillaries, while the endodermal cells are columnar, actively absorbing yolk and transporting it to the same capillaries. In the avascular bilaminar portion the cell types are reversed, a columnar absorptive ectoderm and thin endoderm.

After the egg is laid the amnion folds fuse and the allantois develops as the usual hind gut outgrowth eventually forming a chorioallantoic membrane over half the inside of the egg. The trilaminar yolk sac persists over the other half; the bilaminar segment is finally a mere remnant (Luckett, 1977) (Figure 4.17).

The trophectoderm over the late-gestation trilaminar yolk sac and chorioallantois is said to be thin, which would facilitate haemotrophic exchange, but there are no detailed studies available to verify this.

(c) Metatheria (Marsupialia)

Seven major families

Dasyuridae: insectivores and carnivores
Didelphidae: American opossums
Peramelidae: bandicoots
Macropodidae: kangaroos, wallabies
Phalangeridae: arboreal Australian opossums (*Trichosurus*)
Phascolarctidae: koala
Vombatidae: wombats

There is an excellent recent review of marsupial reproduction (Tyndale-Biscoe and Renfree, 1987, and Chapter 7, this volume).

Metatheria have even less yolk than Prototheria, cleavage is complete (holoblastic) and the hollow blastocyst is retained in the uterus initially bounded by a shell membrane.

Pregnancy is completed within the duration of one ovarian cycle; there is no system for prolonging the life of the corpus luteum.

Most families have similar fetal membrane development to Prototheria, but the allantois is smaller and forms a chorioallantoic placenta in only a few species (Figure 4.17).

The bilaminar yolk sac persists to the end of pregnancy absorbing uterine secretions by endocytosis before and after shell membrane rupture. Amino acids are taken up by this route and the yolk sac lumen can contain up to 10 times the concentration in the maternal plasma. The trilaminar yolk sac occupies as much as two-thirds of the egg surface and shows a thin trophectodermal layer over the yolk sac capillaries, suggesting a predominantly respiratory function.

In most families the trophectoderm of the bi- or trilaminar yolk sac is loosely apposed to the uterine epithelium. After the shell membrane disappears in mid- to late pregnancy some species show a trophectodermal invasion of the uterine epithelium from a discontinuous annular zone close to the junction of bi- and trilaminar portions of the yolk sac. The invasive trophectodermal process may be a syncytium (Didelphidae, *Philander*) (Enders and Enders, 1969) or cellular (Dasyuridae; *Sminthopsis*) (Figure 4.17) but normally does not cross the uterine epithelium basement membrane although there is one report that it surrounds superficial maternal blood vessels (Tyndale-Biscoe and Renfree, 1987). There are interesting parallels here with the initial stages of girdle formation in the horse (section 4.3.6.a).

The allantois is reported to form a chorioallantoic placenta in only three families, Phascolarctidae, Vombatidae and Peramelidae, and only the last has been investigated in detail. In the peramelids, *Perameles* and *Isoodon*, the allantois vascularizes the trophectoderm in the last one-third of a very short 12-day pregnancy (Padykula and Taylor, 1976). It forms a chorioallantoic placenta in close apposition to the uterine epithelium

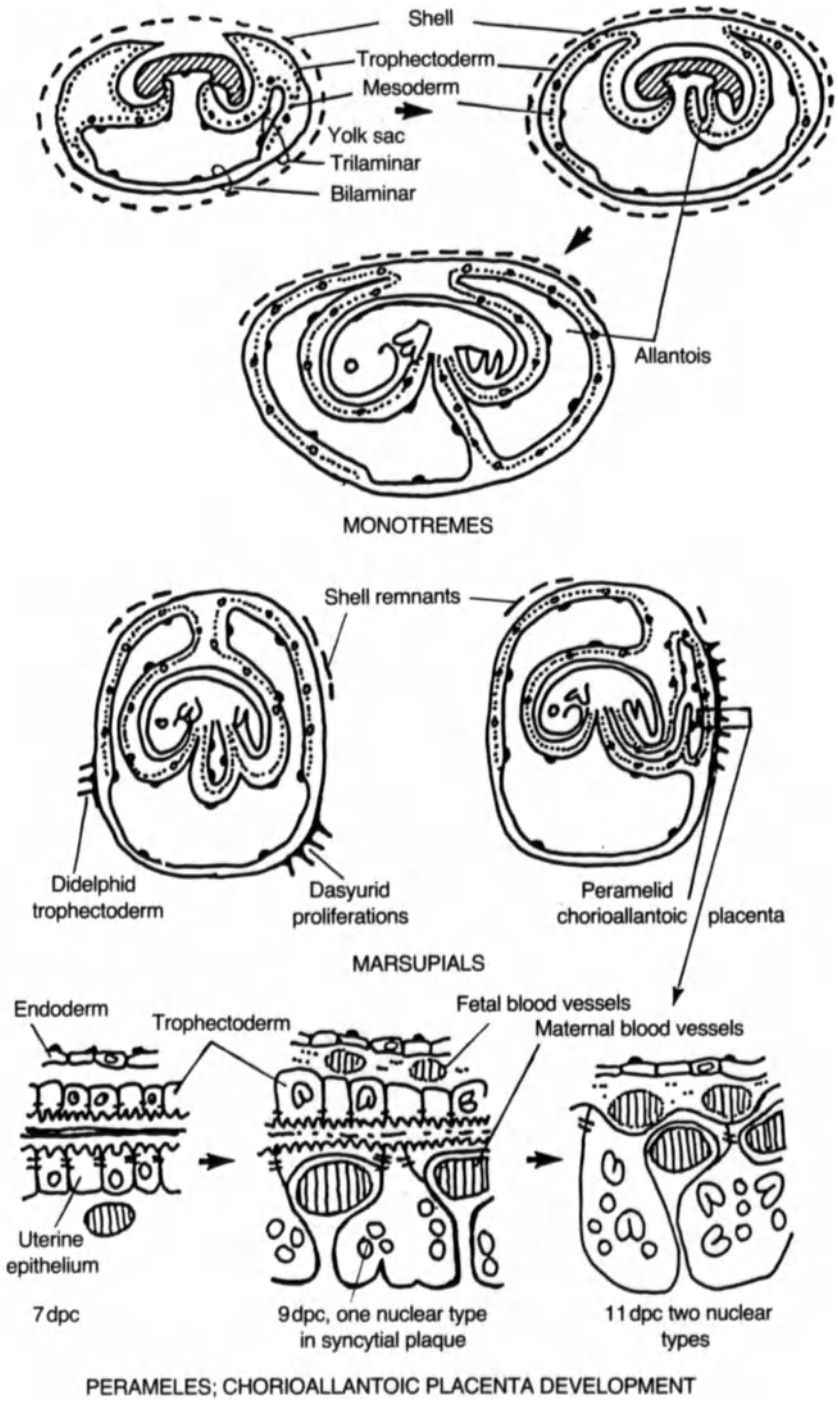

Figure 4.17 Placental membranes in monotremes and marsupials.

occupying a far smaller area than the persistent bi- and trilaminar yolk sac placentas (Figure 4.17). In *Perameles* at 9 days post coitum or post ovulation, the entire uterine epithelium apposed to the conceptus develops from a unicellular layer into individual plaques of syncytium containing uniformly small round nuclei. The uterine capillaries deeply indent these syncytial plaques. The apposed trophectoderm is undifferentiated and unicellular with large irregularly shaped nuclei. As the vascularization of the chorioallantoic trophectoderm increases, the fetal blood vessels indent the epithelium and now two sorts of nuclei are recognizable in the uterine epithelial syncytial plaques, small round ones and others with large irregular profiles. Eventually the unicellular trophectoderm can no longer be distinguished and only very thin laminae continuous with the syncytial plaques separate maternal and fetal blood vessels (Padykula and Taylor, 1976) (Figures 4.17, 4.18 and 4.19).

From the time course of the trophectodermal disappearance and the evidence of the two types of nuclei in the syncytial plaques it seems that the unicellular trophectoderm cells fuse with the uterine epithelial syncytial plaques. Such fetomaternal cell fusion would significantly reduce the number of membrane barriers between fetal and maternal blood and greatly facilitate fetomaternal exchange. The trophectoderm does not vanish but forms part of a fetomaternal hybrid syncytium directly analogous to the similar system produced in sheep and goat chorioallantoic placentas by fusion of fetal binucleate cells with uterine epithelial cells (section 4.3.6.b).

The chorioallantoic placenta in the peramelids supports considerable embryonic growth. Even though their gestation is the shortest of any marsupial, their neonates are relatively well developed at birth (Tyndale-Biscoe and Renfree, 1987). This indicates that the chorioallantoic placenta may well be more efficient than the yolk sac type.

The marsupials thus show several features, such as trophectodermal invasion and formation of chorioallantoic fetomaternal hybrid tissue, which have close parallels in certain eutherian placentas. This seems to be another example of parallel evolution, the same functional demands producing similar structures from basically the same fetal membrane repertoire, rather than any indication of an evolutionary relationship between the groups.

4.3.6 EUTHERIA

(a) Epitheliochorial placentation (pig, horse)

In this form of placentation the uterine epithelium and trophectoderm come into contact, the fetal and maternal microvilli interdigitate and placental development essentially involves a vast increase in area with no loss of any layers between the fetal and maternal bloodstreams. The exclusively cellular layers may become exceedingly attenuated, reducing the diffusion distance as pregnancy proceeds, but all persist to term (Amoroso, 1952; Steven 1975a, 1983; Ramsey, 1982; Mossman, 1987).

The uterine glands are numerous and actively secreting through pregnancy (Bazer and First, 1983), and there are fetal expansions over the gland mouths, forming areolae consisting of cells specialized for histotrophic absorption. The domestic pig placenta will be described as the basic type, and variations on that pattern considered for the horse, American mole (*Scalopus*) and the primates (lemurs and *Galago*).

Pig, *Sus scrofa*

Oestrous cycle: 21 days

Ovulation: spontaneous
*Uterus: bicornuate
Litter: 6–12

Gestation: 114 days
*Implantation: superficial
*Amniogenesis: folding
*Yolk sac: initially large and vascularized, remnant persists, apparently functional to 50 dpc
*Chorioallantois: forms definitive placenta
*Shape: diffuse, simple villous
*No decidual reaction
*Interhaemal membrane: epitheliochorial
Accessory placental structures: areolae (Brambel, 1933; Friess *et al.*, 1981)

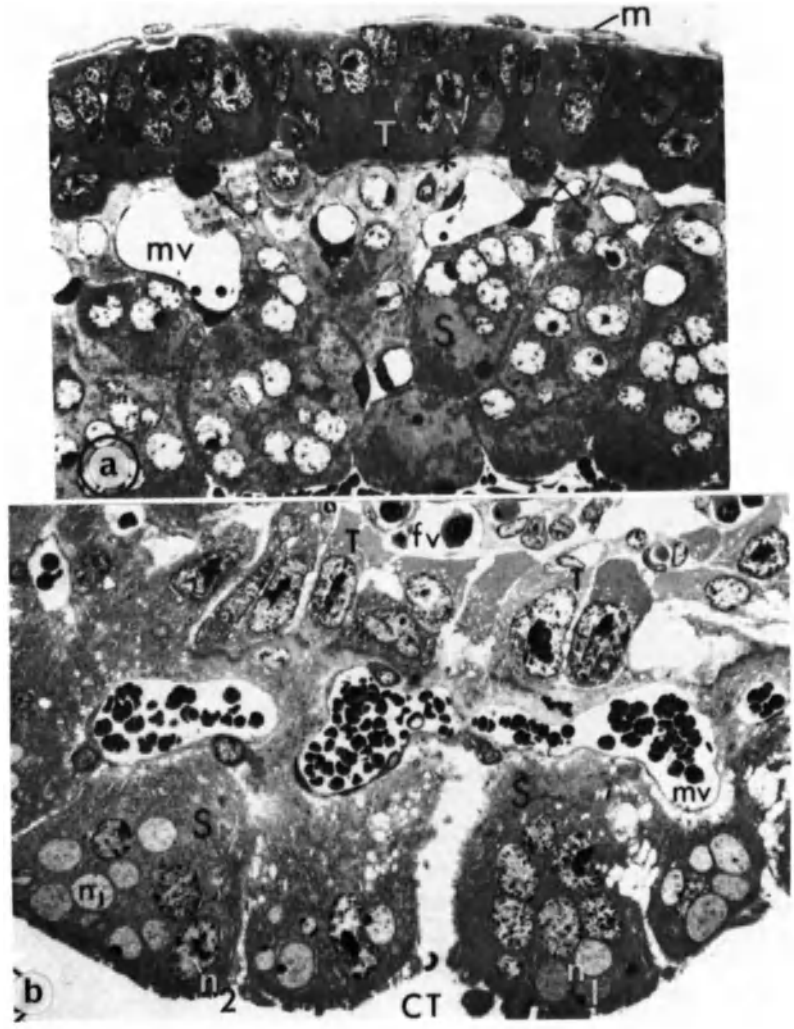

Figure 4.18 Development of chorioallantoic placenta in marsupials (compare with bottom of Figure 4.17). (a) 7 mm crown–rump (CR) length; close apposition (*) between the cellular fetal trophectoderm (T) (m, fetal mesoderm) and uterine epithelial syncytial plaques (S). Note that the plaques are deeply indented by the maternal capillaries (mv). *Isoodon*, × 400. (b) 10 mm CR. The fetal blood vessels (fv) do not indent the cellular fetal trophectoderm (T) in the way that the maternal vessels (MV) indent the uterine epithelial syncytial plaques (S). The plaques contain two sorts of nuclei: n_2, morphologically similar to those in the trophectoderm cells; and n_1, similar to those in the original syncytial plaques. CT maternal connective tissue. *Perameles*, × 400.

The major characteristics (*) are found in the families Suidae, Hippopotamidae and Camelidae (Mossman, 1987).

Pig fetal membranes At implantation (15 dpc, see below) the conceptus is a mostly trilaminar blastocyst. The yolk sac forms what is probably a briefly functional bilaminar absorptive yolk sac placenta before its attachment to the trophectoderm is disrupted by growth of the allantois. The yolk sac lumen then collapses but still retains a good blood supply. Healthy endodermal cells with enormous mitochondria and large amounts of smooth endoplasmic reticulum are found in the yolk sac up to 50 days of gestation (Tiedemann and Minuth, 1980).

Between 22 and 28 dpc the allantois expands to contact and vascularize most of the inner surface of the trophectoderm. This forms the chorioallantoic placenta and the vascularization also spreads into the amniochorionic membrane over the back of the embryo (Amoroso, 1952) (Figure 4.1).

Development of the pig placenta At 8–11 dpc the pig conceptuses are flaccid spheres reaching 10 mm in diameter and have been spaced evenly throughout the uterus probably by contractions of the uterine musculature (section 4.2.9a). Between 10 and 12 dpc the conceptuses secrete oestrogens (Geisert *et al.*, 1982a; Bazer *et al.*, 1984, 1989) and an interferon-like molecule between 11 and 17 dpc (Cross and Roberts, 1989). A minimum of four conceptuses are necessary to stimulate the uterus to modify its prostaglandin secretion so that the luteal progester-

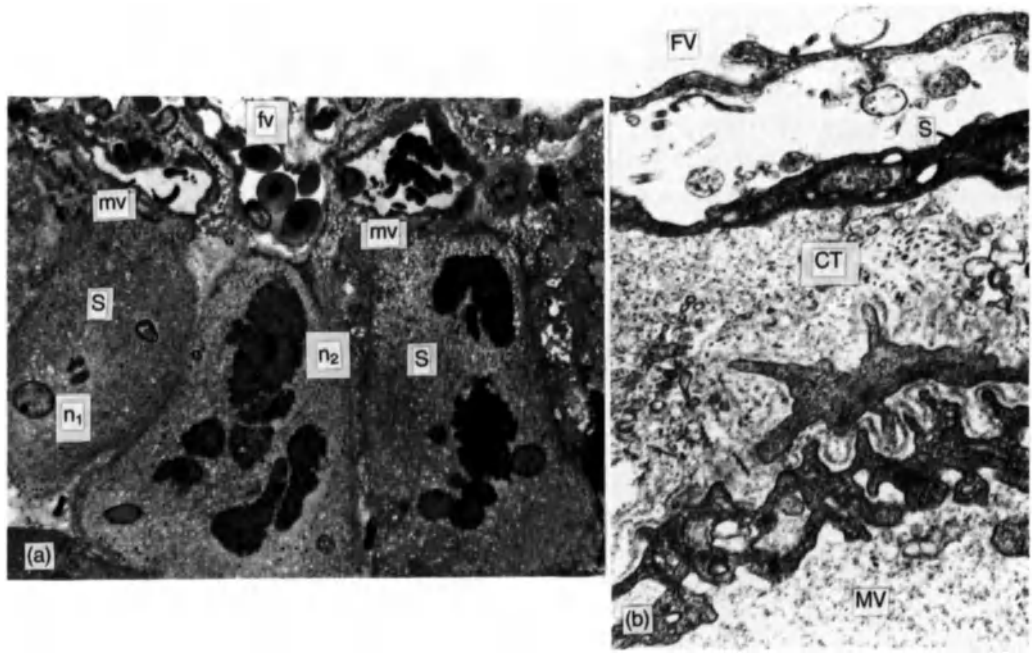

Figure 4.19 Definitive structure of the chorioallantoic placenta in marsupials. (a) Near term, 12 mm CR. The fetal trophectoderm is no longer visible but the fetal blood vessels (fv) are separated from the maternal (mv) by only a thin layer of cytoplasm continuous with the syncytial plaques (S), which contain two sorts of nuclei (n_1, n_2). *Isoodon*, × 480. (b) 12 mm CR. Electron micrograph of the attenuated cytoplasmic layer (S) between fetal (FV) and maternal (MV) blood vessels. CT, maternal connective tissue. *Isoodon*, × 15 000. (From Padykula and Taylor, 1976.)

one production is maintained. Subsequent fetal death may result in litters of less than four (Polge *et al.*, 1966). There is also evidence for an optimal length of uterus per conceptus at 20–25 dpc (M.C. Wu *et al.*, 1989).

The oestrogens also stimulate secretion from the uterine epithelium and glands (Geisert *et al.*, 1982b). This produces specific proteins which are thought to be involved in the remarkable reorganization and subsequent immunological readjustments necessary for successful implantation of the conceptus and continued luteal growth (Roberts *et al.*, 1985; Bazer *et al.*, 1989). Similar proteins are produced by the uterus of a non-pregnant pig treated at the correct stage of the cycle with artificial oestrogens (Geisert *et al.*, 1982c).

The 10 mm spherical conceptus extends in about 24 h to become a 150-mm thread stretched along the considerably corrugated uterine epithelium (Figure 4.20a) (Perry and Rowlands, 1962).

No DNA or RNA synthesis or any mitoses occur during this structural remodelling (Geisert *et al.*, 1982b; Mattson *et al.*, 1990). Once elongated, the conceptus thread interacts with the immediately underlying uterine epithelium. From this time (12–13 dpc) marked changes throughout the uterus in the structure of the subepithelial capillaries, notably increased fenestrations, have been described (Keys and King, 1988) and assumed to indicate increased permeability. However, the local increase in permeability in the immediate vicinity of the blastocyst reported by Keys *et al.* (1986) could not be verified by subsequent work (Keys *et al.*, 1989). On 13–15 dpc the fetal and maternal epithelia come into close apposition, involving loss of microvilli and considerable glycocalyx erosion, along the strip region (Dantzer, 1985). As the fetal and maternal microvilli reform they now interdigitate. This increases the fetomaternal exchange area by 10–12 times over a flat apposition (Baur, 1977). There is no good evidence for formation of any junctions between the fetal and maternal epithelia or for penetration of their tight junction apical seals by cellular processes from either side. Neither epithelium forms even a limited syncytium at any stage of gestation (Dantzer, 1985). There are few differences in the fine structure of the uterine epithelium between the cycle and early pregnancy (Keys and King 1989, 1990). Since fetal trophectodermal syncytium formation has been reported from ectopic pig blastocysts transferred into the pregnant endometrium below the uterine epithelium (Samuel and Perry, 1972), this layer may be instrumental in blocking fetal syncytium formation and possible subsequent invasion. No decidual changes have been reported in the endometrium at the implantation site.

At 17 dpc proliferation of fetal trophectoderm over the gland mouths has started to form the regular areolae, where the fetal and maternal epithelia become widely separated by glandular secretion (Amoroso, 1952) (Figures 4.20b,c and 4.21a).

About 7000 regular areolae per conceptus are present, fairly evenly spaced, from early gestation to term (Figure 4.20c). They triple in area between 30 and 114 dpc forming 10% of the total chorioallantoic surface area at midgestation and 4% at term (Brambel, 1933). They show a characteristic fine structure (Sinowatz and Friess, 1983) and a broad spectrum of enzyme activities (Skolek-Winnisch *et al.*, 1985; Firth *et al.*, 1986a,b). Uteroferrin, an iron-containing glycoprotein, is among a variety of molecules synthesized in the gland cells (Chen *et al.*, 1975; Stroband *et al.*, 1986). This is released into the lumen, taken up by the areolar trophectodermal cells and transferred to the fetus, for which it represents an important iron source (Raub *et al.*, 1985). The larger and less frequent (about 1500 per placenta) irregular areolae have significantly different fine structure from the regular type, but nothing is known of their specific functions (Figure 4.21) (Brambel, 1933; Perry, 1981).

At 18–22 dpc the conceptus expands so that it touches the uterine epithelium round

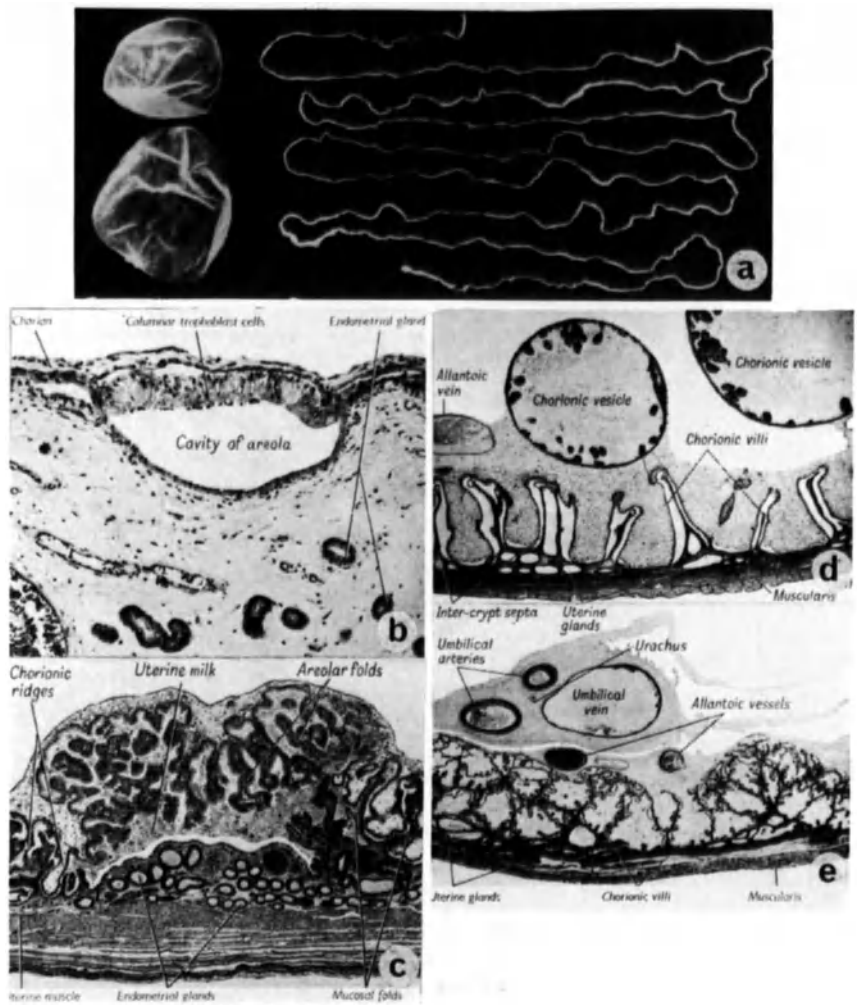

Figure 4.20 Epitheliochorial placentation. (a) Note the remarkable change of the shape of the pig blastocyst from a 5-mm-diameter sphere at 10 dpc to a 1-m-long thread at 13 dpc, × 0.5. (From Perry and Rowlands, 1962.) (b and c) Development of a regular areola in a pig placenta. (b) 23 dpc, × 80. (c) mature, 111 dpc, × 25. (d and e) Section through mature lemuroid placentas. (d) *Loris*, × 15. (e) *Galago*, × 7. Compare with the pig placenta in Figure 4.21.

the entire circumference and establishes microvillar interdigitation over the whole area of the trophectoderm (Dantzer, 1985; Hasselager, 1985). Further growth in the area of the fetomaternal junction is accomplished by development first of folds and then division of these into simple villi (K. Michael *et al.*, 1985; Wigmore and Stickland, 1985) (Figure 4.22).

The result is to maximize the surface area available for exchange between the fetal and maternal capillaries and minimize the distance between them. This is achieved in the pig by development of a meshwork of capillaries just under the epithelium of each fetal and maternal villus. Injection of latex or resin into the fetal or maternal vasculature and examination of the resulting casts of the

blood vessel architecture shows that the fetal and maternal villus meshworks are complementary and each is supplied by an artery running up one side of the villus before dividing near the apex into a capillary meshwork which drains to veins around the base of the villus (Figures 4.9, 4.23 and 4.24) (Tsutsumi, 1962; MacDonald, 1975, 1981; Leiser and Dantzer, 1988) (for the physiological exchange implications of this arrangement see section 4.2.5c).

Increase in size and branching of the villi can be accommodated by expansion of the capillary meshwork. As the conceptus grows the fetomaternal junctional area and the transport capacity of the placenta increase continuously right up to term (K. Michael *et al.*, 1985). The villi and folds show local differentiation of structure. The trophectodermal cells at the bases of the fetal villi are tall, columnar and specialized for histotroph absorption; they are apposed to similar columnar maternal uterine epithelial cells, often with cell debris between (Dantzer *et al.*, 1981). The fetal and maternal blood vessels are situated just below the basement membranes. The structure is analogous to a miniareola with material produced by degeneration of, or secretion by, the maternal epithelium rather than a gland. In contrast, at the sides and tips of the fetal villi (sides and base of the maternal villi) both epithelia are thin and deeply indented by blood vessels from each side (Figures 4.22b and 4.25) (Steven, 1983).

This reduces the interhaemal diffusion distance to as little as 2 μm, although the same number of membrane barriers is present as at

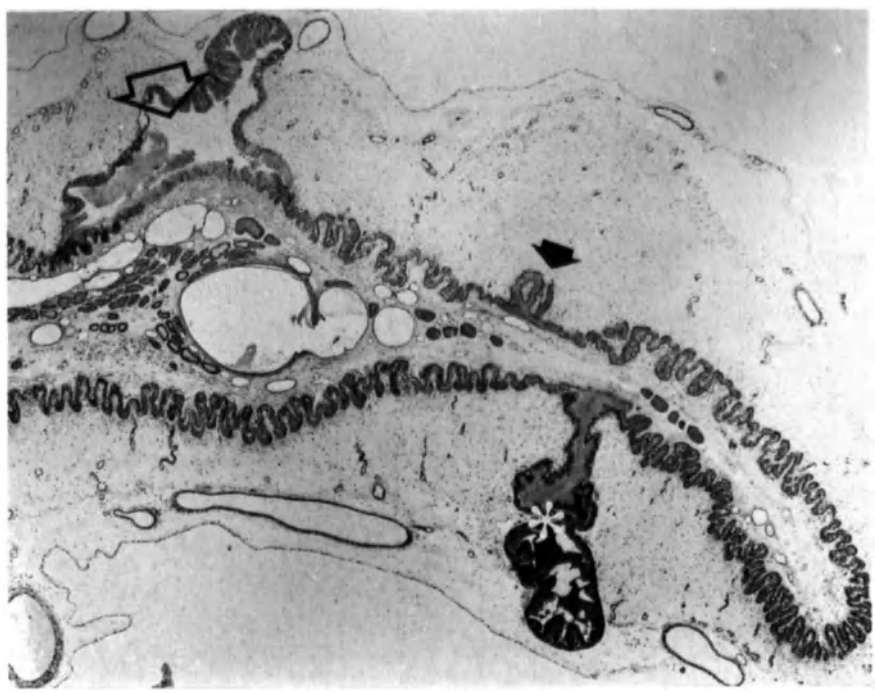

Figure 4.21 Epitheliochorial placenta of the pig. Light micrograph showing a maternal mucosal fold whose sides consist of fetal villi inserted into endometrial crypts, seen at higher magnification in Figure 4.22b. A chorionic vesicle (asterisk) and irregular (open arrow) and regular (closed arrow) areolae can be seen. The section passes through the extreme edge of the regular areola, whose characteristic structure is better illustrated on Figure 4.20c. 107 dpc, × 12.

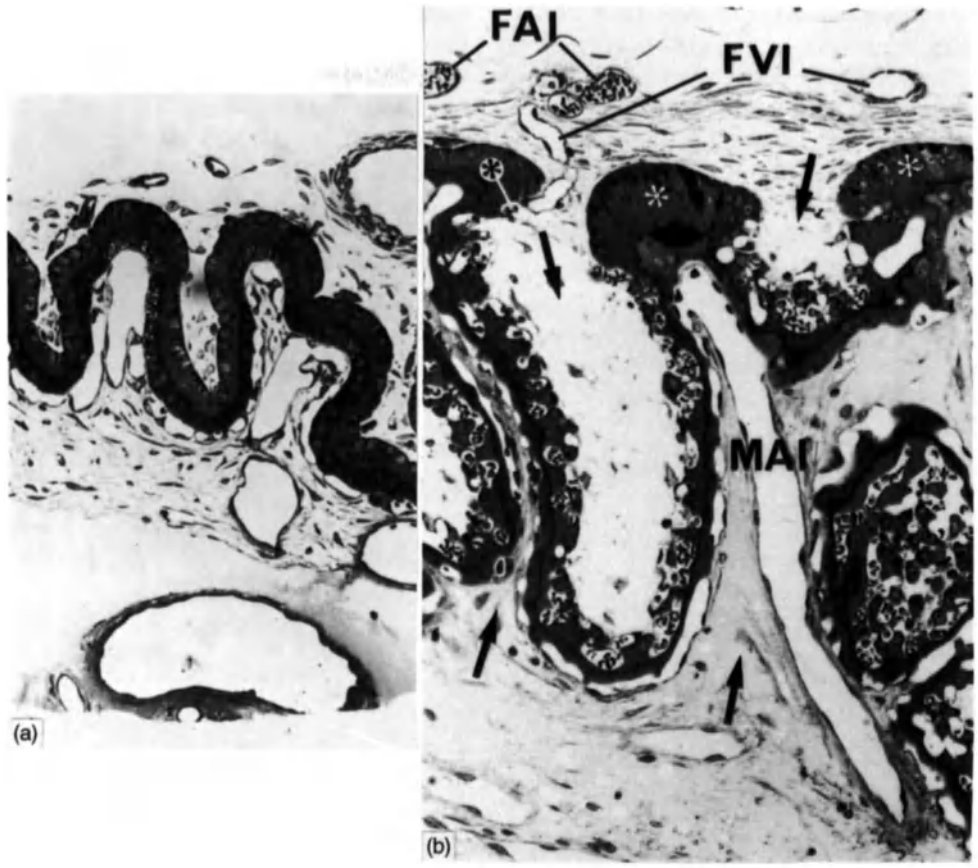

Figure 4.22 Epitheliochorial placenta of the pig. Development of the placental villi which form the fetomaternal haemotrophic exchange area. Note the increase in regional differentiation. The uniform trophectoderm and uterine epithelial cell layers forming the folds of (a) develop into very attenuated layers deeply indented by fetal and maternal capillaries around the apex and sides of the fetal villus in (b). However, at the base of the fetal villi in (b) the trophectoderm cells are considerably enlarged (asterisks) and are involved in pinocytotic, histotrophic uptake. Upward arrows, sides of maternal crypts; downward arrows, fetal villi; FAI fetal arteriole; FVI fetal venule; MAI maternal arteriole. (a) 33 dpc, × 130. (b) 99 dpc, × 170.

the base of the fetal villi where the interhaemal distance ranges from 20 to 100 μm (Figures 4.22 and 4.25).

Indentation of the blood vessels into the epithelia increases as pregnancy proceeds (Figures 4.22 and 4.25). There is no evidence for any active process of 'tunnelling into' or 'invasion' of the epithelia by the blood vessels. The endothelium is always separated from the epithelium by a basement membrane. It seems likely that indentation results from differential growth, the endothelium growing less quickly than the epithelium.

During pregnancy the fetal and maternal villi can be separated manually but there is always some maternal epithelium pulled away with the fetal side and vice versa. At parturition the placenta separates cleanly at the microvillar fetomaternal junction and the incidence of retained placentas (see synepith-

eliochorial placentation) is negligible. There is a massive release of relaxin from the corpora lutea as a result of the rise in prostaglandins which triggers parturition (First and Bosc, 1979). Processes initiated by these hormonal changes (Bazer and First, 1983) are no doubt involved in releasing the microvillar interdigitation between fetal and maternal epithelia to allow an easy placental separation.

Horse, Equus caballus

Oestrous cycle: 22 days

*Ovulation: spontaneous
*Uterus: bicornuate
Gestation: 336 (± 20) days
Litter: one, rarely two (Ginther, 1989)
*Implantation: superficial
*Amniogenesis: folding
*Yolk sac: initially large and functional to 38 dpc
*Chorioallantois: forms definitive placenta
*Shape: diffuse, microcotyledonary, villous
*No decidual reaction.
*Interhaemal membrane: epitheliochorial
Accessory placental structures: trophectodermal girdle producing endometrial cups; areolae

The major characteristics* are found in the Perissodactyla families.

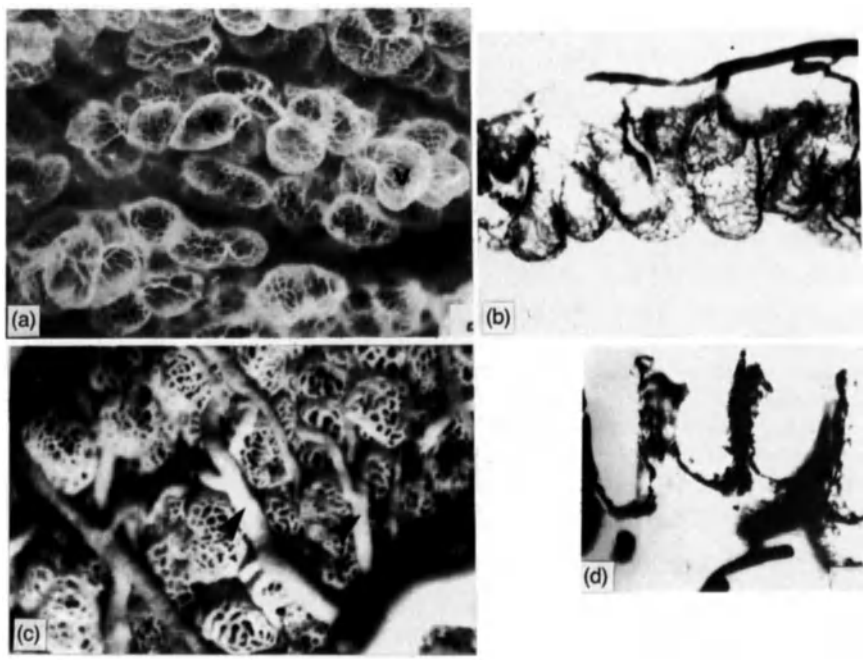

Figure 4.23 Epitheliochorial placentation. Pig placenta vascular supply demonstrated with corrosion casts (a and c) and cleared sections of injected specimens (b and d). See also Figures 4.8, 4.9 and 4.24. (a) Latex injection of fetal blood supply viewed from the maternal side showing the capillary network in each villus (v). 105 dpc, × 40. (b) Injection of the fetal blood supply shows the villus capillary net in cross section. 105 dpc, × 40. (c) Latex injection of the maternal vasculature viewed from the back showing the network of capillaries at the base of each crypt with their supplying or draining arterioles and venules (arrowheads). 105 dpc, × 40. (d) Injection of the maternal blood supply demonstrates on a section the maternal crypts into which the fetal villi fit. 75 dpc, × 50. (From Tsutsumi, 1962.)

Equidae, horse, donkey, zebra
Tapiridae
Rhinocerotidae

The unusual length of standing heat in horses (4–5 days; compare with sheep, 1 day; pig, 1½ days) and the consequent uncertainty about the time of ovulation makes days post coitum a far less reliable indicator of gestational age than in the other domestic species. Use of the more accurate days post conception is only realistic if the preovulatory surge in luteinizing hormone is monitored in the maternal blood for a particular pregnancy.

Like the pig, the definitive horse placenta is a simple apposition of unchanged fetal and maternal epithelia for haemotrophic exchange with a large number of areolae for histrophic transfer (Steven, 1982). Unlike the pig, the horse conceptus does not elongate and implantation (fetomaternal microvillar interdigitation) occurs much later at about 45 dpc (pig 15 dpc) (Ginther, 1979). Uniquely, the equid trophectoderm produces (between 30 and 40 dpc) a girdle around the conceptus of binucleate cells which migrate into the maternal endometrial stroma to form the gonadotrophin-producing endometrial cups (Allen *et al.*, 1973; Allen, 1982). This pregnant mare serum gonadotropin (PMSG) is now known as equine chorionic gonadotropin (eCG).

Horse fetal membranes At 20 dpc the 30–40-mm spherical conceptus has a fully formed amnion and the allantois is just visible as a small outgrowth of the hind gut (Figure 4.26a).

About one-third of the conceptus is bilaminar and most of the rest forms a rapidly

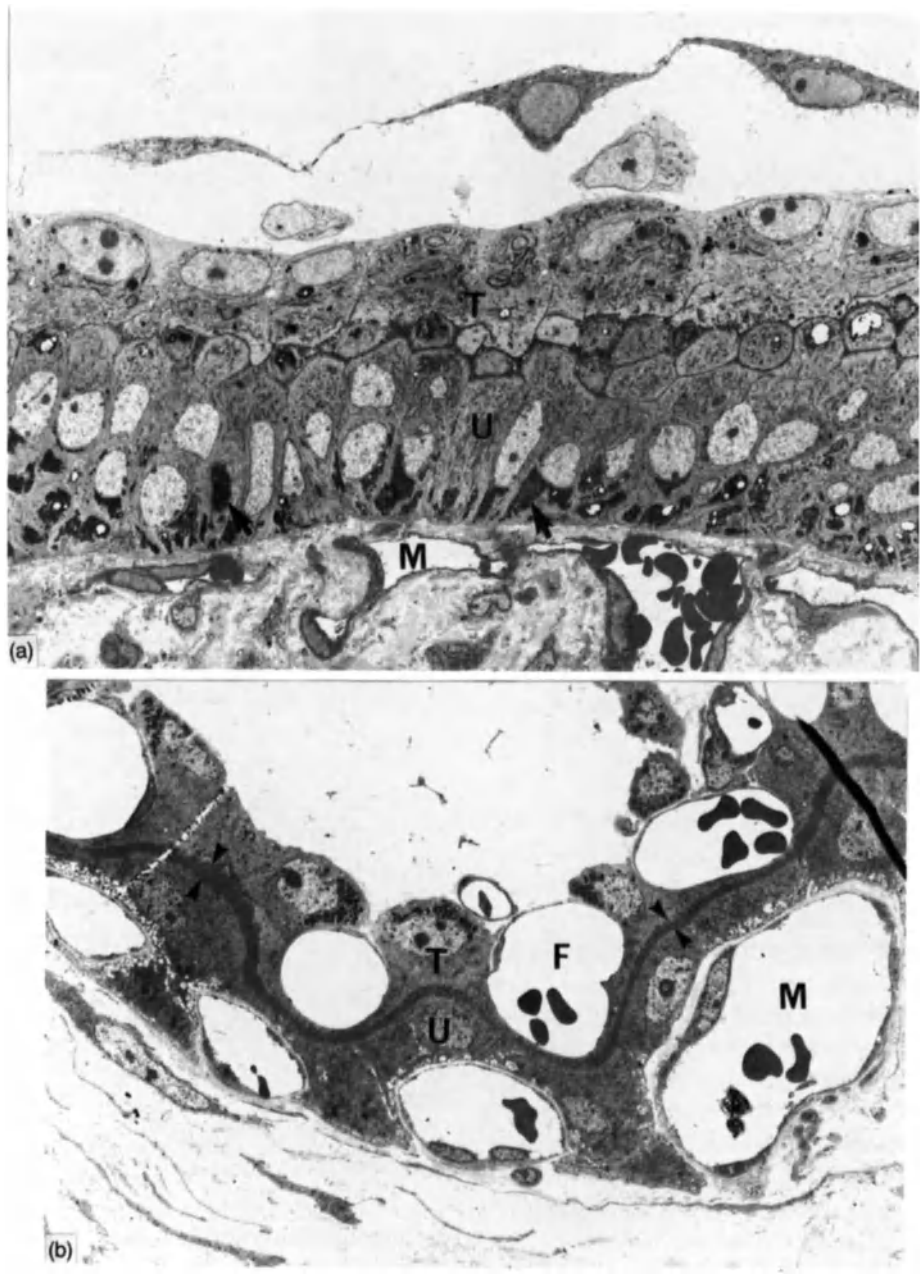

Figure 4.25 Epitheliochorial pig placenta. (a and b) Electron micrographs at the same magnification illustrating the development of the extreme indentation of the blood vessels into the trophectoderm (T) and uterine epithelial layers (U). The depth of the microvillar interdigitation can clearly be seen in (b) (arrowheads). F, Fetal vessels; M, maternal vessels; arrows, glycogen in uterine epithelium. (a) 16 dpc, × 400. (b) 109 dpc, × 400.

vascularizing trilaminar absorptive choriovitelline layer. By 25 dpc the allantois has formed a vascularized chorioallantoic cap over the embryo and its further expansion reduces the relative extent of the still absorptive choriovitelline layers. From 25 dpc a band of trophectodermal cells proliferates at the boundary between the chorioallantois and the trilaminar yolk sac to form the chorionic girdle (Figures 4.26 to 4.30).

By 40 dpc these cells have migrated into the maternal endometrium to form a ring of endometrial cups (Figures 4.26a and b and 4.28) and the yolk sac is reduced to a vestige within the umbilical cord. Subsequent growth of the conceptus is based entirely on the chorioallantois. Unlike the pig there is no amniochorion formation since the conceptus is isolated from the chorion by growth of the allantois (Figure 4.1). The umbilical cord is unusually long, having amniotic and allantoic portions linking the fetus to the membranes (Whitwell and Jeffcot, 1975; Ginther, 1979).

Development of the horse placenta The conceptus moves freely between the two horns of the uterus between 12 and 16 dpc as it expands from 12 mm to an 28-mm sphere. This has been demonstrated by ultrasonography and is presumably caused by contractions of the uterine musculature. Maternal recognition of pregnancy probably occurs between 14 and 16 dpc based on changes in prostaglandin content of the uterine vein (Sharp *et al.*, 1989). At 17 dpc the expanding conceptus reaches a critical diameter and fixes in the caudal portion of the horn which offers most luminal resistance (Ginther, 1983, 1984a,b; twin conceptuses, Ginther, 1989). It can subsequently be detected by rectal palpation as a uterine swelling. Recent evidence suggests that there is little or no subsequent migration because of closure of the uterus around the conceptus with development of a considerable muscular tone in the myometrium. Cellular interaction is initially limited by an acellular capsule around the embryo which is produced by the trophectoderm after the conceptus reaches the uterus (9 dpc) and persists until 21–22 dpc then ruptures and disappears (Betteridge, 1989). Subsequently, it is probably the bilaminar portion of the yolk sac which adheres to the uterine epithelium. The adhesion is tenuous and if the uterus is cut open between 22 and 40–50 dpc the conceptus is expelled by the internal pressure in the uterus (Ginther, 1979). There is a copious secretion from the uterine glands during this time (Zavy *et al.*, 1984), most of which is absorbed initially by the trilaminar yolk sac (from 16 to 28 dpc) and later by the chorioallantois.

From 27 to 35 dpc the avascular trophectoderm at the boundary between the chorioallantois and the trilaminar yolk sac proliferates to form a 'chorionic girdle' many cells thick (Figures 4.26a and b, 4.28, 4.29 and 4.30) (Allen, 1982; Enders and Liu, 1991a). Initial cell interaction (30–33 dpc) between mother and fetus is indicated by localized changes in lectin labelling of the uterine epithelium apposed to the developing girdle (Whyte and Allen, 1985). By 35 dpc the apical cells of the girdle have become binucleate, start to produce eCG (Figure 4.31b) and express MHC-1 antigens (Donaldson *et al*, 1990, 1992).

They then invade the uterine epithelium against which they are pressed by expansion of the conceptus against the firm uterine muscular tone (Figures 4.26, 4.30 and 4.31). The first binucleate girdle cells protrude pseudopia into and are said to push through the body of the uterine epithelial cells, well away from their tight junction seal (section 4.2.9c). They are then briefly delayed by the basement membrane of the uterine epithelium (along which they may migrate into uterine glands) and finally invade the endometrial stroma between the uterine glands (Allen *et al.*, 1973; Enders and Liu, 1991b) (Figures 4.26, 4.30 and 4.31). The uterine epithelium is subsequently phagocytosed

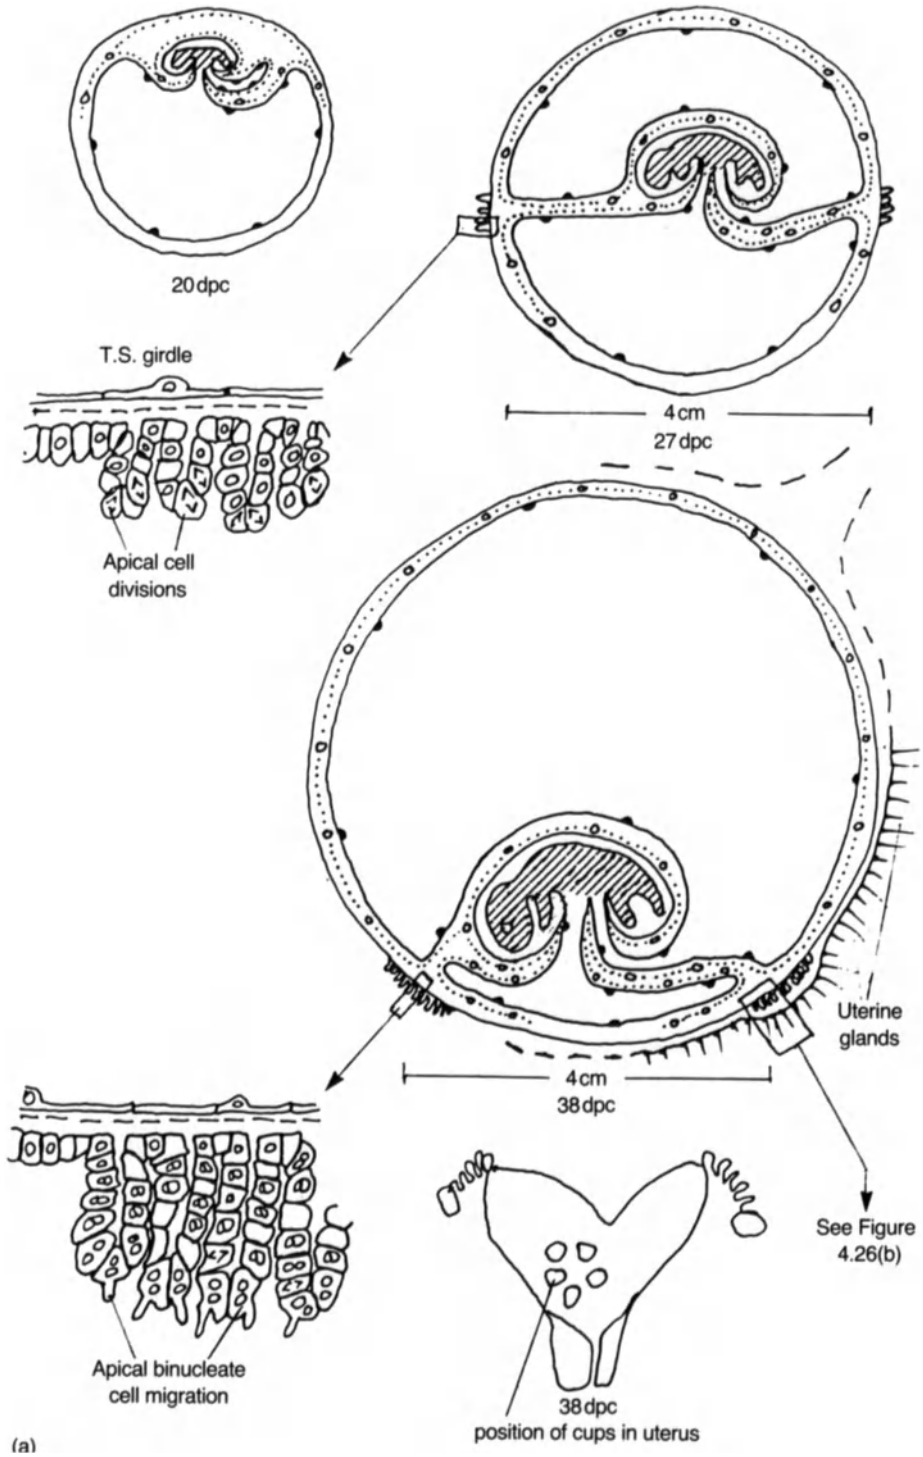

Figure 4.26 (a and b) The cellular changes in the development of the endometrial cups in Equidae.

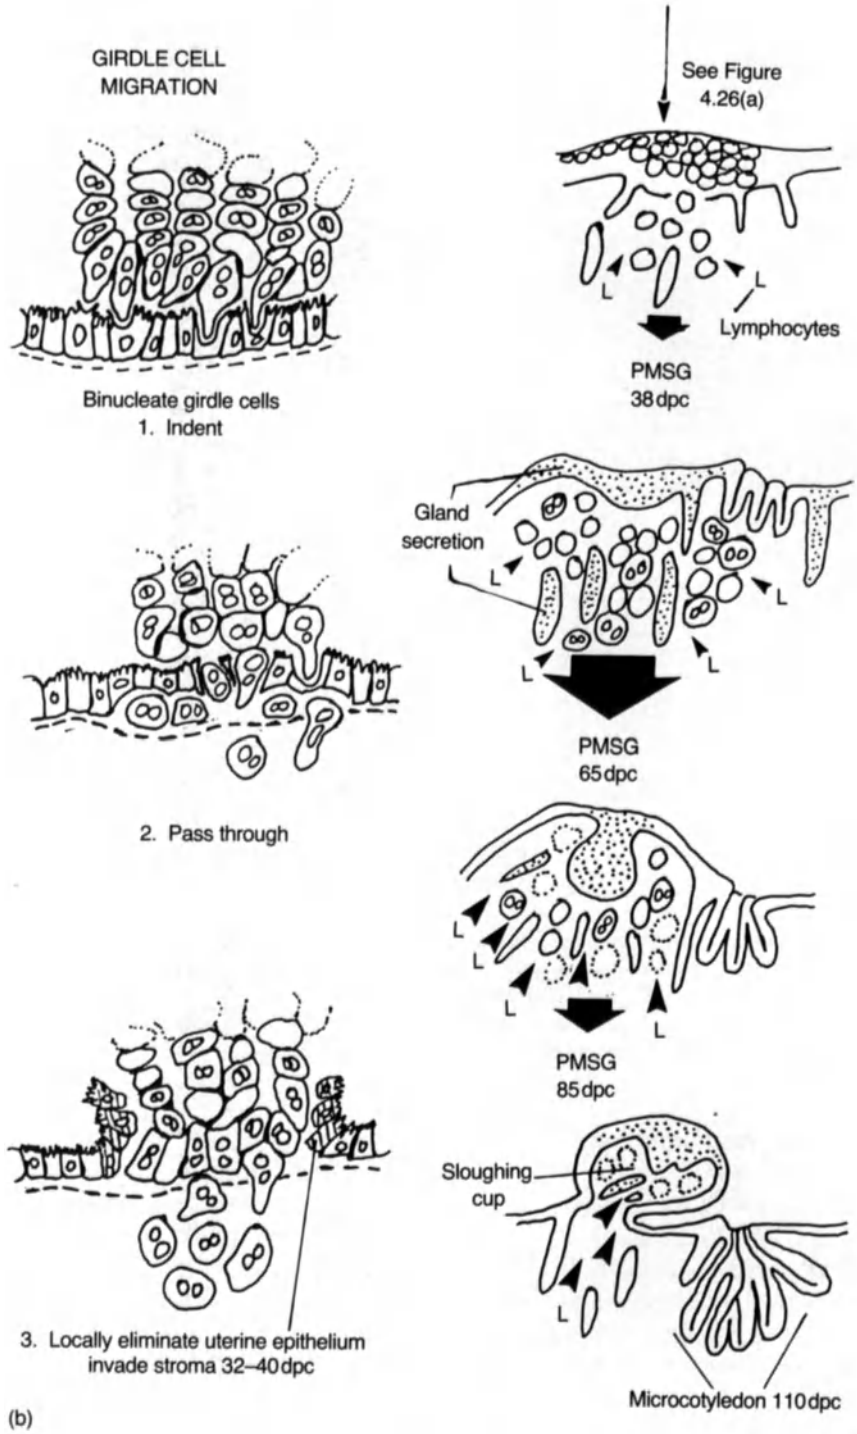

Figure 4.26 *continued*

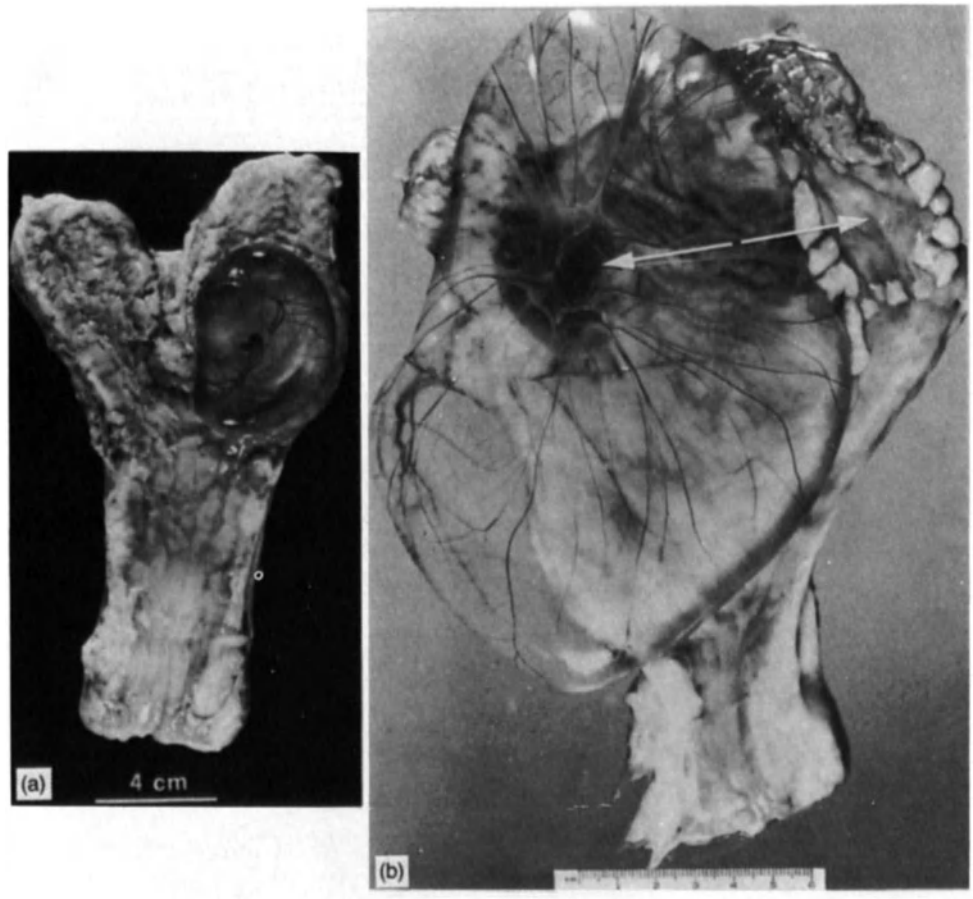

Figure 4.27 Horse conceptus, chorionic girdle and endometrial cups. The chorionic girdle forms between 28 and 36 days post coitum (dpc) around the conceptus in a band immediately above the junction of the allantois and yolk sac. The girdle remains the same size while the allantochorionic sac expands above it. Compare the diameter of the 30-dpc conceptus in (a) with the ring of cups in (b) from which the 60-dpc conceptus has been reflected (arrows). (a) 30 dpc, × 0.4. (b) 60 dpc, × 0.5. (From Ginther, 1979.)

and removed by continuing binucleate cell migration (Figure 4.31), which allows the whole chorionic girdle free access to the endometrial stroma (Figure 4.26).

Once in the uterine stroma (36–40 dpc) the binucleate cells have not been seen to divide but develop into masses of very large cells forming a ring of 'endometrial cups' (Figures 4.26 and 4.32).

The uterine epithelium grows in from the sides to cover the cup area. These cup cells secrete eCG which appears in the maternal (but never the fetal) circulation via the capillaries and lymphatic vessels in and around the cup. The mature cup cell has a cytoplasm full of mitochondria, rough endoplasmic reticulum cisternae and a large Golgi apparatus (D.W. Hamilton *et al.*, 1973) (Figures 4.33 and 4.34).

Ultrastructural immunogold studies have shown that eCG is localized in the Golgi cisternae and in small dense granules similar to those found in the migrating girdle cell and present both in the Golgi region and at the

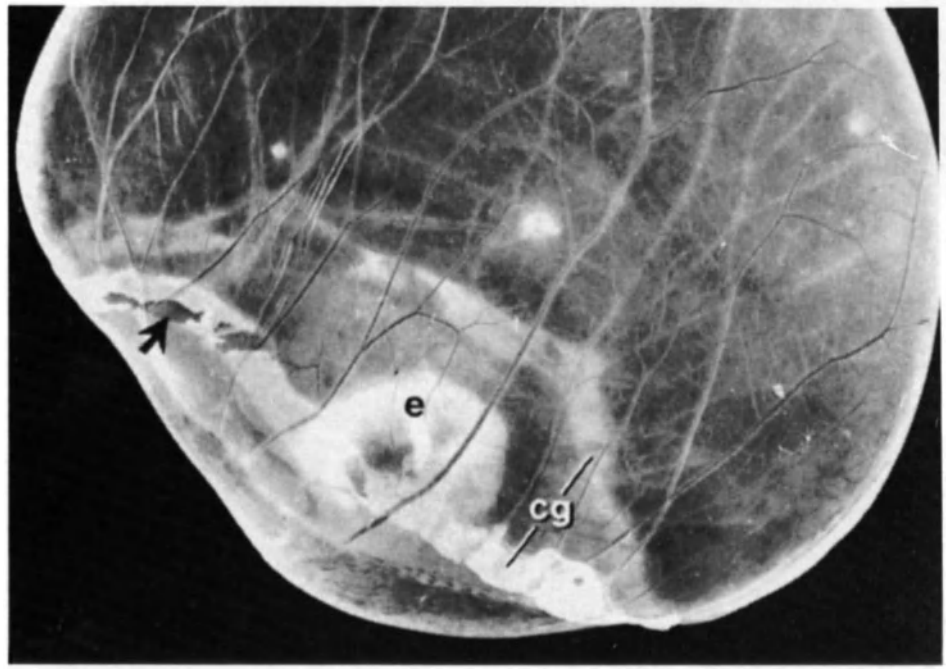

Figure 4.28 Horse conceptus, chorionic girdle. A 37-dpc conceptus with a clearly visible girdle (cg) from which some girdle cells have been lost on removal from the uterus (arrow). e, embryo. 37 dpc, × 2. (From Ginther, 1979.)

peripheral plasmalemma (Figures 4.31 and 4.34). Release of eCG would therefore seem to be by the usual exocytotic mechanism as found for other protein hormones. The amount of eCG produced depends on the size of the cup, which is determined by the number of fetal binucleate cell migrants. This last seems to depend upon the genotype of the conceptus. For example horse ♀x horse and horse ♀x donkey crosses produce large cups, while donkey ♀x donkey or donkey ♀x horse produce small cups (Allen, 1982).

Cells scraped from the girdle between 36 and 37 dpc will grow in tissue culture to form large, usually binucleate, cells which produce considerable amounts of eCG for up to 200 days (Allen and Moor, 1972; Figure 4.33b). On the analogy of the ruminant binucleate cell it seems unlikely that binucleate girdle cells can divide, so any increase in cell numbers in culture would have to be based on division of the uninucleate (stem?) cells of the girdle. Fetal cells, already binucleate, isolated from endometrial cups will not divide or persist successfully in culture.

Maternal lymphocytes and macrophages start to accumulate at the edge of a cup as soon as it establishes itself (Figure 4.32). Maximum secretion of eCG from the cup occurs between 50 and 80 dpc, after which the lymphocytes start to invade and kill the cup cells. The uterine glands in the cup also produce a considerable amount of secretion at this time (Figure 4.32), presumably stimulated by the cup cells. This glandular secretion contains very large amounts of eCG secreted by the cup cells, but surprisingly this does not reach the fetal circulation.

The variation of cup size with genotype, the lymphocyte accumulation and the ability of the cup cells to secrete eCG in tissue culture (Figure 4.33) for up to 200 days suggests

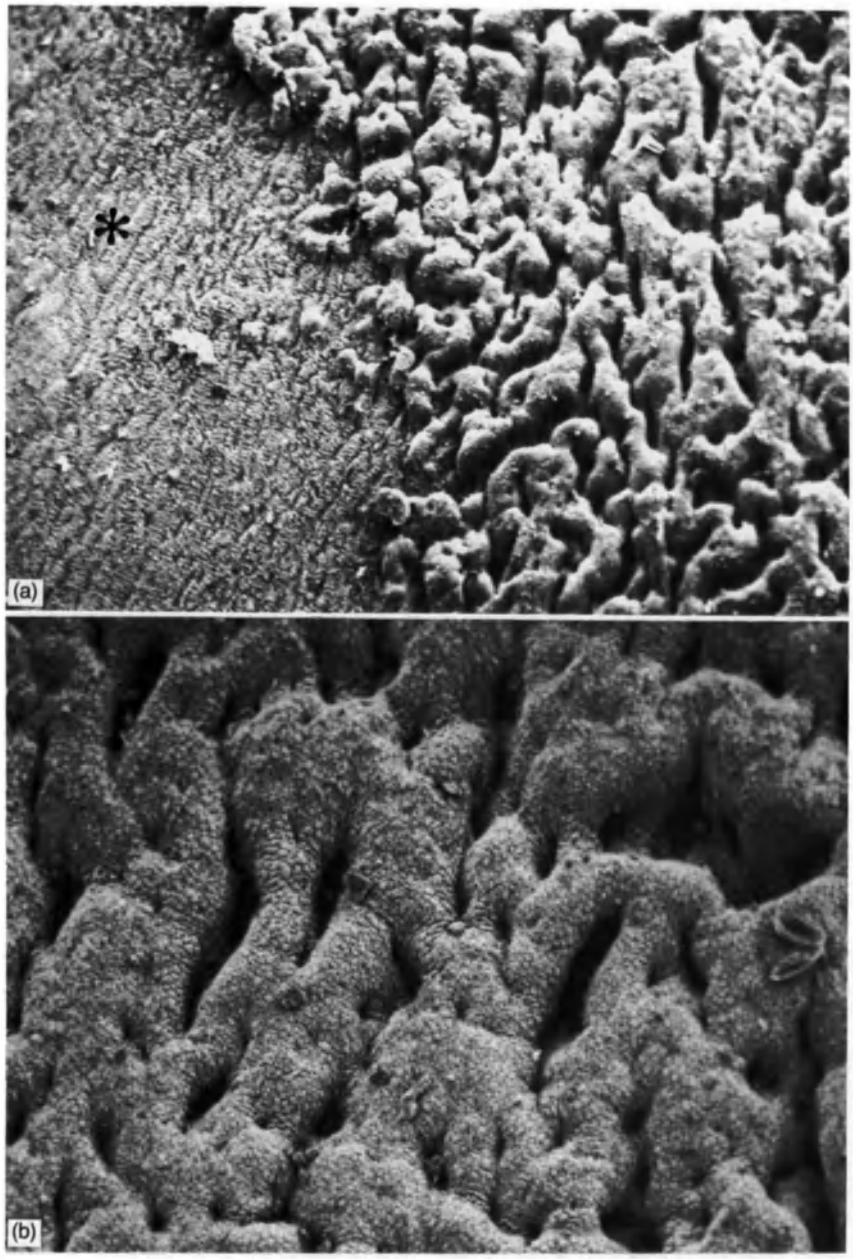

Figure 4.29 Horse conceptus, chorionic girdle. (a) Scanning electronmicrograph of a 32 dpc girdle. Compare the thickness of the unmodified trophectoderm outside the girdle (arrows): (c) Electron micrograph of the apex of fetal chorionic girdle at 37-dpc. Most of the cells are binucleate (e.g. asterisks). (a) 30 dpc, × 25. (b) 36 dpc, × 25. (c) 37 dpc, × 1100. (a and b) courtesy of Dr W.R. Allen.

that the cytolysis and regression of the cup cells is caused by an immunological reaction rather than a programmed cell death (Allen, 1982). Subsequently, the whole mass of degenerating cup tissue is everted from the endometrium, encapsulated by the overlying allantochorion, and remains as a necrotic residue in the allantoic cavity (Whitwell and Jeffcot, 1975). The uterine epithelium grows over the scar from the edges (Ginther, 1979).

Interspecific embryo transfer experiments (e.g. zebra conceptus into horse, Summers *et al.*, 1987) have shown that as long as there is some cup development, however small, normal gestation results and usually 'pregnancy-specific antibody' is elicited in the maternal blood. However, a donkey conceptus transferred to a horse produces neither a cup reaction nor pregnancy antibody and abortion usually follows between 80 and 100 dpc in the presence of a massive lymphocyte infiltration throughout the entire endometrium, ostensibly similar to the infiltration round a normal size (horse in horse) cup. In some

cases this abortion can be blocked by infusing pregnant mare's serum (but not eCG alone) or paternal lymphocytes into the mare between 20 and 80 dpc (Allen *et al.*, 1987).

Once a horse has carried one donkey pregnancy successfully (and this is as yet entirely unpredictable) with or without treatment, then most subsequent donkey conceptuses are carried to term without further therapy – the system displays immunological memory.

The girdle and the early cup cells are the only allantochorionic cells to express MHC antigens (Crump *et al.*, 1987; Donaldson *et al*, 1990, 1992). Presumably, it is this exposure to MHC (and other trophoblast antigens) which stimulates the maternal immune system to produce the antibodies and/or recruit suppressor lymphocytes necessary for a successful pregnancy.

At 35–38 dpc the allantois has vascularized

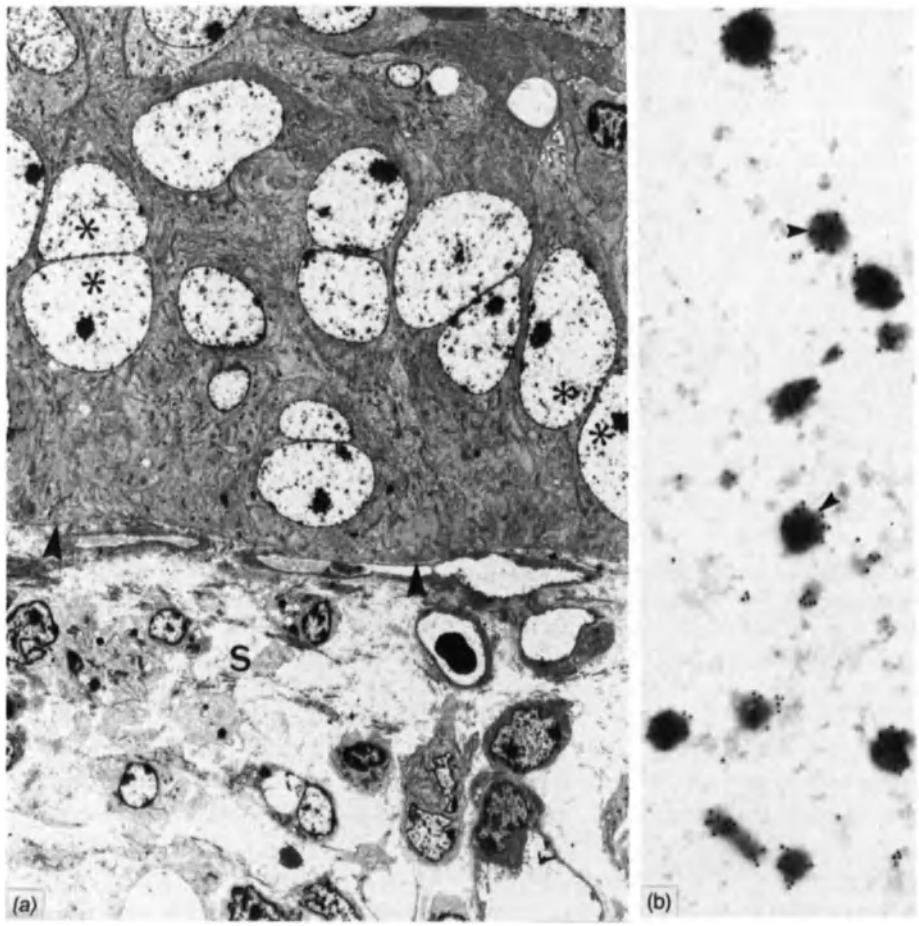

Figure 4.31 Horse chorionic girdle. (a) The fetal chorionic girdle has invaded and eliminated the uterine epithelium but further migration into the maternal endometrial stroma (S) is delayed by the residual basement membrane (arrowheads) of the epithelium. Most girdle cells are binucleate (asterisks). 37 dpc, × 1700. (b) Binucleate girdle cells in the position shown in (a) often contain groups of small granules. This section has been processed with immunocytochemical methods to demonstrate that the granules contain equine chorionic gonadotrophin indicated by the gold colloid marker (arrowheads). 37 dpc, × 30 000.

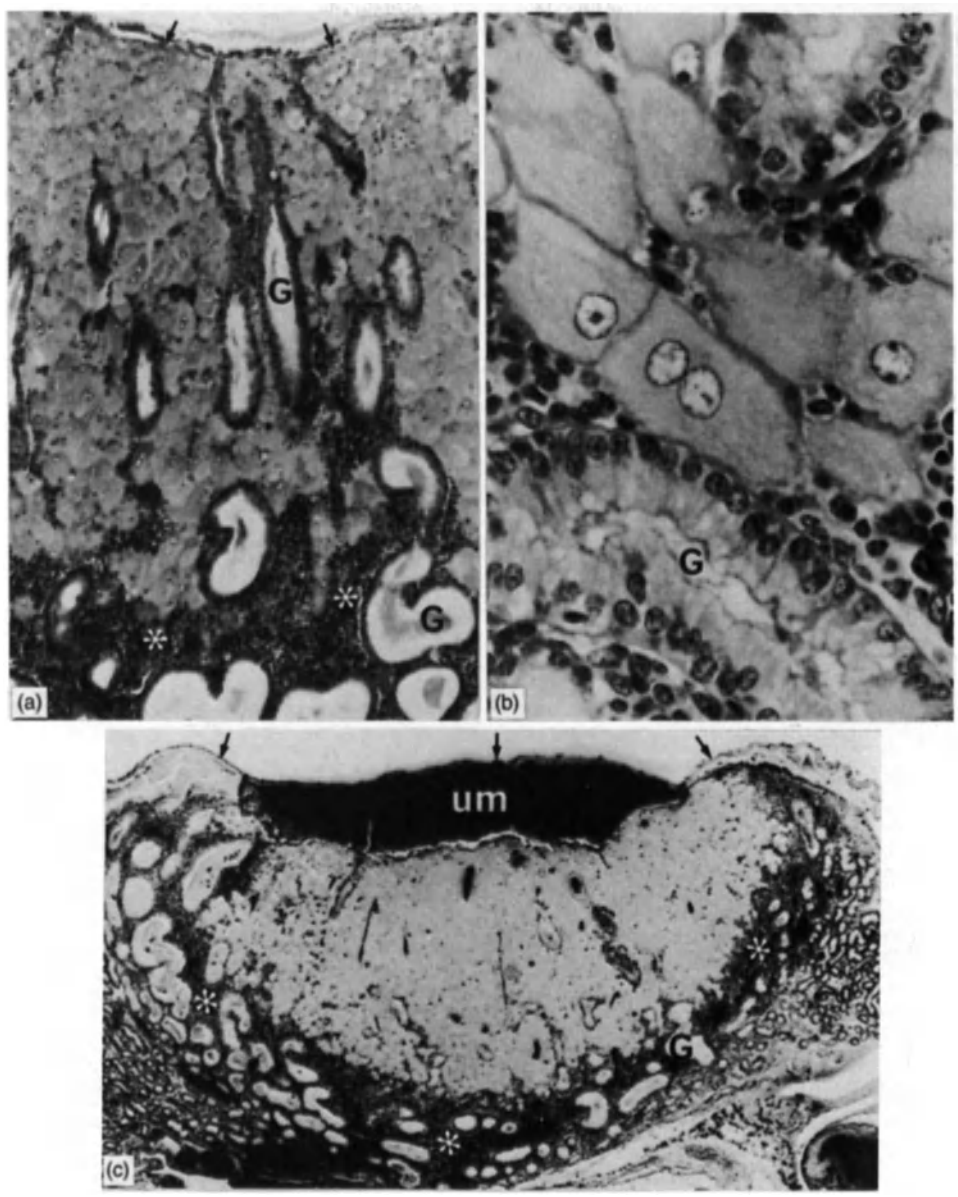

Figure 4.32 Horse endometrial cup structure. (a) Section through a newly formed cup at 40 days post conception (dpc) with cup cells closely packed around the uterine glands (G). The uterine epithelium (arrows) reforms rapidly after migration of the girdle cells is completed at 38–40 dpc. There is an accumulation of lymphocytes around the base of the cup (asterisks). (b) Note the large size of the cup cells compared with the gland cells (G). (c) Mature cup (60 dpc) with accumulated secretion (um) localized between the allantochorion (arrows) and the cup. Considerable numbers of lymphocytes have accumulated in a continuous zone (asterisks) around the cup. (a) 40 dpc, × 70. (b) 40 dpc, × 2000. (c) 60 dpc, × 30. (a–c from Ginther, 1979.)

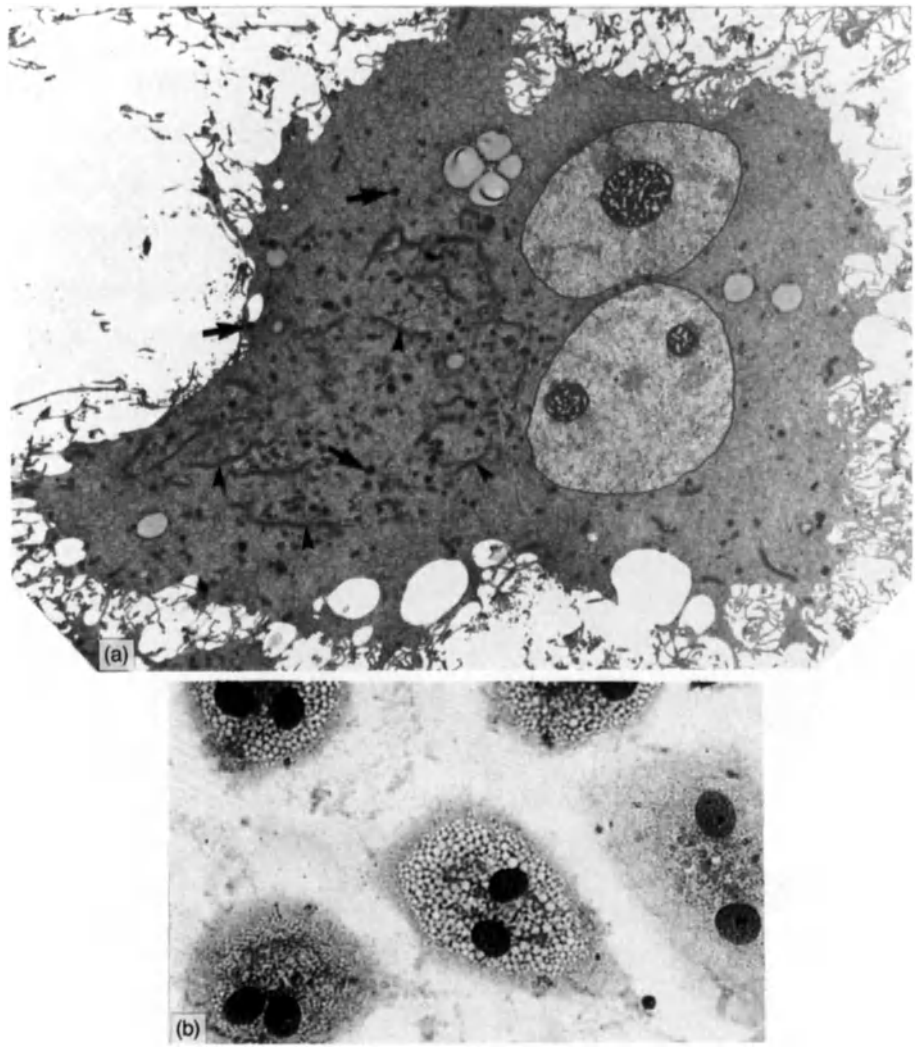

Figure 4.33 Horse endometrial cup cells (a) *in vivo* and (b) *in vitro*. (a) An electron micrograph of a characteristic binucleate cell from a 50-dpc cup fixed by perfusion *in situ*. The material was processed without osmium and stained with phosphotungstic acid (Wooding, 1980). This emphasizes the two nuclei and extensive Golgi cisternae (arrowheads) and small granules (arrows) in a typical endometrial cup cell. 50 dpc, × 3200. (b) Light micrograph of cells isolated from a 35-dpc girdle and grown in tissue culture for 50 days. They are very large, characteristically binucleate and produce considerable amounts of eCG. The cytoplasm accumulates numerous lipid droplets giving a stippled appearance, × 1300. (Courtesy of Dr R. Moor.)

more than 90% of the total trophectoderm, and this is the earliest stage at which microvillar interdigitation between uterine epithelium and trophectoderm has been reported (Steven, 1982). The fetomaternal cell sheets then produce villi by a process of complementary growth. Fetal villi are formed over the entire surface of the conceptus except over the openings of the numerous endometrial glands. Here the trophectoderm

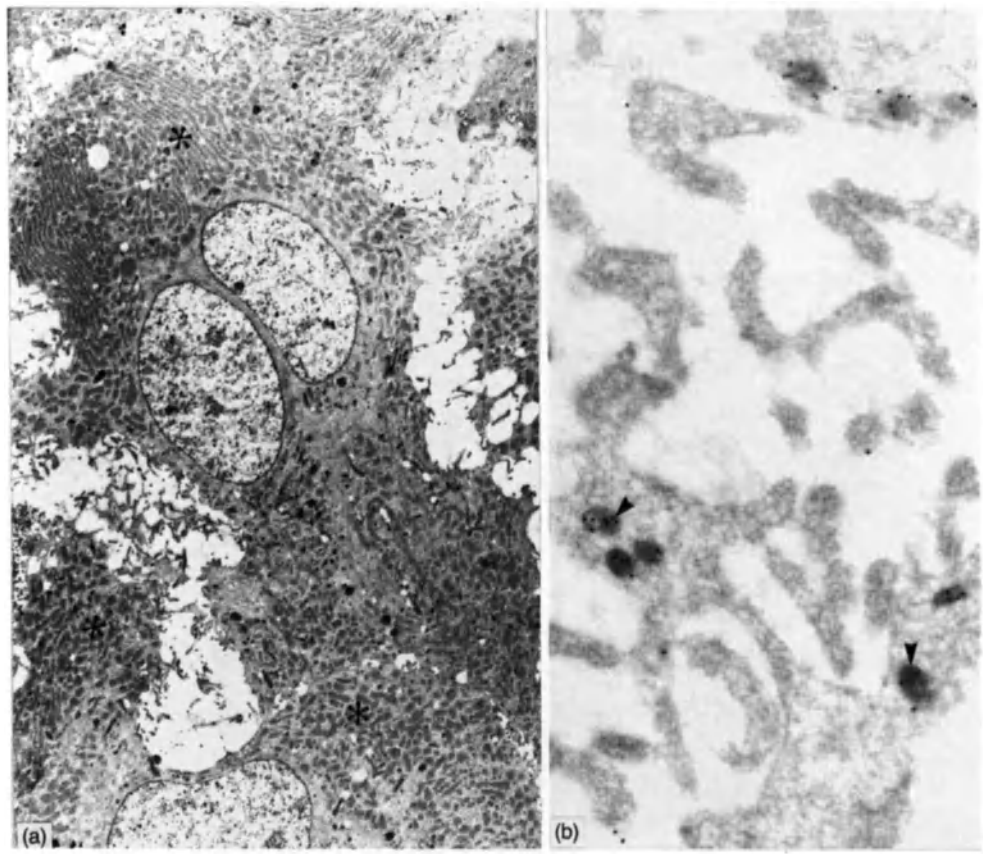

Figure 4.34 Horse endometrial cup cells. (a) Electron micrograph of cells processed without osmium and stained with phosphotungstic acid followed by lead citrate which enhances the massive arrays (asterisks) of rough endoplasmic reticulum cisternae filling most of the cytoplasm of the cup cells. 50 dpc, × 3200. (b) The small granules produced by the Golgi apparatus of the cup cells (see Figure 4.33a) contain eCG as indicated by the immunogold colloid marker (arrowheads). They are usually located peripherally but never seem to accumulate in any number. 50 dpc, × 44 000.

develops a dome of highly absorptive columnar cells over the gland mouth and its secretion, forming areolae exactly as in the pig, if a little smaller in size (Figure 4.35).

By 60 dpc the fetal villi are longer and have started to group together between the areolae. Further extension of the villi with secondary branching plus the development of a bounding maternal connective tissue capsule produces the characteristic microcotyledon between the glands, each 1–2 mm in diameter at term (Samuel *et al.*, 1974) (Figures 4.26, 4.35 and 4.36).

After girdle cell migration has finished (about 40 dpc) there is no published evidence for any specialized cells or any syncytium in the trophectoderm or uterine epithelium. Like the pig, the trophectoderm is uniformly uninucleate and its microvilli are closely interdigitated with the uniformly uninucleate uterine epithelium. This fetomaternal junctional area increases (as does fetal weight) throughout pregnancy by mutual growth of the fetal and maternal epithelia (Baur, 1977), and both are increasingly indented by their initially subepithelial capillaries (Samuel *et*

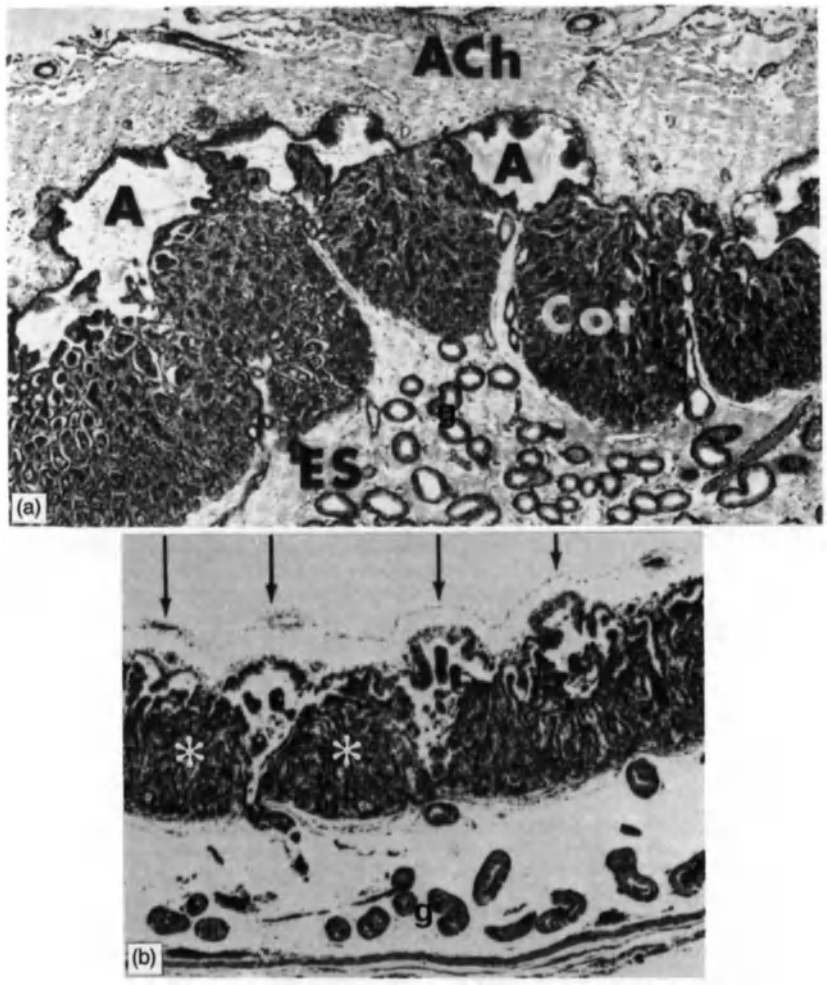

Figure 4.35 Epitheliochorial placentas. The horse (a) with its microcotyledons (Cot) with areolae (A) between in the allantochorion (ACH) has a very similar placental architecture to the American mole, *Scalopus* (b). In (b) the areolae are indicated by arrows, the microcotyledons by asterisks. In the endometrium (ES) of both there are many glands (g) which empty into the areolae. (a) Mid-pregnancy, × 20. (From Bjorkman, 1970.) (b) Late gestation, × 37. (From Prasad *et al.*, 1979.)

al., 1976). Indentation is most marked in the fetal trophectoderm but is not so extreme as observed for the pig.

There are no extravasations of maternal blood at the microvillar junction (as found in ruminants and carnivores) so iron transport is presumably based on a similar carrier system to the pig protein uteroferrin in the glandular secretions. A similar protein has been reported in the horse (Zavy *et al.*, 1979, 1984).

The trophectodermal cell fine structure changes during pregnancy. At 200 dpc there is a considerable amount of smooth endoplasmic reticulum and this persists to term. Rough endoplasmic reticulum is found from 180 dpc to term, when the number of dense bodies (probably lysosomal) has also increased considerably (Samuel *et al.*, 1976).

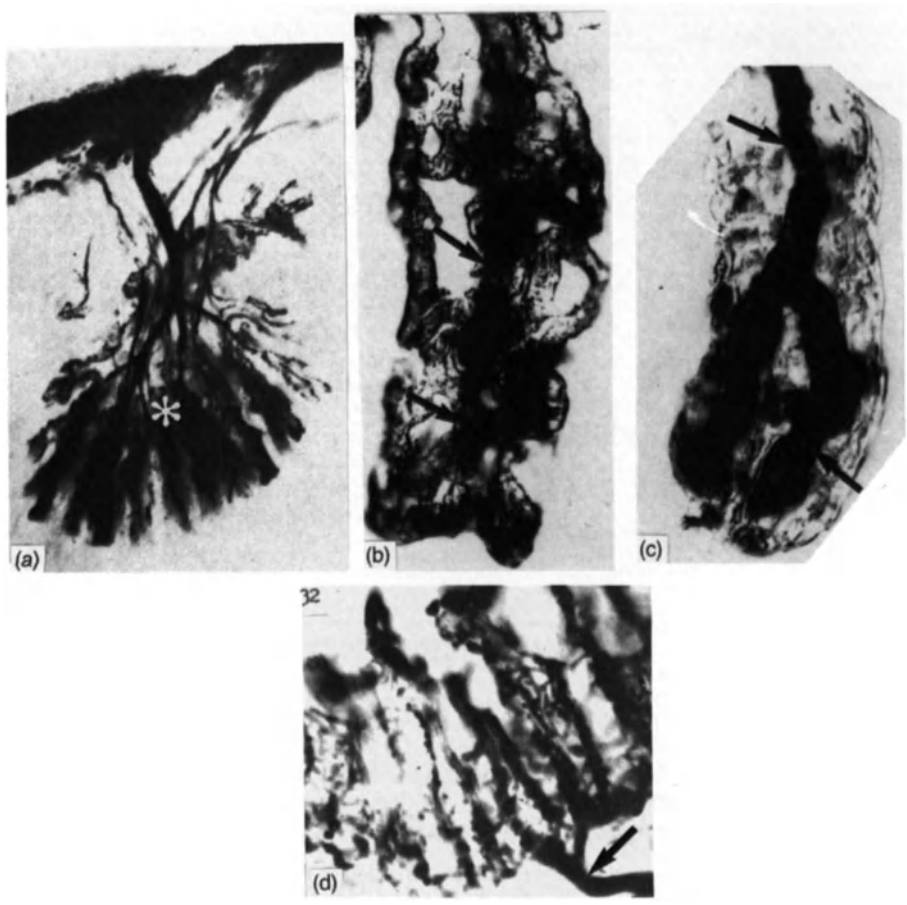

Figure 4.36 Horse epitheliochorial placenta. (a–d) Vascular injections illustrate the tuft of fetal vessels forming a microcotyledon (asterisk), and partly filled villus tips show that there is a central arteriolar supply (arrows, b and c). (d) The capillary network forming the maternal cotyledonary blood supply with a large draining venule (arrow). (a) 210 dpc, × 40. (b) 195 dpc, × 400. (c) 195 dpc, × 400. (d) 150 dpc, × 70. (All from Tsutsumi, 1962.)

The endocrine profile of the horse during pregnancy is complex (Allen, 1975, 1982) (see Figure 4.37).

A peak level of 10 ng/ml serum progesterone is initially produced at 8 dpc by the primary corpus luteum, but this secretion gradually decreases. The eCG produced by the endometrial cup cells starting at 38 dpc then stimulates ovulation and the production of the secondary corpora lutea, which increase the progesterone levels considerably (up to 14 ng/ml). As the cups and secondary corpora lutea regress (100–150 dpc) the placenta takes over production of a much reduced level of progesterone (3–4 ng/ml), presumably related to the considerable amount of smooth endoplasmic reticulum in the trophectoderm of the microcotyledons. Oestrogens are also produced, mainly oestrone and the unique equid B-ring unsaturated oestrogens equilin and equilenin (Allen, 1975; Pashen *et al.*, 1983; Haluska and

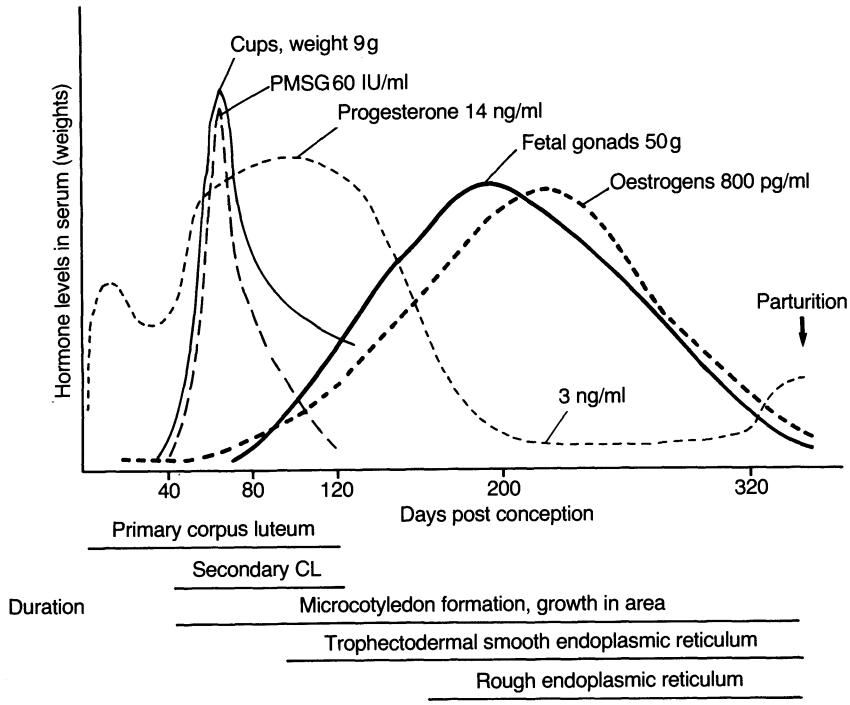

Figure 4.37 Comparison of the endocrine changes in the serum and the development of endometrial cups and fetal gonads during pregnancy in the horse. Note that the lifespan of the corpora lutea correlates with high progesterone levels; the levels necessary to support pregnancy in second half of gestation are much lower and are supplied by placental synthesis. (Data from Ginther, 1979, and Samuel *et al.*, 1974, 1976.)

Currie, 1988). Precursors for the oestrogens are produced by the hypertrophied interstitial cells in the **fetal** gonads (Figure 4.37).

The pattern of blood vessels is very different in the horse fetal villus when compared with that in the pig. There is a central arteriole which passes directly to the villus tip before dividing into a peripheral capillary network draining back down the villus to its base (Figures 4.9 and 4.36). The maternal arteries run first to the tips of the maternal villi or septa which are inserted between the bases of the fetal villi. The blood then drains down through a meshwork of peripheral capillaries to the collecting veins at the base of the maternal villus (septum) (Tsutsumi, 1962; Steven, 1982) (Figures 4.9 and 4.36).

This arrangement should allow classical countercurrent flow between fetal and maternal capillaries assuming they run alongside one another for a sufficient distance. At parturition the interdigitated microvilli of the fetal and maternal cells separate by a process probably requiring changes in adhesion at the molecular level. The short fetal villi and maternal septa (villi) then disengage, probably as a result of decrease in blood pressure and/or volume. There is rarely any problem with separation and expulsion of the membranes at partus (Steven *et al.*, 1979). Details of the decrease in systemic progesterone (Bazer and First, 1983) and increases in prostaglandin and oxytocin at this time are given in Haluska and Currie (1988).

Other epitheliochorial types *Scalopus aquaticus*, the American mole, is an insectivore with a bicornuate uterus, producing an average litter of four after 35 days of gestation. Implantation is superficial with no apparent decidual formation, the amnion forms by folding and there is a functional yolk sac until term. The definitive chorioallantoic placenta is diffuse villous and epitheliochorial with numerous areolae (Prasad *et al.*, 1979).

Scalopus is the only insectivore known with an epitheliochorial placenta, most are haemochorial with a few endotheliochorial examples (Mossman, 1987). However, they all have a similar yolk sac development, with a mesometrial bilaminar yolk sac which persists to term and a functional trilaminar choriovitelline placenta on the lateral and antimesometrial, glandular uterine walls. The vitelline capillaries are displaced by development of the allantoic circulation to produce the simple villi. The chorioallantoic villi are collected into groups similar to the microcotyledons of the equid type but they lack the connective tissue capsule (Figure 4.35b). The uterine epithelium is extremely thin (< 1 μm) in places and required EM studies to prove that it persists (Prasad *et al.*, 1979). Areolae develop over the mouths of the uterine glands separating the villus groups. At parturition, separation occurs at the fetomaternal microvillar junction.

Scalopus with its epitheliochorial placenta has obvious skeletal and developmental affinities with insectivores such as *Talpa*, the European mole (endotheliochorial placenta), and with the shrews and the European hedgehog (haemochorial placentas). This emphasizes the point that animals of very similar phyletic origins, size, habitat and reproductive behaviour can have widely differing definitive placental structures. Alternatively, it may be taken as a demonstration that the transition from epitheliochorial through endotheliochorial to haemochorial is a relatively simple developmental change.

Another very different order, Pholidota (scaly anteater or pangolin) has a similar epitheliochorial placenta to Equidae with grouped short villi between frequent areolae (Mossman, 1987).

Cetacea, the whales, porpoises and dolphins, have diffuse epitheliochorial placentas like that of the pig with short villi or folds and numerous areolae opposite the mouths of uterine glands. None of these have yet been investigated in detail with the EM (Mossman, 1987).

The strepsirhine primates, lemurs, lorises and bushbabies (galago), all have diffuse epitheliochorial placentation based on narrow slender or short fat individual villi with large bulbous areolae between (Figure 4.20d and e; compare with Figure 4.21, pig). At implantation *Galago senegalensis* is reported to produce a specialized area of giant trophoblast cells which remove the uterine epithelium and act as an anchorage point for the conceptus (Butler, 1967). This is reminiscent of the trophectodermal protrusions into the uterine epithelium produced by some of the marsupials (Enders and Enders, 1969). In both cases these giant cells are transient and do not contribute to the definitive placental development. Whether the implantation is produced by delamination intrusion or fusion is not yet clear. In the definitive placenta of the lemur *Microcebus* a discoid structure with no uterine epithelium (Grosser's syndesmochorial) has been claimed (Reng, 1977), but insufficient detail can be seen to verify this; and a giant, possibly double, cell layer has been suggested for *Galago demidovii* (Mossman, 1987). Both these structures would be very atypical and it needs EM resolution to unravel the details. A recent ultrastructural study of the definitive placenta of *Galago crassicaudata* emphasized the simplicity of the basic epitheliochorial villus pattern (B.F. King, 1984).

The Camelidae and Tragulidae (chevrotains) are reported to have large branched folds and villi forming diffuse epitheliochorial placentas (Morton, 1961). What is more

important is they are said to have some (Camelidae) (Lennep, 1961) or many (Tragulidae) (Mossman, 1987) binucleate cells in the trophectoderm. It has been suggested that these BNCs may be equivalent to ruminant BNCs, capable of migration and fusion to form fetomaternal hybrid tissue at the fetomaternal interface (section 4.2.6b). However, a recent EM study on the camelid, llama, could find no evidence for any significant numbers of BNCs with the characteristic ruminant structure (Steven *et al.*, 1980a). Any uninucleate epithelium or tissue normally produces a low level (1–3%) of cells with two nuclei, but these have identical ultrastructure to their uninucleate neighbours. The Camelidae BNCs are probably in this category (Lennep, 1961). The Tragulidae report needs further investigation, as it suggests that there are as many BNCs (15–20%) as are normally found in a ruminant but present in a diffuse noncotyledonary placenta. This might provide valuable clues as to why placentomes form.

(b) Synepitheliochorial placentation (sheep, cow)

In Grosser's syndesmochorial category (almost exclusively ruminants) the uterine epithelium was said to be lost and the trophectoderm apposed to the maternal connective tissue directly. Further work demonstrated that the uterine epithelium persisted to a variable degree but was considerably altered. It has recently been shown by a variety of techniques that ruminant fetal trophectodermal BNCs invade the uterine epithelium and fuse to form fetomaternal hybrid syncytial plaques at the junction of the fetal and maternal tissue (Wooding, 1982a,b, 1984) (Figures 4.38 and 4.39).

This is so different from the epitheliochorial category that it amply justifies a separate grouping.

'Syndesmochorial' is of obscure derivation and we propose synepitheliochorial as a much more descriptive and easily understood category (section 4.2.3c). All ruminant placentas so far investigated have BNCs which produce the fetomaternal hybrid syncytium with uterine epithelial cells but the degree to which the maternal epithelium is significantly altered does vary. The 'syn-' indicates the contribution of the BNC-derived syncytium and the retention of 'epitheliochorial' emphasizes that large areas of simple fetomaternal apposition are present in the definitive placenta (Wooding, 1992).

The synepitheliochorial placenta has three identifying characteristics: the BNC in the fetal trophectoderm (section 4.2.7b) which form a structurally separate population among the uninucleate trophectodermal cells from which they are derived; the fetomaternal syncytium formed by BNC fetal migration and fusion with some or all of the maternal uterine epithelial cells; and the cotyledonary chorioallantoic placental organization, with the restriction of fetal and maternal villus elaboration to discrete regions (placentomes) based on pre-existing non-glandular caruncular areas on the uterine epithelium (Amoroso, 1952) which are well developed in the fetal lamb uterus by mid-pregnancy (Wiley *et al.*, 1987). A placentome is formed by enmeshed fetal villi and maternal crypts; the tuft of fetal villi is correctly referred to as a cotyledon and the corresponding maternal structure is a caruncle (Figures 4.40 and 4.41).

However, cotyledon is also frequently used for the whole structure, so that a 'maternal cotyledon' corresponds to a caruncle. Ruminant placentas may be oligocotyledonary with 3–8 large placentomes, as in deer, or polycotyledonary with numerous (20–150) but smaller placentomes as in cows, goats and sheep (Figure 4.4). Since there are a finite number of caruncles per uterus, although a singleton conceptus may not utilize all the sites it will have more placentomes than twins, which can only have about half the total number each. However, the twins will have larger individual placentomes and their

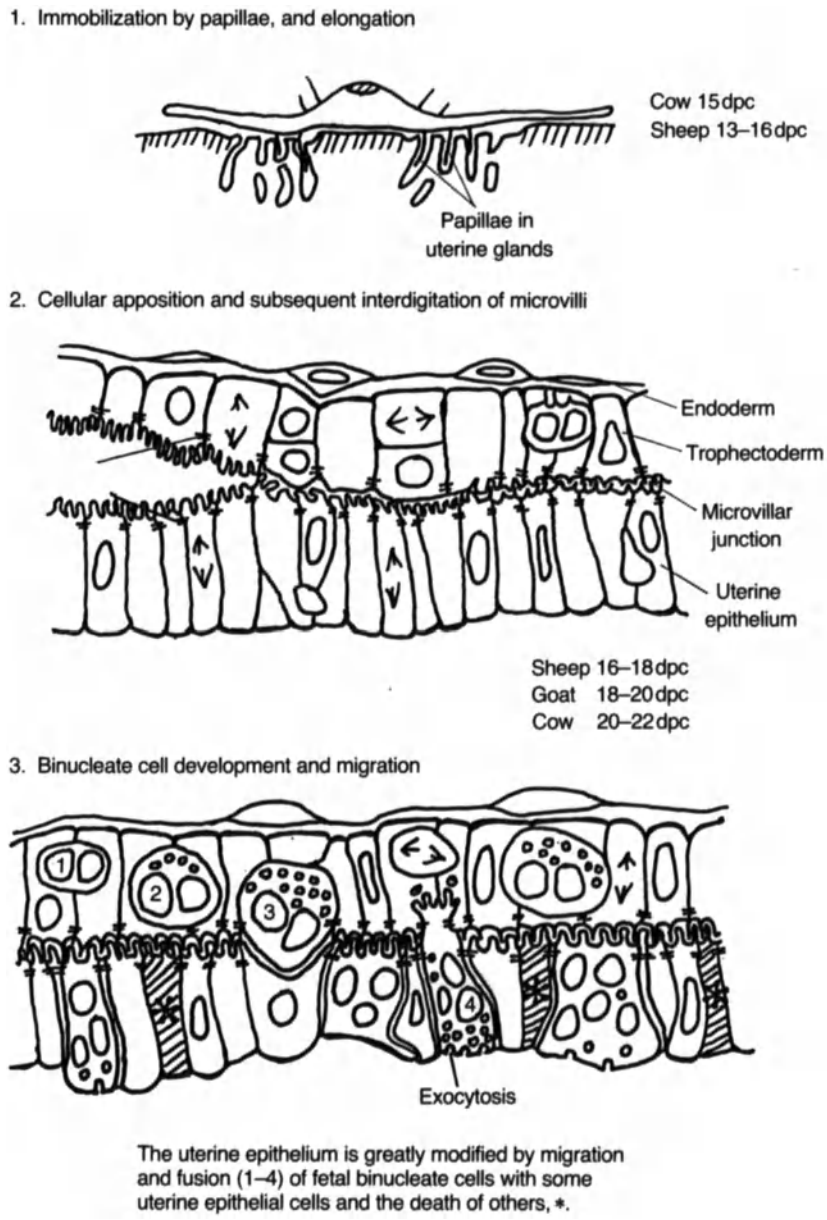

Figure 4.38 The cellular changes at implantation in the ruminants.

combined mass will be greater than that of the singleton. There is a close correlation between conceptus placentomal mass and birthweight of the fetus (A.W. Bell, 1984, 1991), and recent studies indicate a pivotal role for IGF-1 and -2 in placental growth (Bassett, 1991; Geisert *et al.*, 1991; Owens, 1991). Placentomes also differ in gross structure, being concave to the fetal side in sheep and goats, but convex in the cow and flat in antelopes (Amoroso, 1952). The differences are probably without functional significance

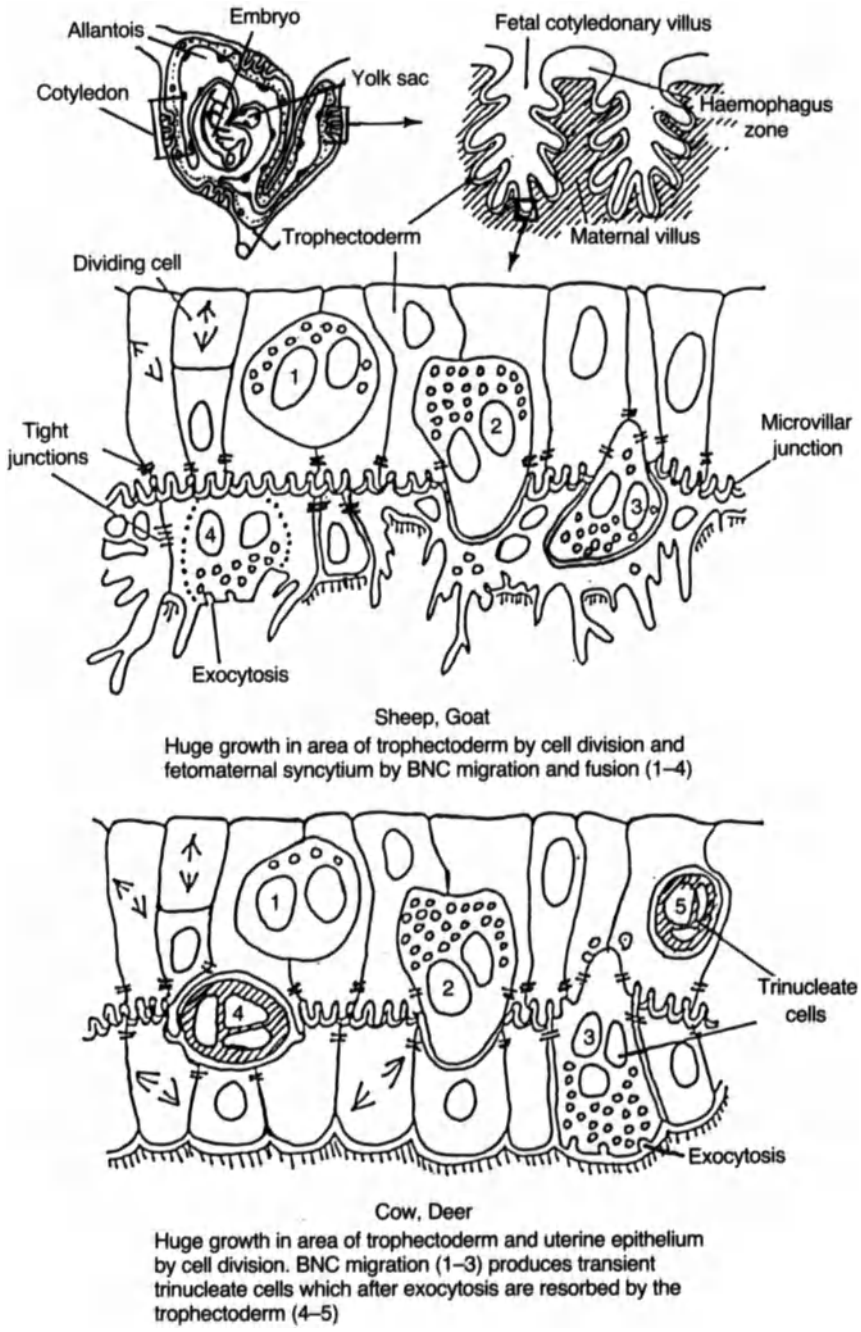

Figure 4.39 The binucleate cell contribution to the definitive ruminant placenta.

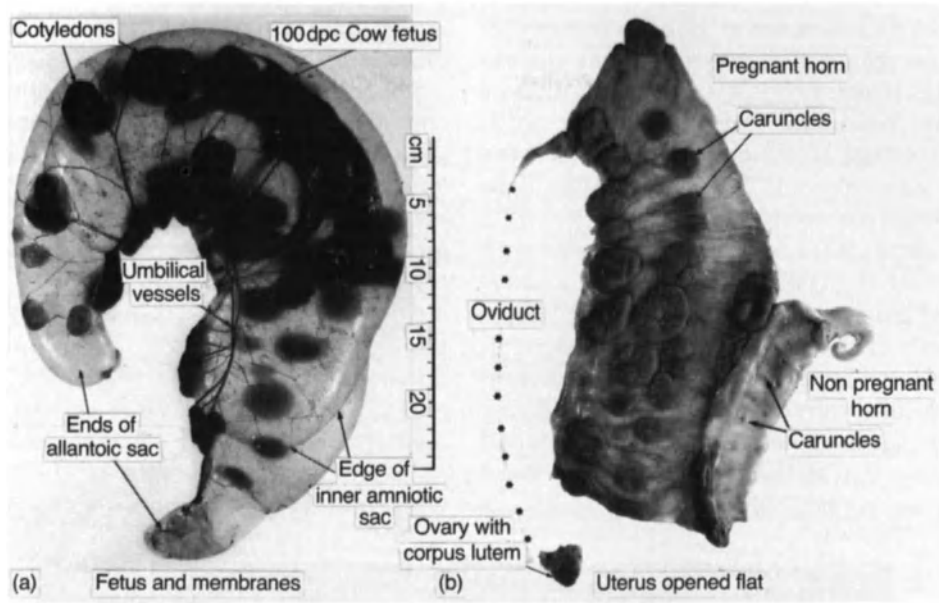

Figure 4.40 Synepitheliochorial placentation. (a) Cow fetus within intact extraembryonic membrane sac(s). Unusually this conceptus was contained within one horn only of the uterus (b), which has been opened out flat. Note the increase in size of the caruncles in the pregnant horn which *in vivo* were enmeshed with the fetal cotyledons. (a and b) 90 dpc, × 0.25.

since if the sheep (normally concave) has some of its caruncles removed surgically from the non-pregnant uterus then the usually adequate resulting placenta has fewer, larger, but now convex, cotyledons (Harding *et al.*, 1985). Hradecky *et al.* (1988) found no consistent correlation between the number or size of cotyledons with the length or degree of branching of the villi in a wide variety of ruminant placentomes.

A logical sequence of villus development can be assembled starting with a completely diffuse epitheliochorial placenta with short stumpy individual villi as in the pig. The microcotyledonary epitheliochorial placenta of the horse is slightly more complex and has small tufts of longer more slender villi. Trophectodermal binucleate cells make a fleeting appearance in the girdle but never assume any permanent structural role in the definitive equid placenta. The sheep polycotyledonary synepitheliochorial placenta has much longer villi more clearly aggregated into discrete placentomes, with characteristic BNCs which play a central role in the formation of the mature villus. The cow has fewer, larger placentomes with more complexly branched villi (Figures 4.40 and 4.41) but the BNCs form only transient fetomaternal minisyncytia. The deer has the most extreme villus aggregation, into 3–8 very large placentomes with villus structure and minisyncytium formation from BNCs very similar to the cow. It is not suggested that this is an evolutionary sequence but it does indicate possible variations of the basic epitheliochorial placenta which exploit the system of villus amplification of the fetomaternal exchange area. Fetomaternal hybrid syncytium formation based on BNCs seems to be central to this villus expansion.

The advantage of concentrating the villi into ever larger placentomes is not obvious but it does result in a considerable increase in the fetomaternal exchange area per gram of delivered fetus. Compact cotyledondary pla-

centas have 5–10 times as much fetomaternal exchange area per gram of fetus as diffuse placentas (Baur, 1977). It is, however, unclear why the ruminant should need so much more exchange area than the horse or if there are any advantages in a few large rather than many small placentomes.

The fetal trophectoderm has microvilli closely interdigitated with those of the uterine epithelium or derived syncytium, forming the characteristic microvillar junction. In the cotyledon local separation at this junction plus a local intermittent vascular leak forms haemophagous zones, large in sheep, small in the cow, in which stagnant maternal blood is apposed to tall columnar trophectoderm which actively phagocytose the red blood cells (Burton, 1982).

There are two major types of synepitheliochorial placenta: the sheep and goat type, with more than 90% of the original caruncular uterine epithelium modified to fetomaternal syncytial plaques; and the cow and deer type, with a similar proportion of (reformed) cellular uterine epithelium but with continuous formation of transient trinucleate minisyncytia (Figure 4.39). In the intercotyledonary areas, after the first third of pregnancy, both types have a cellular uterine epithelium containing characteristic intraepithelial lymphocytes (Lee *et al.*, 1992) but with only occasional minisyncytia produced

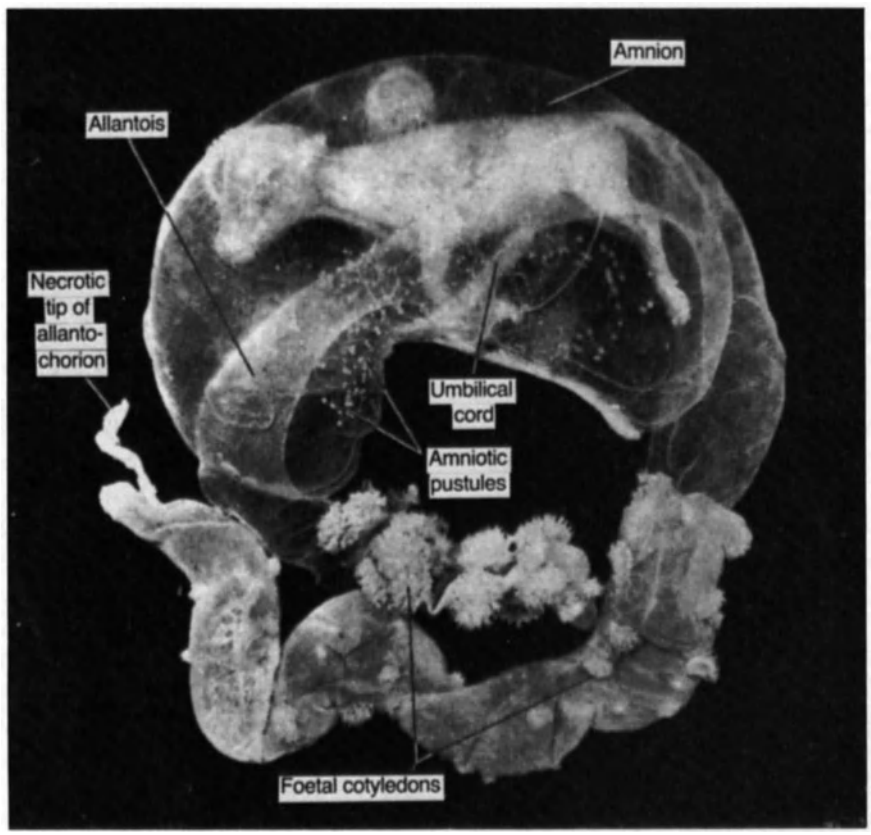

Figure 4.41 Synepitheliochorial placentation. A similar cow conceptus to that in Figure 4.40 but the chorion has been dissected away over the central region to reveal the amnion and the allantois. The villi on the fetal cotyledons on the non-dissected part are well demonstrated; they are clumped into apparently solid masses in Figure 4.40a. 100 dpc, × 0.66.

by BNC migration and fusion (King and Atkinson, 1987). There are small areolae over the mouths of the glands. The percentage of fetomaternal exchange surface contributed by the intercotyledonary area decreases rapidly until at term it is less than 2% of the total in the cow (Baur, 1972).

Development of the sheep and cow placenta will be described as the basic ruminant types.

Sheep, Ovis aries; *cow*, Bos taurus

Oestrous cycle: 16 days, sheep; 21 days, cow
Ovulation: spontaneous
Litter: 1–4
Gestation: about 150 days, sheep, goat; about 280 days, cow, depending on breed
Implantation: superficial; chorionic papillae into glands to immobilize conceptus in sheep and cattle
Amniogenesis: folding
Yolk sac: vascularized by 16 dpc (sheep), 20 dpc (cow) reduced to insignificance by 30 dpc by growth of the allantoic sac.
Chorioallantois: Forms definitive placenta, allantoic sac never surrounds the amnion as in the horse but the allantoic mesodermal vessels vascularize the entire chorion (Figures 4.40 and 4.41).
Shape: Cotyledonary with complex villous structure. The cotyledon number varies from 3 to 150 depending on species.
No decidual reaction
Interhaemal membrane: synepitheliochorial; migratory trophectodermal binucleate cells form fetomaternal hybrid tissue from implantation to term
Accessory placental structures: areolae in intercotyledonary areas; haemophagous zones at bases of fetal cotyledonary villi, larger in sheep than cattle

Most ruminant families share the characteristics above.

Cervidae: deer, moose
Giraffidae
Antilocapridae: pronghorns
Bovidae: cattle, sheep, goats, antelopes, buffalo, bison, gnu

However, the Tragulidae, chevrotains from Java, are reported to have a non-cotyledonary placenta with villi diffusely distributed on the mesometrial side only. BNCs are said to be present in the trophectoderm and the uterine epithelium is probably cellular (Mossman, 1987).

Ruminant fetal membranes The ruminant morula enters the uterus about 4–5 dpc, transforms to a blastocyst, and loses its zona pellucida as it expands two or three times (Rowson and Moor, 1966). One genus (roe deer, Aitken, 1974) arrests the development of the blastocyst (diapause) at this stage prior to implantation. The physiological mechanism is not understood. Bazer and First (1983) provide an excellent summary of the details of uterine secretions, the maternal hormonal levels and structural changes from oocyte to blastocyst in ruminants. Subsequent hormonal changes are detailed in Heap *et al.* (1983).

In the sheep and cow the spherical conceptus comes to rest in a predictable region in the uterus (S.Y. Lee *et al.*, 1977), presumably as a result of myometrial contractions, and immobilizes itself by extending trophectodermal papillae, cellular protrusions, down the glands (Figure 4.38) (Wooding and Staples, 1981; Guillomot and Guay, 1982; Wooding *et al.*, 1982). The conceptus then expands and elongates to fill the uterine lumen (Wintenberger-Torres and Flechon, 1974; Wales and Cuneo, 1989). In the sheep or cow and many other ruminants, if there are two conceptuses each implants about one-third of the length of the uterus up from the cervix, one in each horn of the bicornuate uterus (S.Y. Lee *et al.*, 1977). Single conceptuses implant in a similar position, not always on the side they first enter the uterus, and may eventually expand into both horns. The location of the implantation sites are characterized by local oedema which can be monitored

with i.v. injections of pontamine blue (Boshier, 1970), although no obvious changes can be demonstrated on the two surfaces prior to attachment (Guillomot *et al.*, 1982).

As the blastocyst elongates *in vivo* or *in vitro* it produces considerable amounts of specific proteins (including an interferon from the trophectoderm) which are thought to have important roles both in maintenance of the corpus luteum and immunological defence of the blastocyst (Hansen *et al.*, 1985; Bazer *et al.*, 1986; Fincher *et al.*, 1986; Knickerbocker *et al.*, 1986; Helmer *et al.*, 1987; Sasser and Ruder, 1987; Salamonsen *et al.*, 1988; Bazer *et al.*, 1989; Farin *et al.*, 1989; Ing and Roberts, 1989; Lifsey *et al.*, 1989; Roberts, 1989, 1992; Nephew *et al.*, 1990; Farin *et al.*, 1990; Guillomot *et al.*, 1990; Roberts *et al.*, 1990). In the absence of such trophectodermal proteins, luteolysis is induced by prostaglandins transferred from the uterus by lymphatic and venous countercurrent exchange to the ovarian artery (Heap *et al.*, 1985). Tissue culture studies have recently demonstrated that uterine epithelial cells can be grown (Munson *et al.*, 1990) which can secrete more prostaglandin to the mucosal than the luminal compartment (Cherny and Findlay, 1990).

The yolk sac is fully vascularized by 16 dpc in the sheep but has only a transient existence and is soon displaced by the rapidly elongating allantoic sac. This forms a tubular structure along the full mesometrial aspect of the conceptus by 25 dpc having started as a tiny diverticulum from the hind gut at 16 dpc (Figures 4.1, 4.38, 4.39, 4.40 and 4.41). The allantoic vascularization rapidly spreads over the entire chorion including the extensive amniochorion (Bryden *et al.*, 1972).

Implantation can be defined in ruminants by the start of the BNC migration and fusion with the uterine epithelial cells (16 dpc sheep, 19 dpc goat, 20 dpc cow) (Figures 4.38, 4.42 and 4.43).

No overt endometrial cellular alterations have been reported in any ruminant, and no decidual reaction results from the changes in uterine epithelium from cellular to syncytial (Boshier, 1969; Guillomot *et al.*, 1981; C.E. Smith *et al.*, 1990). However, the uterus grows and the blood flow through the uterine vasculature increases considerably between 11 and 30 dpc (Reynolds and Redmer, 1992). Although the sheep/goat and cow/deer types have significantly different definitive synepitheliochorial placental structure, at implantation BNC migration and fusion produces the same conversion of the caruncular epithelium from cellular to fetomaternal syncytial plaques (Wathes and Wooding, 1980; Wooding, 1984; Wango *et al.*, 1990a,b). At the earliest stage of BNC migration in the sheep, evidence from serial section counting of the number of nuclei within each cellular boundary in the uterine epithelium indicates that possible fusions are restricted. A BNC can fuse with the apex of a single uterine epithelial cell to form a trinucleate cell (TNC) and further BNCs can fuse apically to extend this minisyncytium to five or seven nuclei or beyond. No evidence was found for any minisyncytia with two or four nuclei (Wooding, 1984; Wango *et al.*, 1990a,b). Thus, the syncytia in the uterine epithelium do not result from random lateral fusion of uterine epithelial cells which would produce a continuous range of nuclear numbers per minisyncytium. There is no technical problem in recognizing cells with two nuclei since the same studies clearly confirmed that the trophectoderm consisted of uninucleate cells and BNCs (Wooding, 1984; Wango *et al.*, 1990a,b).

By 20 dpc (sheep) 22 dpc (goat) and 24 dpc (cow) continued BNC migration and fusion coupled with cell death produce syncytial plaques which cover the flat caruncular surface (Leiser, 1975; G.J. King *et al.*, 1979; Wathes and Wooding, 1980; Wooding, 1984; Wango *et al.*, 1990a,b). The maximum number of nuclei per plaque in sheep was estimated to be 24, and the plaques are bounded by tight junctions significantly different from

those sealing the uterine epithelial cells (Morgan and Wooding, 1983). The occasional uterine epithelial cell persists also. There are more frequent uninucleate cells remaining in sheep intercaruncular areas but here too, at this early stage, in the sheep and cow syncytial plaques replace the uterine epithelium to a considerable extent (G.J. King *et al.*, 1981; G.J. King and Atkinson, 1987). The intercaruncular uterine epithelium is re-established after 2–3 weeks by rapid division of residual epithelial cells, mostly from gland orifices.

Villus development in the caruncular areas starts at 24 dpc (sheep, goat) and 28–30 dpc (cow) (G.J. King *et al.*, 1979). Clusters of BNCs in the trophectodermal epithelium seem to initiate the process. There is no evidence for any invasion of the caruncular endometrium by the fetomaternal syncytial layer; there seems rather to be a mutual growth of both fetal and maternal tissue. Autoradiographic studies with [^{3}H]thymidine later in pregnancy have produced no evidence of tip growth of villi (Wooding *et al.*, 1981), but in the first half of gestation BNCs are undoubtedly concentrated at the tips of the fetal villi (C.S. Lee *et al.*, 1985, 1986a,b). In the sheep the start of villus formation corresponds to the first synthesis of at least one new protein by the BNCs (C.S. Lee *et al.*, 1985; Morgan *et al.*, 1987). A plausible scenario for villus growth would be the production of an extensive tip syncytium by a high level of BNC migration and fusion. This syncytium is extended into the oedematous endometrial stroma by rapid growth and division of the uninucleate trophectodermal cell layer plus tissue pressure and development of an extensive vasculature in the fetal villus core. These processes would be like inflating a rubber glove into a swelling mound of jelly. Alteration of the endometrium to accommodate this villus growth could well be controlled by a BNC product secreted via the syncytium (C.S. Lee *et al.*, 1985, 1986b; Morgan *et al.*, 1987). The maternal endometrial cells, mainly fibroblasts, are gradually reduced in number as villus development proceeds. The larger maternal blood vessels are eventually surrounded by concentric layers of basement membrane-like material plus fragments, possibly of degenerate maternal endometrial cells or possibly of long slender elongations from the fetal syncytium which extend toward the maternal vasculature (Steven, 1975a,b).

In the sheep and goat, occasionally, between fetal syncytium and maternal vasculature there are large individual cells, probably residual endometrial fibroblasts or pericytes. They have a very uniform structure with a cytoplasm filled with much glycogen, tracts of fibrils and a large deeply divided nucleus (Figure 4.69). They are equipped as if capable of considerable synthesis and secretion having numerous dilated cisterna of rough endoplasmic reticulum, and a sizeable Golgi body with a complement of small dense vesicles. They are present throughout pregnancy. In position and structure they closely resemble a cell type in the endotheliochorial placenta (Figures 4.68 and 4.69).

In the sheep when the villi reach their maximum length at 70–90 dpc there is a considerable volume of fetal connective tissue core (Lawn *et al.*, 1969; Steven, 1983). Subsequently, the surface area of the villi (the fetomaternal hemotrophic exchange surface) grows by ever-increasing subdivision of the initial villi until at term there is very little connective tissue in either fetal or maternal villi. These now consist largely of the two blood vessel systems (Figure 4.44) (see Leiser, 1987) with very little separation because of indentation by the fetal vessels of the trophectodermal epithelium and attenuation of both that and the apposing syncytial plaques.

This is best appreciated on tissue fixed by perfusion via both maternal and fetal arteries (Figure 4.44). Corrosion cast studies of the goat villus vasculature suggest a gross countercurrent flow (Figures 4.45 to 4.48; section 4.2.5c) in the cotyledons.

U
3
4

The approximate 250-μm-long capillary meshworks in the terminal villi (Tsutsumi, 1962) may have a cross-current or a mixed cross and countercurrent microflow (see Figures 4.8, 4.9 and 4.48). The villus vasculature in the cow is more complex than in the goat (Figure 4.49) but the gross and microflow systems are probably very similar.

The increase in the area of the syncytium must be generated solely by BNC migration for no nuclear division has been observed in the syncytium. Quantitative investigations (Wooding, 1983) indicate that BNC migration is maintained at the same high level from implantation to term in all ruminants examined so far, and this is corroborated by the autoradiographic evidence in sheep (Wooding *et al.*, 1981, 1993). These results agree well with Baur's morphometric investigations which show a continuous increase in fetomaternal exchange area virtually to term in the cow and in each of the wide variety of other genera he examined (Baur, 1977). However, there are two reports claiming that the cotyledonary villous surface area in the sheep shows little increase in area in the second half of pregnancy (Stegemann, 1974; Teasdale, 1976). The autoradiographic evidence (Wooding *et al.*, 1981, 1993) indicates that the sheep probably does follow the general pattern of continuous area increase with fetal weight but more work is needed to establish this.

The cow and deer synepitheliochorial placental type forms villi in a similar way but the syncytial plaques formed at implantation are overgrown by rapid division of the residual uterine epithelium (G.J. King *et al.*, 1979). There is still a concentration of BNCs at the forming/advancing tips of the villi (C.S. Lee *et al.*, 1986a) but they form only transient trinucleate cells (TNCs or 'minisyncytia') with the uterine epithelium (Figures 4.60 and 4.61) (Wooding and Wathes, 1980); there is no production of the extensive areas of syncytial plaques seen in the sheep (Wooding, 1984). Plainly the syncytial transformation is not essential for villus growth. Rapid cell division in the uterine epithelium plus the contribution from BNC migration and TNC formation is sufficient to keep pace with the trophectodermal expansion in the cow. This produces an interhaemal membrane which is cellular on both sides as in a pig or horse placenta (Figure 4.39). In deer placentas there have been several reports of more extensive minisyncytia than trinucleate cells in the uterine epithelium, usually toward the tips of the maternal villi (W.J. Hamilton *et al.*, 1960; Kellas, 1966; Sinha *et al.*, 1969) but EM is necessary to investigate the detail of this BNC behaviour. Our limited (unpublished) observations on five deer genera (Chinese water, fallow, muntjac, red and roe) indicate that TNC formation is the standard outcome of BNC migration.

Parturition in the sheep is heralded by a fall in progesterone levels. This is induced by cortisol production and secretion by the fetal adrenal, and this and other hormonal changes (Bazer and First, 1983; Thorburn, 1991) possibly including relaxin are probably instrumental in causing a rapid but specific degeneration of the uninucleate trophectodermal layer (which the BNCs survive) (Perry *et al.*, 1975; Steven, 1975b). There is also an increase in the strength and synchrony of the

myometrial cell contractions due to their considerable hormone-dependent development of gap junctions at this time (Garfield *et al.*, 1979, 1988; Cole and Garfield, 1989) and the cervix softens as a result of increased prostaglandin synthesis (Ledger *et al.*, 1983; Magness *et al.*, 1990). Together with the sudden drop at birth in the fetal placental blood pressure these processes are probably sufficient to produce an efficient means of placental separation within 1–4 h in the sheep and goat. The fetomaternal syncytium remains *in situ* on the maternal villi. As soon as the placenta separates there is a massive infiltration of the maternal caruncular residues by polymorphs and macrophages, which produce a rapid degeneration of the tissue, and the whole mass is sloughed at a level just above the myometrium (Van Wyk *et al.*, 1972). The uterine epithelium is regenerated by cellular overgrowth from the glands at the edges of the caruncular areas (Wagner and Hansel, 1969). In the cow the progesterone level falls and cortisol rises in a similar manner at parturition and relaxin may also be involved (Musah *et al.*, 1987) as well as oxytocin (Fuchs *et al.*, 1992), but there is no degeneration of the trophectodermal layer as in the sheep. Release of the placenta depends upon changes in the molecular forces maintaining the microvillar interdigitation, as in the pig or horse placenta. However, the villi are very much longer than those of the pig or horse and this may be the cause of the significant percentage of cow placentas that do not separate easily (Grunert, 1986). BNCs may also have a role at partus (Gross *et al.*, 1991). A 'retained placenta' is one which has not been delivered 12 h after birth.

Methods for isolating pure populations of BNCs have recently been reported in several laboratories. Such BNCs are as versatile in their synthetic capabilities as they are unique in their developmental and behavioural characteristics. BNCs in short-term primary culture have been reported to produce prostaglandins, progesterone (Hamon *et al.*, 1985; Reimers *et al.*, 1985; Ullman and Reimers, 1989; Wango *et al.*, 1991) and placental lactogens (Rhodes *et al.*, 1986; Morgan *et al.*, 1990). However, all isolated BNC populations contain the complete developmental sequence of BNCs, in our experience usually biased towards the young BNCs with few or no granules. This is quite unlike other isolated exocrine cells such as mammotrophs or somatotrophs from pituitary, which consist almost entirely of mature fully granulated cells. The activities of the isolated BNC population could therefore be characteristic of only one developmental stage, and it is difficult to assess their physiological significance without figures for synthesis of these hormones by the other cell types in the placenta (Shemesh, 1990; Ben David and Shemesh, 1990) which are not yet available. BNCs can be isolated because only they are robust enough to survive the procedure; other, gentler methods will be necessary to separate viable populations of the more fragile uninucleate trophectodermal cells or the syncytial plaques.

In our experience, BNCs will survive in viable condition in primary culture for up to 4 days before rapid deterioration and cell lysis. Only occasional cells adhere to the tissue culture flask. No one has reported nuclear division in BNCs and since they are cells at

Figure 4.43 Synepitheliochorial placentation. Implantation (20 dpc) in the cow. Glutaraldehyde, and osmium fixation. Binucleate cells (1 and 2) with characteristic granules (arrowheads) are migrating up to the microvillar junction (open arrows) between trophectoderm (T) and uterine epithelium (U). The uterine epithelium includes a trinucleate cell (3) with granules (arrowheads) and two round nuclei very similar to those in the binucleate cell. This trinucleate is probably a fetomaternal hybrid cell produced by fetal binucleate cell fusion with a uterine epithelial cell (see Figure 4.29 and Wathes and Wooding, 1980). 20 dpc, × 2800.

the end of a developmental process and contain two nuclei they may be terminally differentiated and so incapable of division. Most studies of isolated BNC have demonstrated **release**, not synthesis, of progesterone prostaglandins or placental lactogen, usually at a declining rate (Reimers *et al.*, 1985; Rhodes *et al.*, 1986; Ullman and Reimers, 1989). Progressive death of the cells and passive release of material seems to be as likely an explanation as normal secretion. This is especially true for placental lactogen since normal BNC development includes migration and fetomaternal fusion prior to release of secretory granules by exocytosis. No one has succeeded in reproducing this behaviour in cultures as yet, but recent work has shown that isolated BNCs can synthesize progesterone from pregnenolone (Wango *et al.*, 1991) and placental lactogen from amino acids (Morgan *et al.*, 1990). Certainly the BNC population has considerable synthetic potential, but how far this contributes to the fetomaternal balance remains to be determined.

Structure and function of placental binucleate cells

Binucleate cells, formed by the absence of cytokinesis after a normal nuclear division, are found occasionally in the placentas of a wide variety of genera. There are two basic types of binucleate cell. The first forms discrete populations, with two 2N nuclei in a cytoplasm of characteristic ultrastructure as in ruminant BNCs (Wooding, 1982b) or equid endometrial cup cells (Allen, 1982). The second is sporadically distributed as part of a continuous spectrum of cells with unusual nuclear forms in a cytoplasm indistinguishable from other cells of the range as in rodent giant trophoblast cells (Pijnenborg *et al.*, 1981). Here the binucleate cell form has been suggested to be either in transition to a single large polyploid nucleus or merely evidence of tardy cytoplasmic division (Brodsky and Uryvaeva, 1977; Ilgren, 1983). One of the characteristic properties of the binucleate cell seems to be a capacity for migration from its site of formation. In ruminants it can pass through tight junctions, in the horse through the uterine epithelium and in hamsters and some other rodents it can invade the uterine arteries as deeply as the myometrial layer.

BNCs are most consistently found and in the greatest number throughout pregnancy, in the trophectoderm of all the ruminants so far studied (Wimsatt, 1951; Wooding, 1982b, 1983). They first appear in the trophectoderm of the blastocyst during the third week of pregnancy (day 15, sheep, Boshier, 1969; Wooding, 1984; day 17, cow, Greenstein *et al.*, 1958; day 18, goat, Wango *et al.*, 1990b). They are found in the fetal trophectoderm apposed to the uterine epithelium at the earliest stages of implantation (day 16, sheep; day 18, goat; day 20, cow), and constitute approximately one-fifth of the total trophectodermal cells for almost the whole of the remainder of pregnancy. There is a decrease in the last week of pregnancy in the sheep and goat (Table 4.3).

These generalizations apply to both singleton and multiple pregnancies (Wooding, 1983).

There is no evidence for any specialized stem cell; binucleate cells can originate by division of any uninucleate cell in the trophectodermal epithelium. The division produces two cells, one of which has no apical tight junction. The nucleus of this cell divides again without subsequent cytokinesis, thereby forming a binucleate cell. This binucleate cell rapidly releases any contact with the basement membrane. It therefore starts and usually completes its maturation process with only rare tiny desmosomal-like contacts with the uninucleate cells of the epithelium; no tight or gap junctions have been observed (Lawn *et al.*, 1969; Boshier and Holloway, 1977). There is one published method for growing this epithelium with included BNCs

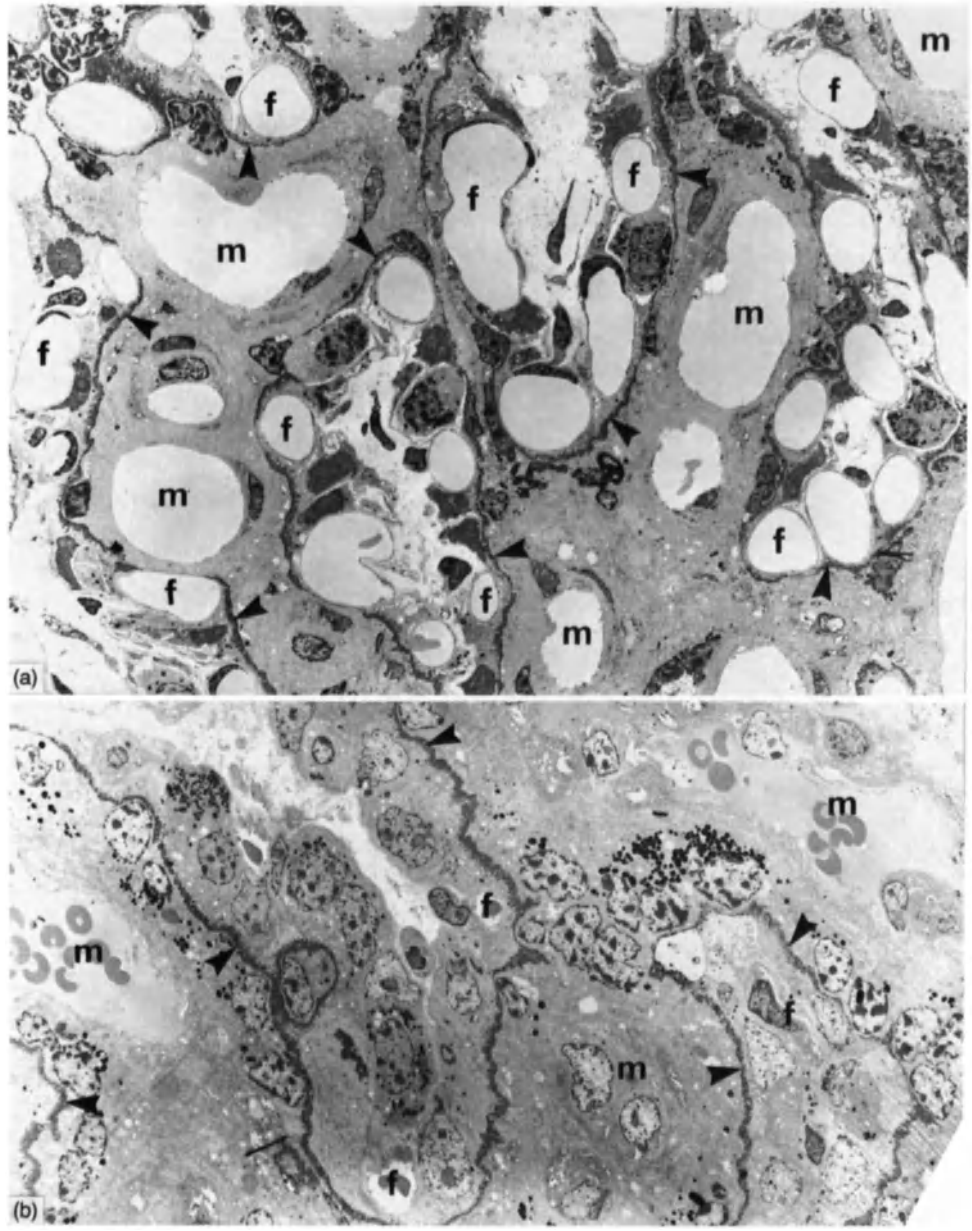

Figure 4.44 Synepitheliochorial sheep placenta. Vascular relationships. Electron micrographs of sections of cotyledons at a similar gestational age (a) perfused with fixative through both maternal and fetal blood vessels (b) fixed by dicing up fresh cotyledon in the same fixative used in (a). Only by the use of double perfusion can an accurate idea be obtained of the relative sizes and dispositions of the blood vessels *in vivo*. The result emphasizes the concept that the placenta should be considered primarily as a close apposition of blood circulations, not a mass of tissue through which blood circulates. Phosphotungstic acid staining on non-osmicated araldite embedded tissue. Arrowheads, microvillar junction (which is **not** the fetomaternal junction, the arrowheads are all on top of the fetomaternal hybrid syncytial layer see section 4.3.6b); f, fetal capillaries; m, maternal capillaries. (a) 130 dpc, × 1300. (b) 128 dpc, × 1300.

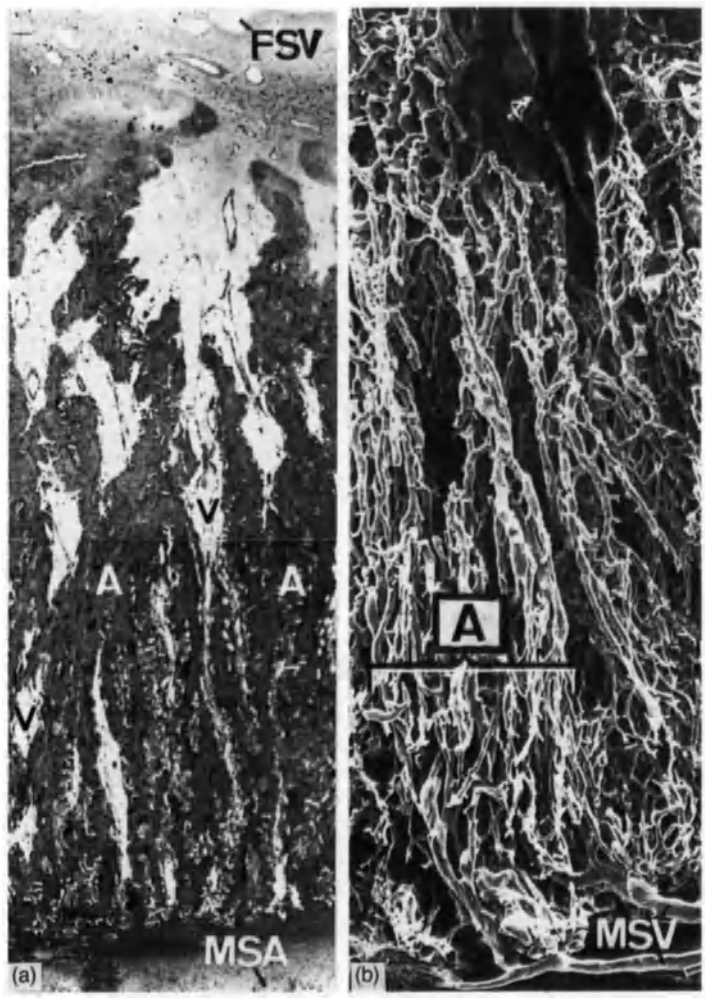

Figure 4.45 Synepitheliochorial placentation. Vascular relationships in the goat cotyledon. (b) Scanning electron micrograph of a vascular corrosion cast showing the maternal capillary meshwork. This links the maternal stem artery MSA (not present on this preparation but which delivers oxygenated blood to the region corresponding to the top of the micrograph) to the maternal stem veins (MSV) at the bottom, which return the blood to the uterine vein. In (b) the maternal network corresponding to the region A in the section is similarly marked. FSV, fetal stem vein. 120 dpc, × 50. (From Leiser, 1987.)

in tissue culture (Steven *et al.*, 1980b). However, we and others have been unable to repeat this work, and although there are more recent methods of growing uninucleate, polarized, trophectodermal epithelium (Ralph *et al.*, 1989; C.S. Lee *et al.*, 1990) no BNCs could be identified in these cultures.

The young binucleate cell has a few mitochondria in a dense, ribosome-filled cytoplasm with no glycogen (Figure 4.50).

It rapidly develops an extensive system of swollen rough endoplasmic reticulum cisternae and a very large Golgi apparatus. The Golgi produces large numbers of dense gran-

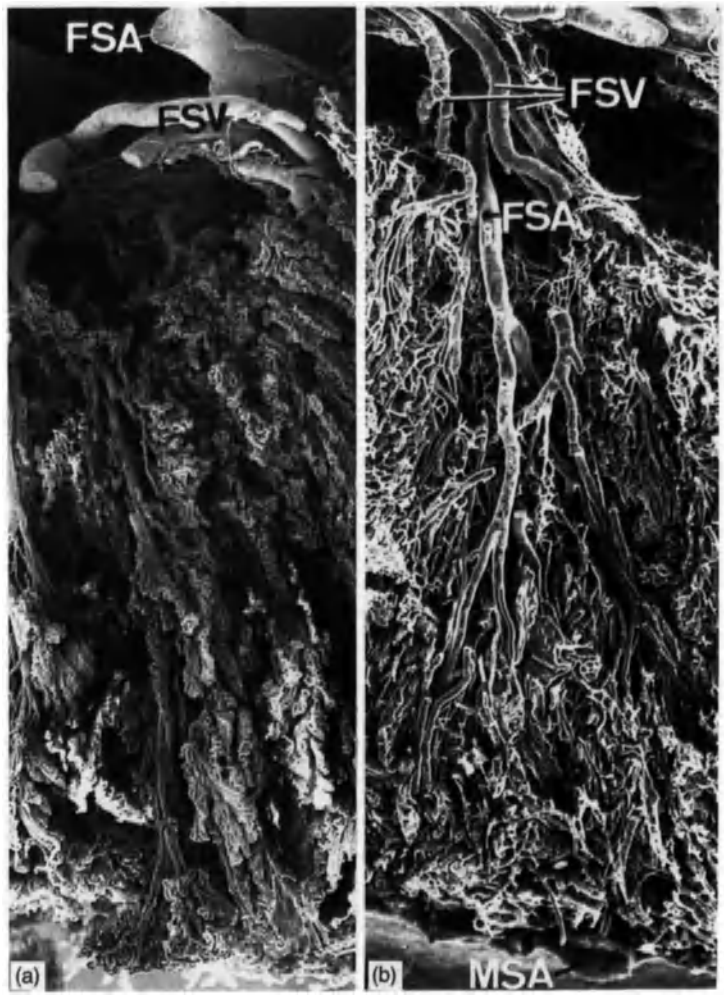

Figure 4.46 Synepitheliochorial placentation. Scanning electron micrographs of corrosion casts of (a) the fetal vasculature and (b) both fetal and maternal blood vessels. The detailed architecture of the blood vessels is well demonstrated, with the fetal capillaries much finer than the maternal. The penetration of the fetal stem arteries (FSA) direct to the tips of the villi is clear in (b). FSA, MSA, fetal or maternal stem arteries; FSV, fetal stem veins. (a and b) 120 dpc, × 35. (From Leiser, 1987.)

ules and the cell grows very large (Figure 4.51).

In the first third of pregnancy in sheep and goat a fully granulated 'mature' binucleate cell frequently also contains a large lipid droplet and/or a membrane-bound crystalline inclusion which are typical of the surrounding uninucleate cells, emphasizing the derivation of one from the other. All the binucleate cells in the trophectoderm can be arranged in a single developmental sequence (Wooding, 1982a,b, 1983, 1984); there is no clear structural evidence for two populations as suggested by Boshier and Holloway (1977).

BNCs from all species so far examined contain a unique structural element, the double lamellar body (DLB). This is a discrete small

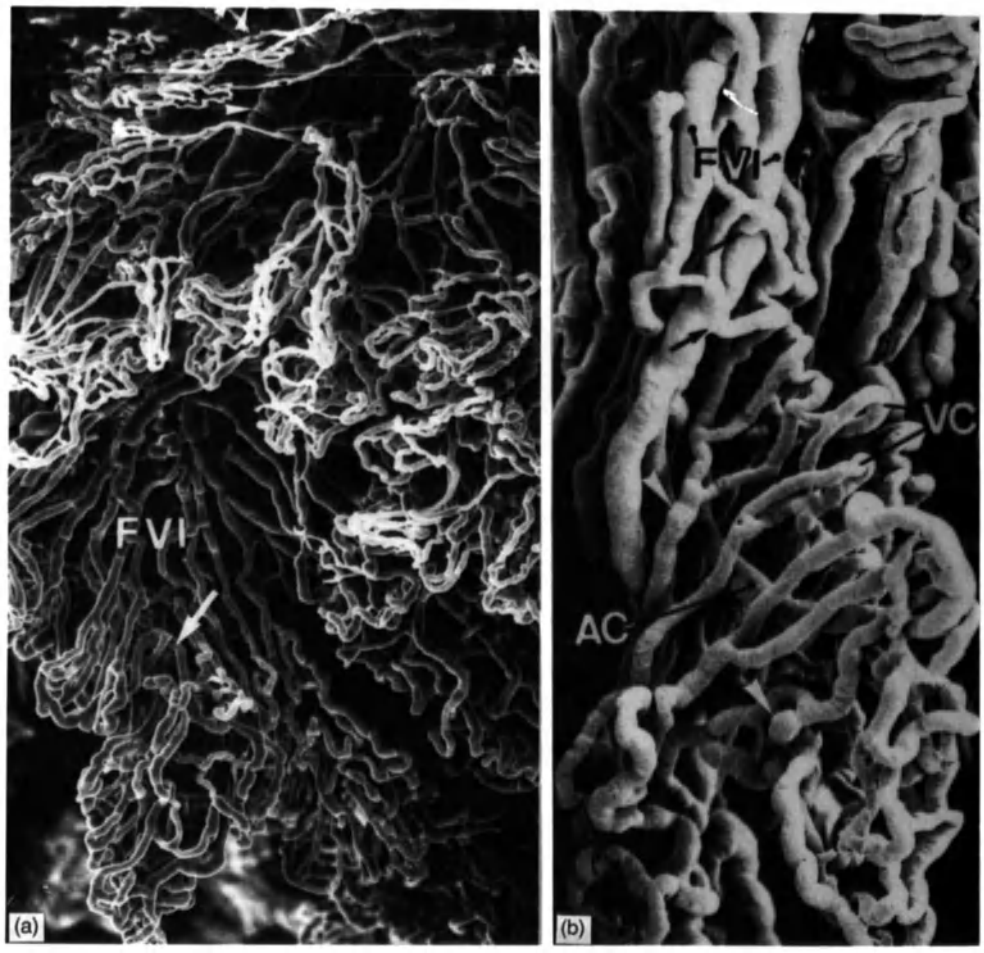

Figure 4.47 Synepitheliochorial placentation. (a) Corrosion cast of the capillaries forming the tips of the goat fetal villi (asterisks). Some villi are connected in series (white arrow, see Figure 4.48). 133 dpc, × 170. (b) Villus tip capillaries showing the central supply arteriole (AC) and venous connections to the next villus (VC). White arrowheads: sinusoidal widenings. 133 dpc, × 330. (From Leiser, 1987.)

area of double membranes of characteristic branching structure intermittently continuous with endoplasmic reticulum cisternae and usually located near the Golgi body (Figures 4.52 to 4.55).

In a recently divided BNC the double membranes have numerous associated small clear vesicles (Figures 4.52 and 4.54). DLBs in mature migrating BNCs lack these clear vesicles as do DLBs in the fetomaternal syncytia, which we consider to be derived from the migration (Figures 4.53 and 4.55).

The DLB thus shows a clear developmental sequence but as yet its function is unknown. Autoradiographic (Wooding *et al.*, 1981), histochemical (Wooding, 1980) and immunogold EM (C.S. Lee *et al.*, 1986b–d) studies show no involvement of the DLB in protein synthesis, placental lactogen storage, phosphatase localization or BNC granule production.

The mature binucleate cell lies very close to the microvillar junction but normally does not form part of the tight junction between

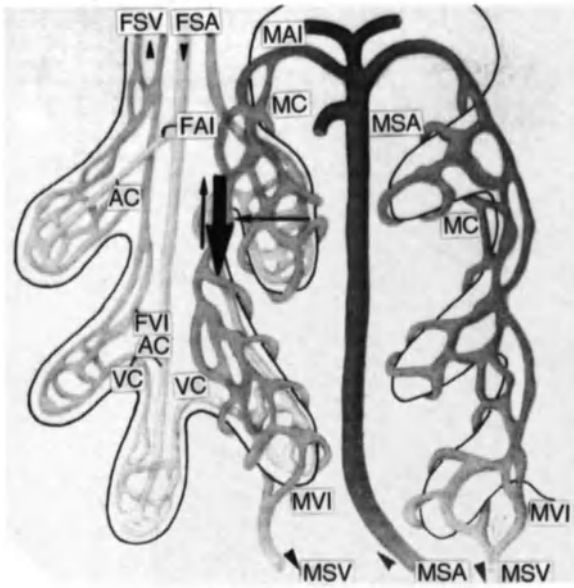

Figure 4.48 Synepitheliochorial placentation. Leiser's (1987) schematic summary of his corrosion study of goat placental vasculature. Both fetal and maternal stem arteries (FSA, MSA) run directly to opposite sides of the placenta, ensuring a grossly counter-current flow. However, the details of the arteriolar distributions are said to indicate a cross-current flow at that level. From the stem arteries (FSA, MSA) the arteriolar supply (FAI or MAI) to each villus tip may be direct (AC) or in series, derived from an adjacent villus (VC, MC). (From Leiser, 1987.)

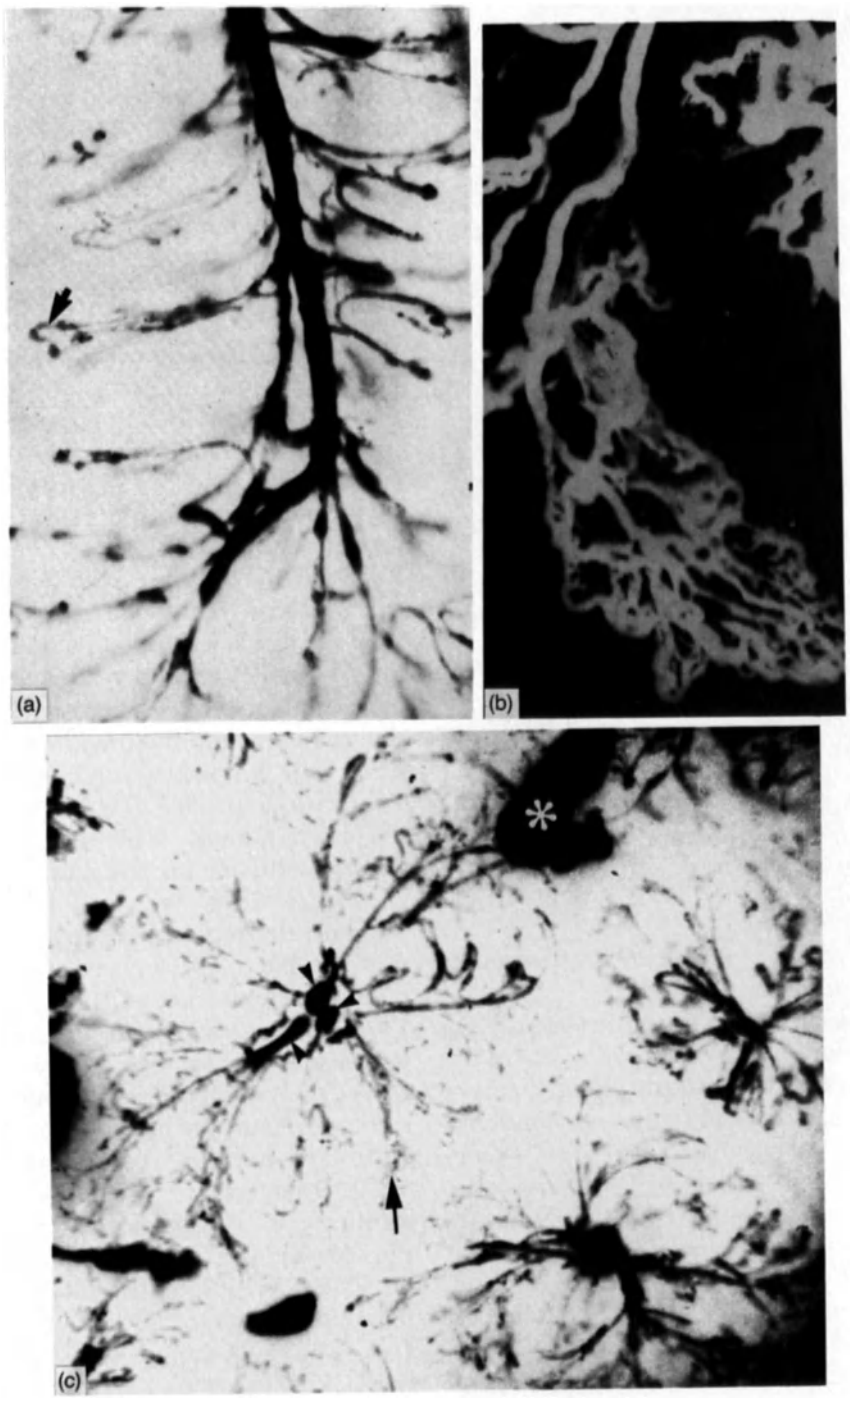
the apices of the uninucleate trophectodermal cells. Migration through this tight junction is the next stage in the binucleate cell life cycle. Throughout pregnancy 15 – 20% of the total population of binucleate cells are part of this tight junction in all four genera enumerated so far (cow, deer, goat and sheep) (Wooding, 1983; Table 4.3). Only mature binucleate cells are found with tight junction structures and micrographs of these cells at all stages of passage through the tight junction (Figures 4.56, 4.58 and 4.59) together with autoradiographic (Wooding *et al.*, 1981) and freeze-fracture (Morgan and Wooding, 1983) evidence (see below) provides a clear indication that these cells are migrating.

This migration starts at implantation and in the goat, sheep and cow produces a syncytium bordering the maternal tissue by fusion of the migrated binucleate cells with some individual uterine epithelial cells plus an elimination of the remainder (Wathes and Wooding, 1980; Wooding, 1984) (Figures 4.38, 4.39, 4.42 and 4.43). In the sheep and goat cotyledon this syncytium persists throughout pregnancy (Lawn *et al.*, 1969) (Figures 4.58 and 4.59). In the cow at implantation there is a transient formation of syncytium by migrated binucleate cells fusing with uterine epithelial cells but only a partial loss of the uterine epithelium. This bovine syncytium is then eliminated by displacement by continuing division of the remaining uterine epithelial cells (G.J. King *et al.*, 1979; Wathes and Wooding, 1980). Subsequently, during the remainder of pregnancy in cow and deer, the migrated binucleate cell fuses with an individual cell derived from the original uterine epithelium to form a transient trinucleate cell (Figures 4.60 and 4.61) which dies after the granules from the original binucleate cell have been released (Wooding and Wathes, 1980; Wooding, 1987) (Figure 4.39).

This migration was suggested by the earliest workers on the ruminant placenta (Assheton, 1906; Wimsatt, 1951), but subsequent electron microscopic investigations were unable to find any supporting evidence (Bjorkman and Bloom, 1957; Lawn *et al.*, 1969; Bjorkman 1968,1970). A study of sheep binucleate cells in 1977, for example, concluded that there were 'no published, well resolved pictures of binucleate cells in contact with the syncytium' (Boshier and Holloway, 1977). By developing a method for selective staining of non-osmicated material with phosphotungstic acid to emphasize only the binucleate cell granules and the microvillar junction (Figures 4.56 to 4.61) (Wooding, 1980) and by subsequent use of ultrastructural (Wooding *et al.*, 1980) and immunocytochemical (Figure 4.57) (Wooding, 1981; C.S. Lee *et al.*, 1986b–d) techniques it has now



(a)
(b)
(c)

been possible to demonstrate clearly both the fact and extent of the migration.

The frequency of migration in the sheep and goat needs to be sufficient to maintain the syncytium, in which no nuclear division has ever been demonstrated, throughout the enormous expansion in area which occurs during formation of the cotyledonary villi. It is clear that static micrographs can never provide direct evidence for a dynamic process. However, injection of radioactive thymidine into fetal sheep or goats and subsequent autoradiography of the fetomaternal interface layers shows that labelled nuclei are initially found exclusively in the uninucleate trophectoderm, subsequently in mature binucleate cells and finally in the syncytium (Wooding *et al.*, 1981, 1993). There was no evidence for a population of binucleate cells which became labelled but did not migrate.

In the goat and sheep cotyledon, maintenance of the substance of the syncytium would seem to be an important function for migration. However, in the intercotyledonary regions in goat and sheep the trophectoderm is apposed to a cellular uterine epithelial derivative, as it is in the whole of the cow and deer placenta, yet binucleate migration still occurs. It has been suggested that the primary function of the migration is to deliver the binucleate cell granules to the plasmalemma bounding the maternal connective tissue (Steven *et al.*, 1978). Exocytosis would then deliver the granule contents close to the maternal circulation, and there is good ultrastructural evidence for such a process from sheep and goat syncytium and cow trinucleate cells (Wooding, 1987; Wango *et al.*, 1990a).

Ovine and bovine placental lactogens (oPL and bPL) have been localized exclusively in the BNC granules and Golgi body and the granules in the syncytium by electron microscopic immunocytochemistry (Figure 4.57). No label was found over the Golgi bodies in the syncytium, indicating that synthesis and packaging of BNC granule contents occurs before BNC migration (Wooding, 1981; C.S. Lee *et al.*, 1986b–d; Wooding and Beckers, 1987). This agrees with the hypothesis of delivery of the granules to the syncytium by binucleate cell migration in order to evade the barrier to diffusion of protein molecules like placental lactogen (PL) provided by the tight junctions sealing the trophectoderm. Placental lactogens have so far been localized only in binucleate cells in the sheep by immunocytochemistry (Martal *et al.*, 1977; Watkins and Reddy, 1980; Wooding, 1981; C. S. Lee *et al.*, 1986b–d; Morgan *et al.*, 1987) and cow (Verstegen *et al.*, 1985; Duello *et al.*, 1986; Wooding and Beckers, 1987). The only claims for localization of oPL to uninucleate chorion cells (Carnegie *et al.*, 1982; Chan *et al.*, 1990) are far less convincing than any of the other studies cited here (see Wooding *et al.*, 1992). Biochemical organelle isolation techniques have also shown that placental lactogens copurify with a granule fraction (oPL, Rice and Thorburn, 1986; bPL, Byatt *et al*, 1986). More recently, hybridization histochemical studies (Milosavljevic *et al.*, 1989; Kappes *et al.*, 1992) have shown that PL mRNA is found only in ovine and bovine BNCs. There are other mol-

Figure 4.49 Synepitheliochorial cow placenta. Vascular structures. The injected and sectioned material (a and c) and the latex cast (b) demonstrate the complexity of the villus structure in the cotyledon. (a) Longitudinal and (c) transverse sections of villi demonstrate the delicacy and detail of the capillaries at the ends of the side branches (arrows). This can also be appreciated in the latex cast (b). There seem to be three vessels in the core of the fetal villus (b, arrowheads), presumably stem arteries and veins. In (c) the largest vessels (asterisks) are probably maternal veins. (From Tsutsumi, 1962.) (a) 105 dpc, × 100. (b) 90 dpc, × 100. (c) 105 dpc, × 90.

*For details of breeds, counting methods, statistical limits see Wooding (1983).
**A migrating BNC is defined as one which is part of the trophectodermal apical tight junction.

ecules, including glycoproteins, present in high concentrations in the binucleate cell granules as shown by immunogold studies (for example, one glycoprotein is defined so far only by its monoclonal antibody SBU-3) (C.S. Lee *et al.*, 1985, 1986b–d; Figure 4.57b) and by their selective staining with periodic acid–Schiff at light microscope level (Wimsatt, 1951; Lee *et al.*, 1985, 1986a) and phosphotungstic acid at electron microscope level (Wooding, 1980; Wooding and Wathes, 1980). This staining is found in cow, deer, goat and sheep binucleate cells.

Another constituent recently claimed for the BNC granules is the acidic 78-kD 'pregnancy-specific protein B' (PSPB or bPAG) (Sasser *et al.*, 1989; Zoli *et al.*, 1992). This is found in the maternal blood of all pregnant ruminants tested so far, but it persists longer post partum than would be expected if it is produced solely in the BNCs (Humblot *et al.*, 1990). There is evidence that, although all BNCs appear similar ultrastructurally, the content of their granules may depend on the location of the BNCs or the age of the conceptus. Ovine intercaruncular BNCs do not express oPL or SBU-3 (C.S. Lee *et al.*, 1985, 1986c,d), and although oPL is present in caruncular BNC in conceptuses from 16 dpc SBU-3 is not found until 24 dpc (Morgan *et al.*, 1987).

Binucleate cell migration, therefore, provides the fetus with a general method of delivering large molecules to the maternal circulation. However, in the sheep, oPL is present in both maternal and fetal circulations and if all binucleate cells migrate to the maternal side it is difficult to understand

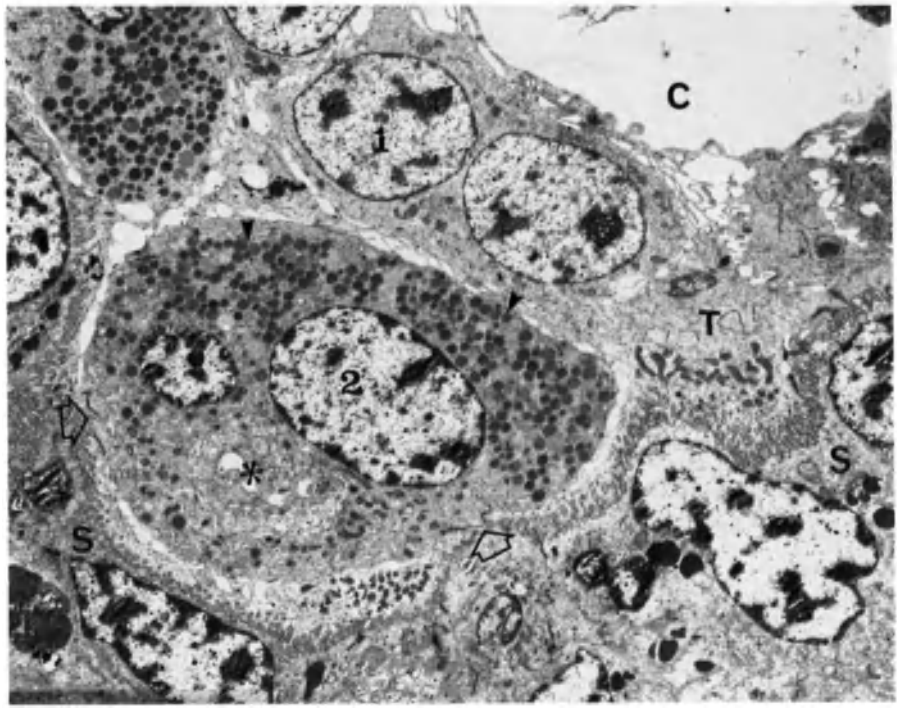

Figure 4.50 Synepitheliochorial placentation. Glutaraldehyde/osmium fixation. Development of fetal binucleate cells (1, young; 2, mature) in the trophectoderm (T) of the definitive placenta of the goat. Note the numerous characteristic granules (arrowheads) and large Golgi body (asterisk) in the mature binucleate cell, which has started to migrate up to the microvillar junction at two points (open arrows). S, fetomaternal syncytial layer; C, fetal connective tissue. 127 dpc, × 2500.

the origin of the fetal serum oPL (Chan *et al.*, 1978; Martal and Lacroix, 1978). What little evidence there is indicates that there is no transfer of oPL from maternal to fetal circulation (Grandis and Handwerger, 1983) or from fetus to mother (Schonecht *et al.*, 1992). This problem is more extreme in the cow, in which the bPL concentration in the maternal circulation is always very much lower than on the fetal side (Beckers *et al.*, 1982; Wallace *et al.*, 1985). Despite this, all the bPL-containing BNCs appear to migrate and bPL-containing granules are found only in BNCs and their derivatives (Wooding and Beckers, 1987). Even allowing for the vastly greater maternal blood volume, the amount reaching the fetal circulation is very significant from the earliest stage measured.

There is no evidence in cow or sheep for a subpopulation of BNCs which degranulate on the fetal side, but there may be a constant low level of release of granules prior to BNC migration, which would be very difficult to detect ultrastructurally. Alternatively, there may be a constitutive pathway for oPL and bPL secretion independent of the conventional regulated exocytotic mechanism (Burgess and Kelly, 1987). This is an important point because exogenously administered oPL elicits biological responses in the fetal sheep (Battista *et al.*, 1990) consistent with earlier suggestions (A.W. Bell, 1984; Gluckman *et al.*, 1987) that oPL may serve as an important somatotrophic hormone in the fetus.

This presence of placental lactogens in both fetal and maternal circulations is in sharp

contrast with the restriction of equine chorionic gonadotropin (eCG) produced by the horse endometrial cup BNCs entirely to the maternal circulation (Ginther, 1979). In this case the BNCs do not mature (i.e. produce eCG-containing granules) until they are in transit to the cup site in the maternal endometrium (section 4.3.6a).

It has been suggested that binucleate cell migration in the sheep can be increased by fetal pituitary stalk section or adrenalectomy, but this was based on the assumption that migration was insignificant in normal pregnancy (Barnes *et al.*, 1976; Bass *et al.*, 1977; Steven *et al.*, 1978; Lowe *et al.*, 1979). Recent quantitative studies have shown in the sheep that there is no significant difference between the BNC migration level in normal pregnancy and that found after a variety of experimental procedures including pituitary stalk section, adrenalectomy, carunclectomy, hypophysectomy and administration of progesterone synthesis inhibitors and EGF (Wooding *et al.*, 1986). The production, maturation and migration rate of the BNCs seem to be totally unaffected by administration of this wide variety of compounds and procedures, as are the oPL blood concentrations (Taylor *et al.*, 1982, 1983). Those agents which initiate the complex hormonal and structural changes leading to parturition do decrease BNC production (not migration) (Wooding, 1982a,b, 1983), but it is not yet possible to identify what factor(s) it is that controls BNC production. During implantation the earliest evidence for binucleate cell formation in sheep (Boshier, 1969) is found at the same time as the first demonstration of placental lactogen in the blastocyst of the sheep (Martal and Djiane, 1977; Morgan *et al.*, 1987) or cow (Flint *et al.*, 1979). In the last week of pregnancy there is a fall in binucleate cell num-

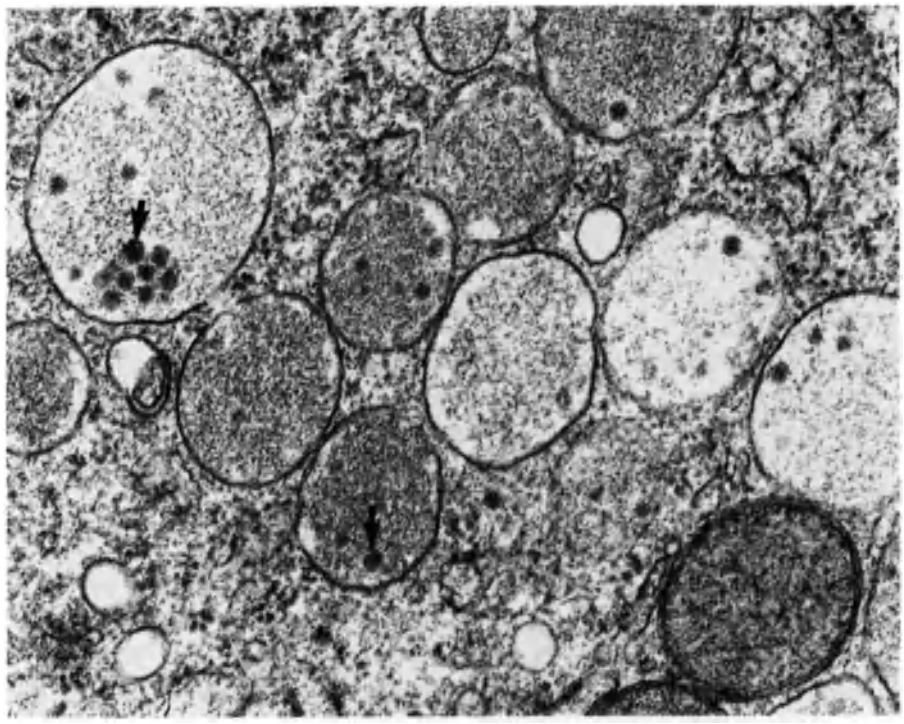

Figure 4.51 Synepitheliochorial placentation. Glutaraldehyde/osmium fixation. Detail from cow binucleate cell showing granules containing characteristic microvesicles (arrows). 49 dpc, × 46 000.

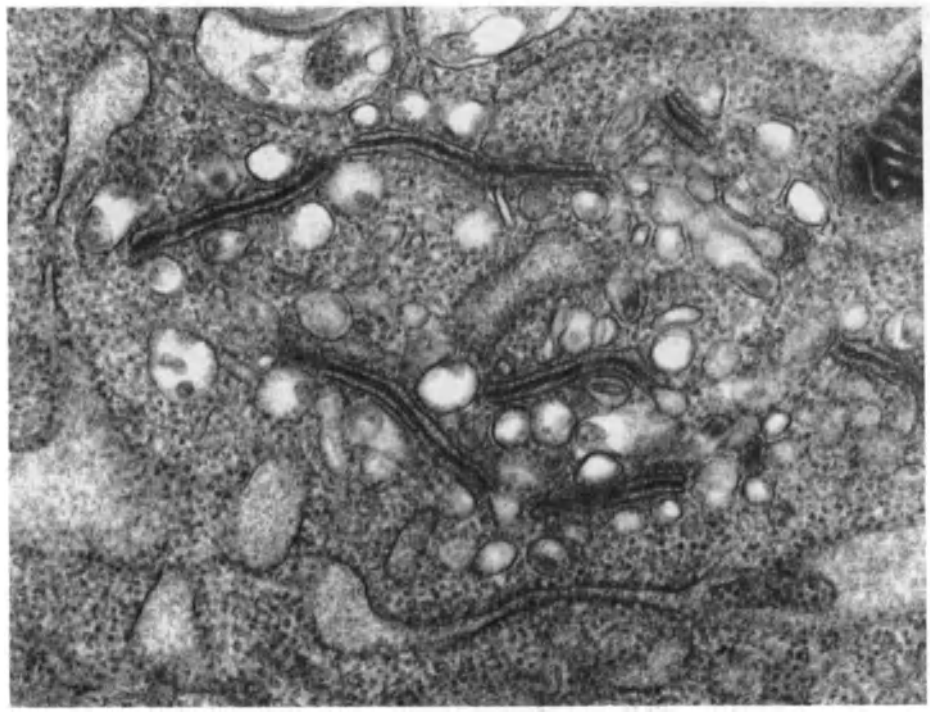

Figure 4.52 Synepitheliochorial sheep placenta (a) The 'double lamellar body' (DLB), characteristic of ruminant binucleate cells, in a young binucleate cell, note the frequent electron lucent vesicles. 114 dpc, × 50 000.

bers and this correlates with a similar fall in oPL concentration in both fetal and maternal circulations (Martal and Djiane, 1977). However, until it is possible to predictably manipulate the oPL concentration, there is insufficient evidence to assume that the blood concentrations are directly related to binucleate cell numbers. It could be that it is the rate of migration of the cells or exocytosis of the granules which is the primary locus of control of release of oPL into the circulation. Interpretation of recent *in vitro* experiments on the control of oPL secretion is difficult because of the complexity of the system. oPL release could originate from unmigrated BNCs (via the presumed route into the fetal circulation) or from granules delivered to the syncytium by BNC migration – the normal route into the maternal circulation. The latter is an order of magnitude greater than the former *in vivo*. Secretion from placentomal slices (said to involve protein kinase C, Battista *et al.*, 1990) will presumably involve both routes, whereas isolated trophectodermal uninucleate and binucleate cells (Burke *et al.*, 1989) will be restricted to only the fetally directed secretion.

There is now a considerable amount of evidence that all ruminant fetal binucleate cells migrate towards the maternal tissues, presumably to deliver the content of their granules to the maternal circulation. At least one hormone is involved in the sheep, goat and cow. The importance of this particular fetal contribution to the establishment and maintenance of pregnancy remains to be established, but there is an increasing amount of evidence that the placental lactogens can modify the maternal metabolism to favour fetal nutrition and growth (Munro, 1980,

1986; Waters *et al.*, 1985; Freemark and Handwerger, 1986; Freemark *et al.*, 1987; Thordarson *et al.*, 1987; Chêne *et al*, 1988; Forsyth, 1991; Handwerger, 1991; Byatt *et al.*, 1992).

(c) Endotheliochorial placentation (dog, cat, bat)

In endotheliochorial placentation no uterine epithelium survives implantation (Figure 4.5). The cellular chorioallantoic trophectodermal cells produce, by division and fusion, a fetal syncytium apposed to an amorphous layer around the persisting maternal endothelium. The amorphous layer (also referred to as the interstitial layer or, misleadingly, 'membrane') is probably produced by the syncytium and is equivalent, ultrastructurally and in molecular constituents, to the basement membrane of the maternal endothelium. It is neither uniformly thick nor continuous; processes of the fetal syncytium penetrate through it to reach a close relationship with the maternal endothelium in places, and it includes occasional large residual endometrial cells. This structure is characteristic of the early and definitive endotheliochorial placentas which are zonary (Figure 4.62).

The zones are made up of grossly parallel fetal villi, which are labyrinthine in architecture. Usually, but not always, there is a large haemophagous zone at the edge or in the centre of the zonary structure. Outside the main zone of the placenta a cellular fetal trophectoderm is loosely apposed to a persistent uterine epithelium and there are small areolae over the gland mouths. Endotheliochorial placentation is characteristic of carni-

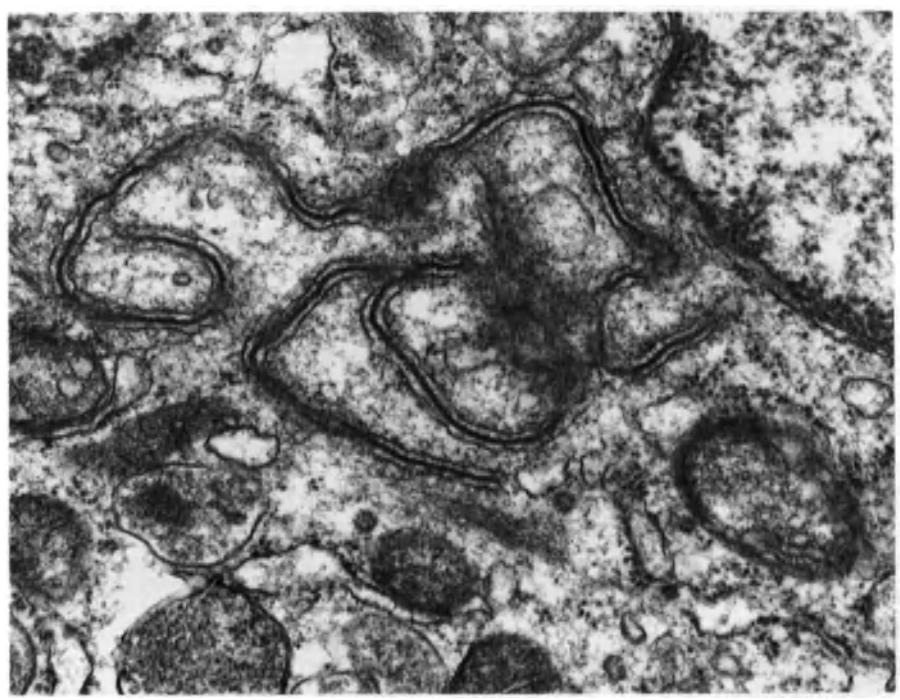

Figure 4.53 Synepitheliochorial sheep placenta. Mature DLB (see Figure 4.52) from the fetomaternal hybrid syncytium which is formed in part from mature binucleate cell migration and fusion, shows no associated vesicles such as those seen in the immature form (Figure 4.54). 114 dpc, × 40 000.

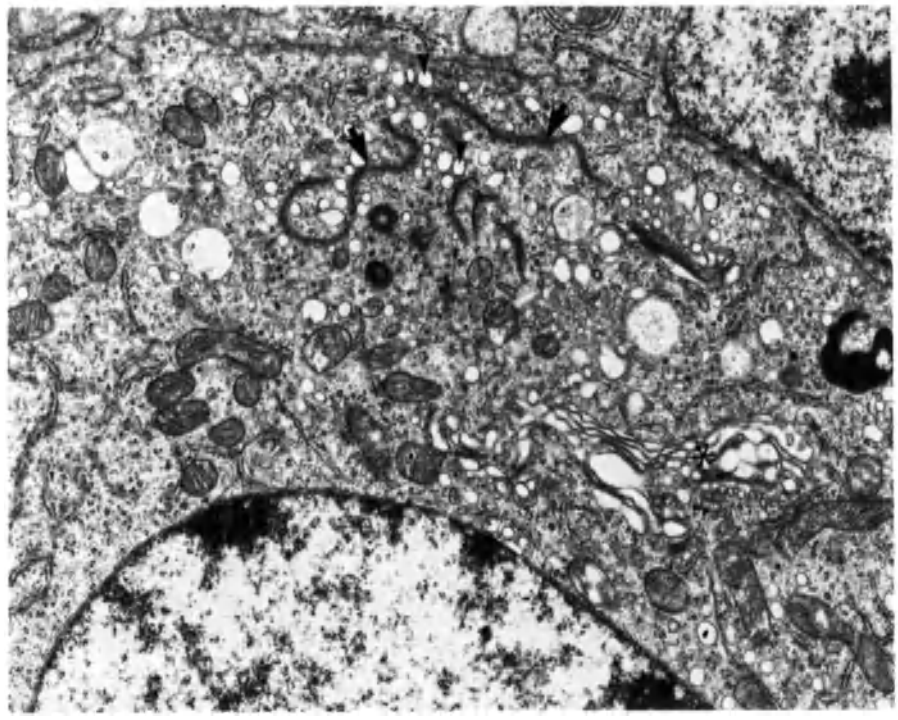

Figure 4.54 Synepitheliochorial cow placenta. The double lamellar body (arrows) has electron lucent vesicles (arrowheads) associated with it in the young non granulated binucleate cell, but there are very few in the mature granulated cell (Figure 4.55) 49 dpc, × 12 000.

vores and many bats but is also found in individual genera in other orders – Proboscidea (elephant), Tubulidentata (aardvarks), Rodentia (*Dipodomys*, the kangaroo rat), Insectivora (*Talpa* the European mole, and *Blarina*, the shrew) and also *Bradypodida* (the sloths) (Mossman, 1987).

The cat and dog will be taken as the characteristic examples of this placental type.

Dog, *Canis familiaris*; cat, *Felis domestica*

Oestrous cycle:
dog, one 21-day cycle during the single yearly breeding period
cat, 15–21-day cycles; several during each of the breeding periods which occur 2–3 times per year
Ovulation: Spontaneous in the dog, induced by coitus in the cat. For endocrinological details during pregnancy see Concannon *et al.* (1989).
Litter: 3–6
Gestation: 55–65 days
Implantation: superficial; central, antimesometrial
Amniogenesis: folding
Yolk sac: well-vascularized choriovitelline placenta up to 24 dpc with non-vascularized short villi of endotheliochorial structure (Figure 4.62). The yolk sac is then separated from the chorion by growth of the allantoic sac but persists to term (Figure 4.62) as a highly vascularized collapsed sac with a characteristic ultrastructure (S.Y. Lee *et al.*, 1983).
Chorioallantois: forms definitive placenta, the allantoic sac surrounds and vascularizes the amnion and chorion
Shape: zonary

Decidua: very infrequent modification of stromal cells in the endometrium just below the invading tips of the villi

Cats, and to a lesser extent dogs, have large cells, probably of endometrial stromal origin, throughout the placental lamellae between the trophectodermal syncytium and the maternal endothelial cells. Most authors refer to them as decidual cells but nothing is known of their function (Figure 4.68) (Wislocki and Dempsey, 1946; J.W. Anderson, 1969; Malassine, 1974). Ruminants have similar cells in an equivalent position (see Figure 4.69).

Interhaemal membrane: endotheliochorial

Accessory placental structures: areolae in paraplacental region. Haemophagous zones at the margin or centre of the zonary placenta (Figure 4.65)

Fetal membranes and placental development The newly pregnant bicornuate uterus has a uniform development of numerous glands around the lumen (Wislocki and Dempsey, 1946; Barrau *et al.*, 1975). In the cat and dog, blastocysts enter the uterus at 5 dpc and establish an even spacing by 8 dpc, at which time they are sufficiently large to distend the uterus. If only two blastocysts are present one implants in each horn about halfway up (Amoroso, 1952). There is evidence for up to 40% transuterine migration between horns in cat and dog (Shimizu *et al.*, 1990).

In several animals with endotheliochorial placentas, such as bears, badgers and seals, the blastocyst can be held in diapause and implantation delayed for several months by physiological mechanisms which are still poorly understood (Enders and Given, 1977; Mead, 1993). Once the blastocyst has

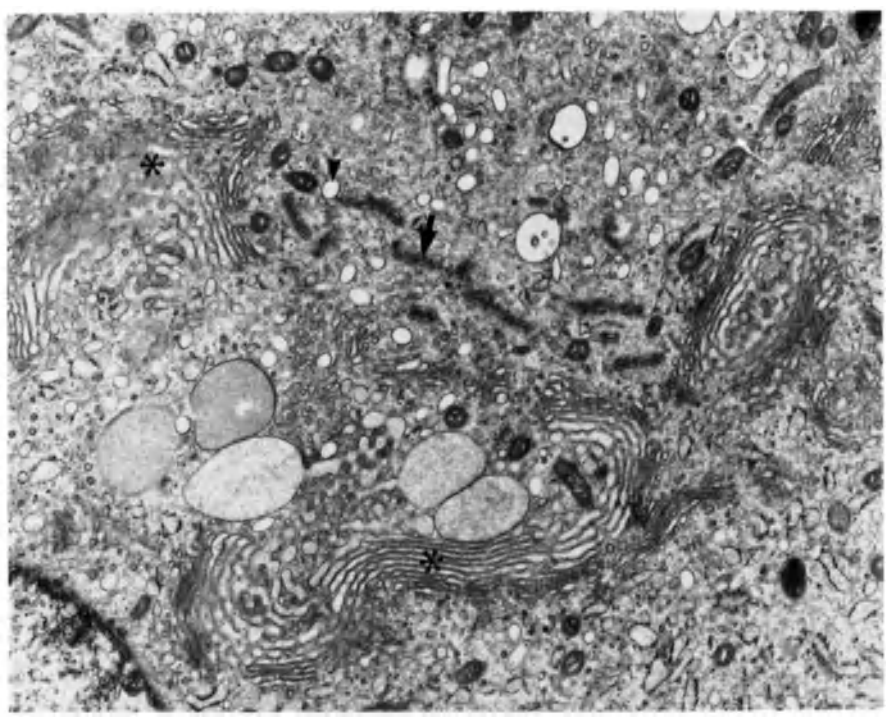

Figure 4.55 Synepitheliochorial cow placenta. The mature granulated binucleate cell has a double lamellar body (arrow) with few associated vesicles. Note the large size of the Golgi body (asterisks) in the mature cell. 130 dpc, × 12 000.

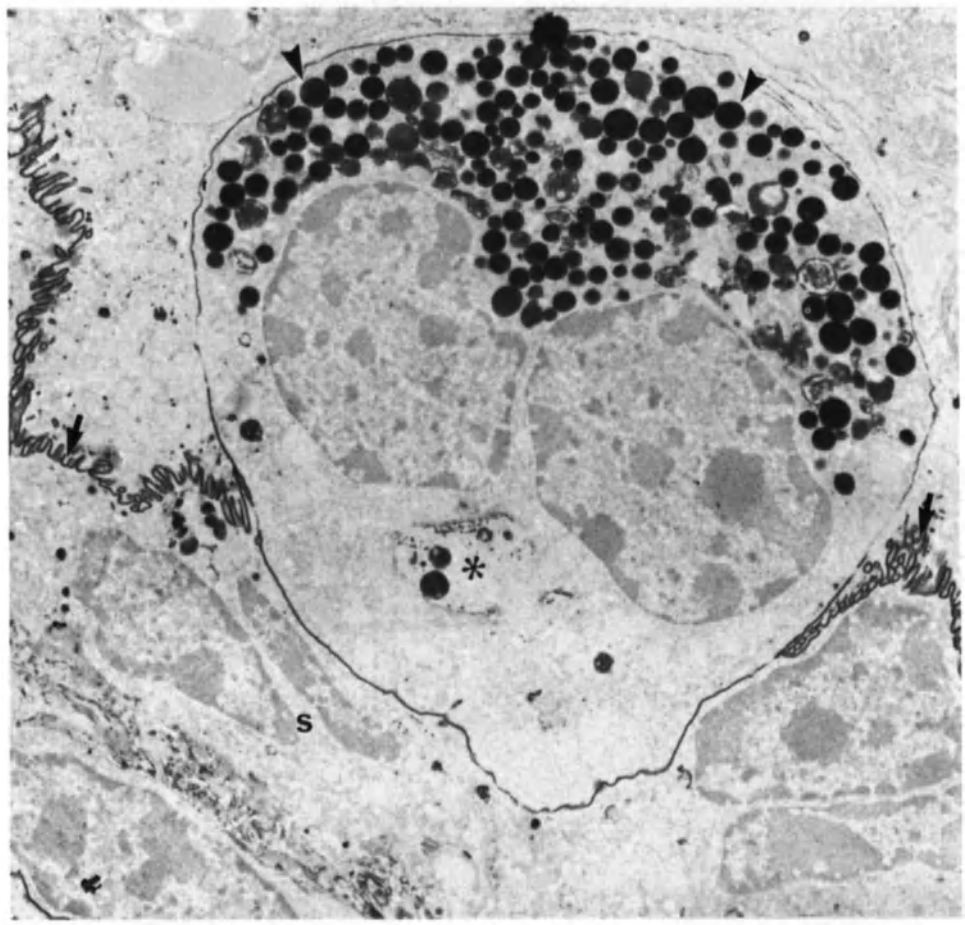

Figure 4.56 Synepitheliochorial sheep placenta. Phosphotungstic acid staining. Binucleate cells migrate across the microvillar junction (arrows) throughout pregnancy carrying their characteristic granules (arrowheads), formed mostly before migration in the Golgi body (asterisk), into the fetomaternal syncytium (S). 114 dpc, × 5000.

expanded to distend the uterus (central implantation) the yolk sac is vascularized over most of its mesometrial half, and a functional trilaminar choriovitelline placenta is formed (Figures 4.62 and 4.63).

In the cat, cellular contact and subsequent interdigitation of microvilli between trophectoderm and uterine epithelium starts on 13 dpc. Around this time full apical junction complexes have been observed (Leiser, 1979) between cells from the two epithelia, but it is not clear whether these are formed as a result of fetal trophectoderm intrusion between, or fusion with, the cells of the uterine epithelium. The uterine epithelium undergoes sporadic lateral fusions and a considerable amount of individual cell death. At this stage the cellular trophectoderm (cytotrophoblast) shows numerous divisions and produces a syncytium inextricably enmeshed with remnants of the cellular and newly syncytial uterine epithelium (Leiser, 1979). The fetal syncytiotrophoblast is actively phagocytic, rapidly displacing and replacing the uterine

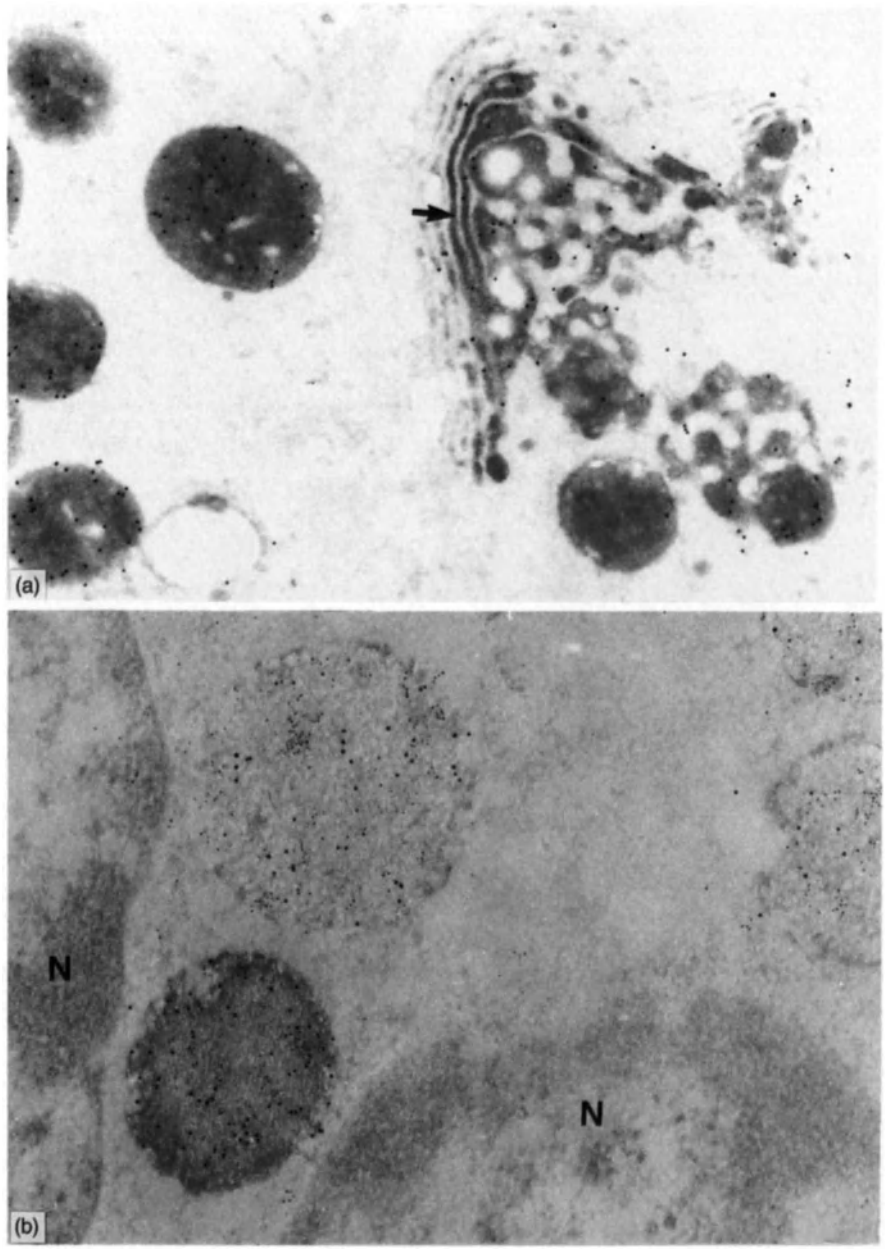

Figure 4.57 Synepitheliochorial sheep placenta. (a) Binucleate cell Golgi body immunostained for ovine placental lactogen. The gold particles localize the lactogen exclusively to the *trans* cisternae of the Golgi stack (arrow) and the granules. 114 dpc, × 38 000. (b) Colocalization of ovine placental lactogen (5 nm gold) and the SBU-3 antigen (10 nm gold) on the binucleate cell-derived granules in the placental syncytium. N, nucleus. (From Lee *et al.*, 1986c). 114 dpc, × 40 000.

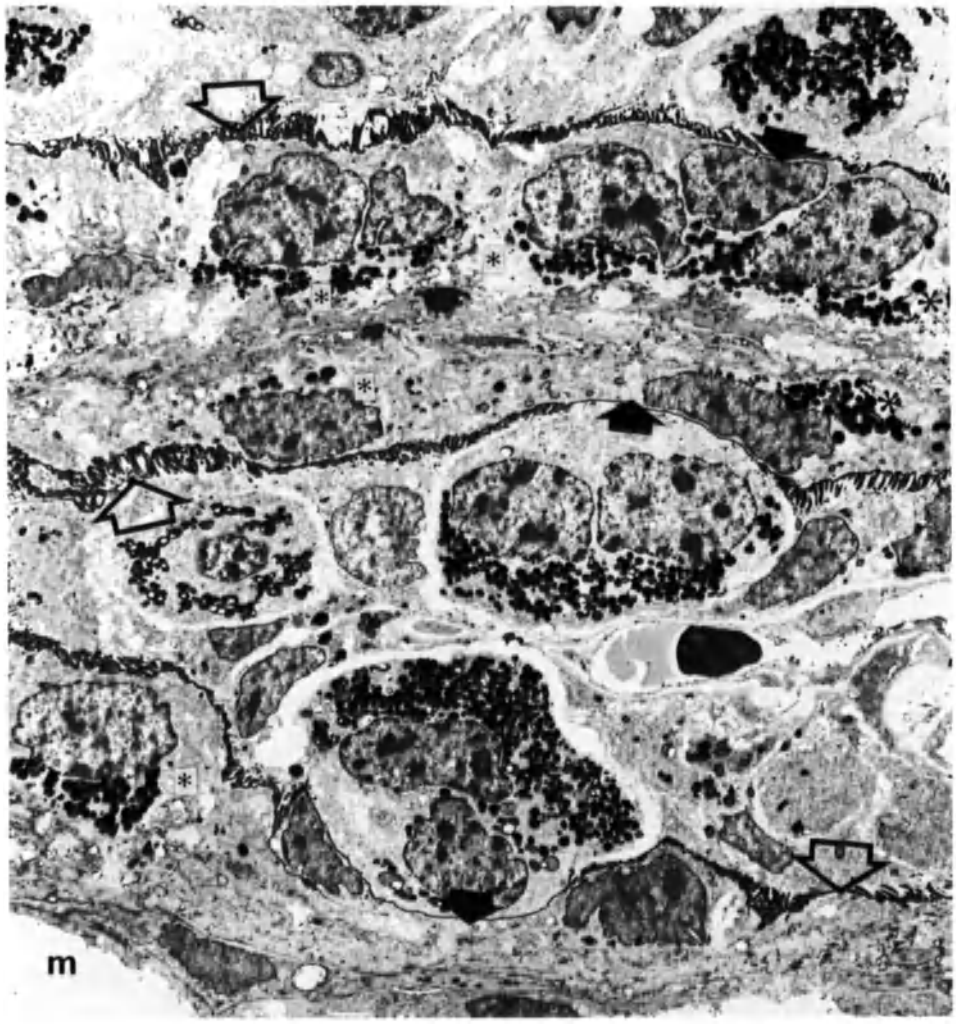

Figure 4.58 Synepitheliochorial sheep placenta. Binucleate cells migrate (solid arrows) across the microvillar junction (open arrows) throughout pregnancy (Figure 4.58, 65 dpc; Figure 4.59, 142 dpc) delivering their granules to the base of the fetomaternal syncytium (asterisks). There are usually many granules in the syncytium at early stages (Figure 4.58) of pregnancy, few are found near term (Figure 4.59). m, maternal blood vessels (see Figure 4.39 and Wooding, 1981). 65 dpc, × 2600.

epithelium (Barrau *et al.*, 1975; Leiser, 1979). It then flows around the maternal capillaries and establishes the endotheliochorial pattern of the interhaemal membrane. The absorption of the maternal uterine and glandular epithelium and the continued erosion of the connective tissue are achieved by swelling masses of syncytiotrophoblast. This is produced by the rapid proliferation of the cytotrophoblast and forms short avascular villi which make up the trilaminar choriovitelline placenta (Figure 4.63) (Amoroso, 1952). These villi extend into the endometrium all over the conceptus, except for the area immediately around the embryo, which has only just completed amnion formation by

fusion of head and tail folds. After the amnion is formed, the allantoic outgrowth from the hind gut rapidly expands into the exocoelomic space around and below the embryo. Fusing with the trophectoderm it forms a chorioallantoic placenta, displacing the yolk sac and its mesodermal vascularization over the whole of the spherical conceptus (Figure 4.62). The allantoic vascularization is much more aggressive than that of the yolk sac and pushes rapidly into the villi. This development of fetal blood vessels plus the prolific generation of syncytiotrophoblast from cytotrophoblast forms the basis of the rapid advance of these villi down the glands, stripping away all gland epithelium (which first transforms into a syncytium) and connective tissue. At the same time the maternal vasculature is expanding and elongating. As Mossman (1987) has pointed out, formation of the zonary placental villi cannot just be based on erosion by the fetal syncytium and its advance into the endometrium, the final length of the villi is much too long for this. There has to be considerable expansion of the maternal blood capillary system. This point can be best appreciated by examination of a developmental series of transverse sections through the cat placenta (Figure 4.63 and 4.64).

The structure of the initial interhaemal membrane is endotheliochorial, as it is at term. Indentation of the fetal cyto- or syncytiotrophoblast by the fetal capillaries is considerable towards the end of pregnancy, and there is usually a definite attenuation of the amorphous (interstitial) layer (J.W. Anderson, 1969; Barrau *et al.*, 1975). The maternal endothelium varies considerably in thickness depending upon the species. In the bear it is typically three to four times thicker than in seals, but the functional significance of the differences is obscure (Amoroso, 1952; Sinha and Erickson, 1974; Wimsatt, 1974).

The area of the interhaemal membrane increases and its thickness decreases as the

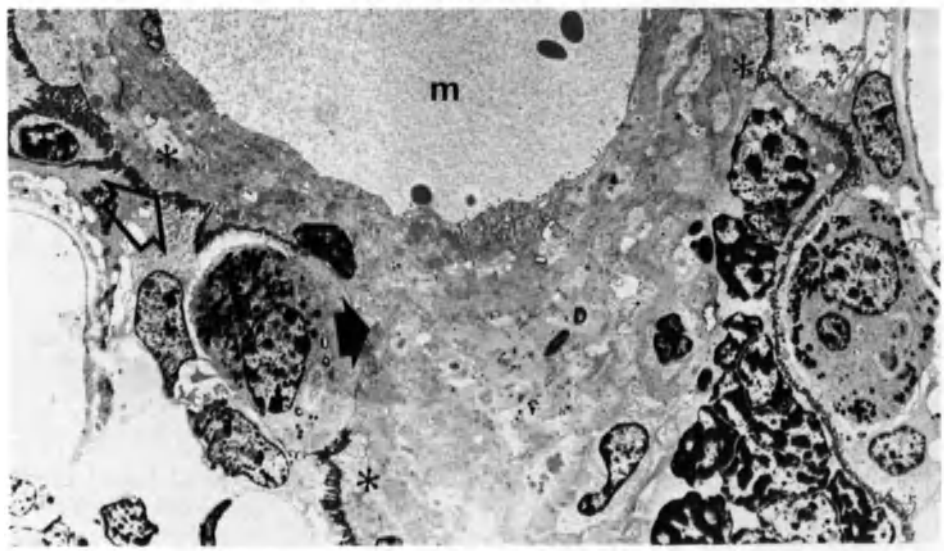

Figure 4.59 Synepitheliochorial sheep placenta. Binucleate cells migrate across the placental microvillar junction (open arrows) right up to term (145 dpc). The micrograph shows a binucleate cell (solid arrow) at day 142 dpc migrating into the fetomaternal syncytium (asterisks) which contains fewer binucleate cell derived granules than at earlier stages (see Figure 4.58). 142 dpc, × 1400.

Figure 4.60 Synepitheliochorial cow placenta. Throughout pregnancy binucleate cells (B) migrate from the fetal trophectoderm (T) across the microvillar junction (open arrow) to fuse with uterine epithelial cells (U) producing trinucleate cells (asterisks). These eventually release their granules (arrowheads) close to the maternal blood vessels (m), die and are resorbed by the trophectoderm (see Figure 4.39 and Wooding and Wathes, 1980) f, fetal blood vessel. 70 dpc, × 4400.

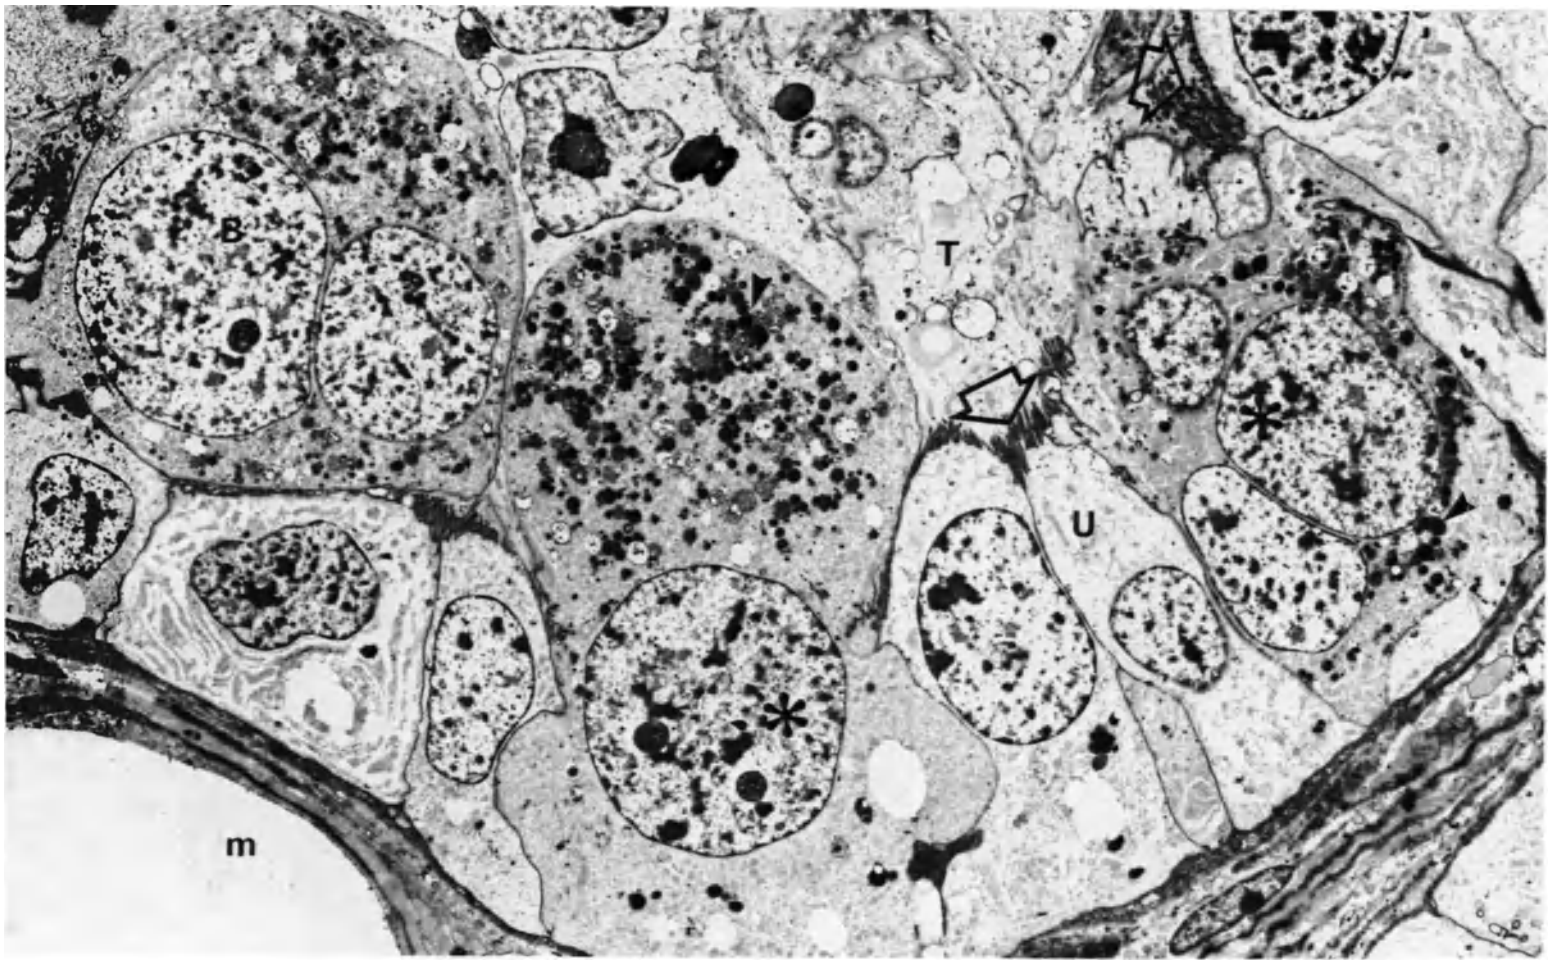

Figure 4.61 Synepitheliochorial cow placenta. For details see legend to Figure 4.60. 130 dpc, × 2700.

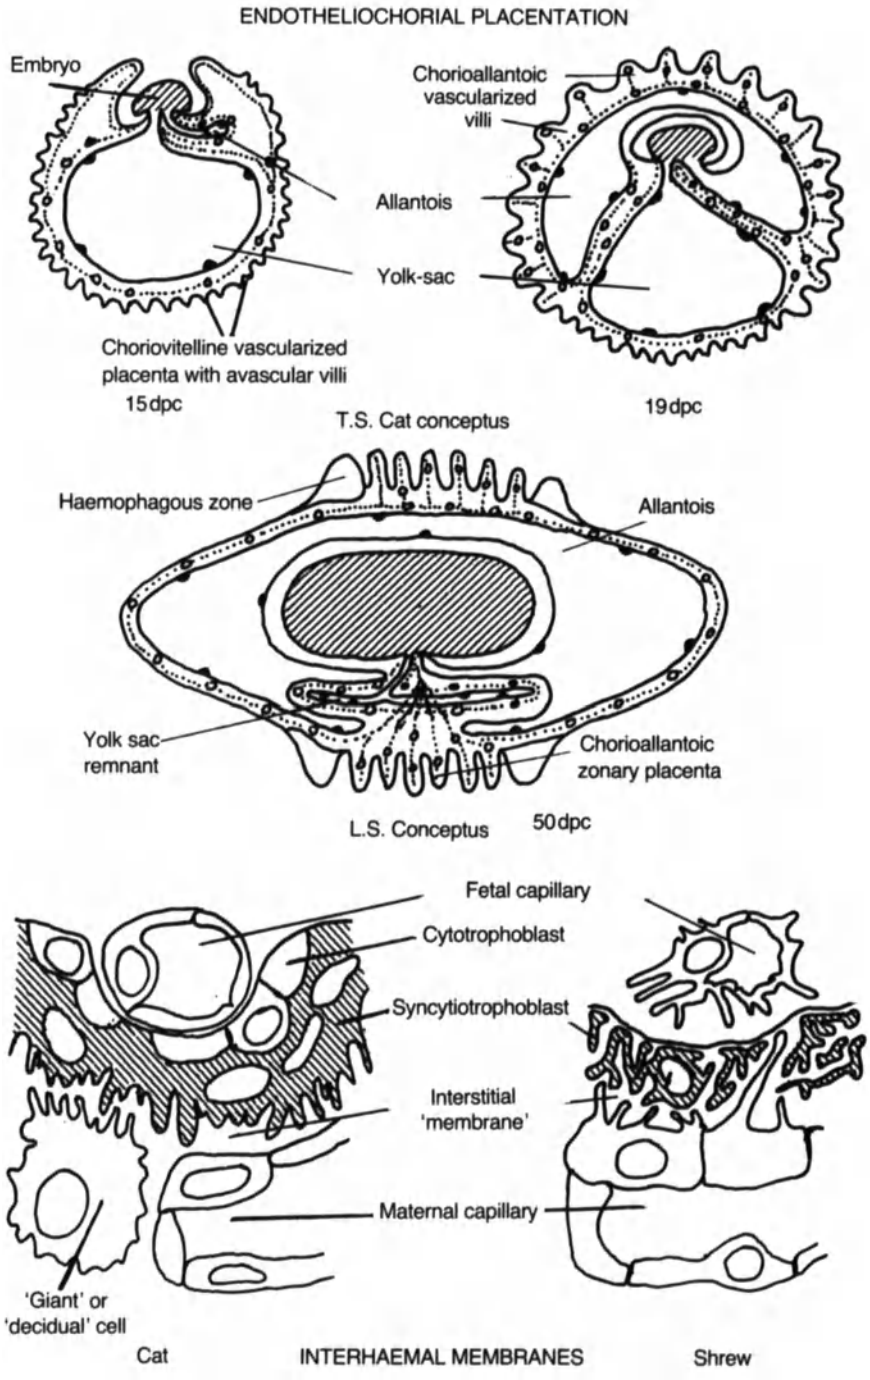

Figure 4.62 Placental membrane development in endotheliochorial placentation, mostly Carnivora.

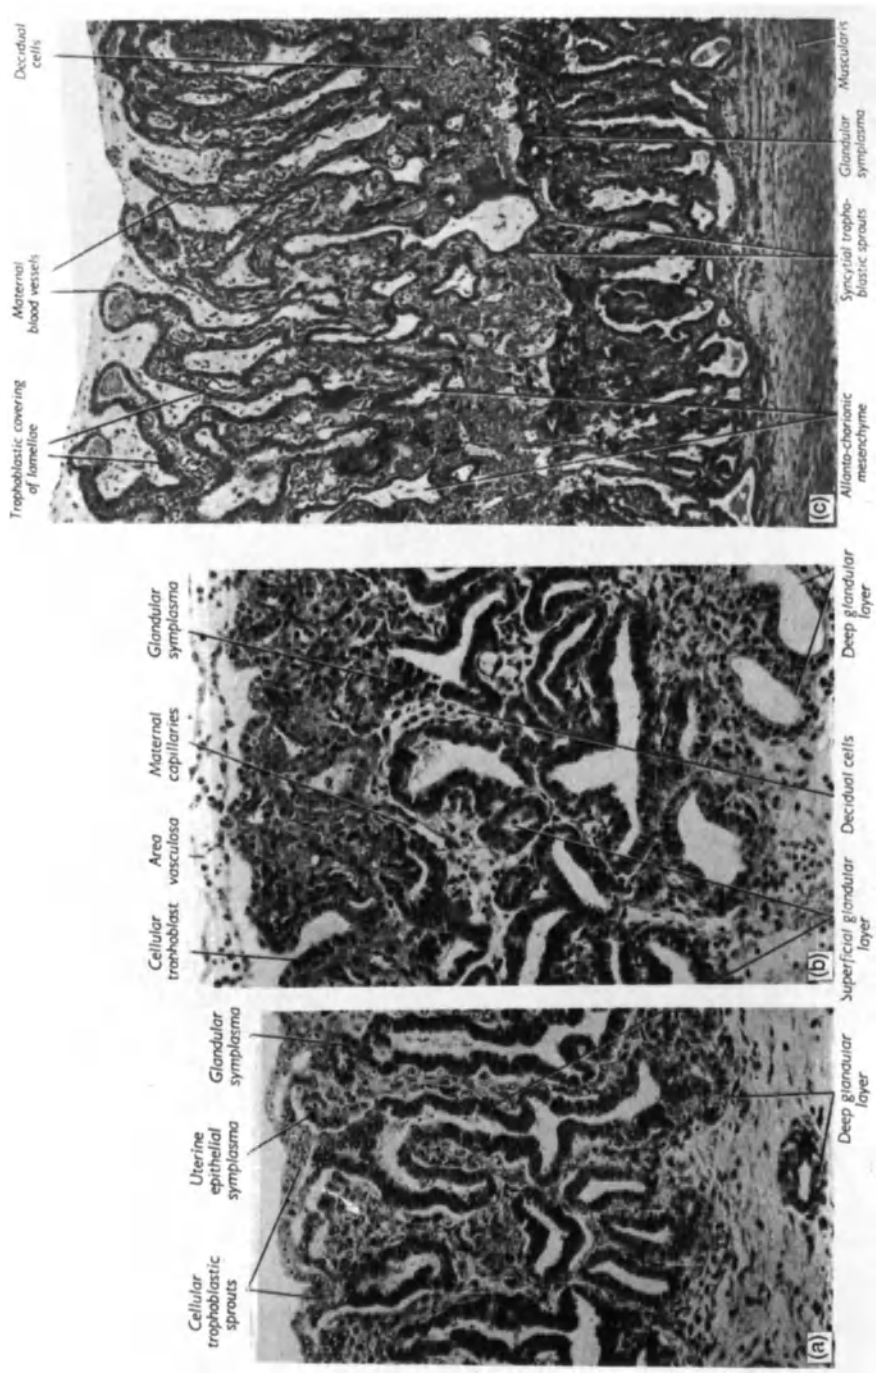

Figure 4.63 Endotheliochorial cat placenta (see Figure 4.62 for diagrams). Developmental sequence all at the same magnification, showing (a) early apposition (13½ dpc), (b) short yolk sac placental villi, non-vascularized (about 16 dpc) and (c) vascularized fetal chorioallantoic villi or lamellae (25 dpc). Note the increase in length of both the fetal villi and maternal crypt sides but the relative constancy of the depth of the glands plus junctional zone. (a) 13½ dpc, × 120. (b) 16 dpc, × 120. (c) 25 dpc, × 120.

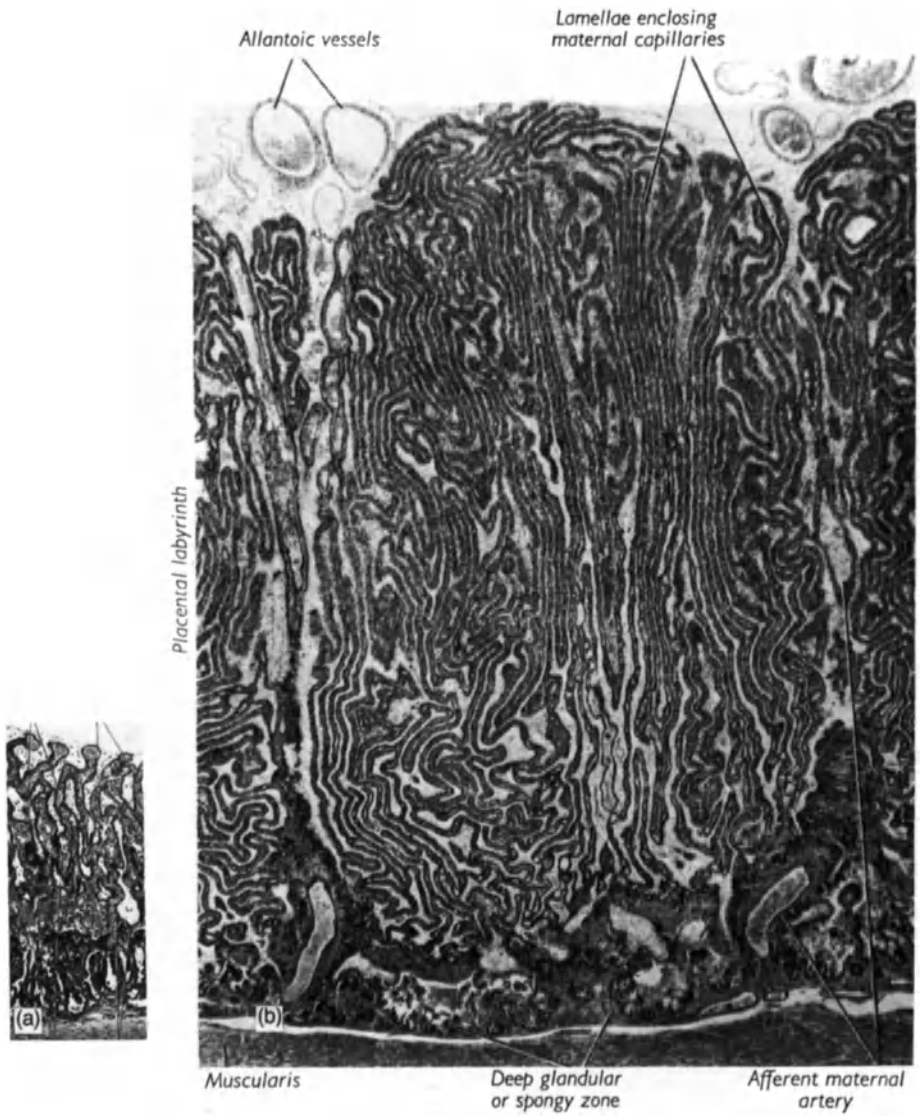

Figure 4.64 Endotheliochorial cat placenta. Placental development showing the enormous increase in length and proliferation of the labyrinthine fetal and maternal lamellae between 25 dpc (a) and about 60 dpc (b) (term is 61–63 dpc). Both (a) and (b) are at the same magnification. (a) 25 dpc, × 24. (b) 60 dpc, × 24.

fetus grows, thus continuously improving the transport potential of the placenta (Baur, 1977).

When the chorioallantoic membrane is first forming, the whole conceptus is expanding and elongating to become sausage shaped, with paraplacental regions outside the central zone of the placental villi. These regions have unchanged cellular trophectoderm and uterine epithelium loosely apposed with small areolae over the mouths of the numerous glands which are actively secreting throughout pregnancy (Leiser and Enders, 1980a). The area of this paraplacental region (Figures 4.62 and 4.65) is macroscopically larger than the zone of the placental villi but probably less than 5% of the total interhaemal area at term.

A characteristically large haemophagous zone develops at the edge or in the middle of the zonary endotheliochorial placenta of carnivores (Figure 4.65). It is lined on the fetal side by high columnar trophectoderm showing all stages of very active phagocytosis and digestion of the red blood cells from the stagnant pool of blood at the fetomaternal interface. On the maternal side the uterine epithelium may be either cellular or syncytial. Transient rupture of the occasional maternal blood vessel is probably instigated by the fetal trophectoderm at the edge of the haemophagous zone, but the details of the mechanism are unclear. The endothelial break is soon repaired and the uterine epithelium reforms over the top (Leiser and Enders, 1980b).

The gross form of the haemophagous zone or organ is very characteristic of the species. Cats and dogs (Figure 4.65) have green or brown borders to their zonary placentas coloured by blood pigment residues, and in the sea otter there is a large central pedunculate sac. There is an excellent review of haemophagous zones by Burton (1982).

The intimate relationship of the fetal and maternal blood vessels in the cat and the relative volumetric insignificance of the tissue in between is elegantly demonstrated by Leiser's SEM study of corrosion casts of the two vasculatures. These clearly show that maternal blood passes directly to the fetal side of the placenta and fetal blood to the maternal side prior to flowing back through their capillary systems. The arrangement of the arteriolar supply to the capillary networks

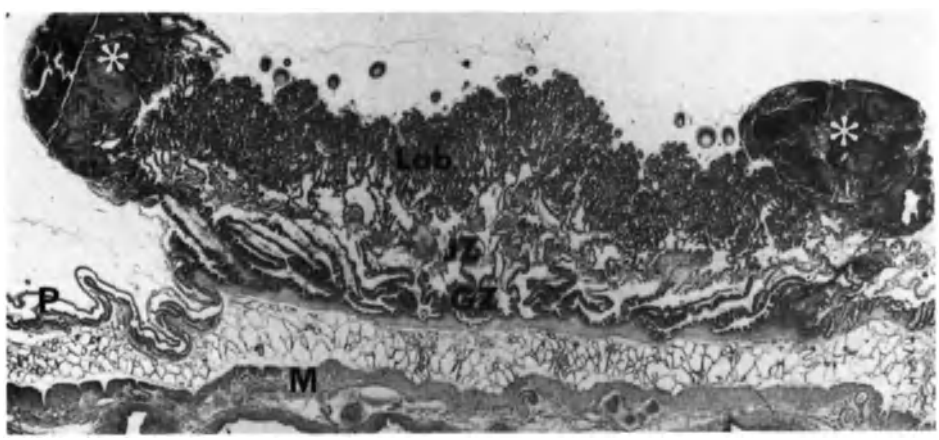

Figure 4.65 Endotheliochorial dog placenta. Cross-section through the zonary placenta of the dog at mid-pregnancy. Note the large marginal haemophagous zones (asterisks). Lab, labyrinthine chorioallantoic placenta; JZ, junctional zone; GZ, glandular zone; M, muscle in uterine wall; P, paraplacental chorioallantoic placenta. About 35 dpc, × 15. (From Bjorkman, 1970.)

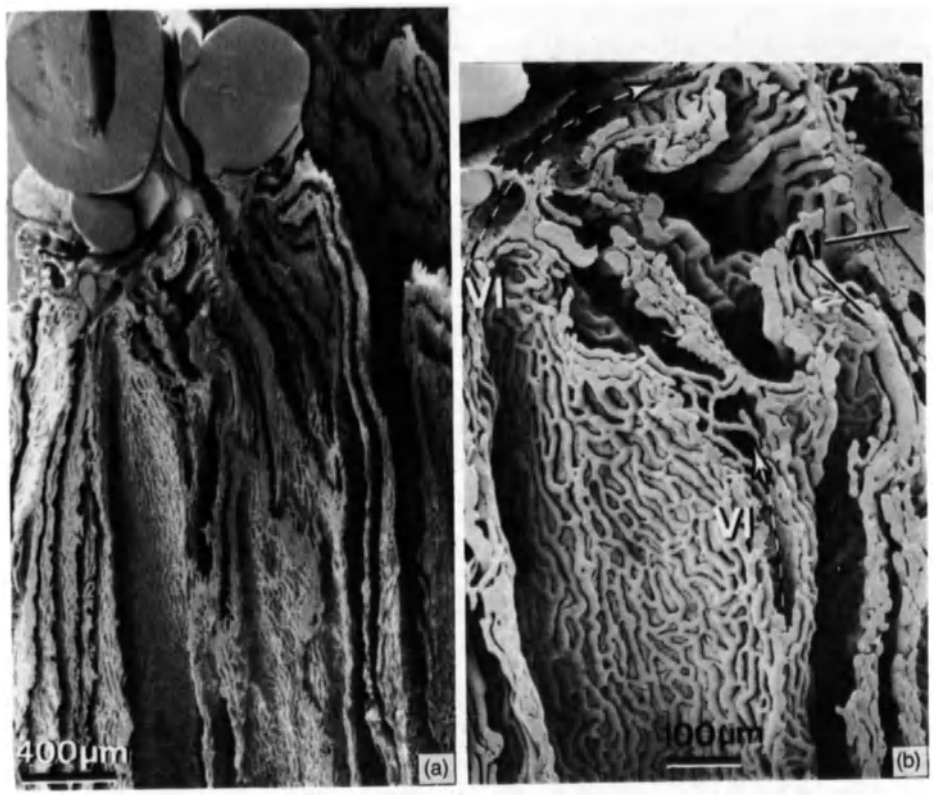

Figure 4.66 Endotheliochorial cat placenta. Corrosion casts of resin-injected vasculature. (a and b) fetal and, Figure 4.67, maternal blood vessels. Note the lamellae formed from the fetal capillary meshwork in the labyrinthine zone in (a) and (b). The casting resin filled fetal arterioles (AI) and capillaries but not the venules (VI), whose lumina are indicated by the dashed arrows in (b). (a) 57 dpc, × 25. (b) 57 dpc, × 100. (From Leiser and Kohler, 1984.)

is such that Leiser considers the flow to be predominantly cross-current (Figures 4.9, 4.66 and 4.67) (Leiser and Kohler, 1983).

Erosion of the original endometrial cells in the dog and cat is practically complete except for a population of cells which are distributed fairly evenly throughout the placenta in the amorphous (interstitial) material between fetal syncytium and maternal endothelium (Figure 4.68).

Wislocki and Dempsey (1946) suggested that these cells originate from fibroblasts. They are typically large, 30–50 μm with a large, or often two large, nuclei. They resemble fibroblasts in their massive fibrillar tracts but also have the swollen rough endoplasmic reticulum and large Golgi apparatus which suggests they may have considerable synthetic and secretory potential (J.W. Anderson, 1969; Malassine, 1974). Once the placenta is established these cells can divide and maintain their frequency as the placenta grows. They are very similar in ultrastructure and position to the residual endometrial cells described above for the sheep and goat synepitheliochorial placentas, and their function is equally enigmatic (Figure 4.69).

Descriptions of endotheliochorial placental development refer to a zone of necrosis in the endometrium at the tips of the advancing fetal villi. In this region the gland epithelium becomes syncytial, the connective tissue

oedematous, and both degenerate. From transverse sections of the placenta the impression given is that the necrotic zone represents an area of total tissue breakdown induced by the fetal syncytium, which then phagocytoses the resulting debris (Amoroso, 1952; Barrau *et al.*, 1975). The process is in fact very selective since the maternal blood vessels pass through this zone completely unchanged and they probably represent 30–50% of the volume of the structures initially present (Leiser and Kohler, 1983). The closest analogy might be a building on extensible stilts, which are sufficiently robust to support and supply the building of the upper floors. These would correspond to the initial chorio-vitelline placenta. The blood vessel 'stilts' would eventually be incorporated into the final structure by growth of the chorioallantoic lamellar placenta. The initial distribution of the maternal vasculature would thus determine the basic pattern of placental development. To accurately test this hypothesis would require corrosion cast studies during placental development, since both volume and distribution of the blood vessels would be critical to the process.

The characteristics of carnivore placentation are remarkably consistent. The initially weakly vascularized endotheliodichorial villous choriovitelline placenta is colonized by the rapidly proliferating allantoic vasculature

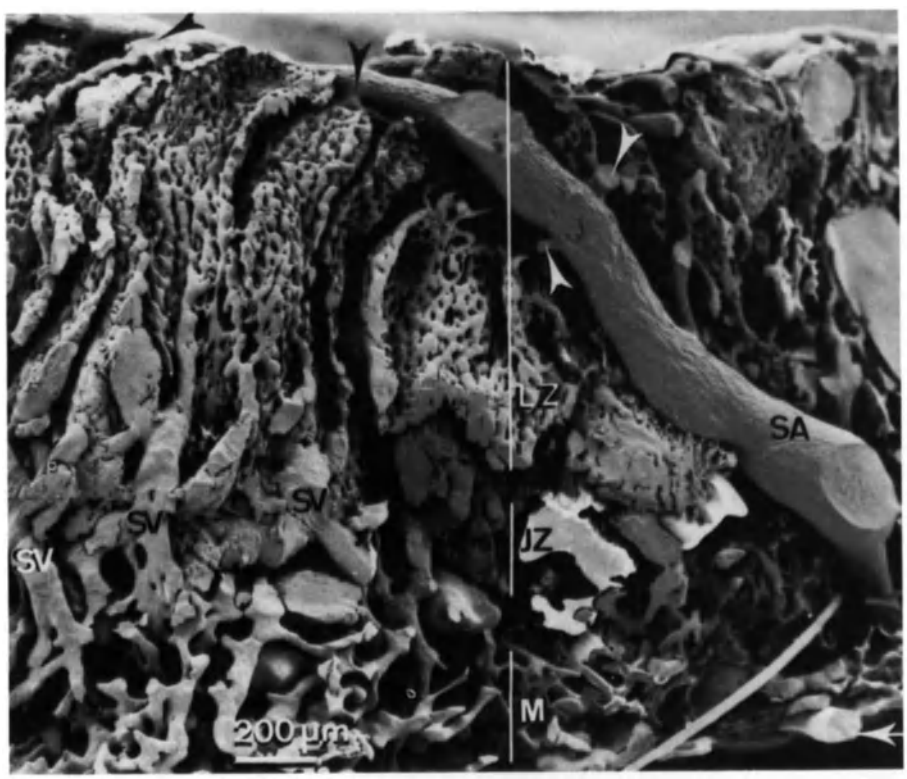

Figure 4.67 Endotheliochorial cat placenta. Corrosion cast of maternal blood vessels. The maternal stem artery (SA) runs through the full depth of the placenta before supplying (arrowheads) the capillaries of the labyrinthine zone (LZ). The capillaries collect into broad venules (SV) in the junctional zone (JZ), which drain into veins (white arrow) in the endometrial muscle layer (M). Compare this figure with the histological cross-section of the dog placenta in Figure 4.65. 22 dpc, × 12. (From Leiser and Kohler, 1983.)

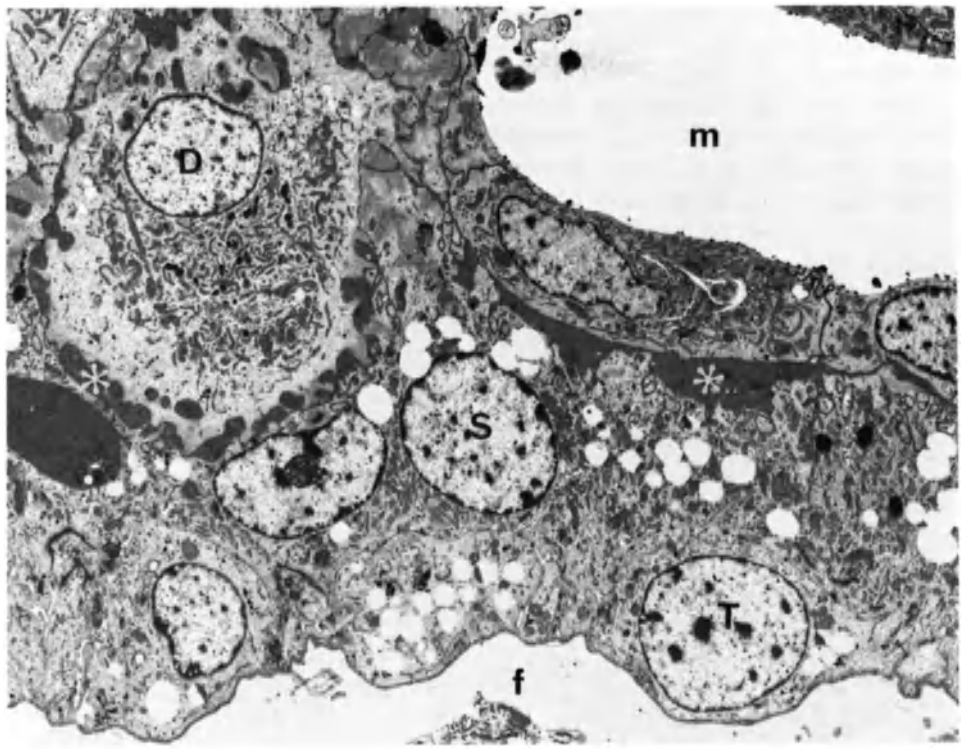

Figure 4.68 Endotheliochorial placentation. Electron micrograph of the definitive interhaemal layers in a cat placenta. 'Decidual' cells (D) in the maternal connective tissue are consistently present. They have extensive rough endoplasmic reticulum, large Golgi bodies and glycogen deposits. This ultrastructure is similar to that seen in cells in a similar position in sheep placenta (see Figure 4.69). f, fetal connective tissue; T, cellular trophectoderm; S, syncytial trophectoderm; asterisks, 'interstitial layer'; m, maternal blood vessel. 35 dpc, × 3000.

to produce the endotheliodichorial chorioallantoic placenta. This is always associated with a haemophagous zone, a large allantoic sac and a significant yolk sac remnant. The only exception so far reported is the hyena, which has the typical large allantois and persistent yolk sac but a haemomonochorial definitive placenta (Figure 4.10a) which still has a marginal sinus similar in size to that of the cat haemophagous zone but filled with circulating rather than static maternal blood (Dempsey, 1969; Oduor-Okelo and Neaves, 1982; Wynn *et al.*, 1990).

There are even more intermediate stages between endotheliochorial and haemochorial structure shown by bats (Chiroptera) (Bhiwgade, 1990; Rasweiler, 1993), of which the families with the more primitive characteristics are endotheliochorial with clearly defined (Emballonuridae) or more diffuse (Megadermatidae) equivalents of a haemophagous zone (Gopalakrishna and Karim, 1979; Mossman, 1987). There is far more destruction of the maternal endometrium by the bat trophectoderm in the haemophagous zone than in carnivores and plainly, if the erosion continued to encroach on the main placenta, the haemochorial type would result, as seen in Desmodontidae (Bjorkman and Wimsatt, 1968), Molossidae (Stephens, 1969; Stephens and Cabral, 1971, 1972; Rasweiler, 1990, 1991), Phyllostomatidae

(Bodley, 1974; Bleier, 1975), Thyropteridae (Wimsatt and Enders, 1980) and Vespertilionidae (Kimura and Uchida, 1984), Pteropodidae and Hipposideridae (Bhiwgade, 1990). Rasweiler (1991) has recently provided an excellent account of the development of the haemomonochorial placenta in *Molossus ater*.

It is possible that the intrasyncytial lamella (ISL) present in all haemochorial bats so far examined closely (Figures 4.11 and 4.99) may be analogous to the endotheliochorial interstitial membrane (Rasweiler, 1993). The ISL consists of a discontinuous system of membrane-bound channels filled with basement membrane-like material. It is usually sporadically continuous with the maternal blood space, but in one molossid bat (Stephens, 1969) is continuous with the fetal syncytiotrophoblast basement membrane instead (Figure 4.11). Transport and skeletal functions have been suggested (see section 4.2.7a). Other families of bats (Hipposideridae, Noctilionidae, Rhinolophidae and Rhinopomatidae, (J.W. Anderson and Wimsatt, 1963; Gopalakrishna and Karim, 1979; Mossman, 1987) are said to have endotheliochorial placentas but no haemophagous zone – thus that linkage is by no means absolute. The endothelial nature of the definitive placenta of the Rhinopomatidae, Emballonuridae, Megadermatidae and

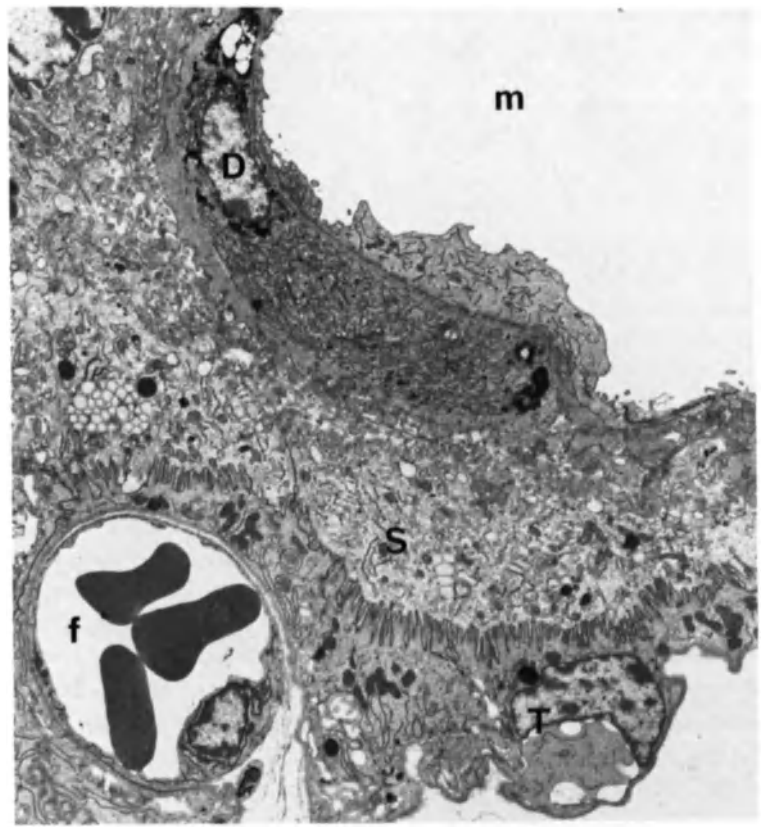

Figure 4.69 Synepitheliochorial placentation. The (maternal) endometrial connective tissue in the mature sheep placenta has 'decidual cells' (D) with similar ultrastructure and in a similar position to those found in cat placenta (Figure 4.68). f, fetal blood vessel; T, cellular trophectoderm; S, syncytial fetomaternal trophectoderm; m, maternal blood vessel. 140 dpc, × 4000.

Rhinolophidae has now been clearly established in a recent comparative electron microscope study (Bhiwgade, 1990). This supports the light microscope evidence that the Noctilionidae are also endotheliochorial (J.W. Anderson and Wimsatt, 1963).

It was only by a study of the ultrastructure that the placenta of the insectivore *Blarina* (common shrew) was shown to be endotheliochorial (Wimsatt *et al.*, 1973). The syncytial trophoblastic layer is uniquely attenuated and profusely fenestrated, and both maternal and fetal capillary endothelial cells extend slender processes from their bases to or through this lace-like trophectoderm (Figure 4.70b).

It certainly would be no barrier to macromolecules but may have some residual role in regulation or prevention of maternofetal cell traffic. A recent suggestion that in the final week of pregnancy it forms no significant barrier at all (Kiso *et al.*, 1990) requires confirmation.

The shrews (Soricinae) also have an unusual annular haemophagous zone with absorptive trophectoderm underlain by vitelline (yolk sac) capillaries (B.F. King *et al.*, 1978) rather than the usual allantoic vascular system as in carnivores or bats. This emphasizes again the plasticity of the fetal membranes with quite different parts adapting to serve the same function. Fenestrated syncytiotrophoblast has been found in only one other order, Bradypodidae, the sloths, again one with an endotheliochorial placenta. Here the layer is more substantial than in the shrews but still essentially porous. There is no haemophagous zone and the rest of the fetal membranes are, according to Mossman (1987), more reminiscent of anthropoids with a very early vascularization of the eventually discoid chorioallantoic placenta and the small non-persistent yolk sac (B.F. King *et al.*, 1982).

Other examples of endotheliochorial placentation very similar to the carnivore interhaemal membrane in structure are found in widely separated orders. Some of these have an accompanying haemophagous zone, as in the Elephantidae (Perry, 1974), but most [the aardvark (Orycteropodidae), two insectivores, *Talpa* (Malassine and Leiser, 1984) and *Tupaia* (Luckhardt *et al.*, 1985), and the rodent, *Dipodomys* (Figure 4.71) (the kangaroo rat, B.F. King and Tibbitts, 1969)] have no equivalent structure.

The endotheliochorial placenta thus appears to be a successful solution for a variety of animals in a wide range of habitats with very different reproductive habits and maternal sizes. A haemophagous zone is a sufficiently frequent accompaniment to endotheliochorial placentation to indicate one advantage in developing a fully haemochorial placenta. Most orders with endotheliochorial placentas also have members with the haemochorial type.

(d) Haemochorial placentation (mouse, rabbit, man, apes, monkeys)

The epitheliochorial–synepitheliochorial–endotheliochorial sequence represents a gradual loss of interhaemal layers. The haemochorial is an apposite end to such a sequence; with the loss of all the maternal tissue, maternal blood irrigates the chorioallantoic fetal trophectoderm directly (Figure 4.5).

Previous suggestions that in some species the fetal trophectoderm is also lost have not been substantiated by subsequent EM studies. The trophectoderm may be very thin but no placenta yet accurately described lacks a trophectoderm or its derivative as a barrier for the maternal blood, although pores in the trophectoderm have been reported (B.F. King, 1992). Depending on the species the trophectoderm may have one, two, or three layers, each of which may be cellular or syncytial. The species-specific pattern is established soon after implantation and is maintained to term.

Fetal placental tissue is usually aggregated in a discrete area, discoid or limited zonary.

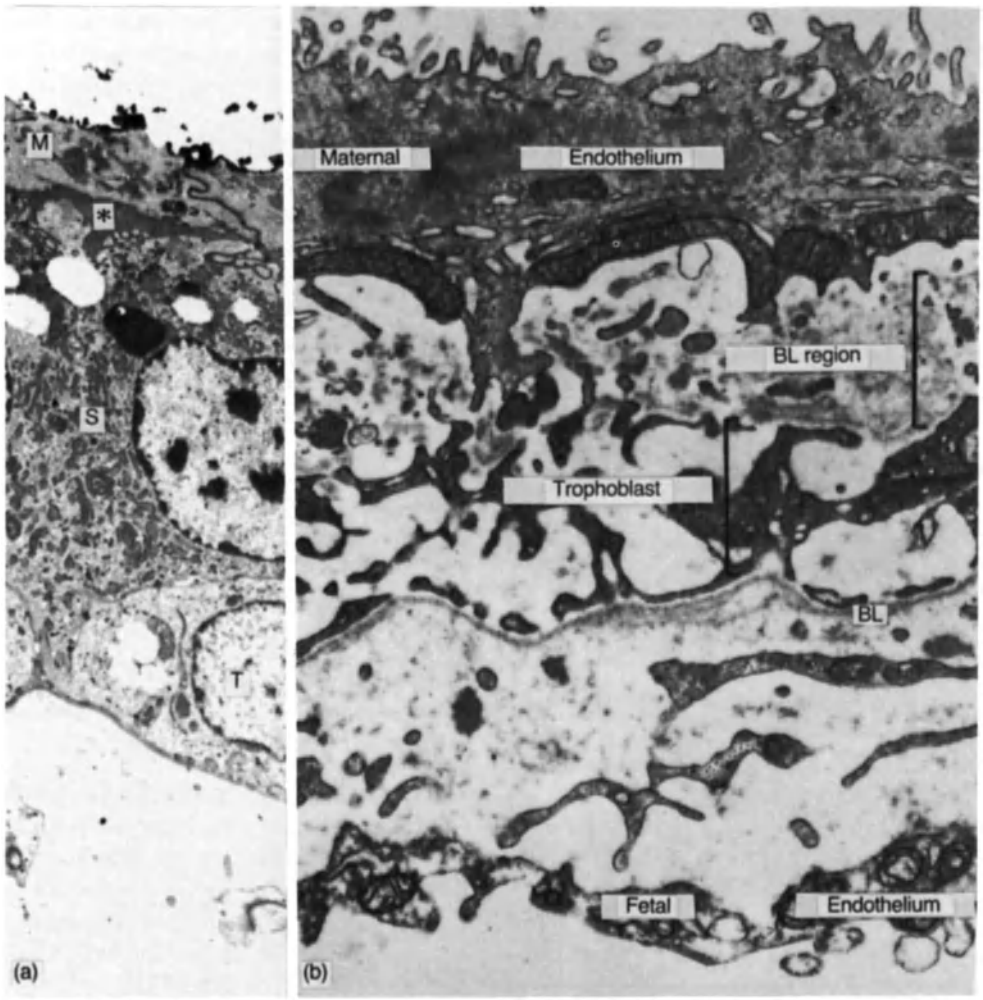

Figure 4.70 Most endotheliochorial placentas display a fairly uniform interhaemal membrane (see Figure 4.68), as typified by the cat (a) with a discontinuous cellular cytotrophoblast (T) which generates the thick syncytial layer (S) separated from the maternal endothelium (M) by a dense acellular interstitial layer (asterisk). However, the insectivore, *Blarina* (b) with its exiguous discontinuous meshwork of syncytiotrophoblast, and the rodent, *Dipodomys* (Figure 4.71), with its extremely thin syncytiotrophoblast layer (Figure 4.71, arrows) clearly demonstrate the variability possible within the endotheliochorial framework. The interstitial layer (asterisk in a; 'BL region' in b; arrowheads in Figure 4.71) is also very different in these examples. BL, trophoblast basement membrane; Fc, fetal capillary; M, maternal capillary. (a) 35 dpc, × 8000. (b) Near-term placenta, × 18 100. (From Wimsatt *et al.*, 1973.)

The structure of the paraplacental area varies, with the yolk sac placenta playing an important role throughout pregnancy in rodents, lagomorphs and insectivores (Figures 4.2 and 4.3) but insignificant in primates. No areolar development has been reported; the glands do not play any significant role except very early in pregnancy.

The erosion of the maternal tissue is considerable, and typically the species with hae-

mochorial placentation induce decidual tissue transformation in the endometrium during placental formation. Again the variation is enormous, with massive decidua in the rodent, moderate in the human and negligible in the rhesus monkey.

It must be emphasized that, although most maternal tissue is lost, major maternal arterial channels persist throughout pregnancy through the full depth of the placenta in most haemochorial placentas supplying maternal blood to the fetal surface (subchorial lakes) of the placenta. Usually several channels persist (rabbit, see below), sometimes only one [in the insectivorean elephant shrew (Starck, 1949)] (Figure 4.72).

The most notable exceptions to this are man, apes and the Old World monkeys.

Haemochorial placentas are rather more varied in gross architecture than previous types with villous or labyrinthine structure and a variable and specific number of interhaemal layers.

As examples of the labyrinthine type with haemotrichorial structure the rat and mouse will be discussed in detail with rabbit (haemodichorial) and man, (haemomonochorial) for comparison.

Haemotrichorial: mouse, *Mus musculus;* rat, *Rattus rattus*

Oestrous cycle: 4–7 days
Ovulation: spontaneous
Uterus: duplex
Litter: 5–9
Gestation: 19 days (mouse) 22 days (rat)
Implantation: interstitial
Amniogenesis: cavitation
Yolk sac: Initial bilaminar yolk sac stretched to disappearing point by mid-pregnancy. No choriovitelline placenta formed. Completely inverted well-vascularized splanchnopleuric yolk sac placenta with villous mesometrial half persists until term (Figure 4.2).
Chorioallantois: Forms definitive placenta, vascularized by allantoic mesenchymal bud (Figures 4.2 and 4.75). The allantoic sac is vestigial or absent.
Shape: discoid, labyrinthine structure
Decidua: extensive development throughout

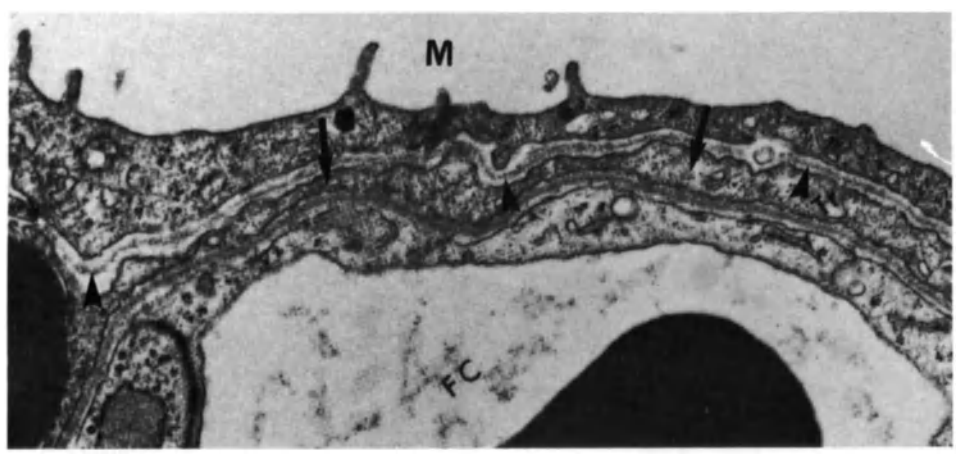

Figure 4.71 Endotheliochorial placentation. The rodent *Dipodomys* has very thin but continuous syncytiotrophoblast (arrows) and interstitial (arrowheads) layers. Compare these structures with those in cat (Figure 4.70a) and shrew (Figure 4.70b) placentas. FC, fetal capillary; M, maternal capillary. Near-term placenta, × 18 000. (From King and Tibbits, 1969.)

pregnancy in the endometrium around the conceptus (see Figure 4.12)

Interhaemal membrane: haemotrichorial labyrinthine, two syncytia next to the fetal tissue and a cellular layer lining the maternal blood space

Accessory placental structure: completely inverted yolk sac

Fetal membranes and placental development

In these rodents the blastocysts reach the uterine lumen on 3–4 dpc and implant after

uterine contractions, finally influenced by the individual blastocysts, have ensured an even spacing. Closure of the uterine lumen then immobilizes the blastocysts and ensures an intimate apposition between blastocyst and uterine epithelium (Enders *et al.*, 1980), a process which may involve specific changes in glycocalyx carbohydrate expression (Kimber and Lindenberg, 1990; Kramer *et al.*, 1990). There is no appreciable swelling of the blastocyst prior to closure, and the blastocyst invariably implants at the antimesometrial side of the uterine lumen, with the embryonic disc mesometrial (Amoroso, 1952; M.H. Kaufman, 1983).

Implantation starts at 5 dpc with intrusion between, or possibly trophectodermal fusion with, the uterine epithelial cells (Figure 4.73) (Bevilacqua and Abrahamsohn, 1989) followed by complete death and delamination of the uterine epithelium (Enders *et al.* 1980; Schlafke *et al.*, 1985; Blankenship *et al.*, 1990 (hamster); Welsh and Enders, 1991a; Blankenship and Given, 1992).

At this stage the blastocyst is bilaminar but mesoderm is starting to form at the edge of the embryonic rudiment underneath the aggregation of trophectodermal cells referred to as the ectoplacental cone. The peripheral trophectoderm of the cone will differentiate into the polar or secondary giant cells which invade the uterine endometrium, by now considerably decidualized (M.B. Parr *et al.*, 1986) (Figure 4.12 and see section 4.2.8 above). Over the antimesometrial two-thirds of the blastocyst, away from the ectoplacental cone, the endodermal cells secrete material which thickens the basement membrane separating the endoderm from the mural trophectoderm which has differentiated into the primary giant cells (Fatemi, 1987; Mazariegos *et al.*, 1987). This thickened basement membrane is then referred to as Reichert's membrane (Figure 4.3). The mural or primary giant cells rupture the maternal blood vessels and form lace-like extensions through which the blood circulates but does not penetrate past Reichert's membrane (M.H. Kaufman, 1983; Welsh and Enders, 1987). The endoderm and primary giant cells then form a non-vascularized bilaminar yolk sac placenta. As the blastocyst develops and increases in size this bilaminar region maintains a similar structure but becomes ever thinner, eroding the decidua capsularis between the giant cells and the myometrium but finally completely rupturing on 17–18 dpc. This exposes the vascularized endodermal layer (referred to as the inverted visceral yolk sac placenta) to the newly restored uterine epithelium (Welsh and Enders, 1983) (Figures 4.3 and 4.12). Absorption of maternal immunoglobulins across this placenta throughout pregnancy is of considerable importance to neonatal immunoregulation (Bainter, 1986).

After the initial differentiation of the giant cells the yolk sac inverts beneath the embryo; above, the allantoic outgrowth from the fetal gut reaches the base of the ectoplacental cone (Figure 4.2). This has been beautifully demonstrated by SEM (Figures 4.74 and 4.75) (Ellington, 1985, 1987).

The cone appears to have three layers: inner, outer and a shell of secondary giant cells invading the mesometrial decidua basalis. As soon as the allantoic outgrowth reaches the bottom of the ectoplacental cone it erodes the endoderm and spreads out into a mesodermal pad closely underlying the inner ectodermal layer of the cone. An excellent pictorial sequence of placental membrane and embryonic development can be found in Rugh (1975).

Considerable structural reorganization together with the stimulation of rapid cellular division in the cone tissue follows and outgrowths of cone cells into the decidualized endometrium initiate the discoid chorioallantoic placenta (Welsh and Enders, 1991b; Enders and Welsh, 1993) (Figure 4.76).

By this time the outer giant cell layer is irrigated by maternal blood and is actively eroding the maternal decidual tissue and

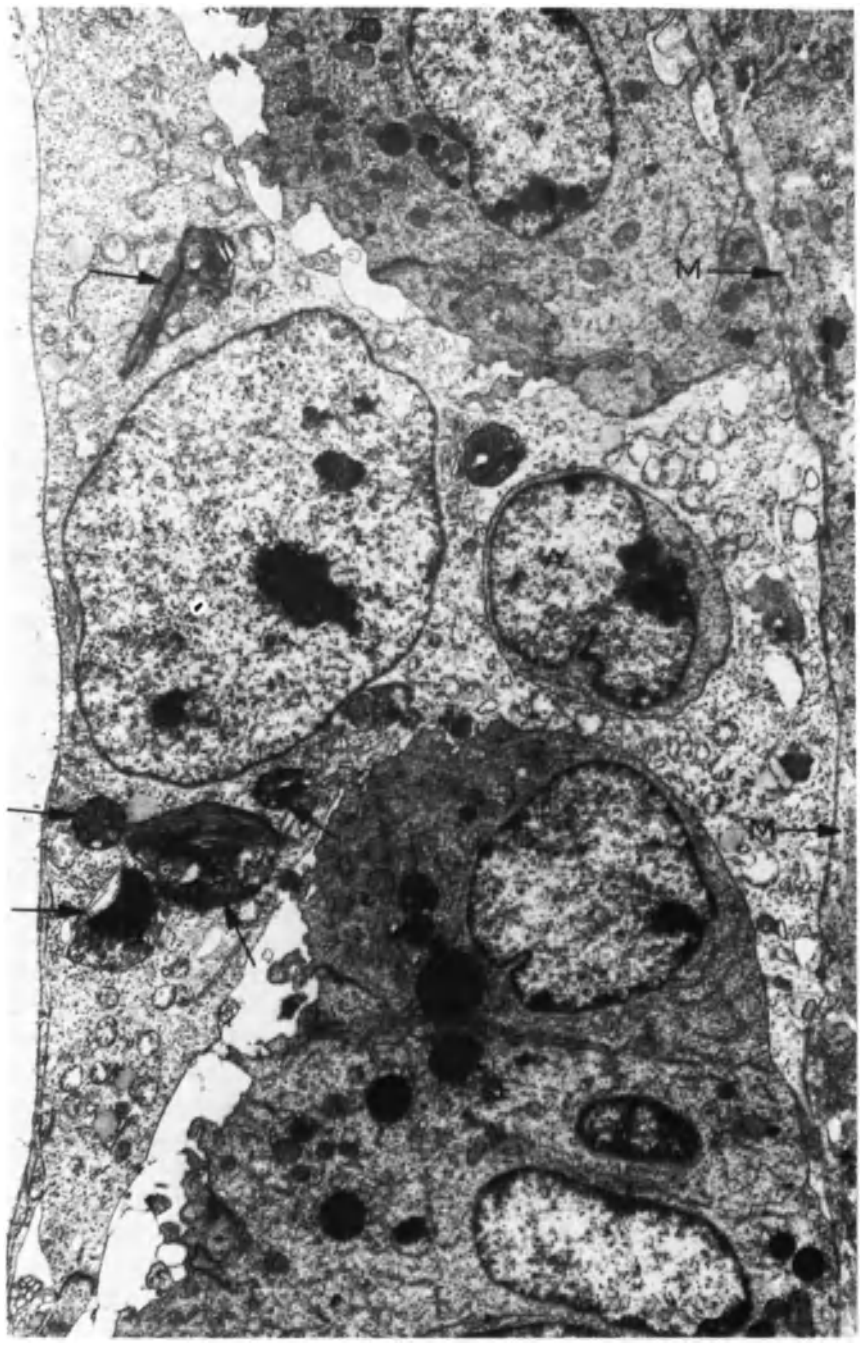

Figure 4.73 Haemochorial placentation. Early implantation in the mouse. A trophectoderm cell (T) containing several lysosomes (arrows) has completely penetrated through to the basement membrane of the uterine epithelium (M), apparently phagocytosing or flowing round a uterine epithelial cell (A) in the process. This could be the result of intrusion or fusion; adjacent uterine epithelial cells seem unaffected. 5½ dpc, × 3450. (From Kaufman, 1983.)

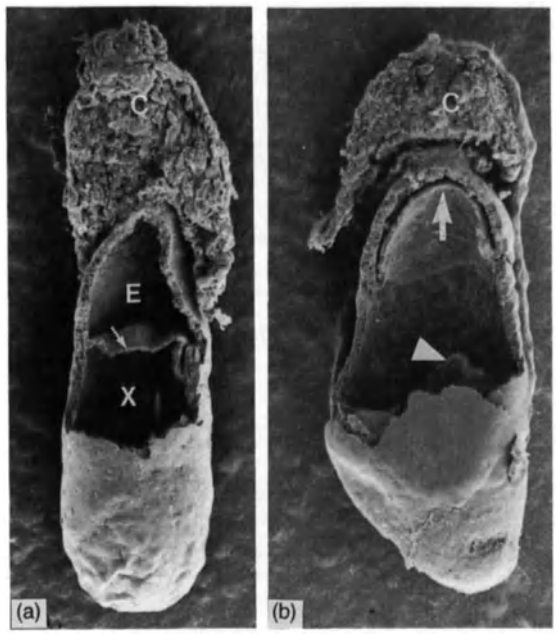

Figure 4.74 Scanning electron micrographs of the rat conceptus after removal of the parietal yolk sac, all at the same magnification, dissected to show the internal membrane development. (a and b) Expansion of the exocoelom (X) inverts the chorion (small arrow) which bounds the ectoplacental cavity to form a double layer of trophectoderm lined with mesoderm (large arrow) under the ectoplacental cone (Figure 4.75a). This forms the basis for development of the allantochorionic placenta when vascularized by growth (Figure 4.75a and b) of the solid mesodermal allantois (arrowheads) which originates from the hind gut of the embryo, here covered by the amnion (A). (a) 9.25 dpc, × 220. (b) 9.25 dpc, × 220. (From Ellington, 1985, 1987.)

expanding into the vascular sinuses. Giant cells do not divide, but are replenished by smaller cells at the surface of the ectoplacental cone. The allantoic vasculature is aggressively growing into the tissues at the base of the ectoplacental cone. The cone is considerably differentiated and is starting to form villi [Metz, 1980 (rat); Carpenter, 1972, 1975 (hamster, which is also haemotrichorial)] (see Figure 4.76). As these villi grow they too extend into the maternal blood sinuses. The fetal blood is then separated from the maternal by three layers, two syncytia derived from the inner ectoplacental cone layers and the outer cellular layer grading into the giant cells. These are the basic interhaemal layers through the rest of gestation and the usual nomenclature is maternal blood/layer I/ layer II/layer III/fetal endothelial basement membrane/fetal endothelium/fetal blood (Figure 4.76).

The fetal villi become confluent with one another as they increase in length at the expense of the decidua basalis tissue, eroding the maternal venous capillaries and colonizing the sinuses. The main maternal arterial channels are not destroyed (about 4–7 per discoid placenta) but run through the whole thickness of the placenta directly to the subchorial lake at the base of the fetal placenta, from where the maternal blood flows back through the labyrinthine network formed by the fetal tissue growth (Figures 4.77 and 4.78).

The persistent maternal arterial channels are initially lined with maternal endothelium but this is displaced and phagocytosed by giant cells at an early stage. The process eventually produces widened channels lined with fetal cells (endovascular trophectoderm) extending as far as the uterine muscle layer [Legrand, 1974 (rat); Pijnenborg *et al.*, 1981 (man); Carpenter, 1982 (hamster); Hees *et al.*, 1987 (guinea pig)].

Growth of a haemotrichorial placenta like that of the rat or mouse presumably is based upon small groups of mitotically active cells continuous with the main attenuated layers (I, II and III) which separate fetal and maternal blood. Layers II and III are in fact syncytial from the earliest stage and, as no nuclear division has yet been reported in such syncytia, some system for growth and extension of the layers is necessary (Davies and Glasser, 1968; Metz, 1980). Layers II and III are very closely apposed and connected by numerous gap junctions whose function is obscure (Metz *et al.*, 1976) (see section 4.2.7a

above). The combined layers form a complete barrier to tracers introduced into maternal (Metz *et al.*, 1978) or fetal (Aoki *et al.*, 1978) circulations. The outermost layer (I) is cellular and fenestrated, and forms no barrier to tracers added to the maternal circulation. Enders (1965) has suggested that this layer I functions by slowing the maternal blood flow and forming local regions of blood stasis behind the fenestrations which facilitate feto-maternal transport. There may be special difficulties in fetal uptake from maternal blood which are alleviated by such a slowing of the flow. Clearly a balance is needed between rapid flow to maintain solute concentrations and efficient capture of the substrates by the translocases in the plasmalemma. All three layers (I, II, III) attenuate during pregnancy but no significant ultrastructural changes have been reported (Jollie, 1969, 1979; B.F. King and Hastings, 1977; Jollie and Craig, 1979; Metz, 1980). The first cells to differentiate are the primary giant cells around the antimesometrial and lateral aspects of the conceptus. At 6–7 dpc they form a more or less continuous shell around the conceptus with the secondary giant cells which differentiate subsequently around the

(From Christofferson and Nillson, 1988.)

edge of the ectoplacental cone. The giant cells have been shown to produce steroids (Deane *et al.*, 1962), placental lactogens (rat, Campbell *et al.*, 1989; Duckworth *et al.*, 1990; mouse, Nieder and Jenne, 1990; hamster, Renegar *et al.*, 1990; reviews, Soares *et al.*, 1991; Southard and Talamantes, 1991) and relaxin (golden hamster, Johns and Renegar, 1990). The giant cells become very large with a characteristically enormous, deeply divided nucleus, of variable but usually very high DNA content (up to 1024 N). As the embryo grows the giant cells become stretched, and some of the secondaries are replaced by cell division in the underlying cone tissue (Ilgren, 1983; M.H. Kaufman, 1983). These secondary giant cells are rarely as large as the primaries and grade into the cells of the trophospongial layer which form a meshwork through which the maternal blood flows. Unlike the adjacent labyrinthine layer there is no fetal vascularization and the trophospongium has a fine structure very different from the giant cells, but both are of the layer I population.

Layers II and III are dependent on the fetus for continued growth and maintenance, since fetectomy at 12 dpc results in their rapid degeneration together with the fetal villi. However, layer I continues to grow after fetectomy as a residual meshwork in which

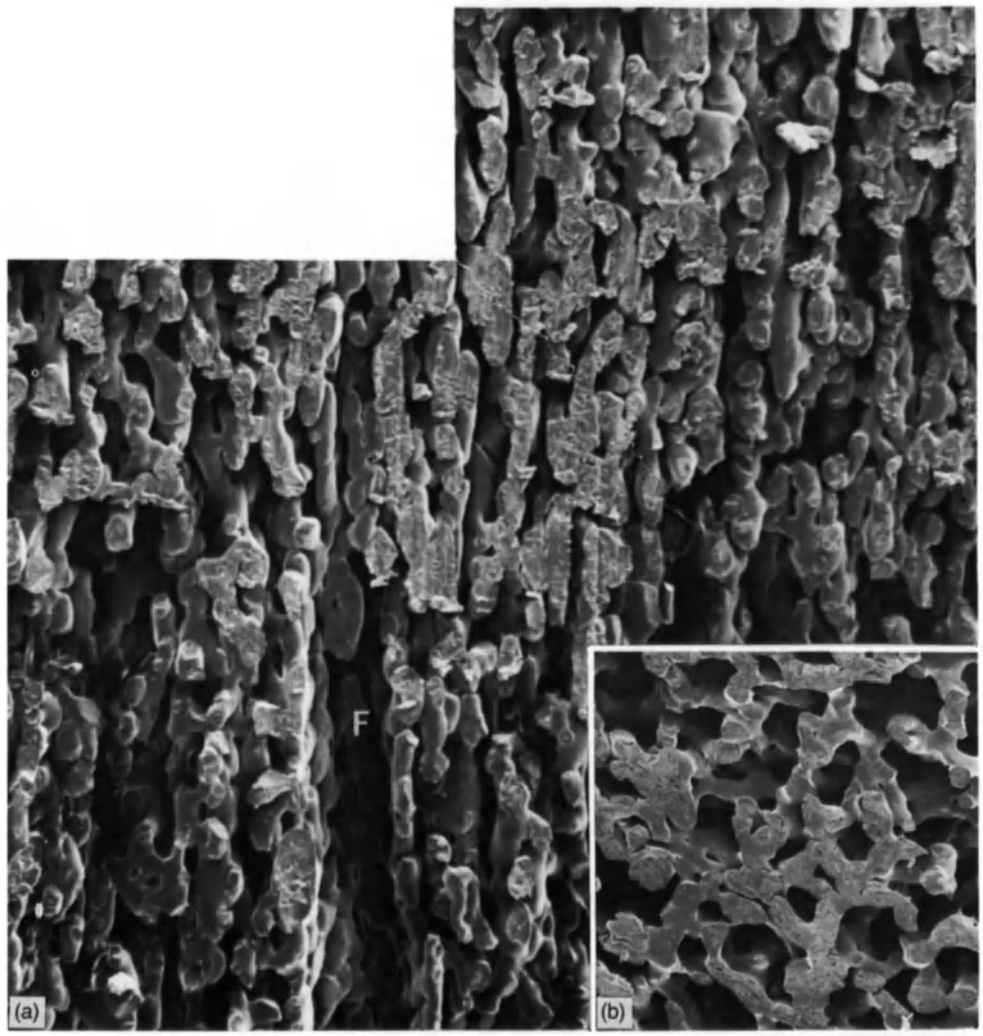

Figure 4.78 Haemochorial rat placenta. Corrosion casts of the maternal labyrinthine blood spaces. The labyrinthine architecture is elegantly demonstrated in (a) with a predominant direction of flow from the chorionic plate (top of micrograph) to the myometrium. (b) At 18 dpc the maternal blood spaces are smaller and there is no obvious direction in the structure. F, space occupied *in vivo* by the fetal vessels and membranes. (a) 22 dpc, × 150. (b) 18 dpc, × 150. (From Christofferson and Nillson, 1988.)

the maternal blood circulates (Davies and Glasser, 1968).

Haemodichorial: rabbit, *Oryctolagus cuniculus*

Oestrous cycle: none
Ovulation: on coital stimulation
Uterus: duplex
Litter: 8–12
Gestation: 30–32 days
Implantation: superficial, antimesometrial
Amniogenesis: folding
Yolk sac: (1) Large bilaminar non-vascular yolk sac persists until 16 dpc, then finally ruptures. Consists of giant trophectoderm cells, a basement membrane (much thinner

than the equivalent Reichert's membrane in the rodents) and endoderm.

(2) Inverted yolk sac placenta, vascularized villus folds adjacent to embryo. Active in uptake of macromolecules, especially immunoglobulins, during pregnancy.

Chorioallantois: definitive placenta vascularized by mesoderm of allantoic sac

Shape: discoid, labyrinthine internal structure

Decidual development: considerable

Interhaemal membrane: haemodichorial

The early conceptus development is very different from the rodents, but differentiation of the yolk sac and chorioallantoic placenta is essentially similar (Amoroso, 1952).

There is considerable blastocyst swelling prior to central implantation between 7 and 8 dpc (Figure 4.79).

Even spacing of blastocysts is achieved by the usual uterine muscle contractions refined eventually by interaction with the expanding blastocysts. Sea urchin eggs introduced into the pseudopregnant uterus are also evenly distributed although they are much smaller than the blastocyst (Boving, 1971).

Changes in the uterine epithelial glycocalyx at implantation are detailed in T.L. Anderson and Hoffman (1984) and T.L. Anderson *et al.* (1986). The first cellular changes at implantation are fusion between apposed syncytial trophectodermal knobs and cellular uterine epithelium, initially at the antimesometrial side and subsequently over the mesometrial side (where the chorioallantoic placenta eventually forms) (Larsen, 1961; Enders and Schlafke, 1971a). The uterine epithelium then fuses into syncytial plaques, each with a fairly constant number of nuclei and characteristic ultrastructure. This change also occurs in pseudopregnancy,

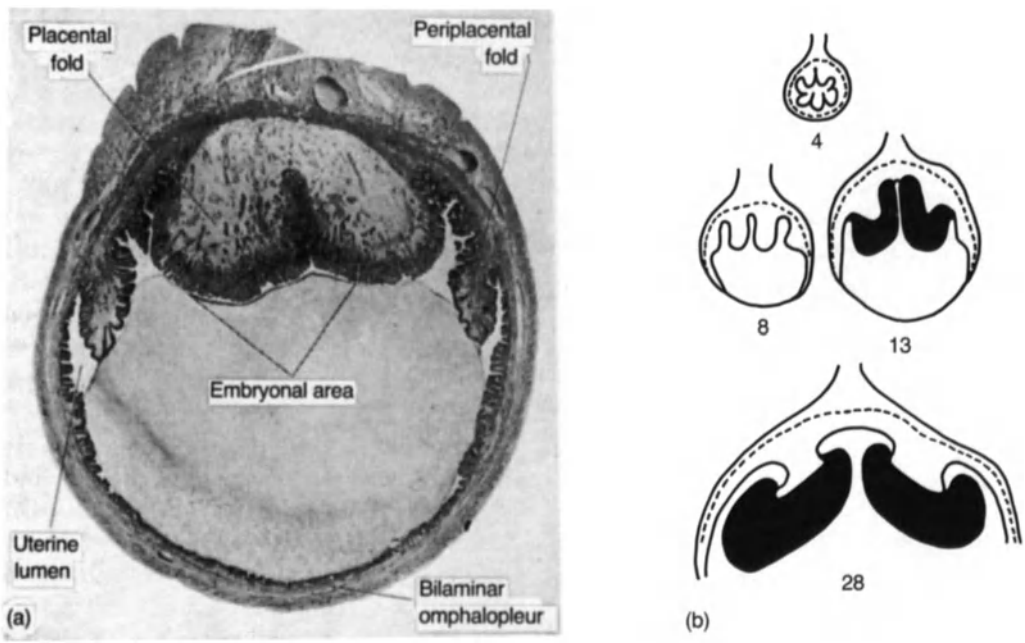

Figure 4.79 Haemochorial placenta of the rabbit. The blastocyst swells considerably before implantation (a). The chorioallantoic placenta develops mesometrially in two cotyledonary masses which increase considerably in extent during pregnancy, as shown diagrammatically in (b) (drawn actual size). (a) 8 dpc, × 7. (b) Traced from Hafez and Tsutsumi, 1966; the numbers indicate dpc; term = 30/32.

and can be induced with the correct hormonal regimen with no conceptus present (Davies and Hoffman, 1975; Davies and Davenport, 1979).

Over the antimesometrial half of the uterus the fetomaternal hybrid syncytiotrophoblast displaces the uterine epithelial syncytial plaques which degenerate into symplasmic masses which are eventually sloughed and removed by phagocytosis. In the absence of a blastocyst or physical trauma the syncytial plaques disappear in a much more controlled fashion. Reversion of individual multinucleate cytoplasmic areas to single uninucleate cells has been claimed (Busch *et al.*, 1986). However, restoration of the uninucleate epithelium seems more likely to be by proliferation of residual uninucleates as in ruminant intercotyledonary areas.

The number of fetal nuclei incorporated into the maternal syncytiotrophoblastic knobs is not known, nor is their fate. Larsen (1961) says they 'dissolve' but offers no pictorial evidence for this. The (feto?)maternal syncytiotrophoblastic knobs which penetrate the antimesometrial uterine epithelium basement membrane seem to be directly involved (Blackburn *et al.*, 1989) in the production of the uninucleate giant cells which form all round the lateral and antimesometrial aspects of the conceptus (Amoroso, 1952). Yolk sac development, with an antimesometrial bilaminar segment which ruptures at 16 dpc, leaving a fully inverted yolk sac placenta, is essentially similar to the rodents.

At the mesometrial pole once the amniotic folds have fused, the trophectoderm over the embryo invades and displaces the uterine epithelial syncytial plaques and subsequently penetrates the maternal endothelium as it did over the antimesometrial region (Hoffman *et al.*, 1990a,b). The invading fetal tissue does not form any structure equivalent to the ectoplacental cone in rodents but presents a broad syncytial front toward the decidualizing maternal tissue, backed by and presumably formed from the cellular cytotrophoblast (Figure 4.79). Thus, as soon as the fetal processes reach the maternal blood spaces they have the haemodichorial structure, layer I syncytial, layer II cellular, which characterizes the definitive placenta (Enders, 1965; Enders and Schlafke, 1971a). The allantoic vesicle has by now (9 dpc) reached the mesometrial trophectoderm and it then actively vascularizes the extending front of fetal tissue. As in the rodents the larger arteries are invaded by trophectoderm (Pijnenborg *et al.*, 1981) but persist as channels running through the full depth of the forming labyrinthine haemodichorial placenta to supply maternal blood to the subchorial lake at the base of the fetal placenta (Figure 4.72) (Hafez and Tsutsumi, 1966; Carter *et al.*, 1971). From here it flows in the newly formed fetal tissue channels and drains via maternal veins. Considering the final dimensions, the placenta must grow by extension of the fetal tissue just as much as by erosion of the endometrium (Figures 4.79 and 4.80).

The definitive placenta does not have quite the same gross sequence of maternal decidua/fetal giant cells/fetal trophospongium (no fetal vascularization)/fetal labyrinth as do the rodents since there are few, if any, giant cells in this area in the rabbit. There is no evidence for any placental lactogen production either. The haemodichorial interhaemal membrane persists but attenuates gradually to term (Samuel *et al.*, 1975). Layer II is normally much thinner than I, but both vary considerably (Figure 4.81a and b) and can be equally thin (Figure 4.81c).

They are frequently connected by small desmosomes and gap junctions (Figure 4.81b). The ultrastructure of the spongiotrophoblast is similar to that in layer I of the labyrinth but quite different from that in the adjacent giant cells (Figure 4.82).

Since the maternal blood flows back from the fetal subchorial lake and the fetal from the opposite maternal side of the placenta, the flows are grossly countercurrent. This does not imply that the fetal blood capillaries run

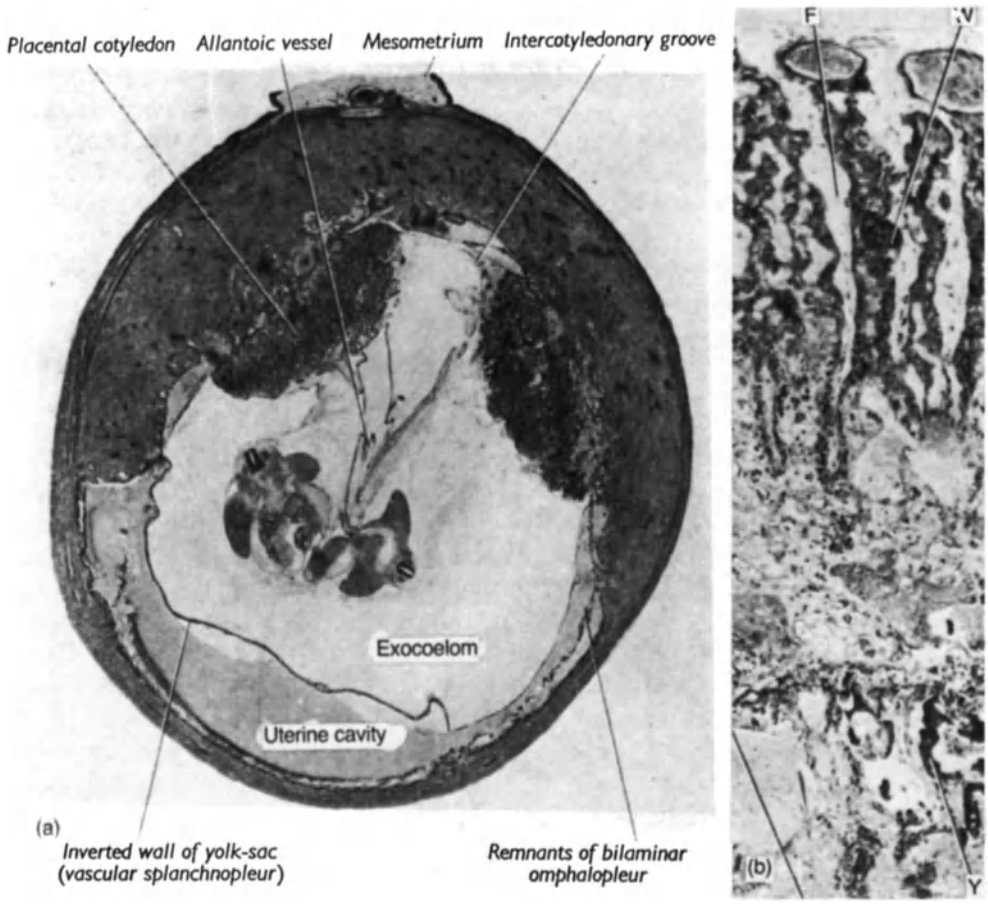

Figure 4.80 Haemochorial placenta of the rabbit. (a) Early development of the two placental cotyledons; the histological structure of this 12 dpc placenta is shown in (b). The fetal villi (F) and the maternal blood sinuses they enclose (W) increase in length continuously so that invasion of the maternal endometrium only accounts for a small proportion of total final depth of the placenta. Note the symplasmic remnant (Y) of a gland in the junctional zone. (a) 12 dpc, × 6.5. (b) 12 dpc, × 6.5.

parallel to the maternal channels through the entire depth of the placenta, but rather that the two blood flows (microflows, see Figure 4.8) maintain a very close relationship for a sufficient distance to allow efficient gaseous exchange. This capillary length is what Mossman (1965) refers to as an 'exchange distance'.

Just before parturition (28 dpc) a discrete thin lamina of uninucleate decidual cells forms on the myometrial side of the decidua basalis (Mossman, 1987). This forms the zone of separation of the placental stalk, which is considerably narrowed at parturition. These two processes, together with contraction of the myometrium, reduce the placental scar to minimum dimensions (Amoroso, 1952). The myometrial contractions are considerably enhanced at this time by the increase in frequency of gap junctions between individual smooth muscle cells (Cole and Garfield, 1989).

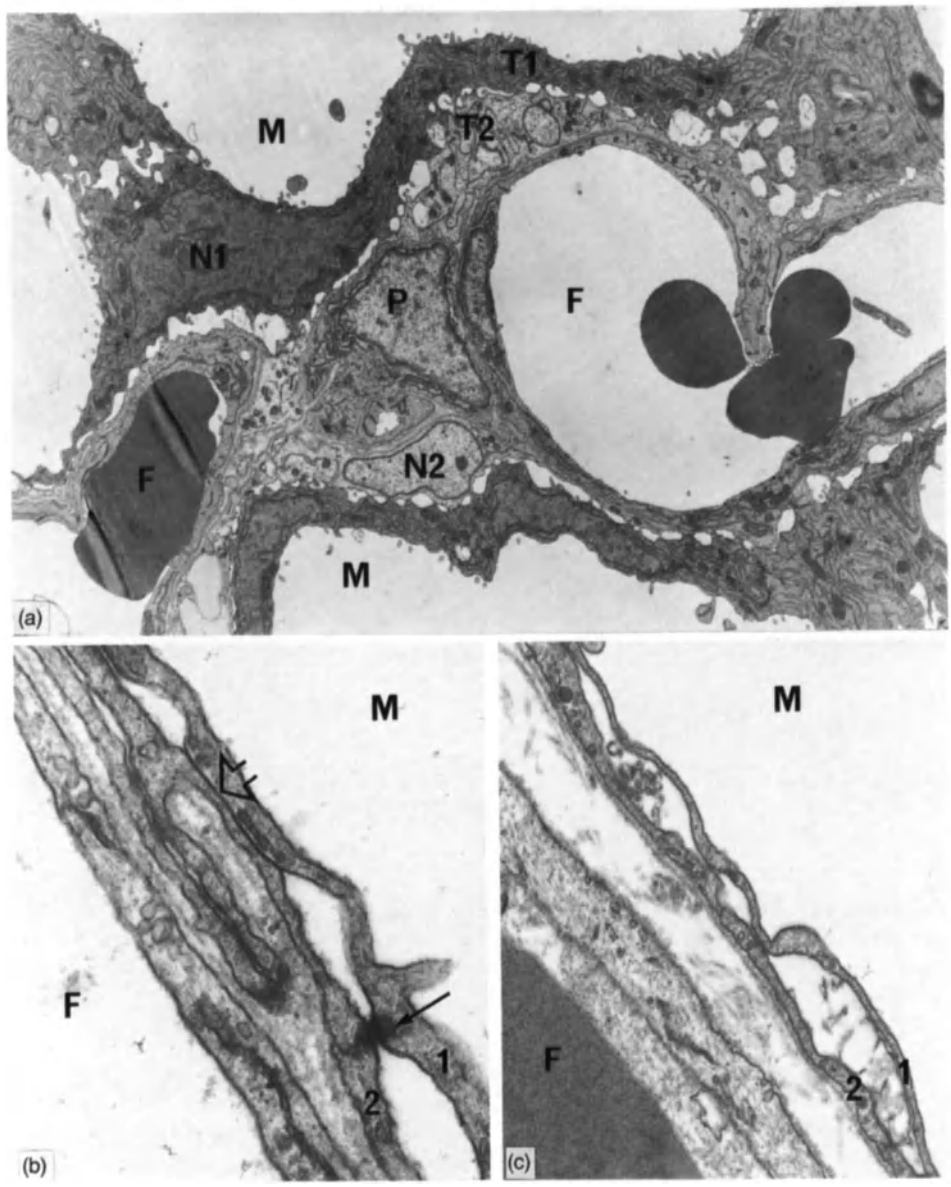

Figure 4.81 Haemodichorial rabbit placenta. (a) Definitive labyrinth structure. The maternal blood space (M) is bounded by two layers of trophectoderm (T1, T2), each of which show nuclei (N1, N2); T1 is a syncytium, T2 unicellular. T1 has far more rough endoplasmic reticulum (asterisks) than T2, which is considerably thinner. F, fetal blood capillaries; P, fetal pericyte. (b) There are frequent gap (open arrow) and small desmosomal (small arrow) junctions between layers 1 and 2. (c) Although layer 2 is usually thinner both layers frequently reduce to an equivalent exiguous extent. (a) 22 dpc, × 4000. (b) 22 dpc, × 35 000. (c) 22 dpc, × 15 000.

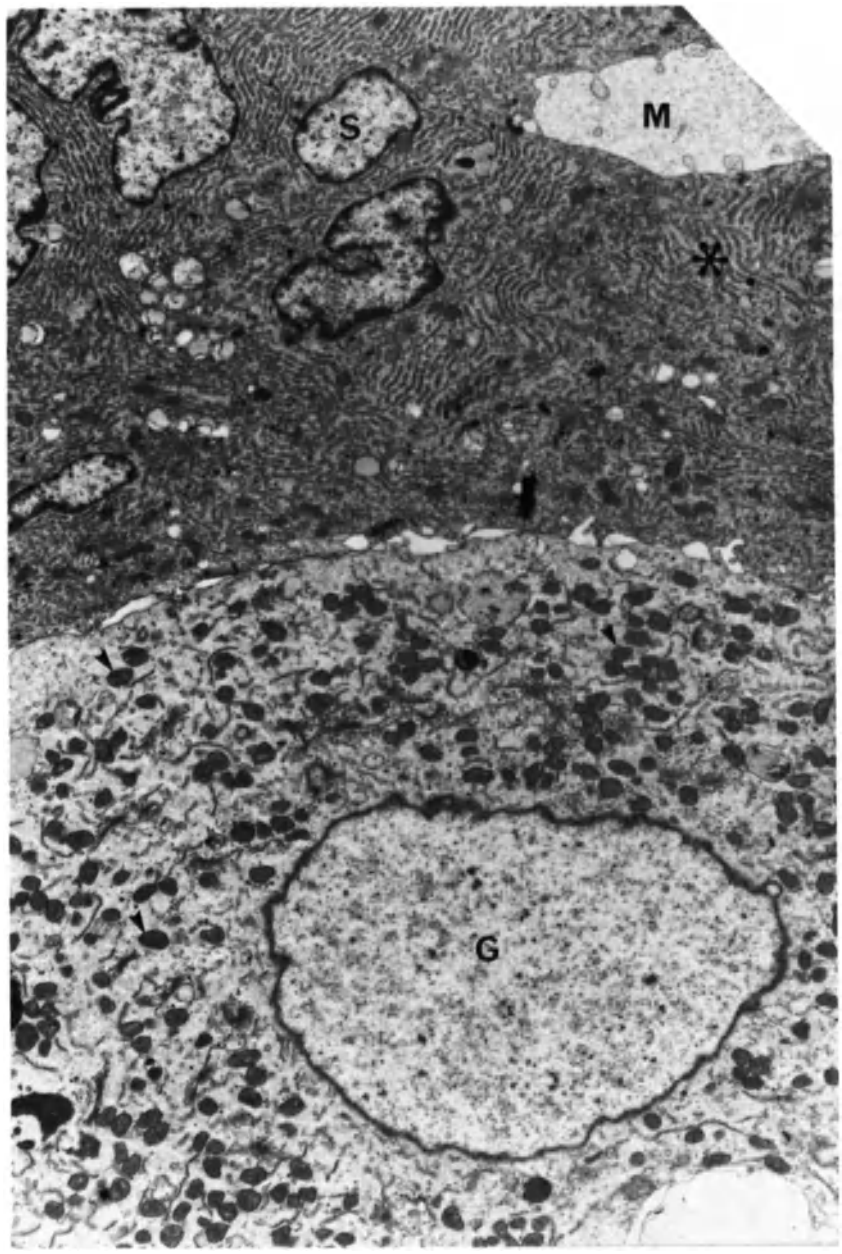

Figure 4.82 Haemodichorial rabbit placenta. The fine structure of the labyrinthine layer T1 on Figure 4.81 is similar to that in the spongiotrophoblast (S) shown here with massive arrays of endoplasmic reticulum (asterisk). The giant cells (G) have a very different ultrastructure with larger and more numerous mitochondria (arrowheads) and scattered individual strands of endoplasmic reticulum. M, maternal blood space. 22 dpc, × 7500.

Haemomonochorial: human, *Homo sapiens*

Menstrual cycle: 28 days
Ovulation: spontaneous
Uterus: simplex
Litter: 1–3
Implantation: interstitial, antimesometrial
Gestation: 270 days
Amniogenesis: cavitation
Yolk sac: The endoderm develops in an unusual manner and initially forms a latticework in the lumen of the blastocyst, only secondarily forming a sac (Luckett, 1978). This never becomes significantly larger or vascularized (Figure 4.2).
Chorioallantois: this forms the definitive placenta
Shape: discoid
Decidual development: considerable
Interhaemal membrane: haemomonochorial

The morula enters the uterus on 4–5 dpc transforms to a blastocyst, loses its zona pellucida and normally implants in the midline of the upper part of the posterior wall on 6 dpc. It is not clear how it is so positioned but uterine closure ensures no significant further movement. Implantation occurs prior to any blastocyst swelling, the cellular trophectoderm produces a syncytial cap which rapidly intrudes through the uterine epithelium and the whole blastocyst passes into the endometrium. The details of this process are not understood. Once the conceptus is established in the endometrium (6–7 dpc, Figure 4.83a and b) active proliferation of the cytotrophoblast produces the basis for rapid syncytium formation (Aplin, 1991).

No nuclear division has ever been reported in the human syncytiotrophoblast, but there are several autoradiographic and morphological studies showing that the cytotrophoblast is the precursor of the syncytiotrophoblast throughout pregnancy (Richart, 1961; Galton, 1962; Tao and Hertig, 1965; Tedde and Tedde-Piras, 1978; Kurman *et al.*, 1984). The syncytiotrophoblast thickens all around the conceptus and on 10–11 dpc lacunae fringed with microvilli develop within its bulk. It is actively invasive and soon breaches the maternal capillaries to start the flow of maternal blood into the lacunae (Figure 4.83c) (Boyd and Hamilton, 1970; Enders, 1989).

Columns of cytotrophoblast cells then proliferate into and through the syncytium to initiate the fetal villi over the whole conceptus (Figure 4.83d). Subsequently, the villi grow preferentially toward the best maternal blood supply so that villus development becomes asymmetric and eventually restricted to an antimesometrial discoid area (Figures 4.84 and 4.85).

The allantoic vesicle is rudimentary in the human but there is a vigorous growth of allantoic mesoderm to vascularize the developing placental villi, which by 20 dpc have grown through the syncytium and spread laterally to form a cellular cytotrophoblastic shell around the conceptus (Figure 4.83d). This is actively phagocytic towards the decidual cells against which it is apposed, and it also produces cells which migrate deep into the endometrium (Aplin, 1991). The maternal spiral arteries are also invaded by cytotrophoblast, which removes and replaces the endothelium and pericytes to produce by mid-pregnancy widened channels completely unresponsive to normal endothelial agonists, through which maternal blood is supplied to the endometrium (Pijnenborg *et al.*, 1983). There is some evidence that if this process is inhibited or blocked there are considerable problems of insufficient blood flow resulting in the hypertensive disorders of pregnancy (Robertson *et al.*, 1986; Shanklin and Sibai, 1989).

As soon as the cytotrophoblast shell has formed around the conceptus (21 dpc) a layer of fibrinoid material is developed between the decidua and the shell (P. Kaufmann, 1981b; Aplin 1991). In man the decidual cells are not packed closely together as in rodents, but are also surrounded by this fibrinoid

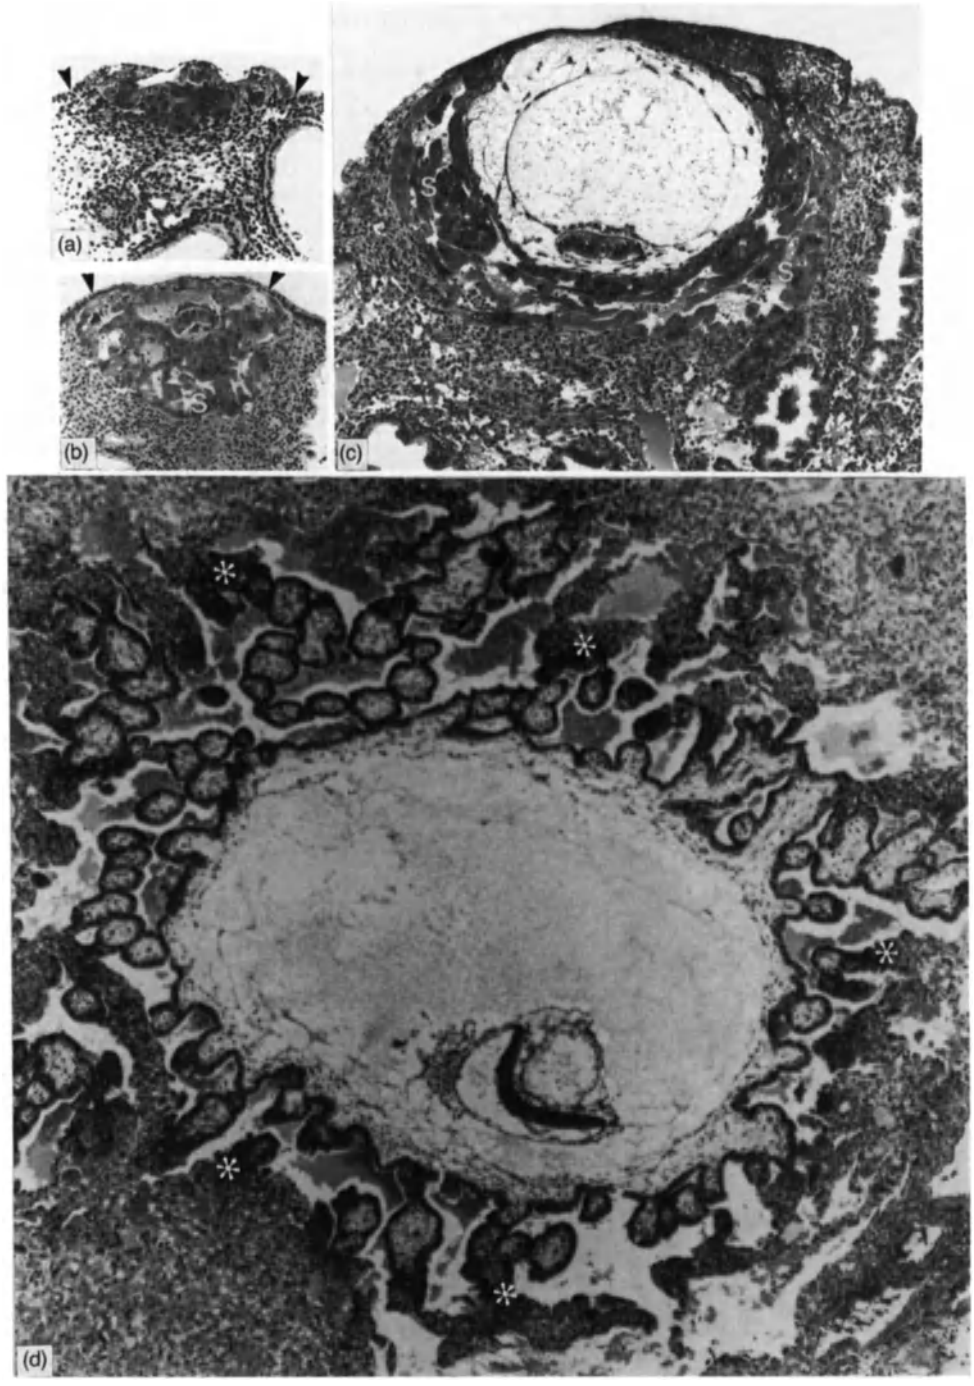

Figure 4.83 Haemochorial placenta in man. Early stages of development, all at the same magnification. (a) The blastocyst passes through the uterine eithelium (a and b, arrowheads) and (b) establishes itself in the endometrium. (b and c) The syncytiotrophoblast (S) forms the initial boundary around the conceptus but (d) with the formation of the chorionic villi all around the periphery a cellular cytotrophoblastic shell (asterisks) develops around the conceptus and facilitates further villus growth. (a) 7½ dpc, × 55. (b) 9½ dpc, × 55. (c) 12 dpc, × 55. (d) 14 dpc, × 55. (From Boyd and Hamilton, 1970.)

material which they synthesize (Wewer *et al.*, 1985; Kisalus *et al.*, 1987). It is thus more likely that the two major fibrinoid layers, Rohr's and Nitabuch's 'striae', are maternal rather than fetal products. They are in no sense continuous barriers between the fetal and maternal compartments since cytotrophoblast cells penetrate past them as far as the myometrium in some cases (Loke *et al.*, 1986). These cells, which may develop into syncytial plaques by fusion, are referred to as 'extravillous' trophoblast (the term includes endovascular trophoblast) (Schiebler and Kaufmann, 1981). They have the same monoclonal antibody plasmalemma markers but lack the hormonal marker hCG typical of villous syncytiotrophoblast (Bulmer *et al.*, 1984; Gosseye and Fox, 1984; Loke *et al.*, 1986; Robertson *et al.*, 1986). Extravillous trophoblast also expresses MHC class I and HLA G antigens, which are absent from villous syncytiotrophoblast (Redman *et al.*, 1984; Loke and King, 1989; Hunt and Hsi, 1990; Hunt *et al.*, 1990).

As with the other haemochorial placentas discussed above, it is clear that most of the villus elongation is due to expansion of the fetal tissue after the initial erosion of the maternal tissue has occurred, since a considerable thinning of endometrial substance must also be caused by the stretching needed to accommodate the increase in conceptus size. Mossman (1987) has evidence that there is very little increase in thickness of the cytotrophoblast shell or the decidua from as early as 25 dpc to term, but the villi increase in length eightfold in that time.

One clue as to the depth of fetal erosion may be the height of the shallow ridges (septae) of maternal tissue which are covered with cytotrophoblast shell (Figures 4.85c and 4.88). They delineate the aggregates of fetal villi which cluster around the points at which spiral arterial channels enter through the basal plate (cytotrophoblastic shell plus Nitabuch's stria). They are presumably produced because there are no villi over the septal region of the basal plate and therefore less erosion.

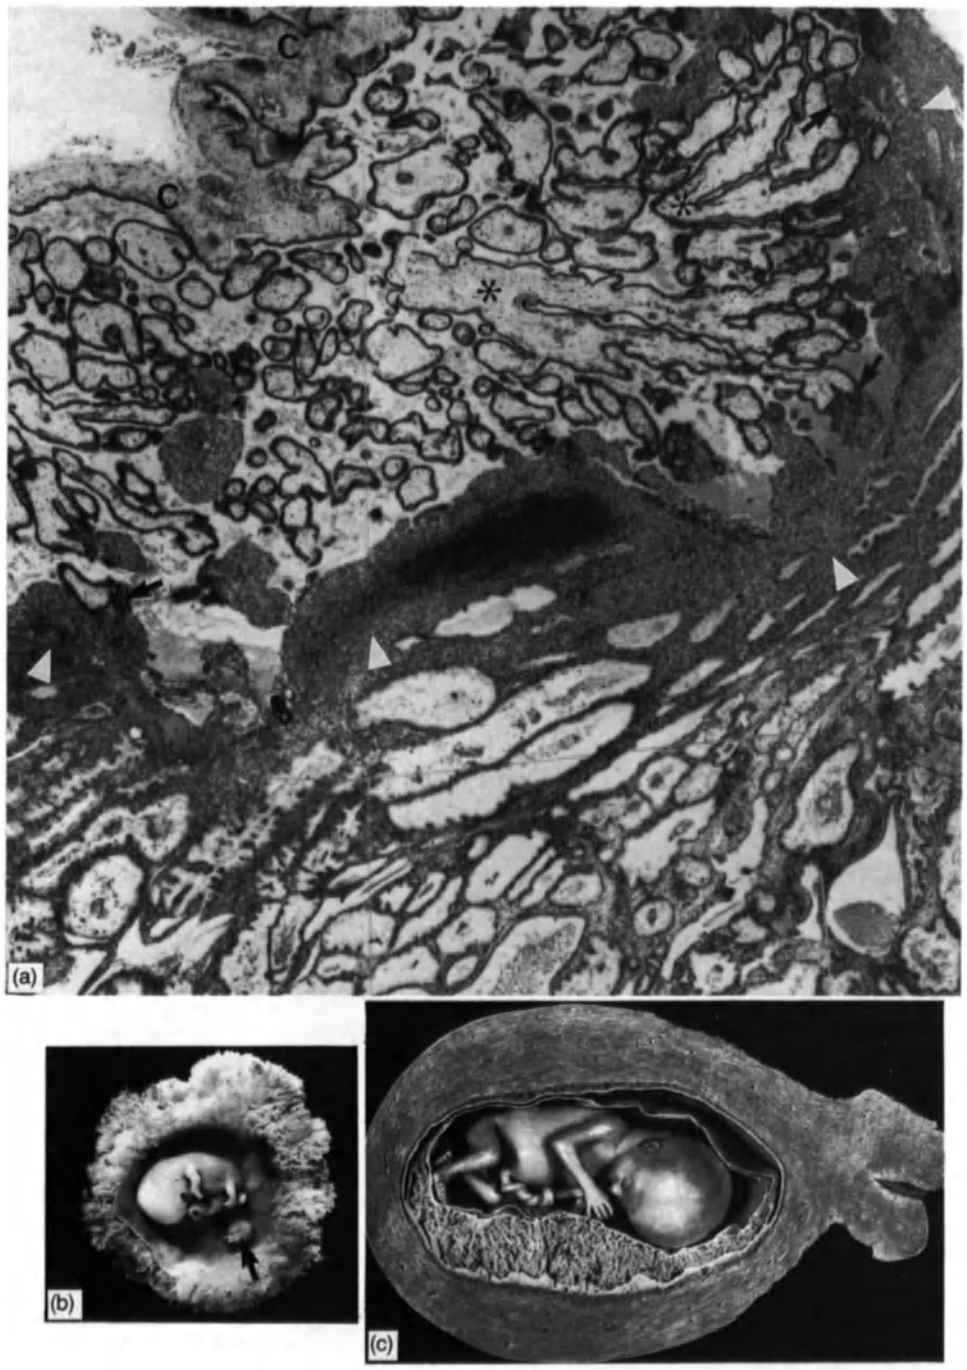
An individual villus consists initially of solid cytotrophoblast, but this is invaded by the allantoic vasculature by 18 dpc. The young stem villus has a cytotrophoblastic tip at its insertion into the cytotrophoblastic shell (Figure 4.84a). Behind this, where the villus is bathed in maternal blood, the cytotrophoblast is covered by a continuous syncytiotrophoblast layer.

The villus elongates and branches, becoming tree like, usually retaining at least one connection via a terminal branch to the basal plate as well as its stem inserted into the chorionic plate (Figures 4.84 and 4.90) (Boyd and Hamilton, 1970; P. Kaufmann, 1981b; Burton, 1987, 1990; Mossman, 1987; Castellucci *et al.*, 1990).

There are three major levels of villus organization, primary or stem, secondary and terminal. Morphometrically there is a progressive loss of villus connective tissue, an increase in the volume occupied in the villus core by fetal blood vessels and a decrease in thickness of the syncytiotrophoblast over the closely adjacent fetal vessels (Kaufmann *et al.*, 1985) (Figures 4.86 and 4.87).

This reaches an extreme in the so-called 'vasculosyncytial' membrane in the terminal villi where the distance from the maternal to fetal blood is reduced to less than 3 μm over 40% of the total area of the terminal villus whose volume consists largely of blood vessels (Figure 4.86) (P. Kaufmann, 1985; Mayhew *et al.*, 1986) (Figures 4.86, 4.87 and 4.88).

Local variations in proliferations of the basal syncytiotrophoblast membrane are also found (Figure 4.87). In man and baboon endogenous C-type retrovirus particles have been observed budding exclusively from the basal syncytiotrophoblast plasmalemma (Kalter *et al.*, 1973). From an early stage the cytotrophoblast layer becomes discontinuous and ever more exiguous. The placenta is



C
C
(a)
(b)
(c)

therefore considered haemomonochorial with only the syncytiotrophoblast forming a significant boundary layer (Figure 4.98b). For a recent review of human placental ultrastructure see Jones and Fox (1991).

The increase in area of the interhaemal membrane depends on cytotrophoblast division and fusion to form syncytiotrophoblast. Intermediate stages of this process have been reported (Kurman *et al.*, 1984). The interhaemal membrane has been shown to grow continuously throughout pregnancy so the cytotrophoblast certainly must survive until term. Placental weight and DNA content increase right up to parturition (Sands and Dobbing, 1985) and division of cytotrophoblast has been demonstrated in tissue cultures of term placenta (Kliman *et al.*, 1986). Simpson *et al.* (1992) have also recently shown morphometrically that the ratio of cytotrophoblast nuclei to syncytiotrophoblast nuclei is constant throughout gestation with no decrease near term.

The definitive placenta consists of groups (or lobules) of 3–5 stem villi bounded by septa (Figures 4.85c, 4.88, 4.89 and 4.90).

Latex injection studies suggest that there is a loose or hollow centre to each lobule and that a maternal spiral arterial channel supplies this hollow centre from its base (Figures 4.89 and 4.90) (Wigglesworth, 1969). Angiographic studies indicate that maternal blood spurts as a 'puff' into each hollow lobule from each spiral arterial channel (Figure 4.89c) and drains by venous exits at the sides and bases of the septa (Figure 4.88) (Ramsey and Donner, 1980). Since the villi are flaccid and clumped in any delivered placenta it is difficult to envisage the three-dimensional architecture during maternal blood flow. A possible analogy might be water flow through fish gills, with the gill filaments equivalent to the secondary and terminal placental villi. These would be separated to capillary dimensions by each 'puff' of maternal blood, closing like a fish gill to prevent backflow. When the blood reaches the interlobular space it would flow out of the wide venous channels in the basal plate and the septa. There is some autoradiographic (Geier *et al.*, 1975), ultrastructural (Critchley and Burton, 1987) and histochemical evidence (Schuhmann, 1982) for significant differences between the villous structure at the hollow centre of the lobule and the periphery, supporting the concept of maternal blood streaming out from the centre. However, the disposition of fetal blood vessels in the terminal villi makes countercurrent flow between fetal and maternal blood channels only one of many possible relationships. The overall result is probably mixed villous flow ('network current' flow, see Figure 4.8) (P. Kaufmann *et al.*, 1985) (Figure 4.88).

At implantation the conceptus does not embed itself very deeply into the endometrium and so the development of villi over the antimesometrial portion is considerably restricted because of the poor maternal blood supply to the thin decidua capsularis and the uterine epithelium boundary (Figures 4.84 and 4.88). In this paraplacental area the original fetal vascularization of the antimesometrial chorionic membrane is lost, as is the

---

Figure 4.84 Haemochorial placenta in man. (a) The chorionic villi increase in length and degree of branching (asterisks) as pregnancy progresses. The villi insert into the cytotrophoblastic shell (arrows) above a zone of decidual cells (white arrowheads). The endometrial glands (bottom third of figure) are eroded and distorted by the growth of the placental disc but they still appear to be actively secreting material. C, chorionic plate, (b and c) Halved conceptuses (c still *in utero*) illustrate the reduction in trophectodermal villi from a uniform halo to a localized disc between 55 dpc and 80 dpc. Note the vestigial yolk sac (arrow) in (b). (a) 25 dpc, × 10. (b) 55 dpc, × 0.5. (c) 80 dpc, × 0.5. (From Boyd and Hamilton, 1970.)

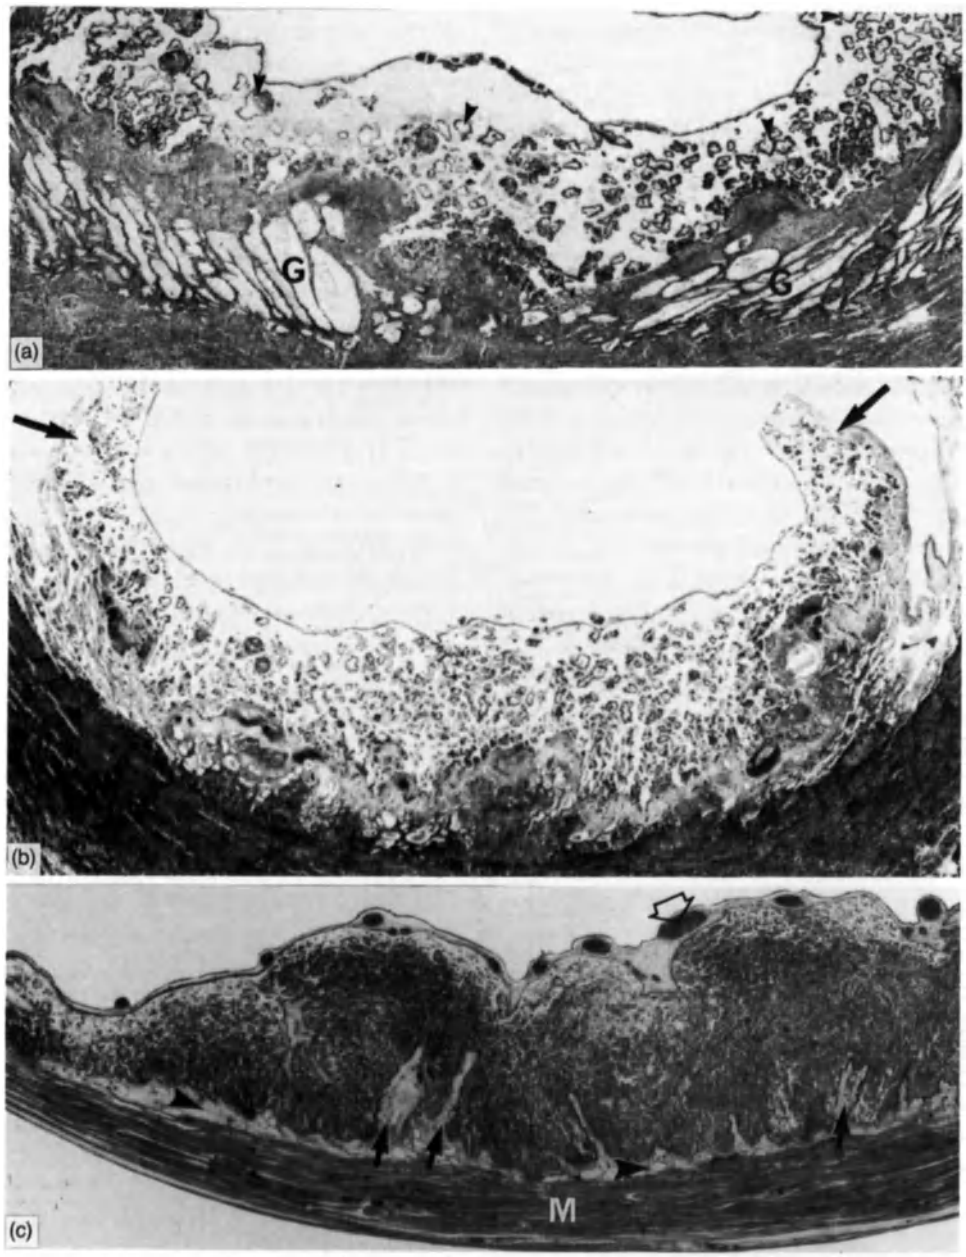


Figure 4.85 Haemochorial placenta in man. Development of the definitive placental disc. (a) The initially broad villi (arrowheads) are arranged evenly around the conceptus at 32 dpc and the basal uterine glands (G) are still extensive. At 42 dpc, (b) the villi are thinner and more frequent in the placental disc area, and have virtually crowded out the uterine glands basally, but are regressing outside the placental disc (arrows). (c) By 140 dpc the villi are much more extensive and closely packed. (This micrograph is only one quarter of the magnification of a and b). Septa (arrows) are now obvious. They are continuous with the thin decidual layer (arrowheads) which lies above the myometrium (M). The septa divide the placental disc into lobules or 'cotyledons' (see Figures 4.63 and 4.64). Open arrow, fetal blood vessel in chorionic plate. (a) 32 dpc, × 6. (b) 42 dpc, × 6. (c) 140 dpc, × 1.5. (From Boyd and Hamilton, 1970.)

syncytiotrophoblast layer, leaving a multilayered cellular chorion with an avascular mesodermal connective tissue layer inside. As it enlarges the amnion joins with this to form an amniochorionic membrane. By the fifth month the growth of the fetus has stretched and obliterated the decidua capsularis and its overlying uterine epithelium. The uterine epithelium over the decidua parietalis is also lost at this time so that the chorion is now apposed directly to the decidua parietalis (see Figure 4.88). This complex membrane (or 'chorion laeve') persists throughout pregnancy though considerably thinned by growth of the fetus. There is some immunohistochemical evidence for prolactin production by the capsularis decidual cells so the membrane is not physiologically inert (Meuris *et al.*, 1980). However, no areolar structures develop since there is no significant glandular presence in the paraplacental region (Boyd and Hamilton, 1970). There are gland remnants embedded in the basal decidua which are synthetically active at term (Nelson *et al.*, 1986).

Since the fetal trophoblast is bathed in maternal blood from the earliest stage of placental development there is no need for any specialized haemophagous zone and iron is probably transported from the maternal blood using the transferrin binding protein. A specialized plasmalemmal site for iron binding has been suggested (Ockleford and Menon, 1977). There is no evidence for any significant phagocytosis of red blood cells by the fetal syncytiotrophoblast. Human chorionic gonadotropin (hCG) and placental lactogen hormones are synthesized and stored in different granules in the syncytium (Figure 4.91) (Johnson and Wooding, 1988; Morrish *et al.*, 1988; Billingsley and Wooding, 1990), which also contains immunoreactivity for α-, β- and γ-interferon (Bulmer *et al.*, 1990), corticosteroid-releasing hormone (Riley *et al.*, 1991), EGF (Hofmann *et al.*, 1991) and IGF-1 and -2 and their binding proteins (Zhou and Bondy, 1992; D.J. Hill *et al.*, 1993).

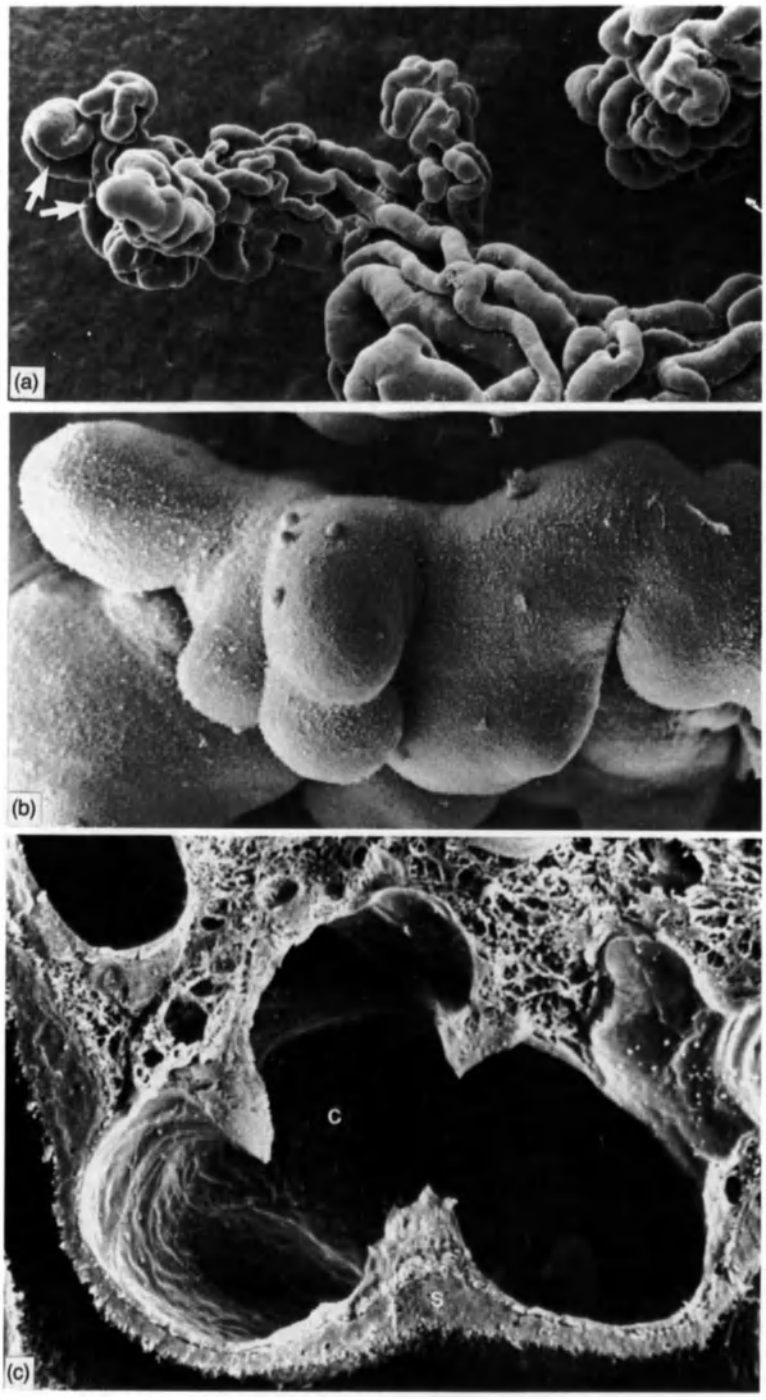
Unlike most animals, there is no fall in progesterone levels prior to parturition in man, nor is there any change in relaxin levels, which anyway are much lower than they were during the first 3 months of pregnancy (see Sherwood, 1988, for an excellent review). Labour in man is also unusual in that it evolves gradually over a period of many days without an abrupt onset as in most species studied. Oxytocin is said to play no significant role until the second (expulsive) stage of labour when it ensures retraction of the uterus and prevents excessive blood loss (Casey *et al.*, 1983). The trigger for human parturition remains controversial but may involve oestrogen precursor production from the fetal adrenal and prostaglandin secretion by amnion and the parietal chorion (Liggins, 1981; Casey *et al.*, 1983).

Other anthropoids: 1. Apes and Old World monkeys

As far as they have been investigated the development and definitive placentation of man and the great apes (chimpanzees, gorillas, orangutans) are virtually identical. The Old World monkeys (catarrhines) have a very different implantation and development, although the definitive structure of the placenta is almost indistinguishable at macroscopic and ultrastructural levels (Amoroso, 1952; Ramsey, 1982; B.F. King, 1986).

The best-studied Old World monkey is the macaque or rhesus, *Macacus rhesus*. Details of the reproduction are identical to those for *Homo* (section 4.3.6d) save that the gestation is only 160 days, the placenta is bidiscoid, implantation is superficial and there is little stromal decidual development but a considerable proliferation of uterine epithelial plaque (Figures 4.92 and 4.93) (Wislocki and Streeter, 1938; Enders *et al.*, 1985).

Plaque only persists for the first month of pregnancy and may be one reason for the limited invasion of the endometrium. It can also be produced by scratch trauma as a prel-



(a)
(b)
C
S
(c)

ude to deciduoma formation (Rossman, 1940). The invasive syncytiotrophoblast of the adherent blastocyst needs only to penetrate into the superficial, greatly hypertrophied endometrial blood vessels to establish a good blood supply (Figure 4.93) (Enders, 1989; Enders and King, 1991; Enders and Welsh, 1993). Once this is accomplished extensive exclusively fetal villus growth can produce the definitive placenta (Figure 4.94) with a villus structure equivalent to man (compare Figures 4.84a and 4.94c).

There is no need for any deeper invasion of the endometrium since the maternal blood supply is always at the base of the placenta, as in the human. Fetal cytotrophoblast does invade the spiral arteries replacing the endothelium as far back as the myometrium but there is less erosion of the arterial elastic sheath than in man. This is probably because the rhesus cytotrophoblastic shell, although it does synthesize connective tissue components (Blankenship *et al.*, 1992), is not at all invasive so there are very few if any cytotrophoblast-derived cells in the endometrial connective tissue to attack and erode the artery wall to the extent seen in man (Ramsey *et al.*, 1976). There seems to be no simple relationship between epithelial plaque or decidua formation and the depth of implantation since the baboon has superficial implantation but no epithelial plaque and no obvious decidual development; the macaque has superficial implantation, extensive plaque and limited decidual development; and man has interstitial development, no epithelial plaque and massive decidualization (Ramsey *et al.*, 1976). All primates are said to have 'extensive decidua' by mid-pregnancy (Enders, 1991).

Rhesus and the African green monkey *Cercopithecus* (Owiti *et al.*, 1989) are good models for studying the functions of the **definitive** human placenta since the structures are closely similar. However, the Old World monkeys are poor models for events at implantation and in early pregnancy in humans because interstitial or superficial implantation with decidua or plaque development are such very different processes (Enders, 1989).

Other anthropoids: 2. New World monkeys

There are two families: Cebidae, including howler, squirrel and spider monkeys; and Callithricidae, the marmosets. There are only isolated studies of the cebids and all prior to the advent of the electron microscope (Wislocki, 1929, 1930; J.P. Hill, 1932). Recently studies have concentrated on the marmoset (*Callithrix jacchus*) since it is relatively easy to maintain in breeding colonies (Moore *et al.*, 1985; Merker *et al.*, 1987; C.A. Smith *et al.*, 1987).

There is no overt menstruation in New World monkeys which correlates with an absence of spiral arteries in the endometrium (Ramsey, 1982). Cyclic proliferation and degeneration of the spiral arteries is thought to be the basis of the menstruation characteristic of other anthropoids (Ramsey, 1982).

Implantation is superficial, usually with considerable epithelial plaque formation (J.P. Hill, 1932) although there is very little in marmosets (Moore *et al.*, 1985).

After attachment (11–12 dpc) the blastocyst

Figure 4.86 Haemochorial placenta of man. (a) Scanning electron micrograph of a corrosion cast of the blood capillary meshwork in the terminal villi. Note the sinusoidal swellings at the ends of the villi (arrows). (b) Scanning electron micrograph of the surface of an intact perfused terminal villus emphasizing that the villus consists almost entirely of blood capillary volume. (c) Scanning electron micrograph of a cross-fracture through a specimen similar to that in (b). Note the considerable size of the capillary (c) and the thin investment of syncytiotrophoblast (s). (a) Term placenta, × 200. (b) Term placenta, × 400. (c) Term placenta, × 1400. (From Burton, 1987.)

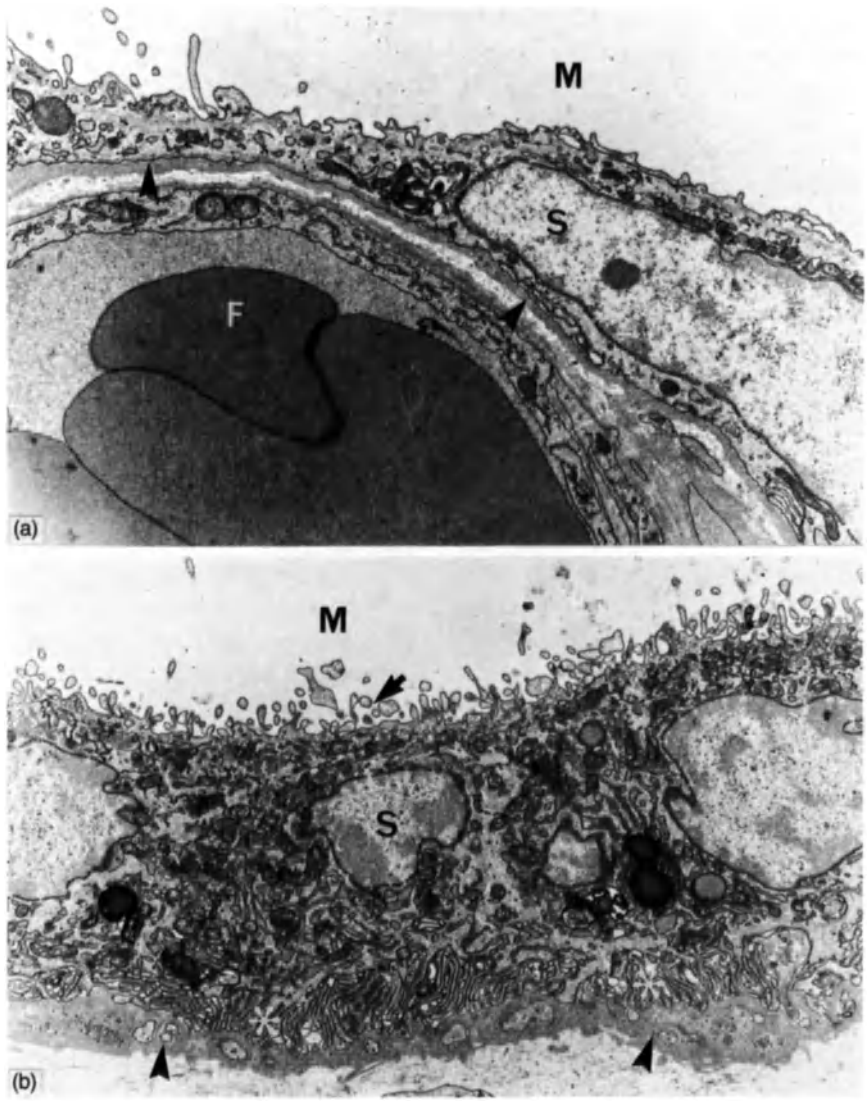


Figure 4.87 Haemochorial placenta of man. Transmission electron micrographs showing variation in local structure. (a) Over the fetal blood vessel (F) the syncytiotrophoblast layer (S) is extremely thin as is the basement membrane (arrowheads). (b) Away from the capillaries the fetal syncytium is thicker and the basal plasmalemma shows a complex elaboration (asterisks), increasing the membrane area equivalent to the microvillar forms (arrow) of the apical membrane. The basement membrane is considerably thickened (arrowheads), M, maternal blood space. (a) Term placenta, × 9000. (b) Term placenta, × 7500.

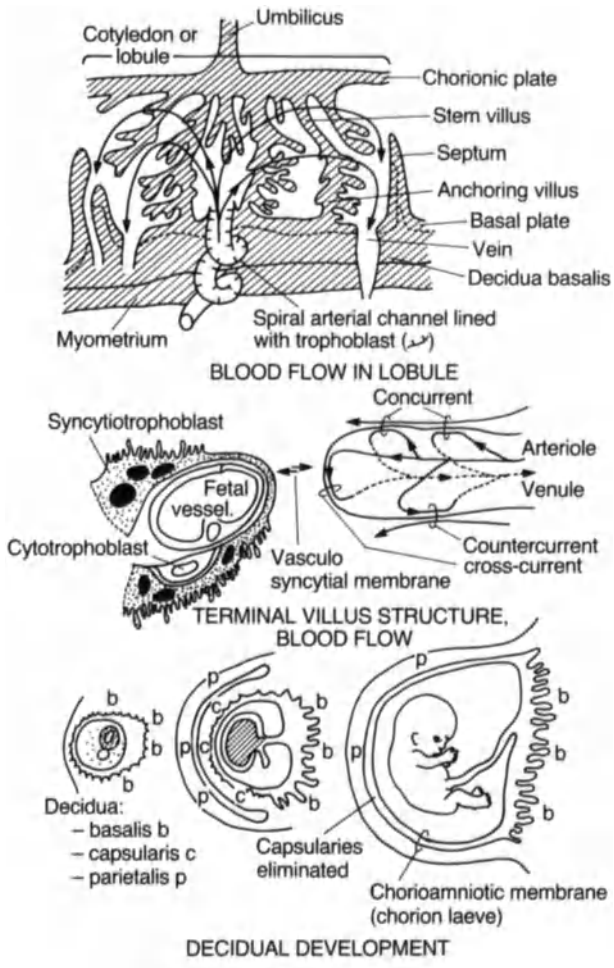

Figure 4.88 Blood flow in the definitive human placenta and development of the decidual tissues.

cytotrophoblast produces syncytium which penetrates the uterine epithelium. Once the stroma is reached the cytotrophoblast proliferates to produce a thick pad of syncytiotrophoblast which surrounds but does not penetrate the superficial maternal capillaries (23 dpc) (C.A. Smith *et al.*, 1987). By this time the epithelial plaque is regressing. The syncytiotrophoblast then develops lacunae within its bulk, but in the marmoset no maternal blood is observed within these spaces until 80 dpc, halfway through pregnancy, when the syncytiotrophoblast finally erodes the maternal endothelium. At this stage the fetal mesoderm pushes into the trophoblast layers, forming vascularized trabeculae within the meshwork of syncytium (C.A. Smith and Moore, 1990). The syncytiotrophoblast not only appears very similar ultrastructurally to that of other primates (C.A. Smith and Moore, 1990) but also has equivalent C-type retrovirus particles budding from the syncytiotrophoblast basal plasmalemma opposite the cytotrophoblast cells. The cytotrophoblast layer becomes discontinuous very early, and these fetal trabeculae are

bounded largely by syncytiotrophoblast. Further development of the placenta is by continual extension and subdivision of the trabeculae to form a complex meshwork bounded by syncytium. The trabeculae become more individual and more slender during later pregnancy (Figure 4.95) (Wislocki, 1929; 1930; Amoroso, 1952; Smith and Moore, 1990).

In the spider monkey, *Ateles*, the thickness of the placental pad does not increase significantly as the fetus grows from 50 to 180 mm (term) crown–rump length (Wislocki, 1930). The process is not villus elongation but one of the continual subdivision of a coarse trabecular meshwork to a finer one with a considerably greater surface area for fetomaternal exchange. The New World monkeys thus achieve a structural basis for a significant blood circulation much more slowly than the Old World monkeys. Possibly in compensation for this, the New World monkeys

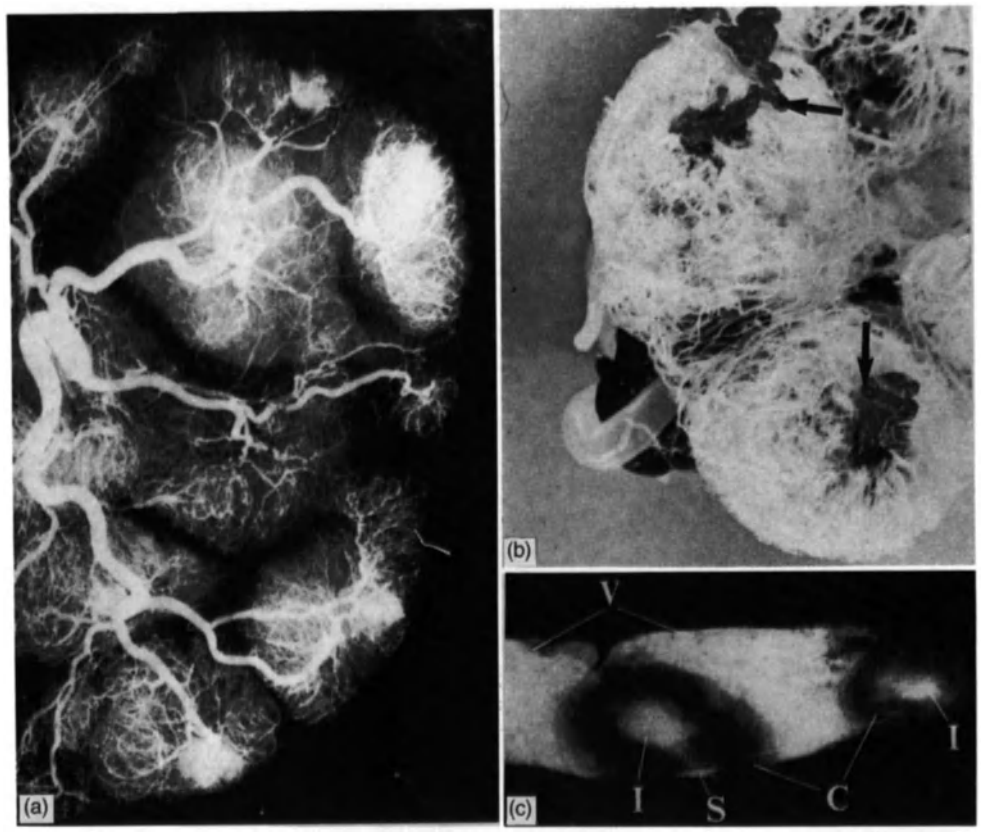

Figure 4.89 Haemochorial placenta of man. Vascular relationships. (a) Injection of the fetal circulation of a term placenta viewed from the fetal side. This illustrates the supply to individual lobules or cotyledons. (b) Latex casts of the fetal circulation (white) and of the maternal spiral arteries (black) of a term placenta viewed from the maternal side. One maternal spiral artery (arrows) enters the centre of each lobule or cotyledon. (c) Section of a term placenta injected via the spiral arteries (S) with X radio-opaque medium. The injection fills a central area (I) in the two lobules or cotyledons (C) but is excluded from the zone immediately surrounding the injection by the densely packed villi. The presence of opaque medium in the intervillous space (V) shows that it was able to pass across the villi but not to leak back. (From Wigglesworth, 1969.)

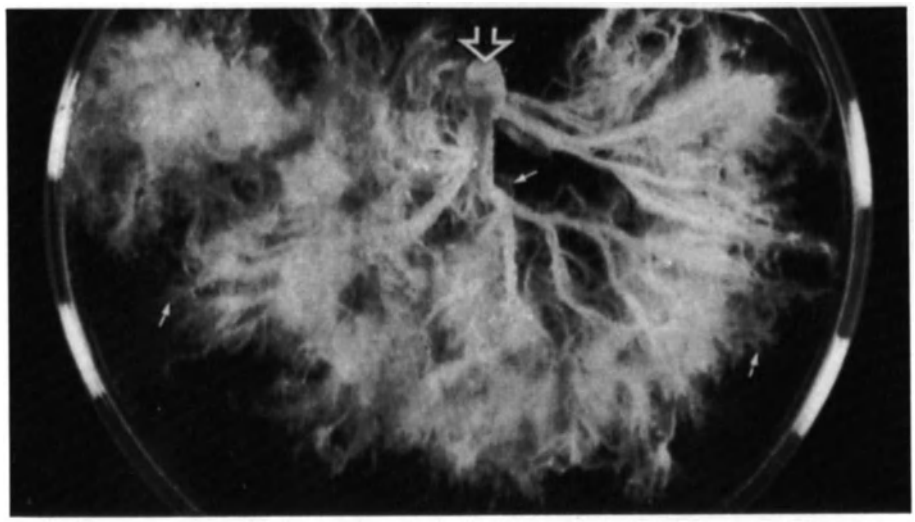

Figure 4.90 Haemochorial placenta of man. Stem villus dissected after trypsin digestion from a term placenta. The chorionic plate insertion was at the open arrow. Two or three of such villi would form one lobule or cotyledon. The finest 'twigs' (arrows) correspond to the terminal villi shown on Figure 4.86. (From Ramsey and Donner, 1980.)

show a massive uterine glandular activity throughout pregnancy (Wislocki, 1929), whereas the Old World monkeys, apes and man have very little. However, the gestation length and placental weight for equivalent-sized neonates is similar in the two groups; there is no evidence that one is more 'efficient' than the other, although the size and degree of fusion of the trabeculae or villi vary considerably (Figure 4.95).

The efficiency of the fetomaternal exchange in New World monkeys may also be influenced by the persistence, uniquely in anthropoids, of one or two wide maternal arterial channels per lobule which run right through the entire thickness of the placental disC and terminate just under the chorionic plate (Figure 4.72). These conduits have occasional openings distributed apparently randomly along their walls and at their tips. The walls of the channels consist of a continuous sheet of cuboidal epithelial cells which are assumed to be of maternal origin. These cells secrete a thick basement membrane like material around the vessels, which persist to term (Wislocki, 1930; J.P. Hill, 1932; Gruenwald, 1973; Merker *et al.*, 1987; C.A. Smith and Moore, 1990).

These peculiar perforated maternal blood channels may indicate one possible route from the rodent-style narrow-meshed labyrinthine haemochorial placenta with a few massive maternal arterial channels supplying a subchorial lake directly to the widely spaced villous haemochorial placenta of man and the Old World monkeys with maternal blood supplied only from the basal plate (Figure 4.72).

Yet again, as many times before in this review, the variety of structures evolved by the different groups far outstrips our ingenuity in justifying them in terms of placental function.

Haemochorial placentation: number and form of interhaemal layers

All placentas so far examined seem to possess at least one persistent continuous trophectodermal layer as well as fetal endothelium to

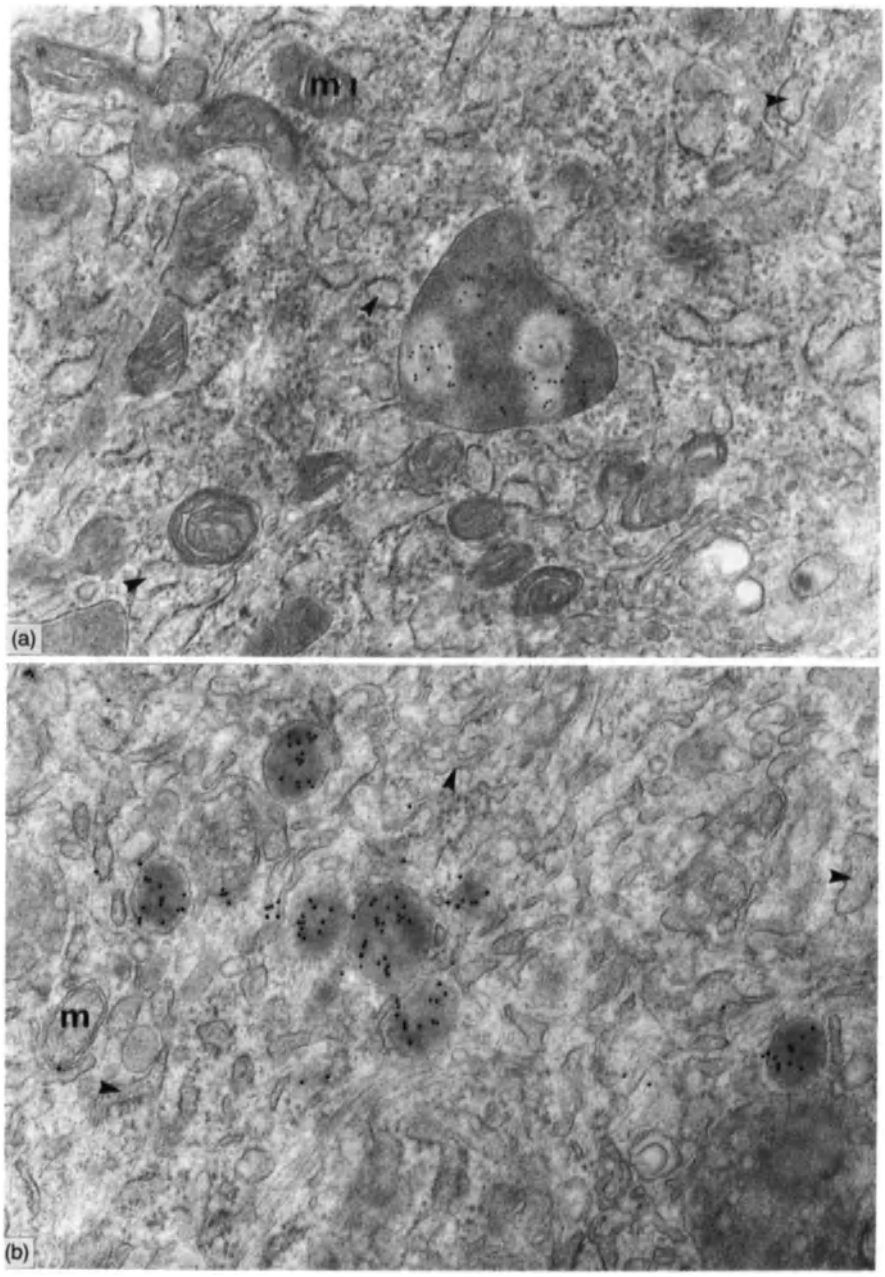

Figure 4.91 Haemochorial placenta of man. Micrographs of syncytiotrophoblast showing localization of hormone storage with immunogold techniques. (a) hCG is found in large irregular-shaped membrane-bound granules. (b) hPL in smaller more uniform-sized granules. Material fixed in glutaraldehyde and osmium and araldite embedded. m, mitochondria; arrowheads, rough endoplasmic reticulum. (a) First trimester placenta, × 28 000. (b) Term placenta, × 39 000.

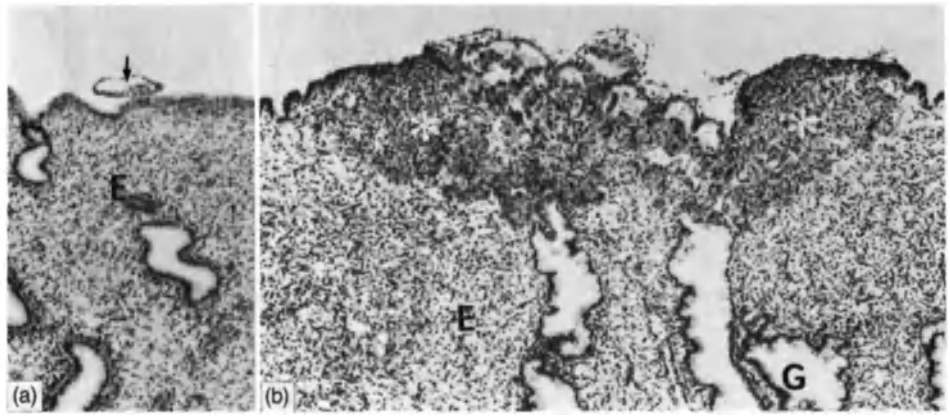

Figure 4.92 Haemochorial placental development in rhesus monkeys. Figures 4.92, 4.93 and 4.94 are at the same magnification. The major differences with human are the superficial implantation (arrow, conceptus) and development of epithelial plaque (asterisks in b and Figure 4.93a) by local proliferation of the uterine epithelium. The superficial endometrial blood sinusoids connect to the spaces within the syncytiotrophoblast (at the open arrows). Once the fetal cytotrophoblast and mesoderm have formed the initial broad villi (b and Figure 4.94a), their subsequent growth is by lengthening and subdivision (Figure 4.94a,b and c). There is little evidence for any significant further invasion of the uterine epithelium. At an equivalent stage of villus development the human (Figure 4.84a) and monkey (Figure 4.94a) placental structure is very similar, but there is no significant decidual development in the monkey endometrium (E). The cytotrophoblastic shell (X) which proliferates from the tips of the villi is particularly well demonstrated. C, chorionic plate; G, endometrial gland. (a) 9 dpc, × 50. (b) 12 dpc, × 50. (From Wislocki and Streeter, 1938.)

separate fetal and maternal circulations. The most efficient arrangement for maternofetal transport is for the maternal blood to circulate against the thinnest trophectodermal barrier compatible with immunological and other constraints. The most complete barrier is a syncytial sheet since there are no paracellular, non-selective routes possible: all molecules reaching the fetus can be screened for suitability by the trophectoderm. A haemomonosyncytiochorial structure of this sort is found in many different orders (section 4.3.6d), but despite its apparent advantages there exist also a remarkable variety of haemochorial trophectodermal organizations with one, two or three layers, each of which may be syncytial or cellular.

There is no evidence that nuclei in any vertebrate syncytium can divide. Recent evidence from human (Simpson *et al.*, 1992) indicates that the ratio of cytotrophoblast to syncytiotrophoblast is constant throughout gestation. Cytotrophoblast division followed by fusion into the trophoblast syncytium is the normal means of increasing its bulk and therefore its potential area. Since a syncytium has considerable plasticity the cytotrophoblast inputs can be scattered, and no continuous cellular layer is necessary. However, some such input is essential if the fetomaternal exchange surface is to enlarge continuously to the enormous extent reported (Baur, 1977) to support the fetal weight increase. In man the syncytiotrophoblast is produced initially from a continuous cytotrophoblast layer. This soon becomes discontinuous and the syncytium can differentiate locally to form the very thin vasculosyncytial membrane over fetal capillaries for example. Individual cytotrophoblast cells persist and are still capable of cell division even after the placenta is shed at term.

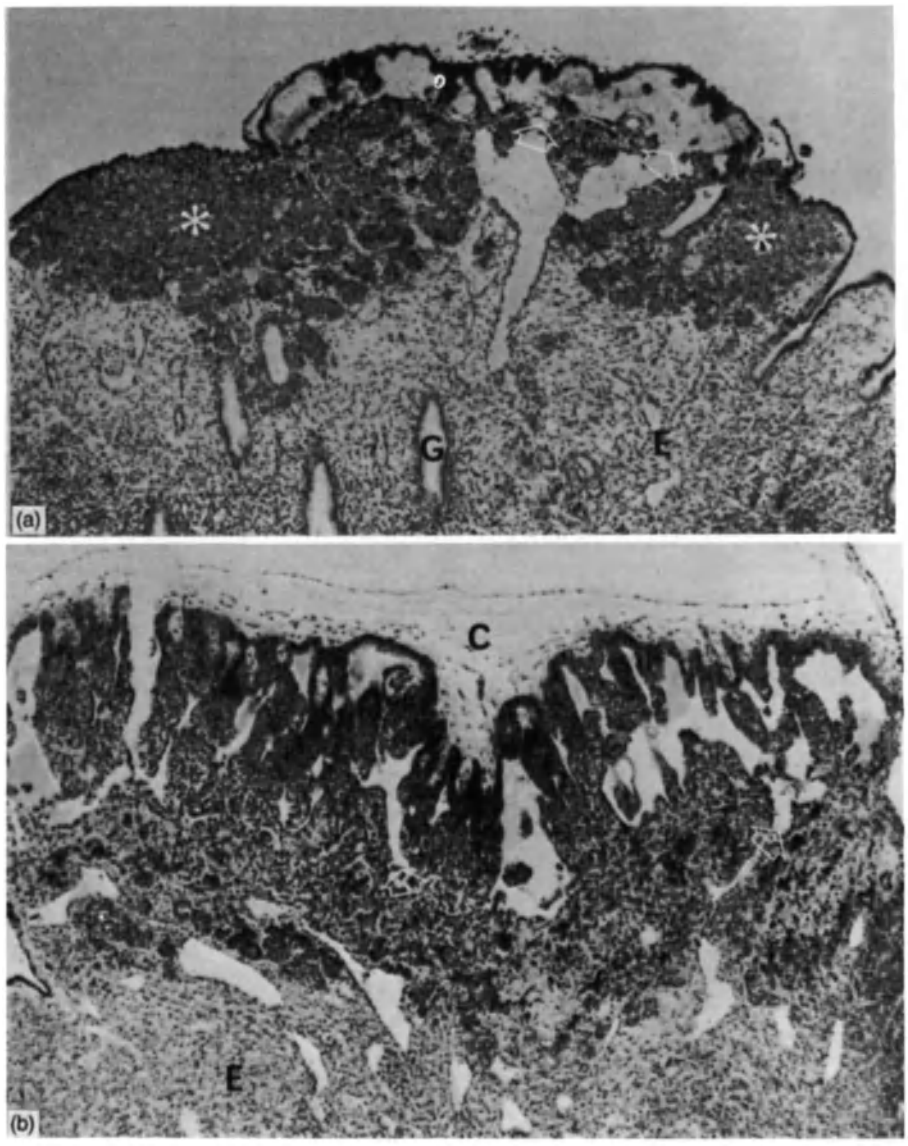

Figure 4.93 Haemochorial placental development in rhesus monkeys. For details see legend to Figure 4.92. (a) 14 dpc, × 50. (b) 17 dpc, × 50. (From Wislocki and Streeter, 1938.)

The characteristic mono-, di-, or trihaemochorial structure is established soon after implantation and, although the layers become thinner and the fetal capillaries indent the layers more deeply as pregnancy proceeds, there is no evidence for any structural simplification (tri- to di- to monochorial or the reverse) during development of any definitive placenta. At present little is known about the reasons for the many different patterns of layering found in haemochorial placentas. The more layers there are the more complete the spatial separation of functions can be. In a haemomonochorial placenta like that of man, numerous different proteins including hormones are synthesized and secreted independently (see Figure 4.91) but all use the same subcellular machinery (Patillo *et al.*, 1983; Morrish *et al.*, 1987). This must require a very complex hierarchy of controls which could be considerably simplified if several different types of cells are available, and there is good evidence for very different ultrastructure in the different layers of the same placenta (B.F. King and Hastings, 1977). Three layers obviously form a more complete barrier to invasion by maternal cells than one, and it is notable that haemomonochorial placentas always have a substantial fetal endothelial cell layer, whereas haemotrichorial placentas frequently show fenestrated fetal capillaries. The reason for the variety of haemochorial structures seems likely to lie in the multiplicity of functions served by the trophectoderm. With our present limited information we can only record the range and wonder.

Haemomonochorial

Cellular trophoblast: *Jaculus*

Myomorph rodents *Jaculus* (desert jerboa) and *Zapus* (jumping mouse) At implantation the germinative cytotrophoblast (layer III) produces a layer of syncytiotrophoblast (layer II), but both are very soon overgrown and disrupted by giant cells (layer I). These giant cells form the channels of the labyrinth in which the maternal blood circulates (Figures 4.76, 4.96 and 4.97).

They are derived from cytotrophoblast cells at the edge of the placental disc (B.F. King and Mossman, 1974; Mossman, 1987).

Hyracoidea, Procavia (rock hyrax) This order is thought to be related to the elephants on skeletal evidence, but the placental structures are very different since the Elephantidae are endotheliochorial (section 4.3.6c). The hyrax cytotrophoblast produces a thick layer of cells replacing the upper layers of the endometrium in the implantation chamber (Sturgess, 1948). By the time the fetus has reached a crown–rump (CR) length of 12 mm (midgestation; Wislocki and Westhuysen, 1940) this cellular layer is almost as thick as is the definitive placenta near term (50 mm CR). The cellular layer transforms into a trabecular meshwork forming channels with cellular walls (Oduor-Okelo *et al.*, 1983) through which the maternal blood drains back to the uterine veins (Figure 4.96).

The blood is delivered to the fetal side of the placenta by persistent maternal arterial channels which pass right through the fetal cell layer. The fetal allantoic arterioles invade the cytotrophoblastic trabeculae as they develop, delivering fetal blood to the maternal side of the placenta, from whence it drains back through a capillary meshwork establishing a grossly countercurrent system of fetal and maternal blood flows. This developmental pattern is very similar to that described (section 4.3.6d) for the New World monkeys but they are haemomonosyncytiochorial.

Bats, Vespertilionidae and Molossidae These orders have genera (*Miniopteris*, Kimura and Uchida, 1984; *Tadarida*, Stephens, 1962, 1969) which produce chorioallantoic definitive placentas based solely on cytotrophoblastic proliferations which engulf the maternal vascular channels. This

produces a labyrinth lined only with cellular cytotrophoblast (Figure 4.11b). Both genera also have transient accessory endotheliodichorial placentas (cytotrophoblast plus syncytiotrophoblast (Stephens and Cabral, 1971, 1972).

Syncytiotrophoblast A wide variety of orders have members with haemomonosyncytiochorial membranes in their definitive placentas: all anthropoids (Figures 4.87, 4.98); one carnivore, hyena (Figure 4.10a) (Oduor-Okelo and Neaves, 1982); two insectivores, cane rat and elephant shrew (Oduor-Okelo, 1984a,b); several rodents such as Marmots (Figure 4.10b), chipmunk, squirrels (Mossman, 1987), guinea pig (Figures 4.6 and 4.7) (Kaufmann, 1981b) and chinchilla (B.F. King and Tibbits, 1976); armadillos (Dasypodidae; Enders, 1982) and anteaters (Myrmecophagidae; Becher, 1931; Walls, 1938); and several bats (section 4.3.6c).

Although nominally haemo**mono**chorial, in practice there are probably always cytotrophoblast cells scattered over the fetal side of the syncytiotrophoblast (Figure 4.98). These are necessary to support the vast increase in area by continual division and fusion into the syncytium, because there is no evidence that nuclei in vertebrate syncytia can divide.

Haemodichorial

There are two types:

1. The cytotrophoblast which generates the syncytiotrophoblast persists as a continuous layer. The circulations are separated by fetal endothelium, cytotrophoblast and syncytiotrophoblast.

This is characteristic of several orders of bats for example, Thyropteridae (Wimsatt and Enders, 1980) (Figure 4.99), Vespertilionidae (Enders, 1982) and Desmodontidae (Bjorkman and Wimsatt, 1968).

All the bats show a characteristic intrasyncytial lamina close to the apex (Figure 4.99).

The rabbit has a similar dichorial arrangement but the cellular layer is very different in structure from the rather uniform columnar cellularity of the bats. (Figures 4.81 and 4.98; Enders, 1965; Samuel *et al.*, 1975). It may be that both rabbit layers are independently generated by cellular inserts on the haemotrichorial pattern (section 4.2.7a).

2. The generative cytotrophoblast is discontinuous but there is an additional cellular layer between the syncytiotrophoblast it generates and the maternal blood. This pattern has been described only in two rodents, the beaver (Fischer, 1971) and the springhaas *Pedetes* (Fischer and Mossman, 1969). There is a considerable initial cytotrophoblast proliferation at the placental site. The syncytiotrophoblast-bound fetal villi grow into this layer, producing a definitive placenta with a cellular outer layer bathed in maternal blood underlain by a syncytial layer. The details of the development of the two layers are not clear.

Haemotrichorial

This is found only in myomorph rodents with just a single pattern of layering in the cricetids (Figures 4.100 and 4.101) (gerbil) and murids (rats, mice, hamsters) (Enders, 1965; B.F. King and Hastings, 1977).

The circulations are separated by fetal endothelium, two syncytial layers and an outer fenestrated cellular layer (section 4.3.6d).

4.4 PLACENTAL ENDOCRINE FUNCTION

4.4.1 PLACENTAL HORMONES

The endocrinology of pregnancy is dealt with in detail in Chapter 11, this volume; however, a description of placentation would be incomplete without some consideration of the general principles of placental endocrine function, and the discussion that follows is limited to these aspects.

As indicated above, endocrine mechanisms have been utilized by a wide range of species to solve many of the problems associated with intrauterine gestation (Fisher, 1986). Hormones secreted by the placenta have been shown in different species to block further ovarian follicular development and ovulation (progesterone and possibly inhibin), thereby preventing superfetation; to block the contractile response of the uterus to a foreign body (such as an embryo) placed in it (progesterone, relaxin); to ensure the continued secretion of nutrients by the maternal endometrial glands (progesterone); to mobilize metabolic reserves such as fats within the maternal organism and to cause mammary growth and development (placental lactogens) so that milk secretion ensues post partum. In some species at the end of pregnancy, the placenta is involved in signalling (through changes in secretion of progesterone and oestrogens) to the mother that the fetus has developed sufficiently for birth to occur and to cause the mother to demonstrate characteristic maternal behaviour

patterns such as nest building. It is perhaps not surprising that endocrine mechanisms should be so important in communication between the fetus and mother, since there is no nervous connection between the two organisms.

(a) Steroids

Progesterone

Progesterone has been shown to be produced by every placenta in which it has been examined in detail. The most frequently applied method for detecting placental progesterone secretion is measurement in peripheral plasma by radioimmunoassay or competitive protein binding; examples of data obtained in this way are illustrated in Figure 4.102.

This method clearly fails to distinguish between progesterone secreted by the placenta and that secreted by other organs, most notably the corpus luteum. Since progesterone is required for the maintenance of gestation in most species, the production of progesterone by the placenta can be detected by eliminating other sources, by ovariectomizing or lutectomizing animals at various stages of gestation, and determining whether pregnancy is maintained. By this means it can be shown, for example, that the sheep's placenta produces sufficient progesterone to maintain gestation in the absence of the ovaries after day 50 post coitum (Casida and

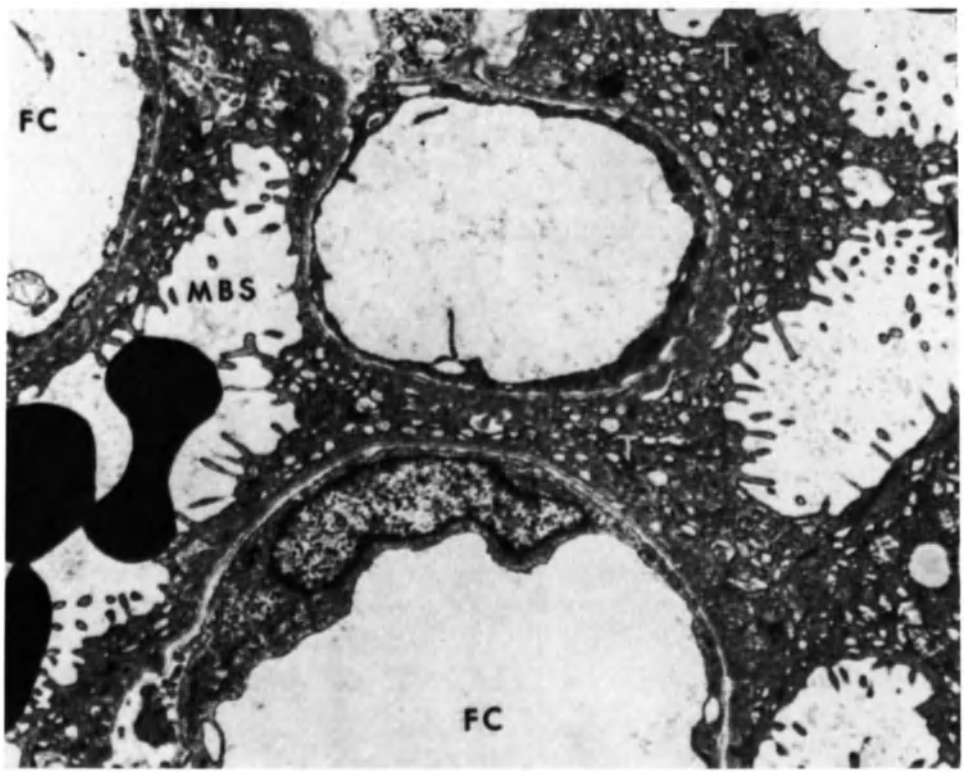

Figure 4.97 Haemochorial placentation. In the monochorial cellular trophectoderm of the rodent *Zapus* it is not possible to distinguish the cellular boundaries at this magnification, the trophectoderm cells are very extensive and very attenuated. FC, fetal capillary; MBS, maternal blood space; T, trophectoderm. Late pregnancy, × 8000. (From King and Mossman, 1974.)

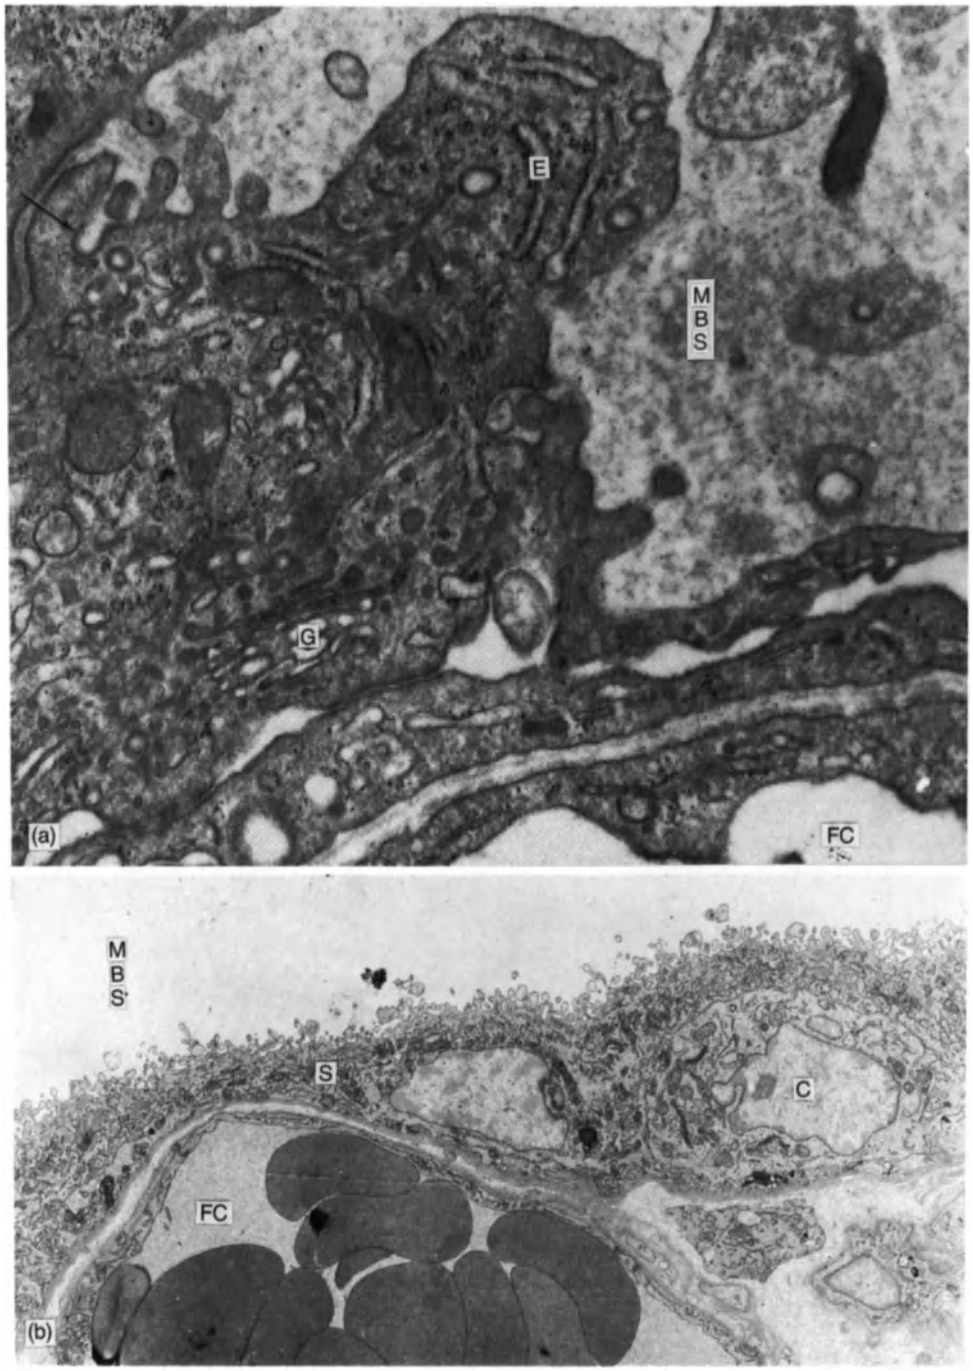

Figure 4.98 Haemochorial placentation. (a) Interhaemal membranes in the haemodichorial rabbit placental labyrinth. The trophoblast layer in contact with maternal blood (MBS) shows numerous coated pits (arrow), abundant rough endoplasmic reticulum (E) and a Golgi body (G). The inner trophoblast layer shows no membrane specializations. FC, fetal capillary. (a) Late pregnancy, × 28 500. (From Enders, 1965.) (b) The human, nominally haemomonochorial, syncytiotrophoblast (S) contains cytotrophoblast cells (C) capable of division and differentiation into syncytium right up to the time of parturition. Term placenta, × 4400.

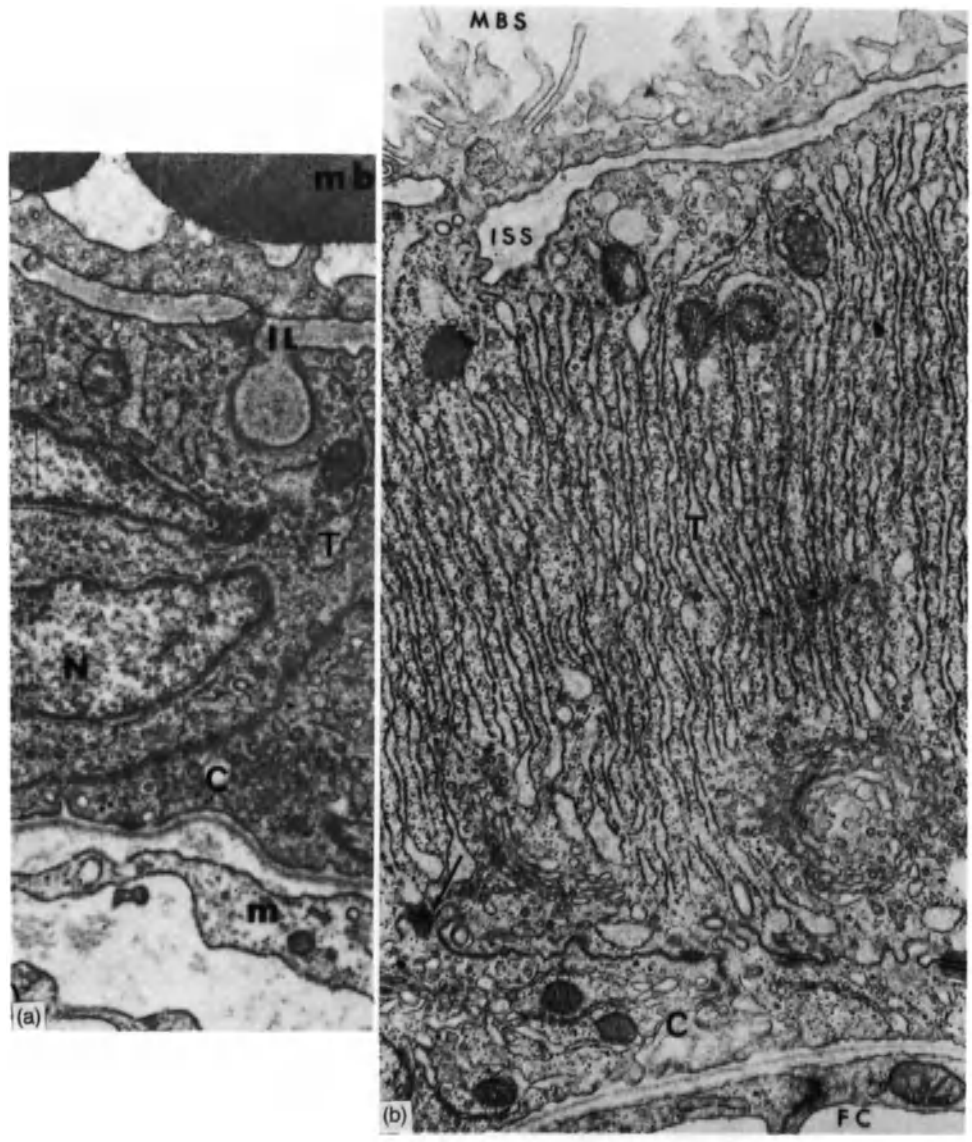

Figure 4.99 Haemodichorial bat placentae. The intrasyncytial lamella (IL in a, ISS in b) in the apical syncytiotrophoblast (T) is much more uniform in thickness, texture and separation from the maternal blood (mb in a, MBS in b) than those shown in Figures 4.10 and 4.11. Compare the structure with that of the endotheliochorial placenta (cat) in Figure 4.68, which is said to be characteristic of many other genera of bats. C, cytotrophoblast; FC, fetal capillary; N, nucleus; M, mesoderm cell. (a) *Thyroptera* near-term placenta, × 17 500. (From Wimsatt and Enders, 1980.) (b) *Myotis* near term placenta, × 22 000. (From Enders, 1982.)

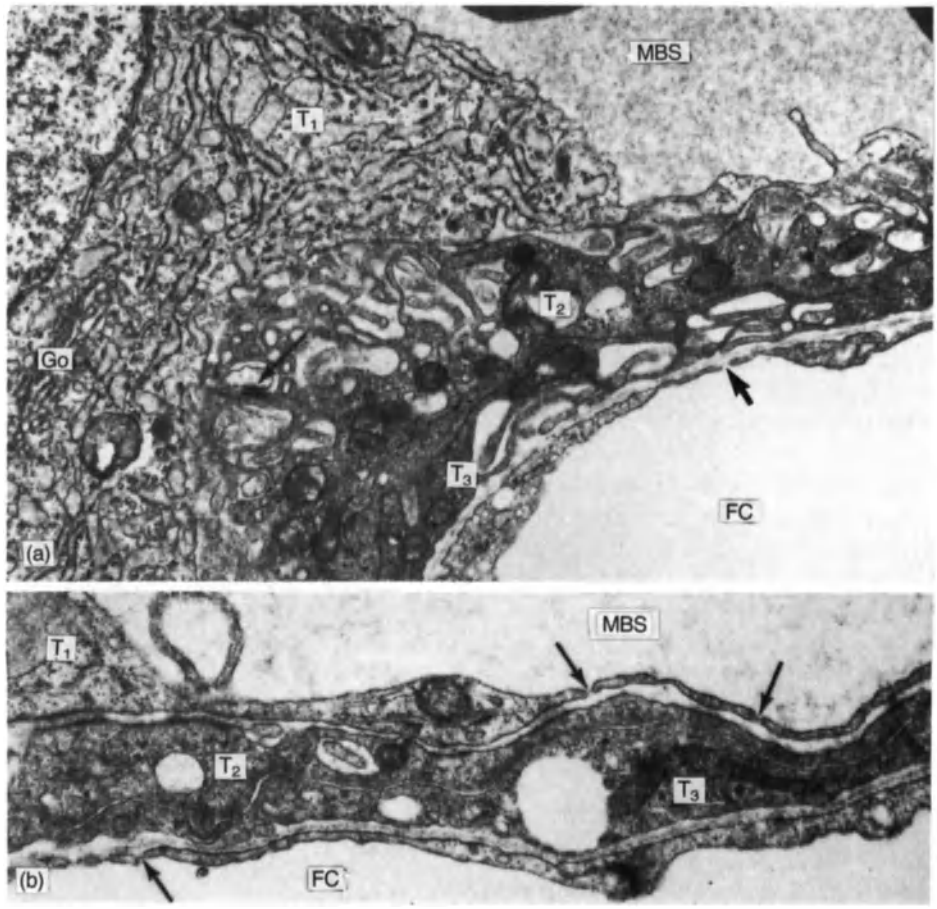

Figure 4.100 Haemotrichorial placentation in myomorph rodents. The triple layering is remarkably consistent in Muridae (rats, mice) and these examples of Cricetidae. Bounding the maternal blood space (MBS) layer T1 is usually cellular but very irregular with thin, discontinuous areas (b, arrows) next to regions containing the nucleus and abundant cytoplasm (a) with a lot of rough endoplasmic reticulum and Golgi bodies (a, Go). Layer T2 is syncytial, connected to T1 via the occasional desmosome (a, arrow), and is usually the widest, frequently showing considerable elaboration of the apical plasmelemma. (a and c) T3 is thinnest and most uniform, linked to T2 via desmosomes and gap junctions and occasionally having proliferations of the basal plasmalemma (a) adjacent to the fenestrated (a and b; upward arrows) fetal capillaries (FC). M, mitochondrion. Arrow in (c), cell boundary junction in T1. (a) *Peromyscus*, near-term placenta, × 17 500. (b) *Lemmus*, near-term placenta, × 22 600. (From B.F. King and Hastings, 1977.)

Warwick, 1945; Denamur and Martinet, 1955). The stage of gestation at which the placenta first produces sufficient progesterone to maintain pregnancy in the absence of the corpus luteum has been termed the stage of the 'luteoplacental shift' (see Csapo, 1977). However, there are animals in which the placenta produces progesterone, but in quantities which are insufficient to maintain gestation following ovariectomy. The goat and the pig are examples of such species; in both cases, ovariectomy at any stage of gestation leads to pregnancy loss (Drummond-Robinson and Asdell, 1926; Meites, *et al.*, 1951; Du Mesnil Du Buisson and Dauzier, 1957; Cowie *et al.*, 1963; First and Staigmiller, 1973). In these animals, as well as in sheep, placental progesterone secretion can be detected by replacing the luteal progesterone in ovariectomized individuals with a synthetic progestagen that does not interfere in the progesterone assay, and measuring progesterone in the maternal peripheral, uterine venous or fetal vasculature. This procedure shows that in goats the placenta secretes increased quantities of progesterone between days 120 and 140 (Sheldrick, Ricketts and Flint, 1980; Figure 4.103), and in pigs it has been used to demonstrate placental progesterone secretion after day 103 (V.A. Craig and A.P.F. Flint, unpublished observations; Figure 4.104).

In sheep, Ricketts and Flint (1980) demonstrated that placental progesterone secretion began at between 50 and 70 dpc, thereby confirming the information obtained after ovariectomy without replacement therapy. This information also confirms the conclusion reached by Thorburn and Mattner (1971) from measurements of progesterone in the sheep subcutaneous mammary vein, which had been anastomosed to a utero-ovarian vein in order to facilitate collection of uterine venous blood by percutaneous venepuncture.

In animals in which the placenta secretes little progesterone it may produce a related but biologically inactive steroid. The goat's

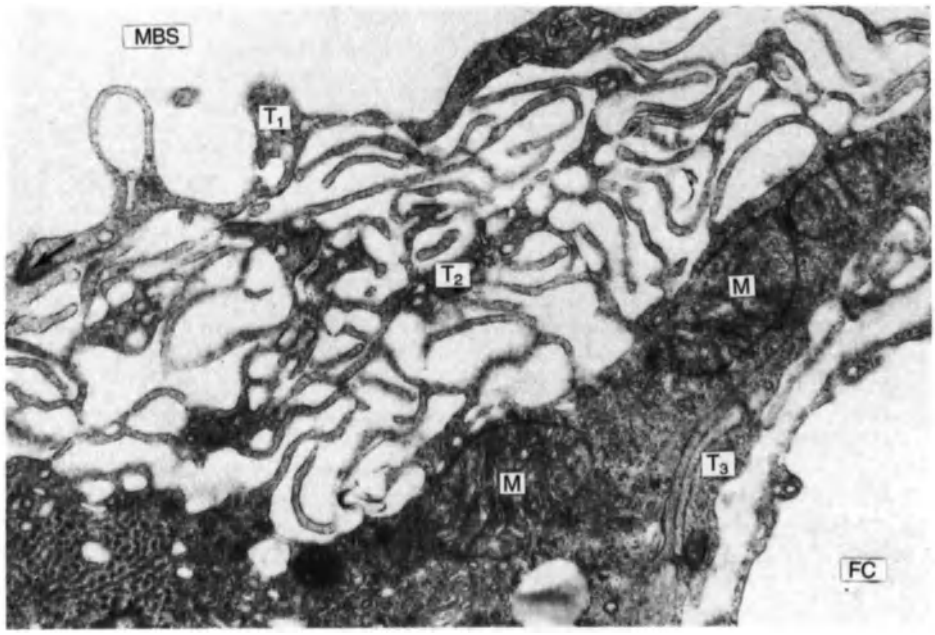

Figure 4.101 Haemotrichorial placentation in myomorph rodents. *Cleithryonomys*, near-term placenta, × 21 300. For details see legend to Figure 4.100. (From B.F. King and Hastings, 1977.)

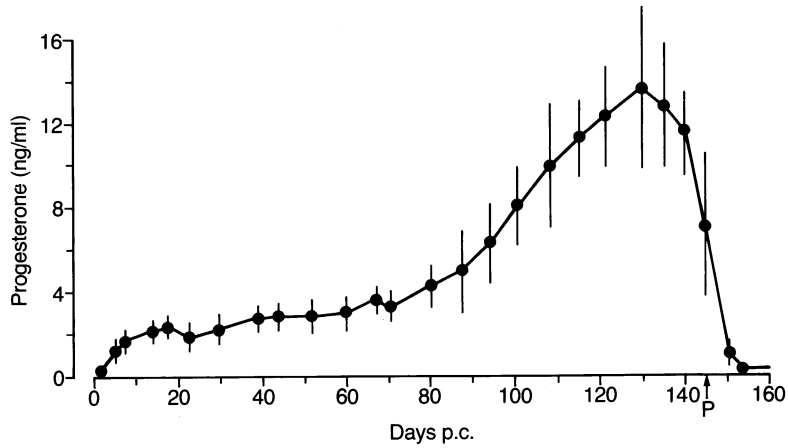

Figure 4.102 Concentrations of progesterone in peripheral circulation in sheep during pregnancy. Note that the corpora lutea are unnecessary for pregnancy maintenance after day 50, and that progesterone concentrations fall before parturition (P) at term. (After Bassett *et al.*, 1969, redrawn.)

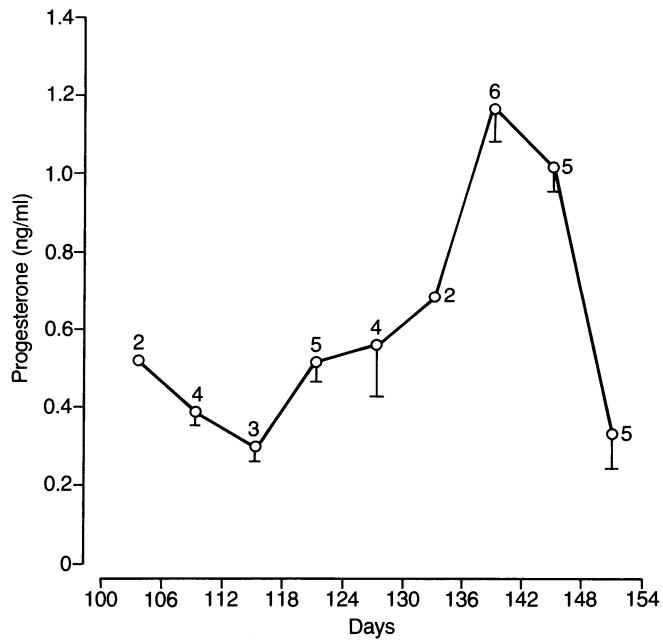

Figure 4.103 Concentrations of progesterone in peripheral maternal plasma during the last third of gestation in four ovariectomized or lutectomized goats. The number of samples assayed is given at each point. All samples were obtained before parturition. Pregnancy was maintained following removal of the corpora lutea by administration of medroxyprogesterone acetate. All kids were born alive. (After Sheldrick *et al.*, 1980, redrawn.)

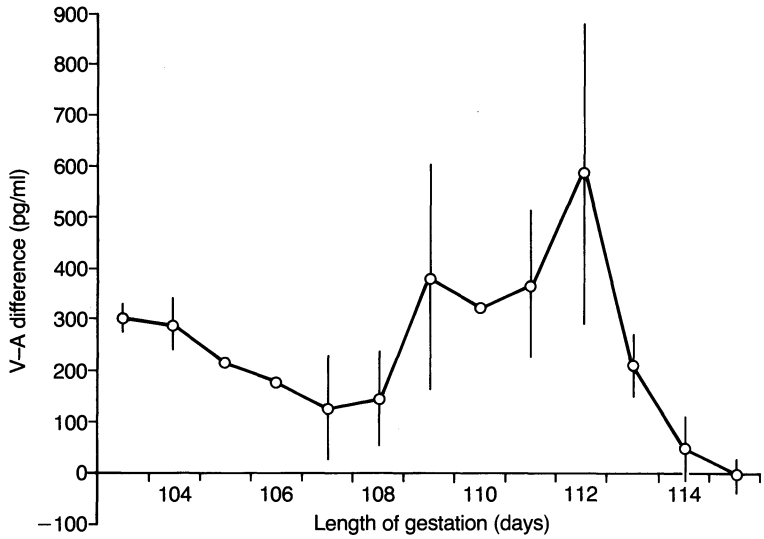

Figure 4.104 Venoarterial concentration differences for progesterone across the uterus in ovariectomized pregnant gilts treated with medroxyprogesterone. Values represent carotid arterial concentrations subtracted from uterine venous concentrations (four animals); mean venous concentration between days 103 and 112 was approximately 1000 pg/ml. Ovariectomy was performed between days 93 and 102; survival of the piglets was normal. (After V.A. Craig and A.P.F. Flint, unpublished.)

placenta synthesizes progesterone in large quantities, but reduces it to 5β-pregnane-3α, 20α-diol before secreting it (Flint *et al.*, 1978); radioimmunoassay of this latter steroid in peripheral plasma during gestation shows that levels change in a manner similar to those of progesterone in sheep (Figure 4.105; Sheldrick, *et al.*, 1981).

One possible advantage resulting from this characteristic is that the supply of precursors for oestrogen synthesis is reduced; oestrogens are luteolytic in the goat and therefore cause pregnancy loss. In those species in which the placenta produces large quantities of progesterone (e.g. the sheep and man) the corpus luteum regresses, presumably due to reduced circulating levels of luteinizing hormone caused by high circulating progesterone levels (see Sheldrick *et al.*, 1980).

Oestrogens

As is the case with progesterone, oestrogen secretion is a common placental endocrine function. However, there are marked differences between species in the metabolic pathways leading to placental oestrogen synthesis. Some animals, notably ruminants, produce oestrogens by synthesis from C_{21} steroid precursors (pregnenolone and progesterone); others (e.g. man), lacking the placental 17α-hydroxylase and C-17,20-lyase necessary for this pathway, produce oestrogens by aromatization of androgens secreted by the fetal adrenal glands, primarily dehydroepiandrosterone sulphate. These latter are said to possess a 'fetoplacental unit', because both compartments are required to complete the steroidogenic pathway to oestrogens. The only species so far thought to possess a fetoplacental unit are man, the equids and, possibly, seals. Examples of patterns of oestrogen synthesis through pregnancy are illustrated in Figures 4.37 (horse) and 4.106 (man).

Oestradiol-17β, generally regarded as the most potent oestrogen on administration in bioassays, is not always the major circulating oestrogen from a quantitative point of view.

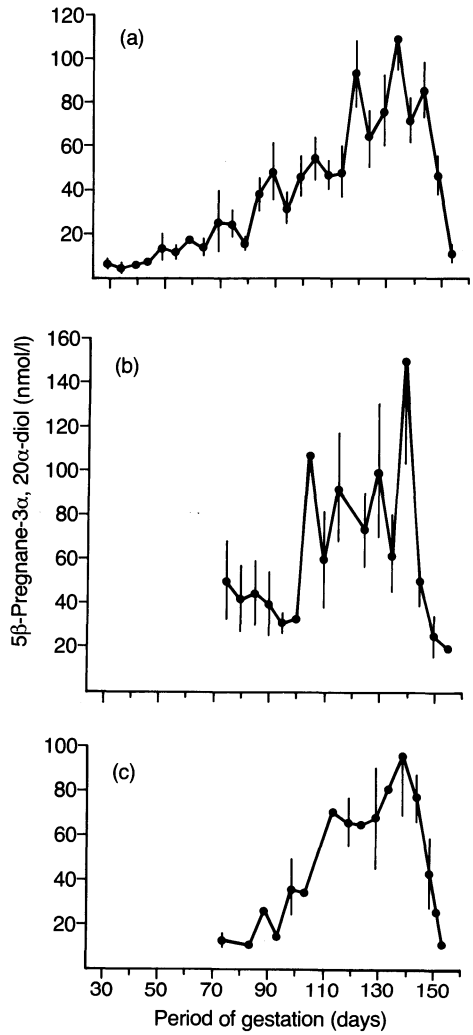

Figure 4.105 Circulating concentrations of 5β-pregnane-3α, 20α-diol in goats during pregnancy. Levels were measured in jugular venous plasma by specific radioimmunoassay from (a) eight untreated animals; (b) five animals treated with medroxyprogesterone acetate and (c) three lutectomized, medroxyprogesterone acetate-treated animals. All samples were taken before delivery of the kids. Lutectomy was performed between days 71 and 75. All kids were born alive. (After Sheldrick *et al.*, 1981, redrawn.)

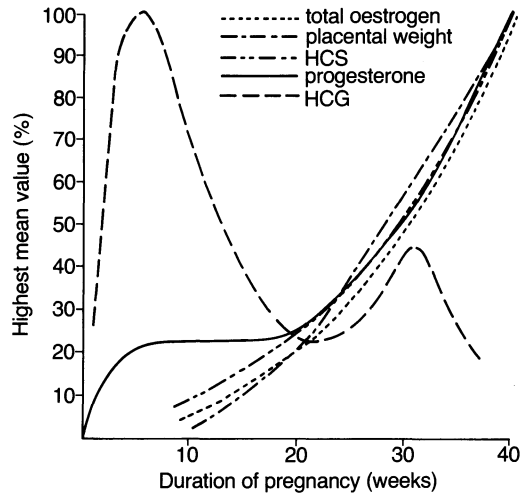

Figure 4.106 Diagram representing changes in placental weight and peripheral plasma concentrations of placental hormones during human pregnancy. Values are normalized to the highest level reached (= 100%).

In man the oestrogen circulating in highest concentration is oestriol, and in goats oestradiol-17α. In most species conjugated oestrogens (sulphates and glucuronides) circulate in higher concentrations than unconjugated oestrogens, though this may reflect more complete hepatic clearance of the latter rather than greater placental secretion of the former.

Control of placental steroid secretion

Factors controlling placental steroid secretion are complex. In some instances the quantity of a steroid produced is proportional to the weight of the placenta; in others the rate of steroid production is limited by supply to the placenta of a substrate; and in yet others there are changes in the activities of placental enzymes at defined stages of gestation which play a major role in influencing the pattern of steroids produced.

An example of the first of these mechanisms is the way in which maternal circulating progesterone concentrations change throughout pregnancy in man (Figure 4.106);

the circulating level clearly follows closely the changing mass of the placenta for the greater part of pregnancy, and although the actual concentration of progesterone in plasma is determined largely by factors influencing its clearance rate (for example, proteins such as cortisol-binding globulin, which also avidly binds progesterone), the increase during gestation is principally due to increasing placental weight.

Increasing placental weight would appear also to contribute to the increasing concentration of oestrogen in the maternal circulation during human pregnancy (Figure 4.106); however, circulating oestrogen levels are limited by the supply to the placenta of fetal adrenal androgens, and can be increased by administering such compounds (e.g. dehydroepiandrosterone sulphate) to the mother. The increase in oestrogen level with advancing pregnancy reflects increased fetal adrenal size. A similar mechanism is thought to operate to control placental production of the B-ring unsaturated oestrogen, equilin, in the horse and other equids; in these species equilin production occurs transiently in mid-gestation and is thought to result from the production of a precursor by the fetal gonad, which hypertrophies at this stage (Figure 4.37) (Pashen *et al.*, 1983). The identity of the precursor is not established, although it has been suggested that it arises via a novel steroid biosynthetic pathway (the sesquiterpene pathway; Bhavnani and Woolever, 1978; Tait *et al.*, 1982).

The third form of control of placental endocrine function, through changes in placental enzyme activity, is neatly exemplified by the effect of raised fetal cortisol concentrations on progesterone and oestrogen secretion at term in ruminants. At term in the sheep the rapid rise in fetal circulating concentrations of cortisol results in the activation of the placental enzyme 17α-hydroxylase/C-17,20 lyase. This converts progesterone into oestrogens, resulting in increased secretion of mostly oestrone sulphate (A.B.M. Anderson *et al.*, 1975; Steele *et al.*, 1976; see also Flint, 1983). These changes in maternal steroid concentrations are thought to cause the onset of uterine contractions by inducing prostaglandin synthesis in the uterus (Mitchell and Flint, 1978b; Thorburn, 1991). The effect of cortisol on the placenta is exerted directly; cortisol induces 17α-hydroxylase in isolated explants of sheep's placenta *in vitro* (Ricketts *et al.*, 1980), and the presence of the glucocorticoid receptor in the placenta is also consistent with a direct action (Flint and Burton, 1984). Similar enzymic changes occur in the goat's placenta at term, in response to raised fetal circulating levels of cortisol (Flint *et al.*, 1978), which are thought to account for the dramatic drop in maternal levels of 5β-pregnane-3α, 20α-diol before term as well as the rise in oestrogen (Sheldrick *et al.*, 1981).

(b) Polypeptide hormones

Polypeptide and smaller peptide hormones secreted by the placenta or acting locally in an autocrine manner have been identified in a limited number of species, principally in primates, rodents and the large domestic animals. The polypeptide hormones studied in depth fall into two groups, the chorionic gonadotrophins and placental lactogens; the former are related structurally and evolutionarily to the pituitary hormone LH and the latter to prolactin/growth hormone (for review see H.J. Stewart *et al.*, 1988).

Chorionic gonadotrophins

The existence of chorionic gonadotrophins with FSH- and LH-like activities has been recognized since observations of the stimulation of gonadal function in rodents by extracts of human placenta and urine over half a century ago (Aschheim and Zondek, 1927; for comprehensive recent reviews see Allen, 1975; Talamantes and Ogren, 1988; Boime *et al.*, 1989). It is however, only with the application of recombinant DNA techniques that

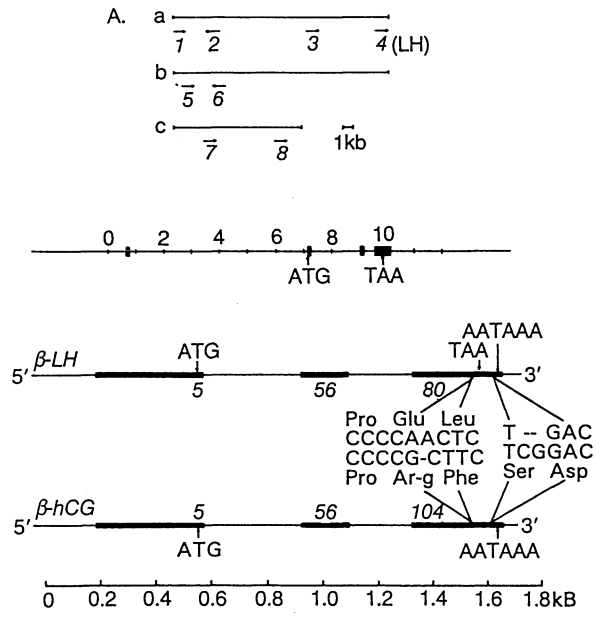

Figure 4.107 Structure of hCG and LH genes. (a) Organization of seven hCG-β and one LH-β subunit gene on three genomic fragments; arrows indicate direction of transcription. (b) Structure of human glycoprotein-α gene; figures above line indicate kilobases relative to an arbitrary point, and exons are thickened. ATG and TAA indicate translation start and stop sites respectively. (c) Evolution of hCG-β from LH-β; exons are thickened, scale is in kilobases and expanded regions illustrate deletions and insertions in the LH sequence giving rise to hCG, as well as the amino acids. Figures above and below exons indicate the number of amino acids coded for by each exon. (From H.J. Stewart *et al.*, 1988, redrawn.)

we are now beginning to understand the origin of these hormones. The chorionic gonadotrophins are glycosylated proteins of molecular weight 38 kDa which have been investigated most fully in primates and equids. They consist of two subunits, α and β. In man, the α-subunit is identical to the α-subunits of the pituitary glycoproteins, LH-α, TSH-α, FSH-α, there being only one gene for this protein which is expressed in the placenta as in the pituitary. In contrast the β-subunit of chorionic gonadotrophin differs from that of LH. It is closely homologous to, but is longer than, LH-β; it has evolved from LH-β through a frameshift mutation, leading to loss of the translation termination codon, with subsequent readthrough into the normally untranslated region of the LH-β gene (Figure 4.107).

As a result a further 24 amino acids are present at the C-terminal end of the hCG-β subunit that are absent from the LH-β chain. The termination codon (UAA) utilized by hCG-β is part of the polyadenylation sequence (AAUAA). There are six hCG-β (but only one LH-β) genes, all arranged in a 58-kbp region on chromosome 19; it is thought however that only two or possibly three are actively transcribed, the remainder representing pseudo-genes. The FSH-β, TSH-β and common α-subunit genes are mapped to chromosomes 11, 1 and 6 respectively; therefore it appears that the duplication of the ancestral β-subunit gene and separation of the resulting genes preceded evolution of hCG-β. Since many species (e.g. mice, Dracopoli *et al.*, 1986) lack a chorionic gonadotrophin, the evolution of the hCG-β gene

must post-date the evolutionary divergence of mice and the primates. A similar arrangement of CG-β genes occurs in the baboon (Crawford *et al.*, 1986); there are, however, considerable nucleotide sequence differences between hCG-β and the baboon hormone.

Chorionic gonadotrophins have not been studied in such detail in other primate species, and most of the evidence for their existence in primates is based on radioimmunoassays and bioassays. Using these procedures, chorionic gonadotrophins have been identified in the placentas of apes and of Old and New World monkeys (Hobson and Wide, 1972; Hodgen *et al.*, 1974). A chorionic gonadotrophin has been isolated from the guinea pig placenta (Bambra *et al.*, 1984), but the evidence for similar molecules in rat mouse or hamster placentas is at present only circumstantial (Talamantes and Ogren, 1988).

The phenomenon of gonadotrophin production by the equine conceptus has been studied in considerable depth; the ready availability of this highly gonadotrophic material (previously known as 'pregnant mare serum gonadotrophin', PMSG; more recently equine chorionic gonadotrophin, eCG) has produced an industry of considerable importance as a result of its use in stimulation of gonadal function, with applications in the treatment of infertility (including human infertility) and in the production of oocytes for embryo transfer. It was long considered that eCG differed from LH in a manner similar to that in which hCG differed from hLH; this appeared particularly likely in view of the fact that eCG, like hCG has a C-terminal extension relative to most LHs. However, it has now been shown that eCG and eLH have identical amino acid sequences; the only difference between them is in the way in which they are glycosylated (see H.J. Stewart *et al.*, 1988).

The observation that hCG is produced by trophoblast neoplasms in very large quantities provides a ready diagnostic method for following the growth and regression of choriocarcinomas and molar pregnancies (see Patillo *et al.*, 1983). The finding that either α-subunit or hCG itself is produced by a range of other non-trophoblastic neoplasms, including adenocarcinomas of the stomach, in which serum hCG can reach levels similar to those found in the first trimester of pregnancy, stimulated speculation that hCG may be responsible for conferring immunity to tissue rejection not only upon carcinomas but upon the developing embryo itself (Amoroso and Perry, 1975). However, experiments with purified preparations of hCG have produced no consistent support for this hypothesis.

Placental lactogens

These prolactin-like hormones have been definitively identified in primates, ruminants and rodents but are thought to be absent in lagomorphs, carnivores, Equidae and Suidae (Forsyth, 1986, 1991; Ogren and Talamantes, 1988; Talamantes and Ogren, 1988; Byatt *et al.*, 1992). As with the chorionic gonadotrophins, our understanding of the origin and structure of placental lactogens (or chorionic somatomammotrophins) has benefited from the recent application of the techniques of molecular genetics; the human placenta is so rich a source of placental lactogen mRNA sequences that human placental lactogen was the first human gene to be cloned (J. Shine *et al.*, 1977). Following its cloning and sequencing, the structure of the placental lactogen gene was shown to be closely related to that of growth hormone, and five hPL genes and two hGH genes have now been identified in genomic fragments (see Miller and Eberhardt, 1983). Clearly these (and the prolactin) genes have evolved by duplication of a common ancestral precursor gene; sequence analysis and application of rules for gauging mutation rates suggests that prolactin diverged from placental lactogen/growth hormone some 400 million years ago, and that placental lactogen and growth hormone diverged about 65 million years ago. Since

the palaeontological records suggest that amphibia evolved about 400 million years ago, and that mammalian radiation commenced some 85–100 million years ago, these events may have coincided. The chromosomal distribution of these genes also indicates that divergence of prolactin from the ancestral placental lactogen/growth hormone precursor preceded separation of the last two hormones, since the human growth hormone and placental lactogen genes are on chromosome 17, the single prolactin gene being on chromosome 6. The human growth hormone and placental lactogen genes are more than 90% identical in nucleotide sequences (including the introns); the homology between the coding regions of prolactin and growth hormone genes is approximately 40%. Rat and mouse placental lactogens have recently been shown to have two forms, which are secreted consecutively, to give rise to a biphasic secretion pattern during pregnancy (Blank *et al.*, 1977; Soares *et al.*, 1983; Colosi *et al.*, 1987; Kishi *et al.*, 1988; Ogren *et al.*, 1989; Faria *et al.*, 1990; Soares *et al.*, 1991). The molecules have been sequenced and cloned (see Colosi *et al.*, 1989, for references). Their synthesis and secretion by the trophoblast giant cells have been studied *in vivo* and with *in vitro* tissue culture techniques (for references see Soares, 1987; Soares *et al.*, 1991; Yamaguchi *et al.*, 1992).

The other principal group of animals in which placental lactogens have been studied in depth are the ruminants (reviews: Forsyth, 1991; Handwerger, 1991; Byatt *et al.*, 1992); however, less is known of the evolution of these hormones than of hPL, although the ovine, bovine and caprine proteins have been purified (Beckers *et al.*, 1982; Murthy *et al.*, 1982; Arima and Bremel, 1983; Byatt *et al.*, 1986; Currie et al., 1990, McNeilly *et al.*, this volume) and the molecules sequenced and cloned (Colosi *et al.*, 1989). Studies have been made of their secretion (Martal and Djiane, 1977; Taylor *et al.*, 1983; Wallace *et al.*, 1985; Battista *et al.*, 1990) and their interactions with target tissue receptors (Emane *et al.*, 1986; Freemark *et al.*, 1987).

(c) Placental peptide hormones

A number of peptide hormones have been identified in human placental tissue, including LHRH, ACTH, MSH, TSH, oxytocin and vasopressin (see Diczfalusy and Trën, 1961; Brody, 1969; Allen, 1975; Fisher, 1986). Of these, the best characterized is LHRH, which has been identified by immunocytochemistry, radioimmunoassay and bioassay (Siler-Khodr and Khodr, 1978; Tan and Rousseau, 1983). The presence of LHRH in placental tissue has been confirmed by the use made of placental mRNA extracts in the isolation of cDNA clones for the LHRH prohormone (Seeburg and Adelman, 1984). Because of the availability of large quantities of human placental mRNA, and the scarcity of human hypothalamic mRNA, placental mRNA was used to prepare a cDNA library which was screened for LHRH sequences using synthetic oligonucleotides predicted from the LHRH amino acid sequence. It has been shown that the LHRH prohormone in the placenta is processed to produce not only LHRH, as in the hypothalamus, but also GAP (gonadotrophin releasing factor-associated peptide) (Adelman *et al.*, 1986). The role of this product in the placenta is uncertain; although it has been suggested to play a role in the control of hCG secretion, this is not fully established.

(d) Placental secretion of non-hormonal polypeptides

Application of immunological techniques has led during the past two decades to the recognition in man of some 30 pregnancy-associated polypeptides in the circulation during gestation, which have no established endocrine action. Some of these substances are of clinical value in pregnancy diagnosis because of their dependence upon normal

placental or fetal function and some have been used as tumour markers. In addition, a number of proteins have been identified which are not secreted, but which are constituents of the placenta. Although principally identified in man, some have been shown to be present in other species. For reviews see Bohn *et al.* (1983), Klopper and Ahmed (1985), Rosen (1986).

A number of the better characterized placenta-specific proteins are listed in Table 4.4.

Of these, SP_1 (Schwangerschaft protein 1), a glycoprotein (containing 29% carbohydrate) of molecular weight 43 000 daltons and isoelectric point pH 4.1, has been used most as an aid to diagnosis of normal pregnancy and determination of gestational age (see Bennett *et al.*, 1978; Klopper and Ahmed, 1985). This protein is identical with the pregnancy-associated plasma protein (PAPP) C of Lin *et al.* (1974), with pregnancy-specific β_1-glycoprotein (Towler *et al.*, 1976) and with trophoblast-specific β_1-globulin (Tatarinov and Sokolov, 1977). Among the functions suggested for the proteins of Table 4.4 are: SP_1, as an immunosuppressive, steroid binding protein; PAPP-A, a role in the inhibition of the caseinolytic activity of plasmin and in control of the coagulation and complement cascades; and for PP_5, inhibition of the activities of plasmin and trypsin (and therefore a possible role in the control of trophoblast invasiveness).

In addition to these proteins, a number of enzymes circulating in raised concentrations during pregnancy in man have been suggested to be products of secretion or cell lysis by or in the placenta. These include a heat-stable alkaline phosphatase (see Contractor, 1983), oxytocinase and a histaminase.

4.4.2 CELLULAR ORIGINS OF PLACENTAL HORMONES

A variety of methods have been utilized to identify the tissues responsible for secretion of placental polypeptide hormones, including immunocytochemistry and *in situ* hybridization, particularly in human placental preparations. Using these techniques, a number of independent investigations of the synthesis and storage of human placental lactogen (hPL) have localized this hormone to the syncytiotrophoblast (Hoshina *et al.*, 1982; and see Allen, 1975; Patillo *et al.*, 1983, and references therein). Recently, using electron microscope techniques hPL has been localized to membrane-bound syncytiotrophoblast granules (Fujimoto *et al.*, 1986; Morrish *et al.*, 1988; Billingsley and Wooding, 1990) and ruminant PLs exclusively to granules derived from trophectodermal binucleate cells (section 4.3.6b) (Wooding, 1981; C.S. Lee *et al.*, 1986b–d; Wooding and Beckers, 1987; Wooding *et al.*, 1992). In rodents PLs have been demonstrated in trophectodermal giant cells by light microscope immunocytochemistry (Hall and Talamantes, 1984; Campbell *et al.*, 1989; Nieder and Jenne, 1990) and *in situ* hybridization (Duckworth *et al.*, 1990). The electron microscopic localization of hCG to granules (which are morphologically distinct from hPL-containing granules) exclusively in the syncytium has recently established this tissue as the most likely major site of synthesis (Morrish *et al.*, 1987; Billingsley and Wooding, 1990). However, hCG mRNA has been demonstrated in both cytotrophoblast and syncytiotrophoblast by *in situ* hybridization techniques and cells of cytotrophoblast morphology can produce hCG in culture (Boime *et al.*, 1989). This is perhaps not surprising since cytotrophoblast forms syncytiotrophoblast and hCG production is thus merely a precocious expression of a major function.

Methods for the localization of steroids in cell layers have recently been reported using antibodies directed against these small molecules coupled to haptens (G.J. King and Ackerley, 1985). At the light microscope level progesterone and oestrogens were localized exclusively in the syncytiotrophoblast in

Table 4.4 Properties of selected placental polypeptides in man

human placenta (Dobashi *et al.*, 1985). However, one would expect that most free steroid will be lost from the tissue during immunocytochemical processing so that a more promising approach is to localize the enzymes unique to steroid synthesis. It should be possible to achieve this with antibodies against them, or by using cDNA probes for their mRNAs. Ultrastructural 'evidence' for steroid synthesis – the presence in a cell of smooth endoplasmic reticulum and lipid droplets – is very unsatisfactory because the correlation is so weak, a reservation which also applies to histochemical methods claiming to localize enzymes such as 3β-hydroxysteroid dehydrogenase. Nonetheless, all the above rather unsatisfactory evidence points to the syncytiotrophoblast as a major site of steroid synthesis in human (Pattillo *et al.*, 1983) and sheep placentas (Ferguson and Christie, 1967) and in trophectodermal giant cells in rodents (Sherman, 1983).

4.4.3 FUNCTIONS OF PLACENTAL HORMONES

The five primary physiological effects of placental hormones listed at the beginning of this section can be provided for by the four main classes of hormone discussed above. However, not all these hormones are secreted by placentas of all species, whereas all five processes are prerequisites for successful intrauterine gestation, so that in some cases they must be provided for by alternative mechanisms.

Broadly speaking, the functions of the placental hormones are as follows, listed here in the order in which they are generally thought to act. In human pregnancy, chorionic gonadotrophin, which is produced immediately following implantation on day 8 or 9 after ovulation (shortly after the 58-cell stage), acts on the corpus luteum to prevent its regression (luteolysis), thereby ensuring a continued supply of progesterone. The requirement for progesterone is met by the placenta after about the sixth or seventh week of gestation (the time of the luteoplacental shift; Csapo, 1977). Progesterone secreted by either the corpus luteum or the conceptus is thought to have several actions necessary for the establishment of pregnancy, including blockade of myometrial prostaglandin production, thereby reducing uterine contractility, stimulation of endometrial gland secretion and inhibition of ovulation, through a negative feedback action on the hypothalamus to prevent FSH secretion.

It should be noted that the luteotrophic role of chorionic gonadotrophin is recognized only in primates; in other species, in particular those with a uterine luteolysin, maintenance of luteal function early in gestation is ensured by inhibition of the secretion of luteolysin by the uterus – an antiluteolytic action. In the sheep, in which this process has been studied in detail, the uterine luteolysin is prostaglandin $F_{2\alpha}$, and its release to the circulation is prevented by secretion by the conceptus of an antiluteolytic protein, termed trophoblastin (Martal *et al.*, 1979; Guillomot *et al.*, 1990) or ovine trophoblast protein 1 (Godkin *et al.*, 1984a; Roberts *et al.*, 1985, 1990; Farin *et al.*, 1989, 1990). The ovine protein, which has recently been shown to be an interferon (Imakawa *et al.*, 1987, 1989; H.J. Stewart *et al.*, 1987), is a relatively low molecular weight compound (16 500 daltons) which is known to interact with endometrial cell membrane receptors (Godkin *et al.*, 1984a,b; H.J. Stewart *et al.*, 1987). A similar protein, bovine trophoblast protein 1, has also been demonstrated in cows (Lifsey *et al.*, 1989).

The principal actions of the other placental steroids, the oestrogens, are thought to be exerted on the myometrium, to cause growth of smooth muscle cells, to accommodate the growing conceptus and to prepare for the onset of parturition (Csapo and Corner, 1952; Michael and Schofield, 1968). In addition, oestrogens have well-defined roles in cellular

proliferation in the endometrium (see Finn and Porter, 1975). Maintenance of high circulating oestrogen concentrations might also be expected to lead to enhanced sensitivity of progesterone-responsive tissues to progesterone, by increasing target tissue progesterone receptor concentrations.

Placental lactogens have been reported to act in a number of ways. Although they are usually considered primarily responsible for mammary development during pregnancy, they most probably act in concert with other hormones to have this effect (Forsyth, 1986), and not all mammals have placental lactogens. Other actions of these hormones include the stimulation of growth factor synthesis (Gluckman *et al.*, 1987; Strain *et al.*, 1987) and effects on maternal metabolism to increase circulating concentrations of metabolites for fetal utilization (Munro, 1980; Chan *et al.*, 1986).

4.5 INTERSPECIFIC EMBRYO TRANSFER AND HYBRID PREGNANCIES: ROLE OF THE PLACENTA

There has recently been increased interest in cross-species hybridization because of the development of embryo transfer techniques and their application to the conservation of endangered species by propagation of rare animals using more readily available surrogate hosts (see G.B. Anderson, 1988). Among notable examples of the application of this procedure are the transfer of the embryos of donkeys (*Equus asinus*), Przewalski horses (*E. przewalskii*) and zebra (*E. burchelli*) to thoroughbred mares (*E. caballus*) (Allen *et al.*, 1986; Summers *et al.*, 1987); *Bos taurus* to *Bos indicus*, *B. gaurus* to *B. taurus* and *Ovis musimon* to *O. aries* (Durrant and Benirschke, 1981); and bongo antelope (*Tragelaptius euryceros*) to African eland (*T. oryk*); (Dresser *et al.*, 1985). Successful application of the technique has been limited to closely related species.

Among the factors limiting interspecific transfers is some form of incompatibility of placentation. In many cases this is likely to include immunological incompatibility. There are two approaches by which this difficulty may be assessed and overcome. Firstly, a consideration of the ability of two species to hybridize may provide an indication of possible success of embryo transfer (Gray, 1971), and there is extensive literature on successful and attempted hybridization experiments. A second approach is in the transfer of inner cell mass cells (of the rare species) within the trophectoderm cells of the host; this technique, which was pioneered as means of identification and manipulation of cell lines in the developing embryo (Gardner, 1975), has been exploited most successfully in crosses of *M. musculus* x *M. caroli* (Rossant and Frels, 1980; Croy *et al.*, 1982; Crepeau *et al.*, 1989).

Because of the large amount of work done with them, sheep x goat crosses are of particular interest in relation to interspecies hybridization. While most authors agree that these hybrid embryos die between the fourth and fifth week of gestation, there have been reports of the birth of live offspring: Bunch *et al.* (1976) described the fertile twin offspring of a female 'Spanish' goat (2n = 60) and a Barbados sheep ram (2n = 54). The hybrids had an intermediate phenotype and chromosome number (2n = 57), and the female progeny was bred back to a Barbados ram, with the resulting twins having 2n = 55. It has been suggested on the basis of morphological examination of the site of placental attachment (and on other grounds) that pregnancy failure in cases of unsuccessful hybridization is caused by immunological rejection (McGovern, 1973; Benirschke, 1983); this is consistent with observations of Croy *et al.* (1982) and Crepeau *et al.* (1989) on rejection of *M. caroli* embryos in *M. musculus*, and with the fact that prior immunization of goats against sheep tissue reduces the length of fetal survival in crosses of these species (McGovern, 1973). Endocrine factors are unlikely to account for interspecies incom-

patibility in sheep x goat hybrids; simultaneous homospecific embryo transfer does not improve the outcome of sheep × goat hybridization, so failure to maintain the corpus luteum is unlikely to be involved. Furthermore, crosses between *O. aries* (2n = 54) and *Ammotragus lervia* (Barbary sheep, 2n = 58) are generally unsuccessful, although the latter species, unlike the goat but like the sheep, has a progesterone-secreting placenta (Flint *et al.*, 1983). Successful goat × sheep chimaeras have been produced by heterologous inner cell mass transfer with homologous trophectoderm (Fehilly *et al.*, 1984; Meinecke-Tillmann, 1984), but there is no information on placental endocrinology in these pregnancies. Transfer of Dall's sheep embryos to the uteri of domestic ewes has generally been unsuccessful (Buckrell *et al.*, 1990). Clearly an exciting prospect in this field is the possibility of storing gametes or even somatic DNA from endangered species; indeed it may one day be possible to revive extinct species using DNA recovered from their carcasses – DNA sequences from extinct animals have already been published.

4.6 VIVIPARITY

4.6.1 FUNCTIONAL REQUIREMENTS

The adoption of viviparity has involved the acquisition by the embryonic membranes of a number of functions not associated with them in the oviparous condition. However, there are functions, such as gaseous exchange, that are evidently necessary in oviparity and viviparity, quite regardless of the length of time for which the embryo is retained in the uterus. The placental functions associated with viviparity, which include endocrine functions (Amoroso *et al.*, 1979) and those involved in the absorption of uterine secretions not found in the egg, should therefore be seen as being superimposed upon those that are more primitive. Unfortunately, too little is known about the intrauterine environment and maternal physiology, in too few species, to permit a synthesis of laws accounting for the various morphological and functional characteristics of fetal membranes in vertebrates in general. Species differences further complicate the issue. Nonetheless, some generalizations can be made.

The need to provide large amounts of yolk *in utero*, for the development of the embryo as occurred during the evolution of elasmobranchs, required the yolk sac enveloping the yolk to become well vascularized, larger and longer lasting. This membrane, being derived from the fetal gut, is well adapted to convey extraembryonic material in the yolk into the fetal circulation by pinocytosis. It serves as an intrauterine organ of exchange in viviparous species in this order. Following colonization of the land, it was necessary for these early vertebrates either to become viviparous or to develop eggs capable of surviving out of water. The adaptations resulting from these pressures are the amnion and the allantois, the former presumably coming into being as a means of providing the embryo with its own private sea, the latter initially as a repository for excretory products and an organ of gaseous exchange. The development of these membranes provided a means for carrying out functions not undertaken by the yolk sac, perhaps because it was too highly specialized for absorption of nutrient of a particular type. The yolk sac is capable of carrying out sufficient gaseous exchange to support early embryonic development in the avian egg; but later in development, when the fetal needs increase, the allantois takes over this role. The allantois is also involved in uptake of nutrients; in the chick, the allantoic capillaries deeply indent the chorionic ectoderm, with which the embryo is surrounded. This not only increases the capacity for gaseous exchange, but also provides a means for the absorption, by the chorioallantois, of large quantities of calcium from the egg shell. Thus in the highly developed avian egg there

is a vascularized yolk sac membrane capable of sustaining gaseous exchange early in development, but mainly adapted for pinocytotic absorption of yolk and a chorioallantoic membrane subsequently developed for gaseous exchange and absorption of mineral.

4.6.2 THE EVOLUTION OF VIVIPARITY

Placentation is associated with viviparity. It is relevant therefore to a discussion of placentation to enquire as to the nature of viviparity. It should be noted from the outset that the terminology – oviparity, ovoviviparity, viviparity – is restrictive, in that each of these categories of parity includes a wide range of forms; for instance the term oviparity covers oviposition of both fertilized and unfertilized eggs, and viviparous organisms include those with both external and internal fertilization (see Guillette, 1991). Furthermore, there are other, equally revealing, characteristics that need to be considered when seeking to categorize forms of reproduction (for example see Crews, 1992). Forms of viviparity and ovoviviparity have been considered in more detail by Mossman (1987) and Clutton-Brock (1991).

The European olm (*Proteus anguinis*), a blind, colourless salamander of the Italian Alps, can be either oviparous or viviparous. When the ambient temperature rises above about 12°C, all of the eggs ovulated by this amphibian (approximately 60) are laid, though not all develop; at lower temperatures a single egg develops in each oviduct, and live young are born. This change in reproductive pattern occurs under artificial conditions, as well as in nature, and has been studied in the laboratory. There are also reptiles which are believed to be both viviparous and oviparous but in different geographic locations: examples are the Mexican lizard, *Sceloporus aeneus* (viviparous in some sites in southern Mexico, oviparous in others); the skink, *Mabuya quinquetaeniata* (viviparous in South America, oviparous elsewhere); the iguana, *Sceloporus variabilis* (viviparous at high altitudes in Veracruz, Mexico); and the vipers *Echis carinata* and *Aspis vipera* (oviparous in some locations, viviparous in others; see Hogarth, 1976; Guillette, 1981).

The existence of animals which can be both oviparous and vivparous or in which closely related species have both characteristics emphasizes one of the most striking characteristics of viviparity: that it is a readily adopted condition. This is further underlined by the wide range of viviparous invertebrates and vertebrates, the large number of times the condition has evolved in different phyla and the variety of methods used (see Shine and Guillette, 1988). That viviparous species evolved from oviparous species is shown by the existence of egg-teeth in embryos of viviparous reptiles.

Viviparity occurs in all classes of amniote vertebrates except birds and takes a number of forms; the organ most frequently utilized for embryonic development is the oviduct or uterus, but there are examples of embryonic development occurring in the ovary (notably in the teleost fishes, in which gestation may occur either in the ovarian follicles as in the family Poeciliidae or in a chamber within the ovary, following ovulation, as in the blenny, *Zoarces viviparus*). Gestation may also occur in the mouth (as in the catfish, *Galeichthys*); in the stomach (as in the Australian anuran amphibian, *Rheobatrachus silus*); and in skin pouches (as in the Surinam toad, *Pipa surinamensis*). In these cases the embryos develop specialized organs for nutrient exchange, including vascular tails and outgrowths from the gills and pericardium; the embryonic membranes of the amniote egg are not utilized for this purpose. These forms of gestation are dealt with in detail in sections 4.31, 4.32 and 4.34 above.

It is difficult to generalize about the forms of viviparity adopted by invertebrates because, as with lower vertebrates, a wide range of organs is utilized. But there are

examples of structures specialized for nutrient exchange in invertebrates, which fulfil the criteria for placentas, as for example in the marine tunicate, *Salpa* (Bone *et al.*, 1985).

The principal advantages conferred by viviparous reproduction appear to lie in the protection the condition provides for the developing embryo against fluctuations in environmental conditions. This is particularly important for terrestrial species, which must if oviparous either return to water to breed or lay an egg protected against desiccation. The main environmental advantages are usually seen as those relating to temperature, availability of water, provision of food for emerging young, selection of a site for birth and protection against predation. The complicated behaviour patterns evolved by birds to ensure incubation of the eggs demonstrate the lengths to which oviparous species must go to provide some degree of homeostasis for their developing offspring. It is not necessarily true that the birth of live young leads to a greater degree of post-partum maternal care: the existence of the monotremes, oviparous mammals, emphasizes the fact that lactation and viviparity are not inseparable conditions. Lactation and endothermy evolved before viviparity in mammals. Nonetheless, it does appear that viviparity may be utilized by species colonizing environmentally extreme locations, for example at high latitudes and altitudes.

Although internal fertilization does not invariably lead to viviparity, one prerequisite for viviparity in amniote vertebrates is a means of transferring spermatozoa with concomitant internal fertilization, and structures for providing and absorbing maternal nutrients at the site at which development occurs. Internal fertilization confers advantages of its own, in as much as it reduces the risks of loss of spermatozoa and interspecies fertilization. It does not, however, invariably involve an intromittent organ; in the salamanders and newts the spermatozoa are frequently deposited in a protective capsule (spermatophore) which the female picks up with the lips of the cloaca.

While organs evolved for internal fertilization show little variability, embryonic absorptive organs, in contrast, take many forms, particularly in amphibia, in which they include specially adapted gills (as in *Gastrotheca*, in which development occurs in maternal skin pouches), and vascularized tails (as in the tadpole of the toad *Pipa surinamensis*, also incubated in a skin pouch). The chorioallantoic placenta provides an amniote example of organs specialized for this role.

With the development of maternal structures specialized for embryonic nutrition the nature of the material secreted (uterine milk) becomes more complex, the metabolic cost to the mother becomes more severe and the weight gain by the conceptus more dramatic (Table 4.2). Furthermore, the dependence of the uterus on endocrine stimulation by ovarian or embryonic hormones also becomes more important, and in both oviparous elasmobranchs and viviparous species with a simple serous type of uterine milk the uterus responds to administered oestrogen with increased vascularization and growth of the oviduct or uterus.

One of the reasons for the relative ease with which viviparity is adopted, particularly among amniote vertebrates, is the nature of the embryonic membranes of the egg, which are the evolutionary precursors of the embryonic membranes of the mammalian placenta (Figure 4.1). These membranes, which are adapted in the egg for gaseous exchange and the absorption of nutrients in the form of yolk, retain these functions in viviparity and take on others. In the mother, in addition, similar structures exist in oviparous and viviparous species for the provision of nutrients to the developing embryo, in the form of either yolk (in oviparity) or histotroph (in viviparity). Thus, limited anatomical alterations are required for the adoption of viviparity, once internal fertilization is achieved. In general, the degree to which the embry-

onic membranes have evolved is related to the dependence of the developing embryo on nutrients derived from the mother. Where there is no nutrient exchange, as in ovoviviparous species, there is no development of egg membranes and, in fact, no loss of the shell membrane. The evolution of placentation in vertebrates and the concomitant decline in the quantity of yolk in the egg parallels the ability to absorb maternal nutrients. The eggs of all viviparous reptiles are yolk rich. Development of placental endocrine function provides a means by which the conceptus is able to affect maternal metabolism in order to ensure mobilization of a sufficient supply of nutrient (for instance through secretion of a placental lactogen).

What then are the most important adaptations associated with viviparous reproduction? A potentially important change involves the corpus luteum and its secretions; as Amoroso (1981) commented: 'although the exact steps through which the corpus luteum was incorporated as an endocrine gland may remain obscure, there can be little doubt that this adaptation was the most important contributing factor in the evolution of viviparity in mammals'. It seems most probable that the existence of progesterone, secreted by a corpus luteum in oviparous species, was exploited in the evolution of viviparity for the purposes of continuing the provision of embryonic nutrition: an example of Medawar's proposition (Medawar, 1953) that 'it is not hormones which have evolved but the uses to which they are put'. Comparison of circulating progesterone levels during the reproductive season in the oviparous turtle, *Chrysemys picta* with that in the viviparous snake, *Natrix fasciata*, emphasizes the importance of post-ovulatory progesterone in the viviparous condition (Porter *et al.*, 1982).

Guillette and his colleagues (Guillette, 1982, 1991; Shine and Guillette, 1988) have suggested that the evolution of viviparity involves selection pressures acting on phenotypic variability in egg retention, with animals in extreme environments retaining oviductal eggs for progressively longer periods. A concomitant thinning of the shell, to allow gaseous exhange, accompanied by increasing maternal nutrient secretion, eventually leads from oviparity, via intermediate ovoviviparous stages, to viviparity. They propose that progesterone, possibly secreted by the adrenal glands, as well as the corpora lutea, causes prolonged retention in relatively stressful conditions, and the effects of progesterone on the mammalian uterus (increased nutrient secretion, decreased mobility and reduced prostaglandin secretion) are consistent with this hypothesis.

Among squamates (lizards and snakes), in which this hypothesis has been most fully developed, oviparous species retain their eggs *in utero* for up to half the period of embryonic development, and post-ovulatory corpora lutea occur in all vertebrate groups (though they are transitory in cyclostomes and birds), and are steroidogenic in all species of reptile. Reptilian corpora lutea are susceptible to regression by prostaglandin $F_{2\alpha}$ (Guillette *et al.*, 1984), and prostaglandin $F_{2\alpha}$ is synthesized by the oviduct in at least one viviparous lizard (Guillette *et al.*, 1988).

All three effects of progesterone facilitate prolonged egg retention and continued luteal function (by delaying luteolysis), and this may explain the apparent ease with which prolonged egg retention has resulted in viviparity in many different species.

However, not all aspects of this hypothesis are supported by experimental data, and although attractive in many taxa (especially the lizards), there is contradictory evidence. Experimental evidence is not available to directly link prolonged uterine egg retention with high levels of endogenous progesterone, or to confirm that raised progesterone secretion can be a direct response to adverse environmental conditions (see Shine and Guillette, 1988), although these questions are amenable to investigation. The possible contribution of relaxin, also secreted by the cor-

pora lutea, and a potent inhibitor of uterine contractility in several species of mammal, should also be considered in this context (see Porter *et al.*, 1982).

The adoption of viviparity, and the establishment of close contact between the developing embryo and the mother, provides an opportunity for the conceptus to influence maternal physiology through endocrine mechanisms. This occurs early in pregnancy in many species, when the conceptus secretes substances which ensure the prolongation of corpus luteum function beyond the period of the oestrous cycle; the time at which this occurs is known as the time of the maternal recognition of pregnancy and it is a well-characterized process, particularly in those species (e.g. artiodactyls) in which it occurs before the attachment of the blastocyst to the uterine endometrium. A number of substances of embryonic origin are responsible for this process, including an interferon (the antiluteolysin which controls uterine production of prostaglandin $F_{2\alpha}$ in ruminants), chorionic gonadotrophins (in primates) and perhaps oestrogens (in pigs). Another substance capable of controlling corpus luteum function is prolactin, which is produced in the decidua, and has been suggested to affect fluid transport across the embryonic membranes (see Porter *et al.*, 1982). Clearly the coexistence in the monotremes of oviparity and lactation rules out the possibility that mammary development and lactation depend exclusively on hormones secreted by the placenta; in fact in some eutherian mammals (e.g. pigs) no mammogenic hormone has been identified in the placenta, although many species, particularly rodents, artiodactyls and primates, produce placental lactogens.

The parallels between oviposition and parturition, particularly as regards similarities in their endocrine control, have been drawn previously (e.g. Toth *et al.*, 1983), and it is tempting to view parturition as oviposition delayed, not least because the same hormones are involved in both processes (see R.E. Jones and Guillette, 1982). The frequent occurrence of a post-partum (as in rodents) or prepartum (as in hares) oestrus and ovulation further emphasizes the similarity: progesterone, oestrogens, prostaglandins and the neurohypophysial peptides, oxytocin or vasotocin, clearly are involved in both cases. However, the trigger to parturition, which in many species arises in the fetus (e.g. fetal glucocorticoid; see section 4.4.1a) differs from that causing oviposition, which resides in the hypothalamus; in fact it may be more appropriate from a fetal point of view to consider parturition as akin to hatching.

In summary, the prerequisites for vertebrate viviparity presumably include the following: (a) acquisition of internal fertilization; (b) development of a corpus luteum which controls endometrial glandular secretion of egg nutrients; (c) either luteal production of a compound such as relaxin, which blocks oviductal smooth muscle, or the acquisition, by oviductal smooth muscle, of the block to contractility induced by progesterone; (d) thinning of the tertiary layers surrounding the egg, and loss of the egg shell, accompanied by a reduction in the number of uterine glands; (e) embryonic absorption of maternal nutrients; (f) a block to immunological rejection of the conceptus; (g) a mechanism for ensuring parturition. The principal disadvantage with this form of reproduction is that the size of the fetal brain at birth, which may have consequences for the intelligence of the offspring, is limited by the size of the mother's pelvic girdle, and it may be no coincidence that relaxin, which reduces uterine contractility, and thereby prolongs uterine retention of the conceptus, also leads to separation of the pelvic symphyses. This is particularly marked in species such as the guinea pig, with large and precocious young.

ACKNOWLEDGEMENTS

We are grateful to our many colleagues who gave their advice, information and illustrations. Our particular thanks to Hamish Batten, Bruce Currie, Allen Enders, Brian Heap, Loren Hoffman, Donald Steven and Steven Wooding for their constructive comments on draft versions, Pamela Blythe, Amanda Hayward, Catherine Blows, Julie Brown and Monica Bradshaw for their multifarious secretarial and concordance skills and patience.

5.1 INTRODUCTION

The pre-eminent function of the human placenta is transfer of nutrients, gases and waste products between the mother and the fetus. At the same time, it is also extraordinarily active in the synthesis of a wide range of proteins and other molecules. Some of these are the structural proteins, enzymes, etc., which are part of the normal functional equipment of cells throughout the body and thus are in no sense specific to this particular organ. The respiratory enzymes are one example. Another example, though slightly more limited in overall distribution, is the group of enzymes responsible for steroid synthesis and interconversion; these do not differ from their counterparts in other steroid-producing tissues. In addition, the placenta contains low concentrations of ACTH-related peptides and hypothalamic releasing hormones, none of which differs significantly from their hypothalamic–pituitary counterparts (J.N. Lee *et al.*, 1981, 1982).

More important, and the theme of the present chapter, are the two most familiar members of the group of proteins which the placenta undoubtedly synthesizes and secretes, and which in the past have frequently been described as 'specific' to this organ: human chorionic gonadotrophin (hCG) and human placental lactogen (hPL). However, it is now apparent that there is no material which is qualitatively specific in the sense of occurring uniquely in the placenta and not in any other site. Thus, most (possibly all) of the classical products of the human placenta, including hCG and hPL, can be found in seminal fluid and ovarian follicular fluid and small amounts of hCG have been recognized in the pituitary gland and many normal tissues (sections 5.3.1 and 5.4.1). This chapter is concerned with the two classical protein hormones of group 1, hCG and hPL.

5.2 HUMAN CHORIONIC GONADOTROPHIN

5.2.1 HISTORICAL SURVEY

The hormones of the placenta have only been studied in detail in the last 60 years, but certain properties of placental tissue were noted much earlier. Medvei (1982) described the use of dried placentas to improve the fertility of Chinese and Javanese women. In parts of Hungary it was the custom for women wishing to limit their families to burn their placentas and mix the ashes in the drink of their husbands. Furthermore, it has long been observed that some female animals eat their placentas and that chimpanzees in labour drink their own urine.

The human placenta was first shown to produce a gonadotrophin by Hirose in 1919 (quoted by Hussa, 1987). Human placental tissue was implanted under the skin of rabbits and morphological changes associated with ovulation and fertilization were observed in the ovaries, uterus and vagina. Similar changes were noted by Aschheim and Zondek (1927a), when they implanted 'hypophyseal' (anterior pituitary) tissue under the skin of immature mice. This resulted in the rapid onset of oestrus as a result of ovarian maturation (quoted by Aschheim, 1930). Aschheim and Zondek (1927b) subsequently discovered that early pregnancy sera and urine contained extremely high levels of this gonadotrophic substance, which they referred to as 'Hypophysenvorderlappenhormons' (hypophyseal hormone). However, the hormone was found at high levels in, and was therefore probably produced by, the placenta and decidua. They concluded that the uterine changes were a result of ovarian follicular maturation and thus indirect effects of the hormone. The morphological changes in the ovaries (multiple follicular growth, rupture and corpus luteum formation) formed the basis for the Aschheim–Zondek bioassay

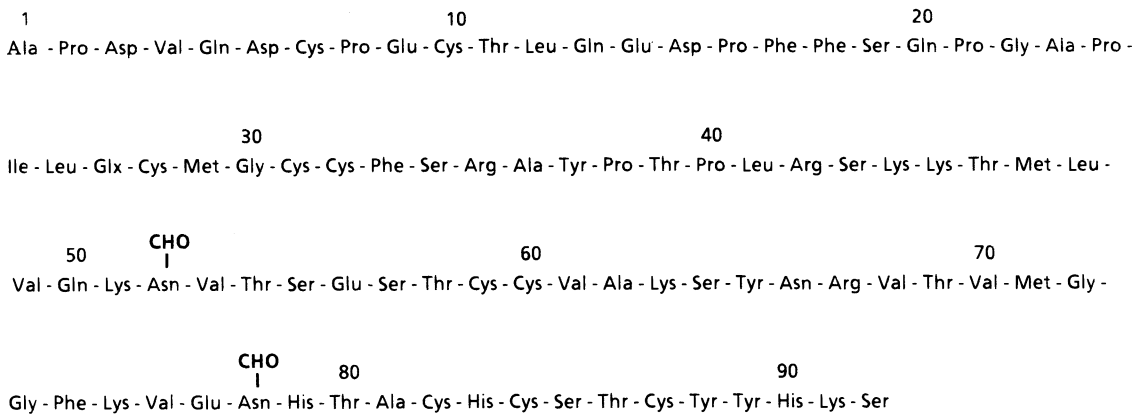

Figure 5.1 Amino acid sequence of the glycoprotein hormone α-subunit. CHO indicates positions of glycosylation. (Adapted from Hussa, 1987.)

for the early diagnosis of pregnancy using a specimen of urine (Aschheim and Zondek, 1927a).

5.3 CHORIONIC GONADOTROPHIN AND THE GLYCOPROTEIN HORMONES

Chorionic gonadotrophin (CG) is a member of a group of four structurally homologous proteins commonly referred to as the glycoprotein hormones. As the name implies, the hormone protein chains are glycosylated; hCG contains approximately 30% carbohydrate by weight. The other members are luteinizing hormone (LH), follicle-stimulating hormone (FSH) and thyroid-stimulating hormone (TSH). CG differs from the other glycoprotein hormones in that it is produced by the placenta whilst LH, FSH and TSH are pituitary products. CG, LH and FSH are gonadotrophins, stimulating ovarian and testicular functions via regulation of gametogenesis and gonadal steroid hormone synthesis. TSH acts on the thyroid gland, resulting in synthesis and secretion of thyroid hormones. All share a common subunit structure of α- and β-peptide chains which are non-covalently joined. The α-subunit (Figure 5.1) is common to all members of the this family whilst the β-subunits differ and confer hormonal specificity.

The subunits are biologically inactive in the free form; only the α–β heterodimer is able to bind to and stimulate the hormone receptors (reviewed by Pierce and Parsons, 1981). The peptide chains show close homology, the greatest being between the β-subunits of LH and CG (81%) (Figure 5.2).

hCG and LH bind to the same gonadal receptor, stimulating steroid synthesis and luteinization. The β-subunits are believed to have evolved from the common α-subunit gene (Fiddes and Talmadge, 1984). LH, FSH and TSH have been found in all mammals studied, and hormones with similar properties have been found in lower vertebrates, including teleost fish (reviewed by Pierce and Parsons, 1981). However, placenta-derived CG-like material is only found in two genera of mammals, primates and equids, having evolved separately within these two (Leigh and Stewart, 1990).

5.3.1 BIOSYNTHESIS

(a) Sources

Chorionic gonadotrophin is secreted by the syncytiotrophoblast cells of the placenta and is present in the blood and urine of pregnant women. First-trimester placental extracts have been shown to contain α- and β-

subunits of hCG, immature forms of these subunits and hCG itself (Tominaga *et al.*, 1989). There are other production sites which include trophoblastic or ectopic neoplasms. With the introduction of highly sensitive immunoassays, hCG or hCG-like material has also been detected in very small amounts in previously unsuspected conditions and tissues. Hartree *et al.* (1983) extracted material similar to hCG from the urine of some normal men and women and from the pituitary. They found quantities ranging from 0.5 to 1.1 μg per gland, which is some 25- to 50-fold less than the content of LH, FSH or TSH. The concentration in acetone-dried pituitaries ranges from 0.4 to 26 ng/mg which is close to that reported for full-term placental powder. The most active fraction was about 5% as potent as hCG itself; this was detected using antisera to the C-terminal residues 123–145 and 116–145, which react to hCG but not to LH. Minute amounts of hCG or the β-subunit have also been found in many normal tissues (Braunstein *et al.*, 1979; Yoshimoto *et al.*, 1979), in pituitaries (Matsuura *et al.*, 1980), especially of post-menopausal females (Armstrong *et al.*, 1984; Huang *et al.*, 1984), and in the urine of non-pregnant subjects (H.C. Chen *et al.*, 1978; D.M. Robertson *et al.*, 1978).

Yoshimoto *et al.* (1979) demonstrated the presence of hCG-like material in all human tissues they tested by a radioreceptor and a β-hCG radioimmunoassay. However, this material did not bind to concanavalin A as did placental hCG, and it was concluded that the material had the protein core of hCG but not the carbohydrate components. It would therefore have little or no biological activity *in vivo*. It seems that the trophoblastic cell is not unique in its ability to synthesize hCG sub-

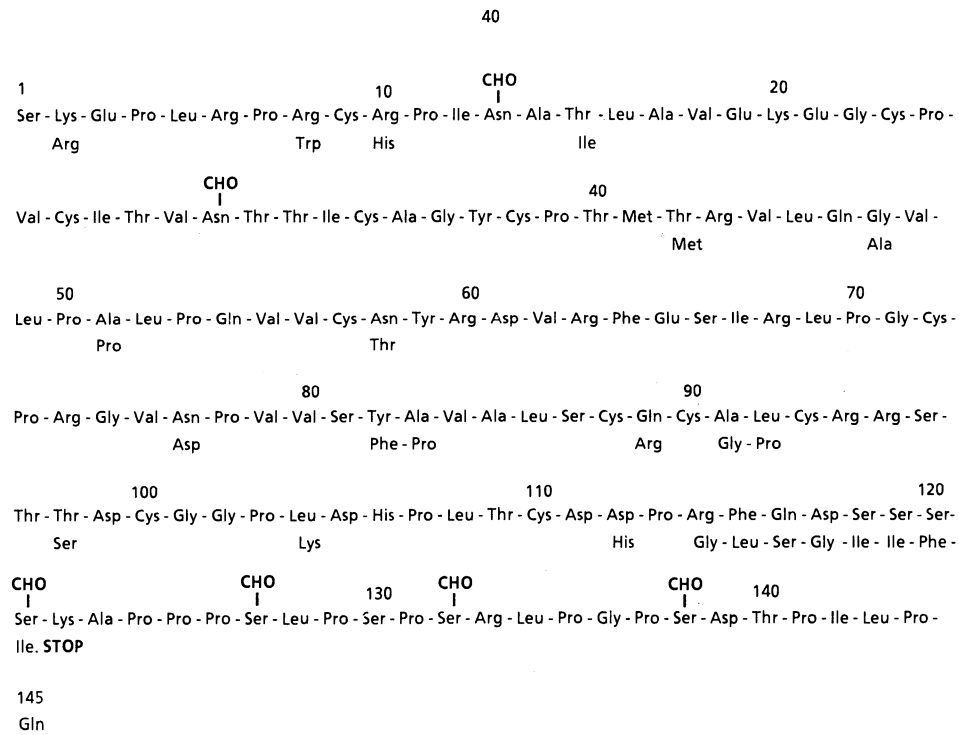

Figure 5.2 Amino acid sequence of the β-subunit of human chorionic gonadotrophin with β-subunit of luteinizing hormone residue differences shown below. CHO indicates positions of glycosylation. (Adapted from Hussa, 1987.)

units but is able to glycosylate and combine these cellular proteins into intact hCG. There is ample evidence for the presence of hCG (and hPL) in seminal plasma (Asch *et al.*, 1977; Ranta *et al.*, 1981; Bischof *et al.*, 1983; J.N. Lee *et al.*, 1983; Salem *et al.*, 1984a) but the levels do not relate to sperm numbers (J.N. Lee *et al.*, 1983). Chan *et al.* (1986) found detectable amounts of β-hCG in almost half the samples of seminal plasma studied. The concentrations were similar in samples from subjects with normal sperm counts and in those with oligospermia and with azoospermia. There were also no differences related to motility, morphology or fertilizing capacity and the physiological role of this β-hCG is at present uncertain. Placental proteins have also been found in ovarian follicular fluid (Westergaard *et al.*, 1985c).

(b) Synthesis of hCG

The common α-subunit is encoded by a single-copy gene on chromosome 6, and the β-subunits of FSH and TSH are encoded by single-copy genes on chromosomes 11 and 1 respectively. The β-subunit genes for LH and hCG are unique in that they form a cluster of seven genes/pseudogenes on the long arm of chromosome 19 (Boorstein *et al.*, 1982; Naylor *et al.*, 1983; Graham *et al.*, 1987). Owing to the close structural and sequence homology of these genes, all are believed to have evolved from a common ancestral α-subunit-like sequence (Fiddes and Goodman, 1980; Fiddes and Talmadge, 1984). This was thought to have been followed by further alterations in the upstream and downstream regulatory elements allowing for the selective expression of these individual peptides. The mechanism of increased gene transcription in pituitary and placental tissues, which specifically express these hormones, is mediated via the cAMP secondary messenger pathway. Though specific releasing hormones have been identified for the pituitary hormones, no known releasing factor has been identified for hCG. However, gonadotrophin-releasing hormone-like material has been identified in placental tissue (J.N. Lee *et al.*, 1981; Kim *et al.*, 1987), but it is not clear whether this is part of a specific control mechanism *in vivo*.

(c) The β-hCG–LH gene cluster

The common α-subunit gene was cloned from a placental mRNA library by Fiddes and Goodman (1979). Shortly afterwards they isolated the cDNA for the β-subunit of hCG (Fiddes and Goodman, 1980). Probing of genomic DNA with the cDNA clones soon established that only one α-subunit gene coded for the common α-subunit peptide of the glycoprotein hormones (Fiddes and Goodman, 1979; Boothby *et al.*, 1981). Analysis of human genomic libraries by Boorstein *et al.* (1982) and Policastro *et al.* (1983) revealed that multiple copy genes hybridized with the β-hCG cDNA. Boorstein *et al.* (1982) estimated that eight copies of β-hCG sequences were present in the human genome. The clone which was identified as 'gene 4' was subsequently shown to be β-LH. β-LH flanked the remaining genes which were arranged in tandem and inverted pairs on chromosome 19 (Julier *et al.*, 1984). This cluster had arisen from β-LH by base substitution in the TAA termination codon, leading to readthrough into the 3′ untranslated region, giving rise to the unique 30 amino acid carboxy-terminal extension (Fiddes and Goodman, 1980; Fiddes and Talmadge, 1984). Independent restriction and recombinant clone analysis by Policastro *et al.* (1986) identified only six β-hCG genes. The structural arrangements of the cluster and position mapping of the six β-hCG genes and β-LH were established by Graham *et al.* in 1987. This was subsequently confirmed by Jameson and Lindell (1988) (Figure 5.3).

The structural and functional organization of the β-hCG–LH gene cluster is of great interest because the presumed gene duplication from which it arose appears to have been followed by functionally significant

divergences within the coding and regulatory sequences (Talmadge *et al.*, 1984a).

(d) Equivalent materials in other species

High levels of chorionic gonadotrophin-like hormones have only been identified in pregnant primates and the pregnant horse. Placental expression of similar gonadotrophins has not been shown for other mammals (Pierce and Parsons, 1981). Using the known nucleic acid homology, β-LH probes have been used in an attempt to identify an equivalent β-CG gene in rats and cattle. Only a single β-LH gene could be detected in these species (Tepper and Roberts, 1984; Virgin *et al.*, 1985). Evidence for placental hormones in primates has been reviewed by Spies and Chappel (1984). There appear to be similarities in the structure of the CG from gorillas and chimpanzees to that from humans, but macaque CG seems to have different antigenic determinants. Tullner and Hertz (1966) recognized CG-like activity in the rhesus

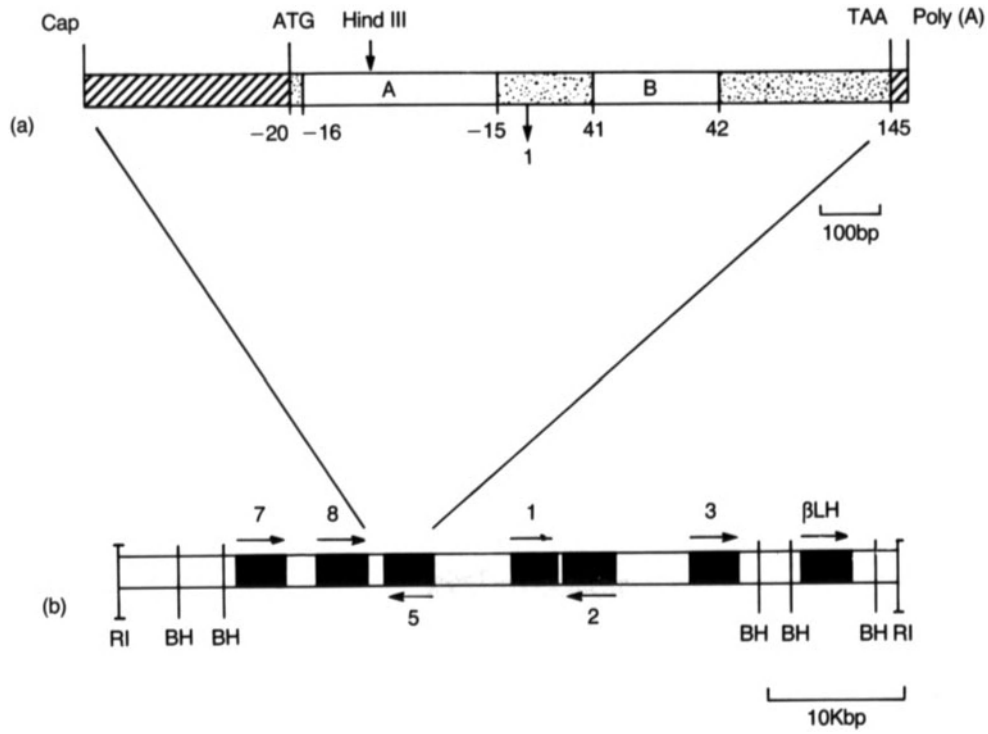

Figure 5.3 Composite structure of the β-subunit of the human chorionic gonadotrophin (β-hCG) gene and the β-hCG–hLH gene cluster. (Adapted from Boorstein *et al.*, 1982, and Graham *et al.*, 1987.) (A) The β-hCG gene/pseudogene structure: stippled areas represent exons and cross-hatched areas 5′ and 3′ untranslated regions. Introns A and B are marked, as are the cap site (Cap), initiation codon (ATG), termination codon (TAA) and polyadenylation site [Poly(A)]. The location of a single HindIII restriction site is also shown. Numbers refer to amino acids, negative numbers being signal peptides. (B) The β-hCG–hLH gene cluster: solid areas represent genes and pseudogenes. The position of the β-LH gene is marked. Numbers refer to β-hCG gene/pseudogenes which are labelled in the order of their isolation and initial sequence mapping (eight related sequences; Boorstein *et al.*, 1982). β-hCG gene 6 is an artefact of gene library construction and is therefore not mapped (gene 4 being β-LH Graham *et al.*, 1987). Arrows represent gene direction 5′–3′. The positions of *Eco*RI (RI) and *Bam*HI (BH) restriction sites are marked.

monkey from about the 35th day of pregnancy. Hobson and Wide (1972) extracted hCG from human placentas and monkey CG (mCG) from placentae of rhesus monkeys (*Macaca mulatta*) and marmosets (*Callithrix jacchus*). The mouse uterine weight test was used to measure the biological activities of hCG and mCG and both were neutralized by the addition of antisera raised to the hCG. There was no divergence from parallelism in the bioassays of the two preparations, but the radioimmunoassay to bioassay potency ratio was much higher than that of mCG.

Pregnancy gonadotrophins in equids have been intensively studied (Allen, 1979; Christakos and Bahl, 1979; Moore and Ward, 1980; Combarnous, 1981; Bousfield *et al.*, 1985). Pregnant mare serum gonadotrophin (PMSG) was first recognized in the 1930s (H.H. Cole and Hart, 1930; Zondek, 1930). It is produced in large quantities between the 40th and 150th days of gestation from the structures known as 'endometrial cups'. It is a glycoprotein with α- and β-subunits and, like hCG, has a C-terminal extension, but it differs from hCG by having FSH-like activity as well as LH.

A CG from the donkey was purified and partially characterized from serum (Aggarwal *et al.*, 1980). This proved to be a glycoprotein with a similar molecular size to the mare gonadotrophin but with slightly less (31% compared with 45%) carbohydrate. In bioassays it was shown to be predominantly LH-like.

The additional carboxy-terminal peptides of the horse and donkey β-CG have very little (if any) amino acid homology with those of the human and the baboon. The frameshift that gave rise to the human and baboon CG carboxy-terminal extension was the result of a single nucleotide deletion at codon 114 of the β-LH gene. In the absence of a published sequence for an equid β-LH gene, the horse and donkey β-CG sequences have been compared with the β-LH sequence of the cow. This has shown that the frameshift responsible for the carboxy-terminal extension is due to a nine nucleotide deletion from codon 112. In addition, there is a loss of amino sequence homology for horse and donkey β-CGs from codon 127. This is due to the insertion of nine additional nucleotides at this point in the donkey β-CG sequence, suggesting independent evolution of β-CG sequences for primates and equids, and indications that further mutations have occurred since the evolutionary divergence of the horse and donkey (Leigh and Stewart, 1990). However, the amino acid sequence of horse β-LH is identical to that of horse placentally derived β-CG (Bousfield *et al.*, 1987). This suggested that in equids the stop codon frameshift which gave rise to the carboxy-terminal extension occurred in the horse β-LH gene. This has now been confirmed by F. Stewart and Maher (1991) and Sherman *et al.* (1992), who have shown that the horse has only a single copy of the β-LH/CG gene. Initial studies also suggest that the same promoter and enhancer elements are responsible for placental and pituitary expression of this equine gonadotropic gene; this is not the case for human expression of CG and LH (Knoll, 1992; Sherman *et al.*, 1992). The variable frameshift and gene duplication events giving rise to β-hCG and lengthened equine β-LH/CG sequences suggest a degree of genetic instability in the ancestral β-LH gene. It would therefore be of great interest to map the evolution of the human β-CG-LH gene cluster through primates of the New and Old Worlds.

(e) β-hCG gene expression

Using transfection into simian virus 40 (SV40)-transformed Chinese hamster ovary (CHO) cells and sequence analysis, Talmadge *et al.* (1984b) found that only β-hCG genes 3, 5 and possibly 1 were transcribed in *in vitro* studies. However, the influence of the promoter sequence SV40 virus could not be excluded. Transfection into non-transformed

mouse Y1 cells (Otani *et al.*, 1988) showed that genes 3, 5 and 8 were transcriptionally active. Assuming that all the genes are regulated by similar promoter and enhancer sequences 5′ of the initiation codon, only genes 3, 5 and 8 are functional. Analysis of mRNA extracted from placental and choriocarcinoma cells by Jameson *et al.* (1987) demonstrated that transcription of β-hCG gene 5 is much the most active (20:1 relative to gene 3). This is in agreement with Otani *et al.* (1988), who found that gene 5 was the most actively expressed, followed by gene 3, then gene 8. A recent study has addressed which of the gene/pseudogenes are silent *in vivo*. Bo and Boime (1992) examined β-hCG mRNA from placenta and from the choriocarcinoma cell line JAR. Though message was detectable from genes 5, 3 and 8 in the expected order of magnitude, message was also detectable from genes 7 and 1 or 2. Furthermore, the message arising from either gene 1 or 2 was shorter than those from the others because of alternative splicing. This indicates that at least five of the six genes are transcriptionally active but that one may undergo alternative splicing. Multiple promoter and enhancer regions are present within 200 bp 5′ of gene 5 of the β-hCG gene cluster (Fenstermaker *et al.*, 1989). However, no known promoter sequences such as the CAAT and TATAA boxes can be found upstream of the cap site of these genes. Expression of β-hCG and α-subunit mRNA by trophoblast and choriocarcinoma cells is responsive to adenylate cyclase/cAMP. Alpha-subunit mRNA expression is 10 times faster than that of β-hCG. This suggests that the activation pathways of regulatory DNA-binding nuclear proteins acting on the cAMP response elements (CREs) adjacent to the α-subunit are not the same as those of the β-hCG genes (Milstead *et al.*, 1987; Anderson *et al.*, 1988; Fenstermaker *et al.*, 1989). All of the glycoprotein hormone genes contain 5′ CRE enhancers which act in conjunction with specific pituitary or placental promoters (Chin, 1988; Jameson and Lindell, 1988; Fenstermaker *et al.*, 1989; Balfour *et al.*, 1990). Expression of the common α-subunit must depend on multiple promoter regions responsive to specific DNA-binding factors occurring in pituitary gonadotrophs and thyrotrophs and in the placental trophoblast (Balfour *et al.*, 1990). Placental expression of the α-subunit only occurs in primates and horses. Unlike the α-subunit genes of the rat (Burnside *et al.*, 1988) and the mouse (D.F. Gordon *et al.*, 1988), which have only one CRE, multiple copies of CRE sequences can be found 5′ of the cap site of the α-subunit gene of primates and horses (Chin and Gharib, 1986). This suggests that a newly evolved promoter element specific to the trophoblast interacts with copies of the CRE enhancer distinct from those involved in pituitary expression of this gene (Knoll, 1992). Down-regulation of the α-subunit in the pituitary is achieved by oestrogen and/ or thyroid hormone acting via nuclear receptors, such as c-ErbA, and specific regulatory elements. For example, down-regulating sequences such as the thyroid response element, which regulates the expression of β-TSH, are also present in the α-subunit gene (Chin, 1988). No such negative-feedback control mechanism has been identified for the β-hCG genes.

(f) Biosynthesis, glycosylation and combination of hCG subunits

Synthesis of intact hCG, like all the glycoprotein hormones, requires the simultaneous activation of both the α- and β-genes. The rate-limiting component of the production of intact hCG and the other glycoprotein hormones is thought to be the rate of the synthesis of the β-subunit. This is supported by evidence that the α-subunit is produced in excess by most glycoprotein hormone-secreting cells. The studies of Milstead *et al.* (1987), which showed much faster transcription of the α-subunit gene in response to

cAMP, would also support this assumption. In pregnancy, maternal serum contains an excess of free β-hCG in the first 3 or 4 weeks post implantation; this is rapidly superseded by large quantities of intact hCG, with very little free β-subunit but a steady increase of free α-subunit (L.A. Cole *et al.*, 1984a; Norman *et al.*, 1985a; Alfthan *et al.*, 1988; L.A. Cole *et al.*, 1990). Kaetzel and Nilson (1988) have suggested that β-LH transcription is not the rate-limiting step in intact LH synthesis. When α-subunit and β-LH genes were co-transfected into CHO cells, selective amplification of the α-subunit gene led to an increase in expression of intact LH. Nevertheless, the pulse-chase experiments of Ruddon *et al.* (1987, 1988) have indicated that the newly synthesized β-LH and β-hCG require time to achieve a conformation appropriate for combination with the α-subunit, thus suggesting that β-subunit synthesis is the rate-limiting determinant. Furthermore, direct comparison between the rates of synthesis of LH and hCG is not possible.

The transfection studies of Corless *et al.* (1987) have shown that free β-hCG, once synthesized, is rapidly secreted. β-LH, by contrast, requires association with the α-subunit before it can be secreted. Until this is achieved, 90% of newly synthesized free β-LH is stored in the cell. α–β association for LH was found to be slow and of poor efficiency. The transfected β-hCG gene product rapidly associated with free α-subunit with high efficiency. In agreement with these studies, Handwerger *et al.* (1987) found that intact hCG and free β-hCG are not stored in trophoblastic secretory granules. By contrast, the free α-subunit can easily be detected in pituitary gonadotroph and placental trophoblast cells. The pulse-chase studies on the JAR choriocarcinoma cell line indicate that precursors of α- and β-subunits undergo changes which allow subunit association (Ruddon *et al.*, 1988). Glycosylation occurs after these crucial conformational changes (Ruddon *et al.*, 1987, 1988). This order of events is supported by the isolation of an incompletely glycosylated form of intact hCG from human placental tissue (H. Wang *et al.*, 1988). No *O*-linked sugars could be detected, only shortened *N*-linked moieties. It is therefore possible that *N*-linked glycosylation begins at the same time as the synthesis of precursors, while *O*-linked sugars are added at the time of subunit association. It should be noted that in these studies only 50% of the β-hCG synthesized by the JAR cell line combined with the α-subunit despite an excess of free α-subunit. This may reflect defects in the processing pathway of this and other hCG-producing carcinomas.

5.3.2 METABOLISM

Only 22% of serum hCG is excreted intact into the urine (Wehmann and Nisula, 1981). Surprisingly, dissociated free α- and β-subunits of hCG are not found in the urine of subjects infused with purified intact hCG. This is not true of pregnancy urine, in which these free subunits are readily identified (Nisula *et al.*, 1989). Clearly the majority of intact hCG is processed by mechanisms other than direct urinary clearance (Sowers *et al.*, 1979). The free subunits of hCG have much faster clearance rates than intact hCG: the mean clearance rate (MCR) of intact hCG is 1.9 ml/min m^2; free α-subunit 50 ml/min m^2; free β-subunit 19 ml/min m^2 (Sowers *et al.*, 1979; Wehmann and Nisula, 1980a; Wehmann *et al.*, 1989). Less than 1% of these free subunits are excreted unaltered into the urine (Wehmann and Nisula, 1980a).

Animal studies have shown that hCG is taken up by the liver, kidney and ovaries. The kidneys are the most important, accounting for 70–80% (Markkanen *et al.*, 1979; K.L. Campbell *et al.*, 1981; Nisula *et al.*, 1989). Hepatic absorption is predominantly via the Kupffer cells of the liver sinusoids and ovarian by the theca/luteal cells. Renal absorption is by cells of the proximal tubules

(Markkanen *et al.*, 1979; K.L. Campbell *et al.*, 1981). Unlike the liver and ovary, virtually no intact hormone can be recovered from kidney tissue homogenates. Kidney homogenate studies have also shown that α-subunit is processed much more rapidly than the β-subunit, which is also retained for longer (Nisula *et al.*, 1989). Whilst desialylation increases hCG MCR by up to 200 times, the quantity of desialylated intact hCG excreted directly into the urine falls to less than 2.5% of that infused (Rosa *et al.*, 1984; Nisula *et al.*, 1989). However, desialylation, and hence exposure of terminal galactose sugars, does not affect liver uptake, nor does blockade of hepatic galactose receptors (Nisula *et al.*, 1989).

A major immunoreactive form of β-hCG found in pregnancy urine is a low molecular weight species clearly distinguishable on Sephadex G-100 exclusion chromatography from intact and free β-subunit of hCG (Kato and Braunstein, 1988). Originally reported in pregnancy urine by Franchimont *et al.* (1972), similar material was also found in the urine of patients with hCG-expressing tumours (Vaitukaitis, 1973). This degradation product of the β-subunit of hCG has been given various names; the commonest designation, 'β-core fragment', is so named because it retains immunological determinants common to the 'core' structure of hCG but not those of the carboxy-terminal peptide (Akar *et al.*, 1988; Wehmann *et al.*, 1987). The β-core fragment has only recently been fully characterized. It consists of two polypeptide chains resulting from tryptic degradation of the β-subunit of hCG. Amino acid residues 6–40 and 55–92 of this subunit, joined by disulphide bridges, constitute the β-core fragment (Birken *et al.*, 1988). It therefore lacks the unique carboxy-terminal peptide and LH/hCG receptor-binding regions. Because it retains conformational immunological determinants common to intact and free β-hCG, it is recognized by many polyclonal antisera raised against (β)-hCG (Iles *et al.*, 1990). β-core is essentially undetectable (< 0.2 ng/ml) in the sera of pregnant women or volunteers and animals infused with exogenous intact hCG and β-hCG. Though detectable in the urine, its appearance in experimental animals and volunteers is delayed for up to 24 h, despite detection of urinary intact hCG very shortly after administration. Furthermore, analysis of rat tissue homogenates following absorption of exogenous hCG reveals immunoreactive β-hCG-like material of the same molecular size as β-core on Sephadex G-100 chromatography (Nisula *et al.*, 1989). Purified β-core infused into volunteers is cleared 100 times faster than intact hCG (MCR 192.0 ml/min m^2). However, further degradation is likely since only 9% of infused material is recovered in the urine (Wehmann *et al.*, 1989). The measurable urinary clearance rate of intact hCG, subunits and core is much lower than the circulatory clearance rates. It is therefore evident that uptake and processing of hCG by body organs, most probably by cells of the renal proximal tubules, is the principal route for hCG metabolism. β-core is therefore likely to be one of these metabolic products and the predominant form of β-hCG immunoreactivity in urine (Wehmann and Nisula, 1980b; Nisula *et al.*, 1989; Wehmann *et al.*, 1989, 1990).

Despite its apparent absence in sera, several workers have suggested that β-core is a distinct product of the placenta and neoplasms (L.A. Cole and Birken, 1988; Kardana *et al.*, 1988). Recently, it has been suggested that the urinary β-core fragment of human chorionic gonadotrophin (hCG) may be a marker in women with non-trophoblastic gynaecological malignancy (L.A. Cole *et al.*, 1988; Y. Wang *et al.*, 1988; Nam *et al.*, 1989; C.L. Lee *et al.*, 1991). This is largely based on the observation that β-core can often be the sole measurable hCG-related tumour marker in some cancer patients (Papapetrou and Nicopoulou, 1986).

More recent studies have shown that immunoreactive β-core-like material is present in urine of pre- and post-menopausal women

with no malignant disease. The levels are five times higher in the post- than the pre-menopausal woman (C.L. Lee *et al.*, 1991). Immunochemical characterization of this post-menopausal material revealed that it was of the same molecular size as the β-core of hCG but considerably more immunoreactive in LH assays than authentic β-core of pregnancy. Significant quantities of intact hCG are not found in the blood or urine of post-menopausal women; however, LH levels are elevated. Theoretically, a breakdown product similar to hCG β-core should result from the metabolism of LH in the kidney. The amino acid sequence of a putative LH β-core would be virtually identical to that of hCG-β-core (Iles *et al.*, 1992).

The process by which intact hCG is metabolized would appear to begin in the blood with the cleavage ('nicking') of internal bonds at residues 43–49 of the β-subunit whilst it is still associated with the α-subunit (L.A. Cole *et al.*, 1993). This is the centre of a major binding loop (residues 38–57) common to both LH and hCG (Ryan *et al.*, 1987). This region is also missing in the β-core molecule of hCG. Identical 'nicking' was described in preparations of LH 20 years earlier (Shome and Parlow, 1973). Thus, both nicked intact hCG and nicked LH have been identified, suggesting a common degradation pathway. The existence of a β-LH core implies the existence of β-TSH core and β-FSH core molecules (Iles *et al.*, 1992).

5.3.3 CHEMISTRY

(a) Methods of extraction

The earliest methods depended on precipitation from urine with acetone or ethanol, but adsorption to benzoic acid is more economical (Katzman and Doisy, 1934). The benzoic acid precipitate can be dissolved in acetone or ethanol, which simultaneously precipitates the adsorbed protein. Adsorption of the hormone from acidified urine to Permutit (Katzman *et al.*, 1943) or to kaolin with subsequent elution in alkali and precipitation from ethanol has also been widely used. Methods are also available for extracting the hormone from placental tissue, trophoblastic tumours or from male choriocarcinomas (Bates *et al.*, 1968; Ashitaka *et al.*, 1972; Pala *et al.*, 1973).

(b) Methods of purification

In early work on hCG, the studies of Got and Bourrillon (1960) are notable because of the thoroughness and care with which they were carried out. Benzoic acid extracts were fractionated on Permutit using a mixture of ammonium acetate and ethanol (60:40, v/v). A potency of 13 000 IU/mg was obtained and some of the chemical characteristics were listed, including the fact that the product was a glycoprotein with approximately 30% by weight of carbohydrate.

Purification procedures reported by later workers have been complicated by the considerable heterogeneity found in the hCG molecule, primarily because of variations in carbohydrate structure. van Hell *et al.* (1968) and Bell *et al.* (1969) used CM-Sephadex or cellulose, gel filtration on G-100 and isoelectric focusing. In the pH range 3–5, several species of molecule were recognized with biological activities ranging from 1700 i.u. to 18 000 iu/mg. The potencies correlated well with the sialic acid contents which varied from 2.9 to 10.7%. Goverde *et al.* (1968) found that a loss of 0.3% sialic acid lowered the biological activity from 18 000 to 12 000. The protein portions of these molecules had relatively constant amino acid composition and were immunologically identical.

Preparations of hCG purified from commercial-grade material by Bell *et al.* (1969) and Canfield *et al.* (1971) have been widely used. Conventional techniques including chromatography on ion exchange and gel filtration yielded material with biological activity consistently between 13 000 and 15 000 iu/mg.

Clearly the definition of purity is not straightforward because of variations in the sialic acid content. Canfield *et al.* (1971) suggested that one criterion for purity should be an analysis of the protein content of the hormone, with 12 proline residues per 100 residues, as was obtained in their own purified material.

(c) Properties

The molecular weight of hCG (38 000) is higher than that of the other glycoprotein hormones because of the extension at the C-terminus of the β-subunit (F.J. Morgan *et al.*, 1975). The isoelectric point, 2.9–3.5, is lower than that of the pituitary gonadotrophins on account of the high sialic acid content, which has been estimated to be about 8.5% (Bahl, 1969; Mori, 1970). The Stokes' radius is 30 Å and the hydrodynamic radius about 25 Å.

(d) Structure in relation to function

The α- and β-subunits of hCG can be reversibly dissociated, as can those of the other glycoprotein hormones (Gray, 1988). The amino acid sequence of the α-subunit (Ryan *et al.*, 1987) is identical to that of the α-subunits of the glycoprotein hormones of the pituitary, but in almost all studies so far some heterogeneity has been reported at the N-terminus. Keutmann *et al.* (1978) found that the full 92 residues (Figure 5.2) made up 60% of the α-subunit, while 30% lacked the last three residues and 10% the last two residues at the N-terminus. However, these forms all recombine with β-subunits to give biologically active molecules so that heterogeneity is apparently of no consequence for subunit interactions or for biological activity.

The first 115 amino acids of β-hCG share 82% homology with β-hLH. Furthermore, there is more than 40% amino acid homology among all the β-subunits of this family. The most conserved regions are around the 12 cysteine residues (Pierce and Parsons, 1981). This suggests similarity in the folding patterns of the β-subunits, a concept which is further supported by the fact that the common α-subunit associates with all β-subunits. In addition, structural domains exposed by common disulphide bonds may be involved in subunit–receptor as well as subunit–subunit interactions; there is significant binding activity of hCG with the LH and the TSH receptors (Ryan *et al.*, 1987). Thus, there are many common secondary and tertiary domains which are probably accounted for by the disulphide linkages.

Disulphide bridges

Full analysis is available for the disulphide bonds of the β-subunits of ovine LH (D. Chang *et al.*, 1975; Tsunasawara *et al.*, 1977), bovine LH and TSH (Reeve *et al.*, 1975), human CG (Mise and Bahl, 1981) and human FSH (Fujiki *et al.*, 1980) (see Table 5.1a).

Despite the conserved position of the half cysteines there is only agreement on the pairing of three of the six bridges: Cys-23–Cys-72, Cys-26–Cys 110 and Cys-9–Cys-100. Detailed analysis is difficult because the disulphide bonds are clustered in regions where few intervening peptide bonds are readily susceptible to hydrolysis. Based on partial reduction and S-^{14}C-carboxy-methylation, Mise and Bahl (1981) assigned the remaining three pairs as Cys-9–Cys-90, Cys-34–Cys-88 and Cys-38–Cys-57. Willey and Leidenberger (1989) constructed a three dimensional molecular model based on published findings, agonist receptor binding, epitope mapping and computer modelling by hydrophobic region/comparative sequence analysis. This assigned the remaining hCG disulphide bridges as Cys-23–Cys88, Cys-34–Cys-57 and Cys-38–Cys-72. Mise and Bahl (1981) postulated that a large receptor-binding loop was stabilized by cysteine residues 38 and 57. Synthesis of this region yielded an agonist with moderate binding activity in a competi-

tive hCG/LH receptor assay (Keutmann *et al.*, 1987; Ryan *et al.*, 1988).

The pairing of Cys-38 with Cys-72 by Willey and Leidenberger (1989) is largely based on a comparison of the sequence and tertiary structure of the intact hCG α–β combined receptor-binding domain with those of the substrate-binding cleft of bovine chymotrypsin. Antigenic mapping studies have shown that some epitopes present in the free β-subunit, particularly those specific for the β Cys-38–Cys-57 loop, are lost upon association with the β-subunit. These epitopes are not masked by the β-subunit; instead, association of the subunits leads to a conformational change, and new epitopes specific for this region arise (R.K. Campbell *et al.*, 1988). Furthermore, intracellular forms of β-hCG have been detected which cannot associate with the free α-subunit. This is possibly due to aberration in the intramolecular disulphide bridges (Ruddon *et al.*, 1988).

The importance of the remaining disulphide bonds in subunit–subunit, secretion and receptor interactions has not been fully established (Ryan *et al.*, 1988). The disulphide pair β-Cys-93–Cys-100 is most accessible to reduction. Since it is part of a receptor-binding region, reduction is associated with loss of biological activity (Pierce and Parsons, 1981; Ryan *et al.*, 1988; Willey and Leidenberger, 1989). Based on the disulphide pairing of Mise and Bahl (1981), a series of site-directed mutagenic constructs replacing the specific cysteine codons for serine or alanine in the β-hCG gene were transfected into CHO cells by Suganuma *et al.* (1989). The normal α-subunit gene was co-transfected

and the proposed disulphide bridge partners of the β-subunit were disrupted by mutating one or both cysteines. The effects of such changes on assembly and secretion of intact hCG were studied by comparing *in vitro* secretion of hCG by CHO cells containing transfected wild-type genes with those containing the mutants. Surprisingly, the findings were inconsistent for individual and paired cysteine mutations. The secretion of intact hCG was greatly reduced with single mutations at Cys-26, -110, -72 and -90, but was reduced too a much lesser extent if the proposed partner was jointly mutated. All other mutations resulted in non-formation of the heterodimer of intact hCG. The free β-subunit of hCG is rapidly secreted once formed. Comparison of the secretion rates of mutant and wild-type genes showed that if intact hCG was not formed the rate of β-hCG secretion was increased. Thus, alteration of cysteine residues impedes and, in most cases, prevents α–β subunit association. However, the stability of the free β-subunit is unaffected.

The pairing of the five disulphide bonds of the α-subunit is also disputed (see Table 5.1b) (Ryan *et al.*, 1987). For example, Willey and Leidenberger (1989) have inverted two of the pairings assigned by the widely accepted reduction/alkylation studies of Cornell and Pierce (1974) and Mise and Bahl (1980) (i.e. Cys-14–Cys-88, Cys-36–Cys-86 instead of Cys-14–Cys-36, Cys-86–Cys-88). In addition, a form of α-subunit which does not combine with the β-subunit has been identified (Beebe *et al.*, 1989). Finally, some of the antigenic conformational changes that occur when the α- and β-subunits combine may be a consequence of intradisulphide bridge partner exchange on both molecules.

Helices and β-pleated sheets

No successful X-ray crystallographic examination of hCG has been achieved. However, estimates of the relative proportions of secondary structural components have been obtained from optical dichroism studies (reviewed by Pierce and Parsons, 1981). For the glycoprotein hormones as a whole, α-helix content is low (5–8%) and the content of β-pleated structures is relatively high (25–40%). Computer modelling based on primary sequence data shows that all β-subunits exhibit homologous regions of extended β-pleated sheeting. For β-hCG the estimates are: 1% α-helices, 71% β-pleated sheeting with 27% β-turns, and 11% random coils. With the two subunits combined the proportion of β-pleated sheeting is reduced to 61% (Pierce and Parsons, 1981). The numerous disulphide bridges indicate a high degree of β-pleated sheeting and the close sequence pairing of cysteine partners is consistent with the high content of β-turns (i.e. α-Cys-86–Cys-88, β-Cys-93–Cys-100).

Glycosylation – heterogeneity and function

The glycoprotein hormones are characterized by large sugar moieties linked to the asparagine (Asn) residues of both the α- and β-chains. The common α-subunit has two *N*-glycosidic-linked complex branched dodecasaccharide moieties on Asn-52 and Asn-78. All the β-subunits have two similar *N*-glycosidic moieties on Asn-13 and Asn-30. In addition, β-hCG has four serine *O*-glycosidic-linked, tetrasaccharide, mucin-type moieties on residues 121, 127, 132 and 138 of the unique carboxy-terminal extension. The composition and biantennae structural arrangement of the sugar moieties, *N*- (Figure 5.4) and *O*- (Figure 5.5) glycosidic, elucidated for pregnancy hCG by Kessler *et al.*, (1979a,b) is still widely accepted.

Microheterogeneity has frequently been found in the structure of these carbohydrate moieties (Endo *et al.*, 1979; Kennedy and Chaplin, 1976; Mizuochi and Kobata, 1980; Bahl and Wagh, 1986; Kobata 1988). hCG oligosaccharides contain *N*-acetylneuraminic acid (NANA, sialic acid) attached exclusively

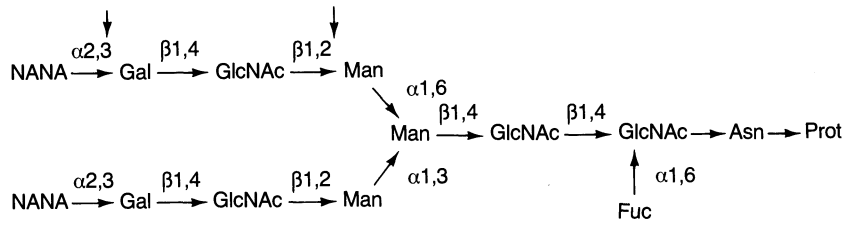

Figure 5.4 Carbohydrate structure of *N*-glycosidic moieties in α- and β-subunits of hCG (Bahl and Wagh, 1986; Ryan *et al.*, 1987). Some chains have been reported to terminate at the points indicated by the arrows. The fucose residue is present only in the β-subunit. NANA: *N*-acetylneuraminic acid (sialic acid); Gal: galactose; Man: mannose; Fuc: fucose; GlcNAc: *N*-acetylglucosamine.

by 2,3 linkage to galactose residues rather than the 2,6 linkage more commonly found in serum glycoproteins such as transferrin and immunoglobulins. The functional significance of this is unknown. Heterogeneity has been reported in the fucose residues attached in some chains to the inner *N*-acetylglucosamine (GlcNAc) residue. The asparagine complex on the α-subunit is not fucosylated. A monoantenna form of this asparagine complex has also been identified in normal pregnancy hCG. The Kessler classic form and the two variant forms described are distributed on the α- and β-subunits of pregnancy hCG in a set ratio (Kobata, 1988). Small amounts of triantennary forms have been described on the β-subunit of pregnancy hCG (Damm *et al.*, 1988). Similar heterogeneity has been described for the serine *O*-linked carbohydrates moieties by L.A. Cole (1987) who identified hexasaccharide, trisaccharide and disaccharide forms in addition to the tetrasaccharide.

Differences in the composition of the oligosaccharides in the α-subunit of hCG and the pituitary glycoprotein α-subunits have been recognized (Nilsson *et al.*, 1986), and although terminal sulphated carbohydrates exist in α-LH none have been found in α-hCG (Parsons and Pierce, 1980). This is explained by the different oligosaccharide-processing enzymes present in the tissues of origin: sulphation of LH in the pituitary is due to sulphotransferase activity not found in the placenta (Green *et al.*, 1986). Blithe and Nisula (1985) recognized differences between the oligosaccharide structures contained in the α-subunit of hCG obtained by dissociation of hCG itself and the forms of the free α-subunit which are recognized in urine of pregnant women. A major difference appeared to be in the higher sialic acid content of the free forms.

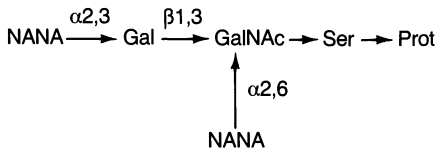

Figure 5.5 Carbohydrate structure of *O*-glycosidic moieties in β-hCG (Kessler *et al.*, 1979b). GalNAc: *N*-acetylgalactosamine.

A hyperglycosylated variant of free β-subunit has been isolated from pregnancy serum and hCG-secreting trophoblast cultures; this contains an additional mucin-type sugar residue *O*-linked to Thr-39 (L.A. Cole *et al.*, 1984b). First identified by Parsons *et al.* (1983) in bovine pituitary extracts, the additional glycosylation prevented subunit association with bovine β-LH (Parsons and Pierce, 1984). However, some studies have shown that the presence of this additional sugar moiety does not affect assembly of the α–β heterodimer (Peters *et al.*, 1989).

Heterogeneity has also been noted in the peripheral chains, some terminating in

NANA and others in galactose or mannose. Whether these differences are related to variations in the post-translational operations which occur during biosynthesis or to degradation during purification is not known.

In neoplastic expression of hCG, considerable variability in the glycosylation has been found (Yoshimoto *et al.*, 1979). The most striking cause of physicochemical heterogeneity of hCG is the variation in the proportion of terminal sialic acid residues present on these sugar moieties. This is responsible for the numerous acidic isoforms of hCG. Yazaki *et al.* (1980) and many others have demonstrated multiple isoforms of pregnancy hCG with pI values between 3.9 and 6.0. The hCG produced by gestational trophoblastic tumours shows increased glycosylation with triantennary branches of the asparagine–sugar moieties. Urinary hCG from patients with choriocarcinoma has a reduced number of terminal sialic acid residues, despite an increase in antennae susceptible to sialation (Nishimura *et al.*, 1981; Mizuochi *et al.*, 1983; Kobata, 1988). This is in contrast to the shift towards acidic isoforms of hCG (predominantly pI 3.5, 3.8 and 4.0) found in serum from choriocarcinoma patients (Yazaki *et al.*, 1980; Mann *et al.*, 1986; Kobata, 1988; L.A. Cole *et al.*, 1990).

In normal pregnancy, isoforms of pI 3.9, 4.0, 4.2 and 4.4 are the most prevalent, with a shift towards the more basic forms as pregnancy progresses (L.A. Cole *et al.*, 1990). This pI isoform shift may be reflected in the ratio of biological assay potency to immunoassay estimation (B/I); this ratio is greatest in early pregnancy (reviewed by Stockell Hartree, 1989). Two factors may explain this changing ratio. First, the presence of sialic acid decreases the rate of hCG clearance from the peripheral circulation because of reduced binding to hepatic lectins (Van Hall *et al.*, 1971). Second, though the affinity of hCG for the LH–hCG receptor is enhanced, the ability of the deglycosylated hCG molecules to trigger a cAMP response is diminished (H.C. Chen *et al.*, 1982; Sairam and Bhargavi, 1985; Keene *et al.*, 1989). These sugar-depleted molecules can act as an antagonist (H.C. Chen *et al.*, 1982; Ranta *et al.*, 1987).

Similar variation in glycosylation is seen with other glycoprotein hormones. Changes in glycosylation may represent control mechanisms for LH, FSH and hCG bioactivity. Changes in pI and B/I ratio are seen during the menstrual cycle and at different reproductive stages such as puberty and the menopause (reviewed by C.A. Wilson *et al.*, 1990).

The carboxy-terminal extension of hCG

β-hCG possesses a 30 amino acid carboxy-terminal extension, which arose following evolution from β-LH. It contains four sites of mucin-type glycosylation at serine residues 121, 127, 132 and 138. Many highly specific assays have been developed using antibodies directed against this region. Indeed, synthetic peptides corresponding to this region constitute the WHO contraceptive vaccine (Stevens, 1986). The role of this unique region in hCG function has only recently been established (Matzuk *et al.*, 1990). Using site-directed mutagenesis, a termination codon (TAA) was introduced at codon 115 of the hCG gene to produce a truncated peptide similar to β-LH. This construct was transfected together with the wild-type α-subunit gene into CHO cells. To address the role of the mucin-like sugar moieties of this region, wild-type α- and β-hCG genes were also co-transfected into the *O*-linked glycosylation-defective murine cell line IdID. The expressed mutant hormones were tested for receptor binding and gonadotrophic activity. *In vitro*, the truncated and *O*-linked glycosylation mutant forms had the same receptor-binding characteristics and stimulatory effects as the wild-type hCG. This finding is consistent with immunological studies which show that the carboxy-terminal region is a surface structure which is still exposed when

hCG binds to the LH–hCG receptor. Thus, this region contributes little to tertiary structure and receptor-binding function (Louvet *et al.*, 1974; Bidart *et al.*, 1987). The carboxy-terminal region has no effect on β-hCG gene expression or α–β subunit assembly (El-Deiry *et al.*, 1989, Matzuk *et al.*, 1990). The *in vivo* activities of the truncated form and glycosylation mutants were 3–4 times less than that of the wild type (Matzuk *et al.*, 1990). This finding is consistent with the glycosylation studies and suggests that the biological function of the glycosylated carboxy-terminal extension is to prolong the circulating half-life of intact hCG.

Theoretical tertiary and quaternary models

Although the linear sequences of all the glycoprotein hormone subunits have been known for over 15 years, little progress has been made in determining the three-dimensional structures. Heterogeneity in the carbohydrate moieties prevents the formation of crystal suitable for X-ray diffraction studies. Only two groups have described the formation of hCG crystals suitable for X-ray analysis after chemical or enzymatic reduction of the carbohydrate moieties with hydrogen fluoride or neuraminidase (Harris *et al.*, 1989; Lustbader *et al.*, 1989). Nevertheless, two tertiary models have been proposed: one by Moyle, Lustbar and Canfield (discussion section of Ryan *et al.*, 1987) is based on the disulphide bond assignment of Mise and Bahl (1981). The second, by Willey and Leidenberger (1989), is based on their assignments of the disulphide bonds. The main differences between the models are in the assignment of three pairs of disulphide bonds on the β-subunit and a further two on the α-subunit. Synthetic peptides have been made which emulate various segments of the α- and β-subunits of LH and hCG. These have been used to determine which peptides bind to the LH–hCG receptor, stimulate testosterone production in the Leydig cell assays and block intact hCG or LH activity. Considerably more peptide (typically 10^9) was required to compete with or match intact hCG (Ryan *et al.*, 1987). Inhibitory binding constants, defined as the concentration required to inhibit the binding of labelled hCG by 50%, were compared: a peptide consisting of α-subunit residues 26–46 was found to be the most effective inhibitor (binding constants: α-26–46 10^{-4} M, α-subunit 10^{-7} M, intact hCG 10^{-11} M). It was also found to block the activity of thyroid-stimulating antibodies. This suggests that the binding site for α-26–46 is close to the immunogenic site recognized by autoantibodies from patients with Graves' disease. A weaker inhibitor region was found at α-76–92 (binding constant $>10^{-3}$ M) (Ryan *et al.*, 1988). The model proposed by Moyle *et al.* (1987) has these two regions internally stabilized by the disputed disulphide bridges. By contrast, the model of Willey and Leidenberger (1989) does not have these binding 'loops' internally stabilized. However, in this model the two binding loops are linked by a disulphide bridge α-Cys-36–Cys-88.

The specific β-subunits of the intact hormones bind directly to receptors. Two major receptor-binding regions have been identified: β-Cys-93–Cys-100 and β-Cys-38–Cys-57. The β-Cys-93–Cys-100 region is common to all the glycoprotein β-subunits and has a binding constant of 10^{-4} M (free β-hCG 10^{-4} M, intact hCG 10^{-10} M). Peptide β-Cys-38–Cys-57 has a similar binding constant (10^{-4} M) but is only common to β-hCG and β-LH. There are three amino acid differences in the primary structure of LH in this region; this is reflected in the slightly greater binding constant for the LH-derived peptide (approximately 10^{-5} M). Thus, this region may represent the hCG/LH-specific receptor-binding determinant (Ryan *et al.*, 1987, 1988). Monoclonal antibodies raised against these receptor-binding regions inhibit the assembly of the intact hormone. Thus, the combined receptor-binding/stimulating region of intact

hCG appears to be at the interface between the α and β-subunits (Bidart *et al.*, 1988; R.K. Campbell *et al.*, 1988; Canfield *et al.*, 1988; Ryan *et al.*, 1988).

Quaternary CG structure and relationship to serine proteases

In the sequence analysis and three-dimensional structural models of Willey and Leidenberger (1989), α- and β-subunit shape was largely based on the similar core structure of chymotrypsin. In chymotrypsin, and all serine proteases, enzymatic activity is a tertiary interaction of remote linear sequence amino acids, serine, histidine and aspartic acid. By homologous modelling, Willey and Leidenberger (1989) suggested that, for hCG, Ser-38 and His-83 on the α-subunit formed a similar active site with the β-subunit Asp-99, the latter being the only conserved aspartic acid residue in all reported β-subunit sequences (Bousfield *et al.*, 1987). Recently, Chen and Puett (1992) changed the hCG β-subunit Asp-99 to an arginine residue by site-directed mutagenesis.

Co-transfection with a bovine α-subunit gene into CHO cells resulted in expression of an intact CG molecule which bound to the LH–CG receptor. However, it could not trigger cAMP production and thus biological activity was abolished. No other mutations were present and similar constructs using wild-type hCG β-subunit gene were effective stimulators of cAMP production. The evidence is that a serine protease-like interaction of hCG α-Ser-38, α-His-83 and β-Asp-99 activating the LH–hCG receptor would imply that cleavage of peptide bonds causes an irreversible change in the conformation of the triggered receptor. Furthermore, this interaction would be common to all glycoprotein hormones when activating their respective receptors. Such a mechanism might have evolved by retaining tertiary/quaternary structures for core cleavage function (receptor activation), whilst the addition of new structures conferred specificity (i.e. receptor binding).

5.3.4 CONTROL MECHANISMS

Regulation of the secretion of hCG by the placenta is not well understood. LHRH-like material has been identified in placental secretions, and it is possible that there is control similar to that of pituitary hormones (Belisle *et al.*, 1986; Elkind-Hirsch *et al.*, 1989). In support of this, Siler-Khodr *et al.* (1983) showed that an antagonist to LHRH inhibited the release of hCG, α-subunit and progesterone from mid-term placentas *in vitro*. This effect occurred rapidly and could be partially restored by LHRH. Gibbons *et al.* (1975) demonstrated that trophoblastic cells synthesize LHRH *in vitro*. There is *in vitro* evidence that progesterone suppresses the release of hCG (E.A. Wilson *et al.*, 1980, 1984a) but there is little information on how progesterone or other factors modulate cellular levels of mRNAs in coding α- and β-hCG. Maruo *et al.* (1986) investigated the effect of progesterone on the production and secretion of hCG in normal placenta and choriocarcinoma. In normal early placentas, progesterone decreased cellular levels of α- and β-hCG mRNAs and there was a fall in the hCG and α- and β-hCG released. Progesterone did not affect hPL mRNA or hPL release. However, choriocarcinoma tissue did not respond to progesterone.

Several other agents modulate hCG secretion. Epidermal growth factor (EGF) can increase DNA, RNA and protein synthesis in cells. Receptors for EGF have been identified in many tissues, including the placenta. EGF does not increase hCG production from normal placentas but doubled the secretion from a choriocarcinoma cell line (Huot *et al.*, 1981; E.A. Wilson *et al.*, 1984b). The placenta is also rich in adrenergic receptors and β-adrenergic-stimulated adenylate cyclase. Shu-Rong *et al.* (1982) found that the adren-

ergic β-receptor agonist terbutaline increased placental hCG secretion but did not affect hPL. Corticosteroids have also been implicated. E.A. Wilson and Jawad (1982) observed that natural and synthetic corticosteroids increased the secretion of hCG from placental tissue *in vitro* and the effect was decreased by progesterone: hPL secretion was not found to be affected by corticosteroids.

Retinoic acid and synthetic analogues of retinoic acid control cell differentiation in many epithelial tissues, and these were found by Chou *et al.* (1983) to induce placental hCG secretion *in vitro* while inhibiting α-hCG secretion. The ratio of α-hCG to intact hCG was also altered in choriocarcinoma cells.

5.3.5 BIOLOGICAL PROPERTIES

Strong circumstantial evidence has dictated the 'classical' function of hCG as the human fetal/placental signal for maternal recognition of pregnancy. In any animal in which the gestational period exceeds that of the oestrous cycle, the conceptus must signal its presence at implantation, halt ovarian cyclicity and maintain the receptive endometrium by rescue of the corpus luteum. This process is essential in many placental mammals. CG is known to have gonadotrophic activity (Aschheim and Zondek, 1927b) and, by virtue of its close structural and genetic homology with LH, it binds and stimulates the LH receptor. Not surprisingly, in primates and equids, CG is the suggested luteotrophic mediator of this process. In early human pregnancy the corpus luteum is the major source of the progesterone, which maintains the thickened endometrium (Csapo and Pulkkinen, 1978). During a normal human menstrual cycle, progesterone levels rise rapidly for the first 6–7 days following ovulation, plateau for 3–4 days then decrease until menses. In pregnancy, by contrast, the corpus luteum continues to produce progesterone for at least 4–6 weeks after ovulation (Tulsky and Koff, 1957). Thereafter it becomes relatively quiescent: at 6–8 weeks progesterone levels transiently decrease, followed by a secondary rise with the independent secretion of progesterone by the placenta (the 'luteal–placental shift') (Batzer, 1980).

There is much evidence to support the view that CG is responsible for the rescue of the corpus luteum. It is secreted very early in pregnancy, being detectable in culture media of preimplantation human embryos 7–8 days after *in vitro* fertilization, and in maternal serum 6–9 days after conception (Braunstein *et al.*, 1976; Fishel *et al.*, 1984; Lopata and Hay, 1988). The progesterone rise during the first 4 weeks following conception follows the rise in maternal serum hCG (Yoshimi *et al.*, 1969). Cultured luteal cells from different stages of development of the corpus luteum show peak hCG/LH receptor concentrations at 20–24 days post menses (Bolton *et al.*, 1980). This coincides with the earliest time at which maternal serum hCG can be detected.

In vitro, hCG stimulates luteal cell production of progesterone and oestradiol (Marsh and LeMaire, 1974; Richardson and Masson, 1981). *In vivo*, administration of hCG can increase the amount and duration of progesterone secretion (Hanson *et al.*, 1971). However, the menstrual cycle is rarely prolonged for more than 2 weeks despite continued administration of hCG (Bradbury *et al.*, 1950). In addition, corpus luteum function wanes and the luteal–placental shift occurs when maternal hCG reaches its peak, i.e. 8–12 weeks. Furthermore, it is somewhat surprising that such a fundamentally important function is mediated in primates by a recently evolved gene only found in this genus (Fiddes and Talmadge, 1984). It is now clear that in ruminants maternal recognition of pregnancy is mediated via a member of the alpha-interferon (IFN-α) family of proteins and is produced by the trophectoderm (Imakawa *et al.*, 1987; Flint *et al.*, 1988). It has still to

be determined whether IFN-α-like proteins also mediate corpus luteal rescue in other non-primate mammals. Interestingly, IFN-α is also a product of the human conceptus and *in vitro* IFN-α increases ectopic expression of free β-hCG by epithelial tumours (Chard *et al.*, 1986; Iles and Chard, 1989a).

Though other early pregnancy factors may play a role in the rescue of the corpus luteum of pregnancy, it appears that CG is essential in early primate and human pregnancy and directly implicated in corpus luteum function. Passive immunization of pregnant marmoset monkeys with anti β-hCG serum results in spontaneous abortion in early pregnancy (reviewed by Hearn, 1976; Chard, 1991). This can be counteracted by the concomitant administration of progesterone. Such experiments have led to the development of experimental contraceptive vaccines using synthetic peptides analogous to the specific carboxy-terminal sequence of hCG (Stevens and Crystle, 1973; Stevens, 1975, 1986).

HCG has also been implicated in the suppression of maternal immune rejection of the fetus. Generalized immunodeficiency is not a characteristic of pregnancy (reviewed by Redman, 1986). Specific immunosuppressive activity has been actively sought and many substances have been implicated, including hCG (reviewed by Hogarth, 1982; Chard and Grudzinskas, 1992). The literature contains many conflicting reports; in general, crude but not pure hCG has immunosuppressive activity on T-cell and B-cell activities *in vitro*. Indeed, molecules of low molecular weight, including preservative phenol, have been separated from crude commercial preparations of hCG and have been shown to be the cause of apparent immunosuppression (Morse *et al.*, 1976; Pattillo *et al.*, 1976; Muchmore and Blaese, 1977). *In vivo*, highly purified hCG suppresses delayed-type hypersensitivity. However, this could be entirely attributed to the gonadal steroids secreted in response to hCG, since castrated experimental animals showed no such immunosuppression (Nisula and Bartocci, 1984).

5.3.6 RECEPTORS

The LH–hCG receptor has been identified in many cells, including those of the corpus luteum, the interstitial tissue of developing follicles and in the granulosa as well as in Leydig cells in the testis. There are about 20 000 sites per Leydig cell and only a minute fraction of the total number need be occupied to produce a full steroidogenic effect (Dufau *et al.*, 1974). Only intact hCG and LH, but not the free subunits, can bind to and stimulate the LH–hCG receptor. The sugar residues of these glycoprotein hormones are essential if this receptor is to be successfully triggered (Keene *et al.*, 1989). The immediate consequence of successful receptor stimulation by hCG is the activation of adenylate cyclase, resulting in the formation and increase in concentration of intracellular cAMP. This secondary signalling culminates in the stimulation of steroid production by the acceleration of the conversion of cholesterol to pregnenolone. The LH–hCG receptor has been cloned and found to be a member of the G protein-coupled receptor family (Loosfelt *et al.*, 1989; McFarland *et al.*, 1989). There are 674 amino acids with a calculated molecular mass of 75 632 kDa, but the *in vivo* isolated protein has a mass of approximately 93 000 kDa. This difference is probably due to glycosylation, for which there are six candidate sites located on the transmembrane domain. The molecule is asymmetrical with classic extra-, trans- and intracellular domains. The structure and function have been reviewed by Dias (1992).

5.3.7 DETECTION AND MEASUREMENT OF hCG

From 1930 until 1960 the detection of hCG in biological fluids depended on bioassay. Many methods were variations on the hyper-

ovulatory response in animals shown by Aschheim and Zondek (1927b). Aschheim and Zondek (1928) used mice; Friedman and Lapham (1931) rabbits; Shapiro and Zwarenstein (1934) toads; Wiltberger and Miller (1948) frogs. Others relied on effects such as the stimulation of other organs by gonadal steroids, e.g. the rat ventral prostate weight assay (Diczfalusy *et al.*, 1950). The same principle is used in current bioassays, in which direct measurement of testosterone release is determined for rat Leydig cells stimulated *in vitro* (Dufau *et al.*, 1974). With the possible exception of the *in vitro* Leydig cell assay, bioassays are expensive, time-consuming (11 h to 7 days), relatively insensitive (250–5000 iu/ml) and non-specific with respect to hCG, LH and FSH. The development of immunoassays in the 1960s (complement fixation, haemagglutination inhibition and latex agglutination procedures) improved assay times (2 min to 1 day) and reduced costs. Nevertheless, sensitivity was no better (500–24 000 iu/ml) (Wide and Gemzell, 1960, reviewed by Hussa, 1987). Competitive binding assays such as radioimmunoassay (RIA) and radioreceptor assays solved the sensitivity problem. However, because of the close homology of hCG and LH there was still significant cross-reactivity with the latter (Catt *et al.*, 1971). Dissociation of the hCG molecule into subunits and preparation of antisera to the free β-subunit led to the development of the much more specific 'β-subunit' RIA (Vaitukaitis *et al.*, 1972). This allowed specific measurement of hCG in the presence of physiological levels of LH. These assays have been the mainstay of quantitative detection technology for hCG since the mid-1970s. The problem of false-positive results with various kits is still reported from time to time and, therefore, there has been increasing use of more specific systems. Rzasa *et al.* (1984) found five false positives in 162 samples investigated with one commercial kit designed to measure intact hCG or β-hCG using a polyclonal antibody, but not with three other similar kits; no obvious reason for the discrepancies could be found. Filstein *et al.* (1983) found 0.6% false positives with two kits based on serum β-hCG assays but not with a third.

A further advance came with the application of monoclonal antibody technology to two-site immunometric assays (Bidart *et al.*, 1985; Schwarz *et al.*, 1985; Valkirs and Barton, 1985). Typically, these use an anti α-subunit monoclonal for capture and a labelled anti-β-subunit for detection; they detect intact hCG but not free subunits. These labelled antibody assays are generally more sensitive and precise than labelled ligand assays. However, the inability of these assays to detect free β-hCG is, as will be shown later, a major disadvantage in clinical oncology.

Ehrlich *et al.* (1982) used a mixture of two monoclonal antibodies to enhance the affinity for antigen. Armstrong *et al.* (1984) developed this idea to obtain maximum sensitivity and specificity in a two-site immunoradiometric (IRMA) system. hCG was extracted from urine by a Sepharose 4B-coupled monoclonal antibody which had a moderate affinity ($K=7 \times 10^8\ M^{-1}$) and 2% cross-reaction with LH. The hCG extracted was then determined by use of a labelled rabbit antibody to the β-hCG C-terminal peptide. The method was capable of measuring about 10 miu of hCG per 24 h with cross-reaction to LH of only 0.0005% and to FSH of 0.016%, possibly due to the presence of small amounts of hCG or β-subunit in the pituitaries from which the hormones were extracted. Another IRMA using two selected monoclonal antibodies was specific for intact hCG and showed no reaction with β-hCG, β-LH, intact LH or the free α-subunit (Griffin and Odell, 1987).

It is now very important to define exactly what is measured by 'hCG' immunoassays. Assays based on the use of an antiserum to the β-subunit of hCG are commonly referred to as 'beta-subunit' assays. Vaitukaitis (1985) pointed out that this is misleading because it implies that only β-hCG is measured when,

in fact, intact hCG, β-hCG and β-core may be detected. Intact hCG is the predominant form of the hormone in blood during pregnancy. However, for many cases of ectopic expression free β-subunit is the principal form produced (Iles and Chard, 1991) and in urine β-core is the predominant metabolite. This limits the use of many highly specific assays. Thus, only those 'β-subunit' assays measuring 'total β-hCG' (intact hCG, free β-subunit and β-core) should be used in oncology. This problem has been addressed by the Fourth Bergmeyer Conference on the Standardization of Assays to hCG. This recommended clear description of all hCG assays detailing the cross-reactivities of intact hCG, free subunits and β-core (Stenman *et al.*, 1993).

(a) Reference standards

The first international standard for hCG was established in 1938 and the second in 1964 by the World Health Organization (WHO) (Bangham and Grab, 1964). The standard preparation is of medium potency prepared from urine by adsorption on to the ion exchanger Permutit (synthetic aluminium silicate), followed by elution in a mixture of ammonium acetate and ethanol. After precipitation from ethanol, pyrogens are removed by adsorption on to calcium phosphate. Lactose is added and the preparation is freeze dried in ampoules; the agreed potency for each ampoule (approximately 6.8 mg) is 5300 IU as determined by bioassay.

The second international standard (2nd IS hCG) was used widely as a reference standard for immunoassays as well as bioassays. However, it contains large quantities of the free subunits and other proteins, being only 20% pure intact hCG on the basis of bioactivity (Bangham and Storring, 1982).

In 1974, large quantities of highly purified preparations of intact hCG, free α-subunit and free β-subunit hCG (batch no. CR119) were donated to the WHO by the Center for Population Research (Washington DC, USA) and the Reproductive Research Branch of the National Institute of Child Health and Human Development (Bethesda, MD, USA). These preparations became the international reference preparations (IRPs) of intact hCG and its free subunits, each ampoule containing approximately 70 μg of the pure material (Storring *et al.*, 1980). These IRPs were assayed with respect to the old 2nd IS hCG by bioassay and immunoassays. Bioassay and receptor-binding assays (which only detect intact hCG) gave similar results. However, immunoassay results varied widely depending on whether the assay measured only intact hCG or intact hCG and free β-subunit.

The immunoassays specific for intact hCG gave results similar to those obtained for bioassays. The Expert Committee on biological standardization assigned a value of 650 IU of IRP per ampoule (9.3 IU per μg) of intact hCG based on bioassay comparability with the earlier standards. The free subunits, having no bioactivity, were assigned IU values equivalent to the mass of purified protein (i.e. 1 IU = 1 μg). This situation has proved confusing since most present assays of hCG are immunoassays measuring mass of specific epitopes. Unfortunately, all such assays use the intact hCG IRP or 2nd IS as standards. In total β-subunit assays pregnancy serum hCG values measured against the 2nd IS are approximately half that of values measured against the IRP hCG. This is simply because the 2nd IS is contaminated with large amounts of the free β-subunit, resulting in greater immunopotency. Samples containing the equivalent IU of intact hCG though very little free β-subunit (i.e. the IRP) will have the same biopotency but less immunopotency. It is also increasingly apparent that there is a wide variation in the composition of intact and free subunits of hCG in clinical samples (Iles *et al.*, 1989, 1992). It has now been recommended that hCG standards should be calibrated in terms

of moles of intact hCG, free β-hCG or β-core (Stenman *et al.*, 1993).

5.3.8 CLINICAL APPLICATIONS – DIAGNOSIS

(a) Maternal levels of hCG in normal pregnancy

Chorionic gonadotrophin is detectable in maternal blood within a few hours of implantation. The levels rise to reach a peak at 60–80 days of pregnancy and then fall to relatively low levels with a small secondary rise towards term. In early pregnancy (up to 28 days) the doubling time is 1.4–1.5 days, increasing to 2.7–2.9 days at 4–8 weeks' gestation (Pittaway *et al.*, 1985a). At term, the levels of hCG in blood, amniotic fluid and placental extracts are substantially higher if the fetus is a female than if it is a male (Brody and Carlstrom, 1965; Crosignani *et al.*, 1972; Wide and Hobson, 1974; Boroditsky *et al.*, 1975; Obiekwe and Chard, 1983a). Urine of pregnant women contains free α-subunit, free β-subunit, hCG and the β-subunit core fragment (Blithe *et al.*, 1988). Not surprisingly, the ratio of the biological to immunological activity of hCG varies at different stages of pregnancy (Kato and Braunstein, 1988) with low ratios in the last two trimesters.

(b) Measurement of hCG as a pregnancy test

Measurement of hCG in urine is widely used as a qualitative test of early pregnancy. Simple kits based on immunoenzymatic procedures are available over the counter. Their sensitivity (typically 25 IU/l) is sufficient to detect most pregnancies at or around the time of the missed period, and a substantial proportion at an earlier stage than this.

The high sensitivity of current technology for hCG measurement leads to two problems. First, at levels below 5 IU/l positive results may occur due to hCG from extrauterine sources (Armstrong *et al.*, 1984); in clinical practice, a single estimate of hCG levels should only be considered positive if it is greater than 25 IU/l or if a lower level is seen to increase twofold or more at an interval of 3 days (Jones *et al.*, 1983). Second, there is a highly significant possibility that a sensitive test may pick up an 'occult' pregnancy. This is a conception which is aborted after implantation but prior to the time of the expected period: there may be no clinical evidence for this situation but hCG can appear transiently in maternal blood and urine. The incidence of the phenomenon has been variously estimated at 15–60% of normal unprotected menstrual cycles (Seppala *et al.*, 1978; Chartier *et al.*, 1979; Miller *et al.*, 1980; Edmonds *et al.*, 1982; R.G. Edwards and Steptoe, 1983; Jones *et al.*, 1983; Whittaker *et al.*, 1983; Wilcox *et al.*, 1985; Sharp *et al.*, 1986; Chard, 1991). Transient appearance of hCG has also been shown in women using an intrauterine contraceptive device (Beling *et al.*, 1976; Landesman *et al.*, 1976; Hodgen *et al.*, 1978).

Measurement of hCG for estimation of gestational age

A single estimation of hPL, hCG or Schwangerschafts-protein 1 (SP1) can be used to estimate gestational age at 4–6 weeks of pregnancy (Whittaker *et al.*, 1983; Lagrew *et al.*, 1984; Westergaard *et al.*, 1985b). In practice the error range is similar to that which can be obtained from an accurate menstrual history or an ultrasound scan.

Threatened abortion

The levels of all placental products, including hCG, are reduced in cases of threatened abortion which subsequently proceed to complete abortion (Nygren *et al.*, 1973; Braunstein *et al.*, 1978; Jovanovic *et al.*, 1978; Jouppila *et al.*, 1979; Masson *et al.*, 1983; Salem *et al.*, 1984b; Yovich *et al.*, 1986). As a clinical test this measurement has been largely superseded by

ultrasound; demonstration of the absence of a fetal heart beat gives the same information more simply and rapidly. However, serial measurements of hCG (i.e. showing failure of the normal rapid rise) may be of value in the period prior to the appearance of the fetal heart beat (Yovich *et al.*, 1986).

Ectopic pregnancy

Circulating hCG is usually present in cases of ectopic pregnancy, and measurement of hCG in blood and/or urine has been proposed as a routine test in all cases of lower abdominal pain in women of reproductive age (Seppala *et al.*, 1980; Braunstein and Asch, 1983; Norman *et al.*, 1985b). A negative result (less than 25 IU/l) virtually excludes the possibility of a pregnancy-related disorder (Romero *et al.*, 1985a). Quantitative estimations of hCG may also be of value, especially in combination with ultrasound examination. A level of hCG greater than 6500 IU/l, with no evidence of a live intrauterine embryo, is particularly suggestive of ectopic gestation (Pittaway *et al.*, 1985b; Romero *et al.*, 1985b).

Fetal congenital abnormality

Trisomy 21, Down's syndrome, is the most common autosomal aneuploidy in which affected individuals survive beyond infancy. The risk of a Down's syndrome pregnancy increases with maternal age, and pregnant women over 35 are routinely offered amniocentesis. This accounts for only 25–30% of all cases of Down's syndrome, representing only 5–7% of the total pregnancy population. During the second trimester, maternal serum α-fetoprotein (AFP) levels are lower in cases of Down's syndrome than normal affected pregnancies (Merkatz *et al.*, 1984). In addition unconjugated oestriol (uE3) is also decreased (Canick *et al.*, 1989) and human chorionic gonadotrophin (hCG) levels are about double those of normal pregnancies (Bogart *et al.*, 1987). Currently the best predictor of Down's syndrome during the second trimester of pregnancy is the combination of elevated hCG, low levels of AFP and low levels of uE3. This 'triple' test can detect about 60% of all fetal Down's syndrome with an amniocentesis rate representing about 5% of the total pregnant population (Wald *et al.*, 1988).

Though this represents a great advance in prenatal diagnosis of Down's syndrome, definitive diagnosis is late. Other markers are being investigated in order to improve the detection rate and decrease the gestational age at which the test is effective. Levels of the free β-subunit of hCG appear to be elevated in the maternal serum of Down's affected pregnancies during the first trimester (Spencer *et al.*, 1992). Furthermore, the measurement of free β-hCG appears to be a superior discriminant of Down's pregnancies than measurement of intact and total β-hCG. Measurement of maternal free β-hCG and AFP is replacing the triple test as the preferred biochemical screening test for Down's syndrome.

(c) Maternal levels of hCG in complications of late pregnancy

By comparison with other placental products, such as hPL and oestriol, there is a very limited literature on hCG levels in complications of late pregnancy. The current evidence indicates that serum hCG levels are higher in primigravidas and in women carrying female fetuses, and that they are also related to birthweight (Obiekwe and Chard, 1982a, 1983a). The levels are elevated in primigravid patients with proteinuric pre-eclampsia (Said *et al.*, 1984). Amniotic fluid and cord blood levels of hCG are elevated in diabetic mothers (Barbieri *et al.*, 1985, 1986).

(d) hCG as a tumour marker

The value of detecting in hCG in clinical samples from patients with trophoblastic disease was recognized soon after its discovery

(Aschheim, 1930). The same bioassay systems were used to detect and monitor the first reported cases of ectopic hCG production by non-trophoblastic tumours (MacFadzean, 1946; Chambers, 1949). Gestational and male testicular germ cell tumours are the best-known categories in which ectopic hCG expression occurs. Monitoring this expression has proved invaluable in the diagnosis and treatment of these once lethal tumours. The third category, non-trophoblastic neoplasms, is the most controversial area of ectopic hCG expression.

Gestational trophoblastic disease

The most efficient marker of any cancer is hCG production by gestational choriocarcinoma and hydatidiform mole. hCG has provided a reliable monitor of staging, course of disease and response to chemotherapy for over 40 years. High pretreatment levels correlate with poor prognosis, i.e. between 1000 and 10 000 μIU/ml are associated with a 2.5% mortality rate, while values exceeding 1 million are associated with a 60% mortality rate (Hussa, 1987). Following treatment, levels are determined every 1–2 weeks. As long as these decrease to within normal limits second line treatment is withheld. Remission is defined on the basis of serum hCG levels of < 5 μIU/ml for 3 consecutive weeks. The policy of the Charing Cross Reference Centre is to continue monitoring every 2 weeks up to 6 months then monthly for 5 years (Bagshawe, 1980, 1984; Hussa, 1987).

Though chemotherapy regimens vary between centres, the levels of hCG determine when and how the therapy is administered. High-level, high-risk, categories receive more neoadjuvant courses once remission is achieved than low-risk groups. In addition, in the absence of clinically apparent disease, persistently elevated serum hCG reflects the existence of tumours that if untreated will progress clinically (Hussa, 1987). In some cases, differential levels of hCG in clinical samples can pinpoint the site of metastases (e.g. a serum–CSF ratio of greater than 60:1 is indicative of spread to the brain) (Soma *et al.*, 1981; Bagshawe, 1984; Hammond *et al.*, 1984).

The hCG found in serum from patients with gestational tumours is predominantly intact hCG. Elevated levels of free α-subunit are also found. Vaitukaitis and Ebersole (1976) suggested that elevated free α-subunit correlates with poor prognosis, in particular chemoresistance. Quigley *et al.* (1980a,b) also suggested that elevated serum α-subunit during remission may identify patients in whom recurrence occurs. Gaspard *et al.* (1980) found that free α-subunit levels were similar to those in pregnancy of similar gestational age. Analysis of the ratio of intact to free β-hCG has shown that in choriocarcinoma there is a greater proportion of free β-subunit than in hydatidiform moles or normal pregnancy (Gaspard *et al.*, 1980; Khazaeli *et al.*, 1989). Not surprisingly, high levels of β-core are detected in the urine of patients with gestational disease. Choriocarcinoma hCG tends to be hyperglycosylated and the extent of this is believed to correlate with malignant behaviour (Kobata, 1988).

Testicular germ cell tumours

More than 95% of all testicular tumours are of germ cell origin. There are two major types: seminomatous and non-seminomatous (or teratocarcinomas). The non-seminomatous tumours are of five histological subtypes: embryonal carcinoma, teratocarcinoma, teratoma, choriocarcinoma and yolk sac carcinoma. It is unusual to find a single histological type in a diseased testis. Even seminoma and non-seminomatous elements can be found simultaneously and a single random biopsy can prove misleading (Caulfield *et al.*, 1990). The frequency of hCG expression varies from 8–9% for pure seminomas to 100% for pure choriocarcinomas. Non-seminomas are more likely to express hCG than seminomas. Non-

seminomatous tumours are sometimes divided into mature or immature teratomas. The mature teratomas contain highly differentiated tissues such as cartilage and bone: whilst the immature forms contain predominantly developmental tissues such as syncytiotrophoblast and yolk sac elements. The oncofetal antigen α-fetoprotein (AFP) is also produced by some testicular germ cell tumours. Unlike hCG, AFP expression is diagnostic of non-seminomatous disease as it is a specific product of the yolk sac. This diagnostic distinction is critical since seminomas are radiosensitive whilst non-seminomas only respond to chemotherapy. Furthermore, incorrect treatment of non-seminomatous tumours with radiotherapy invariably precludes subsequent chemotherapy. As with gestational trophoblastic disease, hCG levels at presentation are prognostic. Patients with levels greater than 10 000 μIU/ml have a poorer 3-year survival rate (53%) than those with levels less than 1000 (85%) (MRC Working Party on Testicular Cancer Report, 1985). Chemosensitivity is a predominant feature of hCG-expressing non-seminomatous tumours and the cure rate is high.

The hCG present in patients with non-seminomatous testicular germ cell tumours is similar to that of choriocarcinoma: predominantly intact with varying amounts of free β-subunit (Norman *et al.*, 1985c). hCG expression by seminomatous disease may also indicate the presence of trophoblastic elements. The overall survival rate for seminomatous disease is 80–97% (Schuette *et al.*, 1985; Thomas, 1985). However, for hCG-positive seminomas there is a 20% mortality rate at 2 years (non-expressors 4%) and a reported correlation with radioresistance (D.A. Morgan *et al.*, 1982; Butcher *et al.*, 1985). Though testicular germ cell tumours predominantly express intact hCG, there are reports of cases in which only free β-hCG is expressed (Light *et al.*, 1983; Rzasa, 1984; Hussa, 1987). Hussa (1987) has estimated the incidence of pure β-hCG-expressing testicular germ cell tumours as 2–4%. However, Saller *et al.* (1990) have reported that in seminomas the predominant species is free β-hCG.

Ectopic expression by non-germ cell tumours

Prior to the development of the β-subunit RIA, studies of ectopic hCG production by non-trophoblast non-germ cell tumours was limited to sporadic case reports. The most frequent sites were lung, liver (hepatoma) and the adrenal cortex (reviewed by Braunstein, 1983). After the development of the 'β-hCG' RIA, Braunstein *et al.* (1973) published the seminal study on expression of hCG-like material by non-trophoblastic cancers. Eleven percent of 906 patients with various non-trophoblastic malignancies had immunoreactive hCG in their serum. Many subsequent reports have given a varying incidence for specific tumours. Baylin and Mendelsohn (1980), Heyderman *et al.* (1985) and Seppala *et al.* (1986) generally agree that the most common occurrence of immunoreactive hCG expression is in pancreatic (50%), gastric (24%) and hepatic (17%) tumours. However, most studies are case reports. Braunstein (1983) and Hussa (1987) both reviewed the literature in detail. Their estimated prevalence of hCG for various tumours is shown in Table 5.2.

Though there are some discrepancies between tumour types, both authors agree that the overall prevalence is low (19–21%), that the levels are usually between 5 and 25 μIU/ml, and that if the criteria for ectopic expression were levels of 25 μIU/ml or greater the overall prevalence would be 1–5% (Braunstein, 1983; Hussa, 1987).

There are technical problems with the assessment of low levels of hCG. The range 5–25 μIU/ml is at the lower and least reliable end of most assays. Several studies have shown that protease activity in clinical samples may give false-positive results (Adejuwon *et al.*, 1980; Hussa *et al.*, 1985). Variant

Table 5.2 Frequency of immunoreactive 'hCG' detection in sera of patients with non-trophoblastic neoplasms

Neoplasm	*Review*	
	Braunstein (1983)	*Hussa (1987)*
Ovarian (epithelial)	39% (101/260)	45% (97/216)
Gynaecological (non-ovarian)	27% (182/686)	32% (248/766)
Breast	26% (336/1311)	25% (167/667)
Gastrointestinal	21% (251/1211)	21% (163/768)
Pancreas	21% (31/150)	38% (23/50)
Head and neck	21% (17/83)	79% (19/24)
Melanoma	20% (38/194)	19% (40/120)
Lung	16% (187/1143)	15% (140/929)
Sarcomas	15% (11/76)	14% (7/51)
Renal	6% (7/18)	5% (7/128)
Prostate	7% (7/102)	10% (7/74)
Bladder	10% (5/48)	–
Multiple myeloma	8% (9/111)	7% (11/167)
Leukaemia–lymphoma	4% (29/814)	0.5% (23/545)
Total	19% (1175/6109)	21% (929/4455)

forms of hCG and subunits have been described in neoplastic isolates, and these may only have limited activity in a given assay (Hussa *et al.*, 1985). Immunoreactive hCG may be found in both tumour and normal tissues (Yoshimoto *et al.*, 1979); these studies are particularly prone to protease interference. Using assays of exceptional sensitivity and specificity Odell and Griffin (1987) have detected immunoreactive hCG at extremely low levels (0.4–7.9 μIU/ml) in postmenopausal serum. Subsequently, they described cyclical surges of hCG paralleling the LH surge during the menstrual cycle of non-pregnant women (Odell and Griffin, 1989).

McManus *et al.* (1976) described immunohistochemical detection of 'β'-hCG on the surface of nearly all (89%) of a group of malignancies. However, subsequent studies have not noted such a high frequency (Bellet *et al.*, 1980). Since β-hCG and intact hCG are rapidly secreted once formed, the specificity of these immunoperoxidase studies is questionable (Handwerger *et al.*, 1987). Given that only a few cases of ectopic hCG expression by non-trophoblastic tumours are genuine, the clinical relevance is also doubtful. Measurement of hCG has no value as a screening test. With gynaecological cancers the levels may parallel disease course (Tormey *et al.*, 1975; Broder *et al.*, 1977), but this is not always the case (Kahn *et al.*, 1977; Rutanen and Seppala, 1978; Stanhope *et al.* 1979; Carenza *et al.* 1980).

Despite the conflicting clinical information, *in vitro* studies have demonstrated hCG secretion by various non-trophoblastic tumours (Ruddon *et al.*, 1979a,b; Rosen *et al.*, 1980a; Iles *et al.*, 1990). Most only secreted one or other of the subunits; this contributed to the finding that the subunits of the glycoprotein hormones are coded by independent genes. It is now apparent that free β-hCG is also produced by many tumours arising from mucosal epithelia and various epithelial gynaecological neoplasms, including ovarian carcinomas (Braunstein *et al.*, 1973; Cole *et al.*, 1988; Cole and Nam, 1989; Iles *et al.*, 1990).

This expression is independent of the α-subunit (Iles and Chard, 1989a, Iles *et al.*, 1990).

Analysis of the genomic DNA structure of choriocarcinoma cell lines by Whitfield and Kourides (1985) showed no rearrangement of the α-subunit gene or the β-hCG–LH gene cluster which would result in aberrant expression. Using similar techniques and restriction enzymes, genomic DNA from β-hCG-expressing bladder tumour cell lines were similarly examined (Iles *et al.*, 1989). No gene rearrangement or amplification was found; furthermore, karyotype analysis did not show any consistent copies or translocations of chromosome 19. It therefore seems likely that such expression is a result of alteration in gene regulation/repression. However, normal urothelia and oral mucosa *in vitro* also secrete free β-hCG into their culture media (Iles *et al.*, 1990), and low levels of immunoreactive β-hCG can be detected in serum and urine of normal non-pregnant subjects (Chen *et al.*, 1976; Armstrong *et al.*, 1984; Huang *et al.*, 1984). It is therefore possible that free β-hCG is a normal product of mucosal epithelia with an as yet unknown function. Nevertheless, the detection of ectopic β-hCG expression by epithelial cancers correlates with a malignant phenotype of poor prognosis (J.E. Martin *et al.*, 1989; Iles and Chard, 1991; Marcillac *et al.*, 1992).

Which of the six β-hCG genes/pseudogenes is expressed by ectopic β-hCG-producing cancers has yet to be determined. At least five might be transcriptionally active. One or more might code for an aberrant form which cannot combine with the α-subunit (Bo and Boime, 1992).

5.3.9 CLINICAL APPLICATION – THERAPEUTIC

(a) Birth control vaccines

There has been much effort to produce a birth control vaccine which would act by neutralizing the action of hCG (WHO, 1985). Antibodies to hCG usually also recognize LH, and this would interfere with menstrual function. To achieve specificity, it is necessary to use the C-terminus of the β-subunit of hCG as the immunogen; this is not present in LH.

In earlier studies chemically altered forms of hCG or of hCG coupled to haptens were used as immunogens (Stevens and Crystle, 1973). Although it was possible to raise antibodies, they cross-reacted with LH and subsequent experiments addressed the β-subunit or fragments of the subunit. Hearn *et al.* (1976) showed that both active and passive immunization with the β-subunit could disrupt pregnancy. Active immunization also caused a marked reduction in the subsequent fertility of the animals. Other experiments with similar results were carried out with β-hCG coupled to tetanus toxoid in several species, including a limited number of women (Talwar *et al.*, 1976).

The optimal immunogen is the amino acid sequence 109–145 of the C-terminal region of the β-subunit of hCG with protein carrier and adjuvants acceptable to humans (Stevens, 1986). Tsong *et al.* (1985) found that the best results were obtained by linking the peptide via carbodiimide with tetanus toxoid. Numerous adjuvants were tried, of which the muramyl dipeptide family were most effective (Nash *et al.*, 1985), and the highest titres were obtained by suspending in saline and emulsifying with Arlacel A in squalene (C.C. Chang *et al.*, 1985). Preliminary clinical trials using this peptide have been carried out.

Most experimental work has used the baboon as a model (Stevens, 1976; Thanavale *et al.*, 1978). Stevens *et al.* (1981) however, found that the cross-reactivity between antibodies to the peptide immunogen and baboon CG was only 3–15%. Even then active immunization was effective in inhibiting fertility in these animals without side-effects.

5.3.10 CONCLUSIONS

Although a great deal has been learned in recent years about the structure and function of hCG, there remains much that is unknown. Study of the three-dimensional structure of the hormone by X-ray crystallography would be a significant advance. Complete sequencing of the entire β-hCG–LH gene cluster is required, as is elucidation of the transcriptional control mechanisms and the evolution of this gene cluster. The studies on structure–function relationship are still incomplete, and most conclusions are still hypotheses.

5.4 HUMAN PLACENTAL LACTOGEN

(a) Historical survey

The presence in the human placenta of a substance having mammotrophic activity was first clearly shown by Ito and Higashi (1961, 1974) and Higashi (1962). Subsequently, Josimovich and MacLaren (1962) demonstrated that the material was immunochemically similar to human pituitary growth hormone (hGH) and that it occurred in maternal peripheral serum, retroplacental serum and placental extracts.

(b) Nomenclature

There is much confusion over the nomenclature of the protein, which is referred to in this chapter as human placental lactogen or hPL. Many other designations have been put forward, including human chorionic growth hormone–prolactin (hCGP) (H. Cohen *et al.*, 1964; Grumbach and Kaplan, 1964), purified placental protein (PPP) (Florini *et al.*, 1966), human chorionic somatomammotrophin (hCS) (Li *et al.*, 1968) and choriomammotrophin (IUPAC-IAB, 1975). The term hCS is widely used and has been advocated by Bewley and Li (1974) on the grounds that it provides a clear description of the relationship of this protein to other hormones. Furthermore, the term 'chorionic' is more specific than 'placental' and is commonly used for other placental hormones such as chorionic gonadotrophin and chorionic corticotrophin. However, most workers consider the term chorionic somatomammotrophin to be cumbersome and inelegant and accordingly the original name of placental lactogen is now preferred.

5.4.1 BIOSYNTHESIS

(a) Source of hPL

As with other 'specific' placental proteins, hPL is a product of the syncytiotrophoblast, though there is evidence that in the very early placenta (4–5 weeks) the cytotrophoblast is the main source of both hPL and hCG (Maruo *et al.*, 1992). The experimental evidence for localization is based on immunohistochemistry (e.g. Ikonicoff and Cedard, 1973; Billingsley and Wooding, 1990; Maruo *et al.*, 1992) and studies with gene probes: using labelled complementary DNA ([^{3}H]cDNA) it has been shown that the bulk of the mRNA for hPL is in the syncytiotrophoblast (McWilliams and Boime, 1980; Sakbun *et al.*, 1990). When isolated cytotrophoblast cells are cultured *in vitro*, fusion and formation of a syncytium is associated with an increase in cytoplasmic hPL (Kliman *et al.*, 1986; Klassen *et al.*, 1989).

The localization of the protein-synthesizing machinery within the trophoblast has been studied by Burgos and Rodriguez (1966), who have shown a clear differentiation between thick areas of the trophoblast cytoplasm, which are rich in endoplasmic reticulum and microvilli and therefore appear to be specialized for protein synthesis, and thin areas without microvilli, which lie in proximity to fetal capillaries and appear to be specialized for the transport of nutrients and waste products. This differentiation is of potential clinical significance because it is possible that a

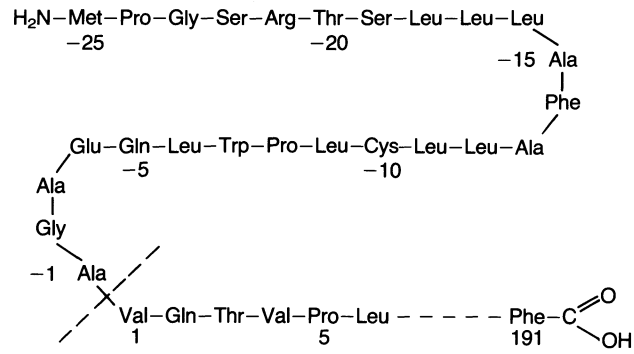

Figure 5.6 Amino acid sequence of the 25-residue 'precursor piece' at the *N*-terminus of hPL.

pathological process might damage the transfer area while leaving the synthetic areas intact. However, most trophoblast pathology is secondary to factors such as occlusion of fetal capillaries in the chorionic villus or maternal decidual arterioles, and it is likely in practice that all areas will be equally affected.

The distribution of hPL in different areas of the placenta appears to be homogeneous, the amount being directly related to the amount of trophoblast in any area (Gau and Chard, 1975). As already noted, production of hPL is not unique to the trophoblast: significant levels are found in seminal plasma (J.N. Lee *et al.*, 1983; Salem *et al.*, 1984a).

(b) Mechanism of biosynthesis of hPL

The basic mechanism of synthesis of hPL in the trophoblast appears to be similar to that of proteins in other tissues. Friesen and coworkers (Suwa and Friesen, 1969a,b) examined the incorporation of ^{3}H-labelled amino acids by placental fragments *in vitro*, and showed that hPL accounts for a substantial proportion (up to 55% in some experiments) of the total labelled protein released into incubation medium. In the tissue itself the ratio of labelled hPL to labelled total protein was much lower (4%), and most of the hPL appeared to be in a high molecular weight form (more than 100 000 daltons). The specific activity of labelled hPL was higher in the medium than the tissue, suggesting the existence of two pools in the latter site: one of rapid turnover and a second, more stable, variety.

Polysomes and messenger RNA from the placenta can direct the synthesis of hPL in cell-free systems (Boime and Boguslawski, 1974; Boime *et al.*, 1976; Cox *et al.*, 1976; Hubert *et al.*, 1981). Synthesis by polysomes from term placenta is four times greater than that of the first-trimester polysomes, and at term hPL represents 10% of the total proteins synthesized (Boime and Boguslawski, 1974). As the efficiency of the first-trimester and term mRNA is similar in terms of amino acid incorporation, it would appear that the relative levels of hPL mRNA are greater in the term placenta (Boime *et al.*, 1976). When free polysomes are used in a cell-free system a 'pre-lactogen' of molecular weight 25 000 is produced; the extra protein or 'precursor piece' is at the N-terminus of the molecule and contains an abundance of leucine residues (Birken *et al.*, 1977; Sherwood *et al.*, 1979). In the presence of membrane fractions from endoplasmic reticulum, the 'pre-lactogen' is converted to authentic hPL; this 'precursor piece' (Figure 5.6) is a 25 amino acid sequence which may play a part in the formation of membrane-bound ribosomal complexes (Blobel and Dobberstein, 1975) (Figure 5.7).

Thus, the primary gene product appears to

be pre-hPL with a molecular weight of 25 000 and it is likely that the high molecular weight material detected by Suwa and Friesen (1969a,b) represented a complex of pre-hPL and membrane components or possibly a stable dimeric form of hPL (two hPL molecules joined by disulphide exchange links) (Schneider *et al.*, 1977).

The genes for hPL and hGH synthesis are organized as a cluster at band q22–24 on the long arm of chromosome 17 and share a 92% sequence homology (George *et al.*, 1981; Selby *et al.*, 1984). There are five genes organized in the following manner: 5′-hGH-N, hCS-L, hCS-A, hGH-V, hCS-8-3′ (Harper *et al.*, 1982; Barsh *et al.*, 1983; Barrera-Saldana *et al.*, 1983). The mRNA products of these genes are heterogeneous, indicating multiple origins of transcription (Selvanayagam *et al.*, 1984). A transcriptional enhancer has been identified 2.2 kb 3′ of the hPL gene at the distal extreme of the hPL–hCG gene cluster (White *et al.*, 1993; Walker *et al.*, 1990). The inactive 'hCS-L' gene has a mutation at the 5′

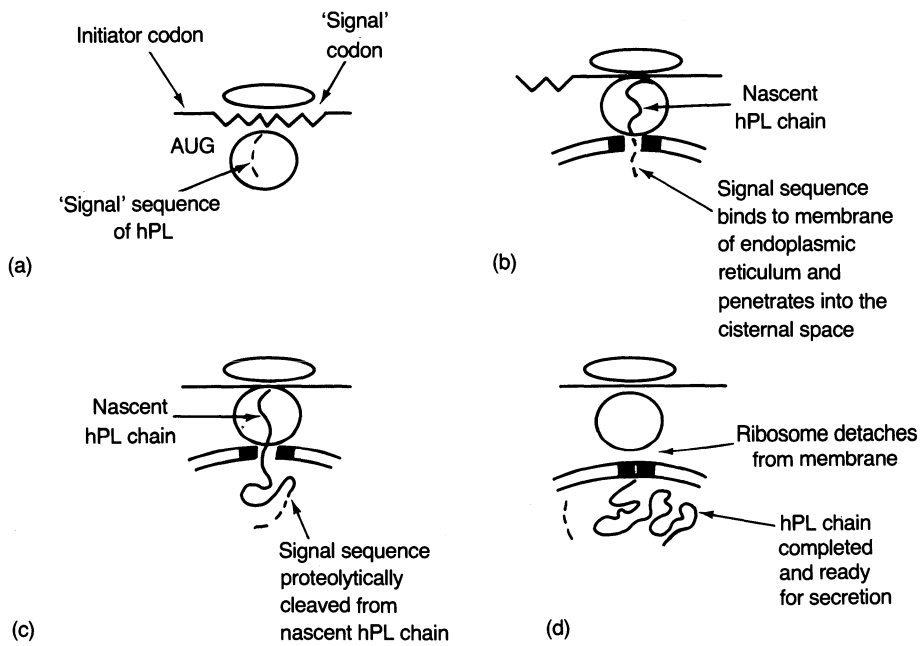

Figure 5.7 A scheme for the synthesis and secretion of hPL by the trophoblast, based on the experimental findings described in the text and the 'signal hypothesis' of protein secretion. (a) Synthesis of hPL is started by an initiator codon (AUG) on mRNA, together with two ribosome units. A unique sequence of codons, immediately to the right of the initiator codon is translated into a unique sequence of amino acids on the *N*-terminus of the nascent hPL molecule. This is the so-called 'signal sequence' of 'precursor piece', which contains a high proportion of the hydrophobic amino acid leucine. (b) The signal sequence binds to a receptor on the membrane of the endoplasmic membrane of the endoplasmic reticulum. This permits the nascent hPL chain to pass through the membrane into the cisterna. (c) The complete hPL chain enters the cisterna as it is translated by the ribosome (the ribosome remains bound to the membrane during this process). The signal piece is proteolytically cleaved from the nascent hPL chain. (d) The authentic hPL chain is completed and the ribosome dissociates form the membrane. This hypothesis explains why pre-hPL, i.v. with the signal sequence attached, is synthesized in cell-free systems containing only free polysomes, while authentic hPL is produced if a membrane fraction is included.

splice site, suggesting that it is a pseudogene (Hirt *et al.*, 1987). The hGH-V gene, previously thought to be inactive, is expressed in the placenta (Frankenne *et al.*, 1987). Varying numbers of gene deletions explain the rare cases of partial or total hPL deficiency (Parks *et al.*, 1985; Simon *et al.*, 1986). Some workers have suggested that the partial deficiency should be regarded as a reversion to the single-gene ancestral state rather than a gene deletion (Chakravarti *et al.*, 1984).

The cytological distribution of the mRNAs for hCG and hPL has been examined by *in situ* hybridization: hCG mRNAs are found partly in the syncytium and partly in the cytotrophoblast, while hPL mRNA is located exclusively in the syncytium (McWilliams and Boime, 1980; Hoshina *et al.*, 1982; Sakbun *et al.*, 1990). This association of hCG with differentiating elements and hPL with fully mature elements is compatible with the high levels of hCG and relatively low levels of hPL characteristic of trophoblast tumours (Goldstein, 1971).

(c) Distribution of hPL

The concentration of hPL in fetal blood is 100-fold less than that in the mother (Kaplan and Grumbach, 1965; Crosignani *et al.*, 1972; Houghton *et al.*, 1984). This differential is common to all specific proteins of the human placenta and is probably due to the fact that the trophoblast is in direct contact with the maternal circulation, whereas it is separated from the fetal circulation by a basement membrane and the fetal capillary endothelium. The concentration of hPL in the venous drainage of the uterus is similar or slightly higher than in the peripheral circulation (Klopper and Hughes, 1978; Grudzinskas *et al.*, 1979; Gusdon and Sain, 1981; Metzger *et al.*, 1985). The levels of hPL in amniotic fluid are 10-fold less than those in the mother (Crosignani *et al.*, 1972). Only small amounts of hPL are excreted in maternal urine (0.5 mg/day against a production rate of 1 g/day), a finding which is not surprising for a protein of this molecular weight. The concentration of hPL in mammary secretions during the last 12 weeks of pregnancy is approximately one-tenth of that in blood (Kulski *et al.*, 1982).

(d) Metabolism of hPL

The rate of synthesis of hPL has been estimated at 1–12 g/day (Beck *et al.*, 1965; Kaplan *et al.*, 1968). The half-life of hPL in the mother, as estimated by the rate of disappearance after delivery of the placenta, is 10–20 min (Spellacy *et al.*, 1966; Pavlou *et al.*, 1972). As with other biological molecules, the disappearance is biphasic with a rapid initial fall (yielding the half-life stated above) followed by a period of less rapid decrease. The differences in half-lives between individual subjects cannot be explained by observational error alone (Pavlou *et al.*, 1972). Each subject has her own characteristic half-life, and this can be attributed to differences in the mode of delivery and the physiological state of the patient.

There is no nyctohemeral rhythm in the maternal levels of hPL (Beck *et al.*, 1965; Samaan *et al.*, 1966; Ayala *et al.*, 1984). The variation over a 24 h period, however, is greater than that which can be attributed to the assay itself (Pavlou *et al.*, 1972); and this nyctohemeral variation is of the order of 6% (Houghton *et al.*, 1982). Thus, a single sample taken from an individual will not be representative of all samples taken from the individual, and the diagnostic significance of hPL levels is increased if serial levels are examined. The day-to-day variation of circulating hPL levels is similar to the nyctohemeral variation at 6% (Masson *et al.*, 1977). The factors responsible for the variation are unknown. Posture has no effect (Ylikorkala *et al.*, 1973), nor does strenuous physical exercise (Lindberg *et al.*, 1973; Pavlou *et al.*, 1973) or bedrest (Letchworth *et al.*, 1974), or a period of heavy smoking (Pavlou *et al.*, 1973). There is no change following the infusion of amino acids

or ingestion of a protein meal (Tyson *et al.*, 1969; Tatra *et al.*, 1977). Claims of fluctuations in levels during normal labour (e.g. Cramer *et al.*, 1971) have not been confirmed in other studies (Gillard *et al.*, 1973). There is no change in hPL levels associated with the onset of normal labour (Gillard *et al.*, 1973) or premature labour (Westergaard *et al.*, 1985a,b).

(e) Placental lactogenic hormones in other species

Protein hormones with lactogenic activity have been found in many but not all mammalian species (reviewed by Forsyth and Bloomfield 1986). Thus, it is found in the placenta of the goat (Buttle *et al.*, 1972; Currie *et al.*, 1977), the rhesus monkey (Walsh *et al.*, 1977), the sheep (Handwerger *et al.*, 1977), rodents (A.M. Kelly *et al.*, 1975), the hamster (Southard *et al.*, 1986, 1987), and the cow (Bolander and Fellows, 1976; Bolander *et al.*, 1976; Buttle and Forsyth, 1976). The most notable exceptions amongst mammals appear to be the rabbit, the pig and the dog (Porter, 1980). The placental lactogens of the chimpanzee, orang-outang and Old World monkeys are immunologically identical or very similar to hPL; the lactogen of the New World squirrel monkey, by contrast, shows only a marginal cross-reaction (Lin and Halbert, 1978). Similarly, there is virtually no immunological cross-reaction between the placental lactogens of the sheep, the goat, the cow and the deer, despite the close similarity of the prolactins and growth hormones in these species (Forsyth and Bloomfield, 1986).

Bovine placental lactogen (bPL)

The cow produces a 32-kDa protein with lactogen-like activity in radioreceptor assays (Eakle *et al.*, 1982; Byatt *et al.*, 1986, 1992). As with other ruminant hPLs, it is delivered to the maternal circulation by migration of binucleate cells of the placenta (Duello *et al.*, 1986; Byatt *et al.*, 1992). The serum levels of bPL remain low during the first two trimesters and thereafter rise rapidly to reach a plateau after 200 days (Bolander *et al.*, 1976). Dairy cows have higher bPL levels than beef cattle; the levels are higher in twin pregnancy but do not correlate with fetal weight or sex (Bolander *et al.*, 1976). Administration of recombinant bPL can increase milk yield and feed intake in the dairy cow (Byatt *et al.*, 1992).

Monkey placental lactogen

Placental lactogens are present in all groups of monkeys. In rhesus monkeys, PL is detectable from day 42 of gestation onwards (Walsh *et al.*, 1977). Maternal levels rise progressively and at term correlate with placental but not fetal weight (Novy *et al.*, 1981). The levels are not affected by protein deprivation, fetal anencephaly, or ligation of the interplacental bridging vessels (Novy *et al.*, 1981).

Mouse placental lactogen

The mouse placenta secretes two placental lactogens: mPL-I and mPL-II. Genes for both of these have been isolated and characterized (Jackson *et al.*, 1986; Shida *et al.*, 1992). Mouse placental lactogen (mPL) can be detected in maternal serum from day 9 of gestation onwards and its concentration increases throughout gestation (Soares *et al.*, 1982). The circulating levels correlate with litter size (Markoff and Talamantes, 1981; Soares and Talamantes, 1983). An increase in mPL levels is found after ovariectomy, hypophysectomy and fasting (Soares and Talamantes, 1985; Day *et al.*, 1986; Lopez *et al.*, 1991). Ethanol administration has no effect on mPL levels (Fielder *et al.*, 1989). *In vitro*, the release of mPL is principally a function of placental mass (Basch and Talamantes, 1986), though secretion of mPL-II can be inhibited by progesterone (Yamaguchi *et al.*, 1992). Some authors have concluded that mPL is an im-

portant lactogenic hormone in the second half of pregnancy in the mouse, when circulating mPRL levels are low (Thordarson *et al.*, 1986). It also appears to be lipolytic in this species (Fielder and Talamantes, 1987). Mouse placental lactogen I increases after day 8 to reach a peak at days 9–11, then declines (Ogren *et al.*, 1989).

Rat placental lactogen (rPL)

Like the mouse, the rat placenta secretes a number of prolactin-like molecules (M.C. Robertson *et al.*, 1982; Deb *et al.*, 1991; Kishi *et al.*, 1992), the levels of which increase in maternal serum during pregnancy. The source is trophoblast giant cells (Soares *et al.*, 1982), and a cDNA has been cloned (Duckworth *et al.*, 1986).

Adrenalectomy and unilateral oophorectomy have no significant effect on maternal rPL levels; bilateral oophorectomy or hypophysectomy leads to a substantial increase (M.C. Robertson *et al.*, 1984). There is an inverse relationship between rPL and rat prolactin during pregnancy (Voogt *et al.*, 1982); rPL may be responsible for the elimination of twice-daily prolactin surges during pregnancy in this species (Yogev *et al.*, 1983). Pregnant rats fed a low-protein diet have decreased levels of rPL and somatomedins, and the latter can be restored to normal by administration of hPL (Pilistine *et al.*, 1984). Administration of hPL can inhibit skeletal growth in young female rats (Chiang and Nicoll, 1992).

Sheep placental lactogen (oPL)

The sheep placenta secretes a placental lactogen with a molecular weight of approximately 23-kDa (Colosi *et al.*, 1989; Warren *et al.*, 1990; Byatt *et al.*, 1992). As with hPL a slightly larger form is synthesized (25-kDa) and a signal peptide is released as part of the secretions process. Ovine PL can be found in granules in trophoderm binucleate cells (Rice and Thorburn, 1986; Wooding *et al.*, 1992). Unlike the human, the hormone is present in substantial quantities in the fetal circulation as well as the maternal, though the levels in the fetus fall while maternal levels are still rising. The maternal levels are related to the number of fetuses present; the concentration reaches a peak at days 130–139 and thereafter falls to the time of delivery (Taylor *et al.*, 1980). Fetal plasma levels correlate with fetal weight (Schoknecht *et al.*, 1991).

In the sheep extensive metabolic studies have been possible. Intravenous administration of oPL to pregnant and non-pregnant sheep may result in a decrease in plasma free fatty acids, glucose, amino acids and insulin (Handwerger *et al.*, 1976). However, Thordarson *et al.* (1987) reported an increase in non-esterified fatty acids, glucose and urea during a continuous infusion of an ovine placental extract. *In vitro*, oPL stimulates glycogenesis by fetal hepatocytes (Freemark and Handwerger, 1986).

Administration of arginine or ornithine is a potent stimulus to oPL secretion (Handwerger *et al.*, 1981), as is infusion of high density lipoproteins (Grandis *et al.*, 1989). Acute hyper- or hypoglycaemia has little or no effect on oPL levels in mother and fetus, but fasting leads to a rise in oPL in both the fetus (Oliver *et al.*, 1992) and possibly the mother. Fasting of pregnant ewes causes a reduction in PL receptors in both the mother and the fetus (Brinsmead *et al.*, 1981; Freemark *et al.*, 1992). Infusion of arachidonic acid produces an increase in maternal but not fetal oPL levels (Huyler *et al.*, 1985). Administration of a 3β-hydroxysteroid dehydrogenase inhibitor, which causes a sharp fall in progesterone levels, has no effect on oPL secretion (Taylor *et al.*, 1982). Similarly, infusion of corticosteroids or corticotrophin has no effect on circulating oPL levels (Taylor *et al.*, 1983a); agents such as chlorpromazine and thyrotropin-releasing hormone, which produce a significant increase in fetal prolactin levels, have no effect on fetal oPL (Tay-

lor *et al.*, 1983b). Neutralization of oPL by *in vivo* administration of antibody to oPL appears to have no effect on glucose, fatty acids, somatomedins or growth hormone, but causes a fall followed by a rise in insulin levels (Waters *et al.*, 1985). *In vitro*, phospholipase C can stimulate oPL release (Rice and Thorburn, 1986).

Ligation of a single umbilical artery, which produces severe fetal growth retardation, is followed by a decrease in maternal levels of oPL but an increase in fetal levels (Newnham *et al.*, 1986a). Restriction of placental growth by removal of uterine caruncles is associated with low levels of oPL (Falconer *et al.*, 1985). The increase of maternal oPL with arginine infusion is also blunted under these circumstances (Newnham *et al.*, 1986b). There is an increase in maternal oPL following fetal nephrectomy (Brinsmead *et al.*, 1980). Ovine PL binds with high affinity to the human GH receptor, despite the fact that the receptor binding site appears to differ strikingly from that of hGH (Colosi *et al.*, 1989).

Goat placental lactogen

The goat placenta secretes a lactogen with properties very similar to that of the sheep (Currie *et al.*, 1990; Byatt *et al.*, 1992).

(f) Extraction and purification

In the 1960s it was demonstrated that hPL could be prepared from placentas by extraction in aqueous media and purified by standard techniques involving fractional precipitation using salts, DEAE chromatography, polyacrylamide gel electrophoresis and gel filtration. It became clear that high pH should not be used in order to avoid deamidation and aggregation with consequent effects on biological activity. In the method of Hunt *et al.* (1981) frozen placentas were extracted in ammonium bicarbonate at pH 7.8 and the hPL was then adsorbed to DEAE-cellulose from 0.1 M bicarbonate and eluted in 0.4 M bicarbonate. There followed precipitation from ammonium sulphate, gel filtration on Sephadex G-100 and polyacrylamide gel electrophoresis. Monoclinic crystals were produced from solution in 0.1 M phosphate, pH 7.8 and polyethylene glycol-1000.

(g) Chemical structure of hPL

Human placental lactogen is a polypeptide of molecular weight 21 000 with a single chain of 191 amino acids and two intrachain disulphide bonds (Niall *et al.*, 1971, 1973). Studies with recombinant fragments generated by limited plasmin digestion and reduction of hPL and hGH have shown that most of the immunological and biological properties of these hormones are associated with the N-terminal 1–134 amino acids (Russell *et al.*, 1981a). Cleavage of the hPL molecule at residue 86 (tryptophan) completely destroys the immunological and biological activity (Russell *et al.*, 1981b). As in hGH, there is a single tryptophan residue buried within the hydrophobic interior of the molecule. Although there is no evidence that this is hydrogen bonded in the native protein as in hGH, there is a transient bonding in the early stages of thermolysin digestion (Bewley and Li, 1984).

(h) Relation of hPL to other hormones

The amino acid composition of hPL is very similar to that of hGH, the main differences being in the number of methionine, histidine and proline residues. There is an 86% sequence homology, and the disulphide bonds are located in homologous portions of each molecule. Most of the differences are near the N-terminus, and of the observed substitutions only one requires more than a single base change in the triplet codon. The amino acid sequences of hPL and hGH are also similar to that of prolactin (23% sequence homology with hPL, 16% with hGH), though prolactin has 198 amino acids and three intrachain disulphide bonds (Shome and Parlow, 1977).

It appears likely that hPL, hGH and prolactin originated from a shorter primordial peptide of 25–30 amino acids. At an early stage a structural divergence produced two evolutionary lines, one with primarily lactogenic activity, the other with somatotrophic activity. At a later stage individual species showed further divergence within these lines, thus yielding the differences between, for instance, the structure of sheep and human pituitary growth hormone and prolactin. Finally, divergences occurred within species leading to the existence of separate pituitary and placental proteins.

(i) Control mechanisms of hPL

In common with other placental products, there is little evidence for the existence of control mechanisms such as those which exist for pituitary protein hormones. However, there is a large and somewhat confusing literature concerning a number of factors which might influence trophoblastic PL production in both the human and other species.

Prolactin

In rats there is some evidence for an inverse relationship between levels of PL and pituitary prolactin (Nagasawa *et al.*, 1976; Tonkowicz and Voogt, 1984), but similar evidence is not available in the human. Hypophysectomy of the rat can lead to a substantial increase in PL levels (Voogt *et al.*, 1985).

Releasing hormones

Thyrotropin-releasing hormone (TRH), which is a powerful stimulant of pituitary prolactin secretion and is also found in the placenta (Gibbons *et al.*, 1975), has no effect on circulating hPL levels (Hershman *et al.*, 1973). Gonadotrophin-releasing hormone (GnRH) has no effect *in vitro* (Khodr and Siler-Khodr, 1978; Siler-Khodr *et al.*, 1986), though administration of GnRH antagonist has a delayed suppressive effect (Siler-Khodr *et al.*, 1983).

Steroid hormones

In the rat, ovariectomy (M.C. Robertson *et al.*, 1984) produces an increase in PL levels. In the sheep, there is no evidence that endogenous progesterone secretion affects PL secretion (Taylor *et al.*, 1982). Similarly, no effect of oestradiol or progesterone has been shown on secretion of PL by human placental cells *in vitro* (Zeitler *et al.*, 1983).

Carbohydrate and lipid metabolism

Because of the close relationship to growth hormone, several groups have examined the relationship of hPL levels to alterations in carbohydrate and lipid metabolism. Blood levels of hPL decrease following intravenous administration of glucose (Burt *et al.*, 1970; Spellacy *et al.*, 1971; Ajabor and Yen, 1972; Pavlou *et al.*, 1973) (Figure 5.8), though Pavlou and his colleagues showed that the change is small and inconsistent, and might also be attributed to trivial mechanisms such as the osmotic expansion of plasma volume which results from injection of a hypertonic solution.

Increases in blood hPL levels have been shown during insulin-induced hypoglycaemia (Spellacy *et al.*, 1971) prolonged starvation (Kim and Felig, 1971; Brinsmead *et al.*, 1981) and intravenous arginine administration (Prieto *et al.*, 1976), but changes are small when compared with those resulting from the administration of pituitary growth hormone under similar circumstances. In sheep, infusion of high-density lipoproteins (HDL) stimulates PL secretion (Grandis *et al.*, 1989). Equally, a number of studies do not support a significant role of carbohydrate or lipids in the control of hPL secretion. There is no change in hPL levels after oral administration of glucose (Pavlou *et al.*, 1973). In the

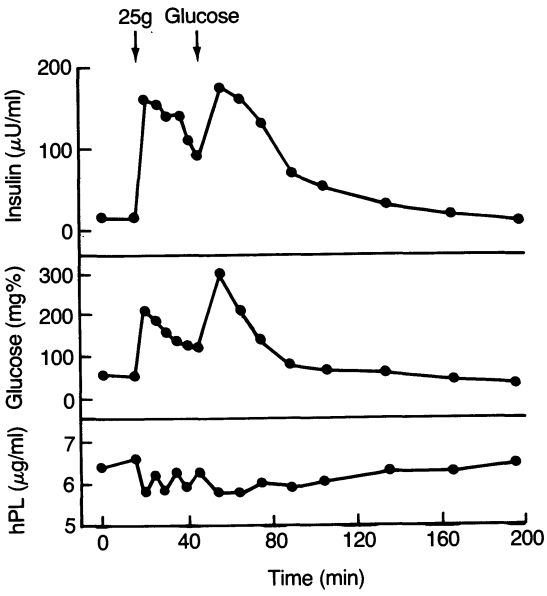

Figure 5.8 Plasma levels of insulin, glucose and hPL in 10 subjects following i.v. injection of glucose.

sheep, maternal hyperglycaemia produces no change in placental lactogen levels in fetus or ewe (Brinsmead *et al.*, 1981). Experimentally induced changes in circulating levels of free fatty acids do not produce any consistent change in hPL concentrations (Morris *et al.*, 1974). The secretion of hPL by dispersed placental cells *in vitro* is not influenced by changes in insulin or glucose concentrations (Zeitler *et al.*, 1983), though contrary results were obtained by Bhaumick *et al.* (1987), who showed that both insulin and insulin-like growth factor (IGF-I) could stimulate hPL production by placental explants.

Other factors

Neither epidermal growth factor (E.A. Wilson *et al.*, 1984b) nor adrenergic β-receptor agonists or antagonists (Shu-Rong *et al.*, 1982) nor corticosteroids (Tatra *et al.*, 1984) have any effect on secretion of hPL by placental cells *in vitro*. Prostaglandin $F_{2\alpha}$ has no direct effect on hPL secretion (Ward *et al.*, 1977). Dopamine reduces hPL production *in vitro* (Macaron *et al.*, 1978), as does transforming growth factor β (Morrish *et al.*, 1991). The latter effect is probably secondary to inhibition of placental differentiation. Ritodrine (Schreyer *et al.*, 1989) and angiotensin (Petit *et al.*, 1989) may enhance hPL secretion *in vivo*.

It has been proposed (Chard, 1981, and Figure 5.9) that the potential for placental production is a function of the total mass of the trophoblast, that the rate of release depends on the concentration of protein in maternal blood in the intervillous space and that this concentration, in turn, depends on the rate of blood flow in the intervillous space.

Thus, hPL will diffuse from the trophoblast cell down a concentration gradient: the faster the rate of blood flow the more rapid is the removal of hPL and hence the steeper the gradient. This hypothesis is compatible with most present evidence and has the important implication that the rate of hPL production and the circulating levels in the mother should be closely related to uteroplacental blood flow. Specific experimental evidence for the concept that the functional mass of the trophoblast is the most important factor in the control of PL secretion comes from studies in the rhesus monkey (Novy *et al.*, 1981). However, studies in the goat have not shown any relationship between short-term variation in uterine blood flow and levels of placental lactogen in the uterine or jugular veins (Hayden *et al.*, 1983). One study (Obiekwe and Chard, 1983a) has shown an apparent sex difference in hPL, higher levels being found in association with a female fetus. This difference is similar to, but less striking than that observed with hCG.

5.4.2 BIOLOGICAL PROPERTIES

(a) Biological effects of hPL

A great variety of biological activities have been proposed for hPL, including growth

promotion, lactogenesis, an effect on carbohydrate and lipid metabolism, stimulation of the corpus luteum, erythropoiesis, inhibition of fibrinolysis and immunosuppression.

Although it is chemically similar to hGH, hPL has only weak somatotrophic activity, variously estimated at 0.1–10% of that of the pituitary protein (Josimovich, 1966; Murakawa and Raben, 1968). However, the growth-promoting activity of hPL may be greater than that of hGH for some fetal tissues (Hill *et al.*, 1985). Sheep fetal fibroblasts have much higher affinity for oPL than oGH (Fowlkes and Freemark, 1992). A placental growth hormone distinct from both hPL and hGH has been described (Hennen *et al.*, 1985) and is the product of the 'silent' hGH-V gene (Frankenne *et al.*, 1987). Maternal levels of hPL are not related to those of insulin-like growth factor (IGF-I) (Kazer *et al.*, 1991).

The extent of the lactogenic activity of hPL has been disputed. Early reports suggested that its potency was some 75% that of sheep prolactin (Josimovich and Brande, 1964). However, later studies showed much lower activity (Friesen, 1965; Florini *et al.*, 1966) (1–4 U/mg in the pigeon crop-sac assay). The potency in the rabbit intraductal assay is greater than that in the pigeon crop-sac assay; a similar discrepancy has been observed with human growth hormone. Studies using intact animals have yielded estimates ranging from 20 to 100% of that of prolactin (Handwerger and Sherwood, 1974). Thus, it is difficult to assign a potency because the apparent lactogenic activity of hPL is highly dependent on the purity of the material examined, on the type of assay and on the animal species used for the assay. Surprisingly, substantial modification of the hPL molecule (reduction and alkylation, oxidation) does not seem to be associated with loss of lactogenic activity (Aloj *et al.*, 1972).

In rodents, hPL has luteotrophic activity and may influence placental progesterone secretion, particularly the interconversion of progesterone and the biologically inactive 20α-dihydroprogesterone (Josimovich and

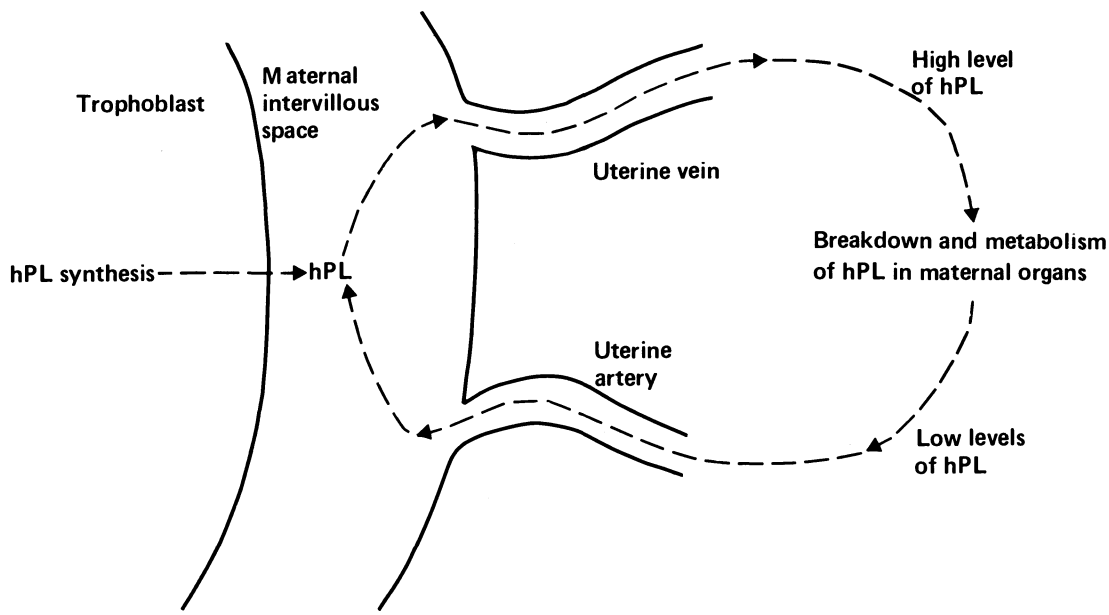

Figure 5.9 How uteroplacental blood flow may control the rate of synthesis of hPL by the trophoblast.

Archer, 1977). Administration of hPL in animals leads to a rise in blood sugar (Burt *et al.*, 1966; Handwerger *et al.*, 1977) and free fatty acids (Riggi *et al.*, 1966); this may be due to increased peripheral resistance to insulin action, though in hypophysectomized rats hPL can cause an increase in insulin release *in vitro* from islet cells (J.M. Martin and Friesen, 1969). Administration of hPL to rhesus monkeys can decrease the hypoglycaemic response to exogenous insulin, without affecting glucose tolerance or the insulin response to glucose (Beck, 1970). PL can modulate insulin production by cultured human fetal pancreas, and it has been suggested that this might contribute to fetal body growth (Swenne *et al.*, 1987).

In the mouse, hPL can stimulate erythropoietin secretion and thus the incorporation of iron into red blood cells (Jepson and Friesen, 1968). In rats, hPL has a direct mitogenic effect on bone marrow *in vitro* (Berczi and Nagy, 1991). Both hPL and hCG can suppress phytohaemagglutinin-induced lymphocyte transformation (Contractor and Davies, 1973; Cerni *et al.*, 1977). The suggestion that either of these compounds plays a significant role in the immune survival of a pregnancy is now largely discredited (reviewed by Chard, 1992).

(b) Biological functions of hPL

It is essential to distinguish between activity and function of hormones. A biological molecule may have a specific effect in an experimental system, but this does not necessarily mean that it is responsible for the same effect in normal physiology. The distinction is especially notable with the biologically active placental proteins: none has been clearly identified as essential for any physiological event, and it has even been suggested that the placental proteins have no biological function but rather are waste products of the general activities of the placenta as an independent organism (Y.B. Gordon and Chard, 1979).

Preparation of the breast for lactation could be an important function of hPL in normal gestation. But there are several other potential candidates for this function, including placental oestrogens and progesterone and maternal pituitary prolactin, all of which are elevated simultaneously. Administration of hPL to non-pregnant subjects in amounts sufficient to yield blood levels similar to those in mid-gestation does not induce lactation (Josimovich *et al.*, 1974). Furthermore, lactation can be induced by breast stimulation even in subjects who have never been pregnant (Anon, 1985).

There are similar reservations on the postulated role of hPL in carbohydrate and lipid metabolism (see Chard, 1992). It is well recognized that pregnancy constitutes a diabetogenic stress, and impairment of carbohydrate tolerance with elevated levels of circulating insulin and free fatty acids are normal findings. It is attractive to speculate that the pregnant woman tends to retain glucose within her circulation where it is available for transport across the placenta to the developing fetus, and that this retention is due to hPL. However, the evidence for this is not strong. Under normal physiological circumstances, there is little relationship between hPL and circulating carbohydrate and lipid levels (see Control mechanisms, section 5.3.4), though a correlation has been shown between hPL and plasma levels of total and free cholesterol, triglycerides and phospholipids measured throughout pregnancy (Desoye *et al.*, 1987). Administration of hPL to non-pregnant subjects leads to impaired carbohydrate tolerance and increased levels of insulin (Beck and Daughaday, 1967; Kalkhoff *et al.*, 1969), but no abnormality in carbohydrate metabolism can be shown in pregnancies in which hPL is absent (Alexander *et al.*, 1982). Furthermore, there are other equally good candidates for an effect on carbohydrate metabolism, such as the pla-

cental steroid hormones (oestrogens and progesterone), which at levels much lower than those in late pregnancy (e.g. in subjects on oral contraceptive agents) can produce all of the changes characteristic of a prediabetic state.

It is attractive to speculate that hPL might be an important growth-promoting factor for the fetus. But this possibility is ruled out by three observations: (i) the somatotrophic activity of hPL is extremely low (1% or less) compared with that of pituitary growth hormone; (ii) the levels of hPL in the fetal circulation are 100-fold less than those in the mother; and (iii) there is no relation between fetal levels of hPL and fetal growth (Houghton *et al.*, 1984).

The lack of any obvious function of PL in human pregnancy is supported by some animal studies. In the sheep, maternal hyperglycaemia produces no change in PL levels in fetus or ewe (Brinsmead *et al.*, 1981). Also in the sheep, neutralization of PL by antibodies does not affect glucose metabolism, or the circulating levels of somatomedins, growth hormone, progesterone or cholesterol (Waters *et al.*, 1985).

(c) Receptors for and mode of action of hPL

Studies on specific tissue receptors for hPL, similar to those available for hGH, are sparse. However, the chorion laeve is believed to contain a lactogen receptor which binds hPL and prolactin (Herington *et al.*, 1980). This receptor is deficient in cases of polyhydramnios (Healy *et al.*, 1985). There is evidence for receptors on the fetal liver in a variety of species (Hill *et al.*, 1988; Freemark *et al.*, 1989). Human PL can bind to the extracellular domain of the prolactin receptor; tight binding is zinc dependent (Lowman *et al.*, 1991). A number of studies have suggested that there may be circulating endogenous binders of placental lactogen (Gusdon *et al.*, 1970, Heal and Gluck, 1980; Southard and Talamantes, 1989).

5.4.3 MEASUREMENTS

(a) Immunoassay for hPL

The majority of studies on hPL have been carried out using radioimmunoassay (see Chard, 1979), though other types of immunological assay have been developed, in particular enzymoimmunoassay (EIA) (Dittmar *et al.*, 1979; MacDonald *et al.*, 1980), fluoroimmunoassay (FIA) (Chard and Sykes, 1979) and turbidimetric assay (Collet-Cassart *et al.*, 1989). The various immunoassays for hPL and the principles underlying them have been reviewed in detail elsewhere (Chard, 1979, 1982, 1983).

(b) Biological and receptor assays for hPL

Though the effects of hPL have been studied in a number of biological systems, these systems have never been used for measurement of the concentration of human PL in biological fluids. Some use has been made of receptor assays (extracts of mammary glands) for the measurement of placental lactogens in other species, e.g. the rat (P.A. Kelly *et al.*, 1976), the cow (Eakle *et al.*, 1982) and the goat (Currie *et al.*, 1977).

5.4.4 CLINICAL APPLICATIONS – DIAGNOSIS

The earlier literature on the diagnostic applications of hPL measurement was reviewed in great detail by Letchworth (1976). Subsequent reviews include those by Chard and Klopper (1982) and Chard (1984). At the present time measurement of circulating hPL is little used as a test of placental function or fetal well-being (Chard, 1987).

(a) Maternal levels of hPL in normal pregnancy

Placental lactogen is detectable in maternal blood soon after implantation; thereafter the levels rise progressively to reach a plateau

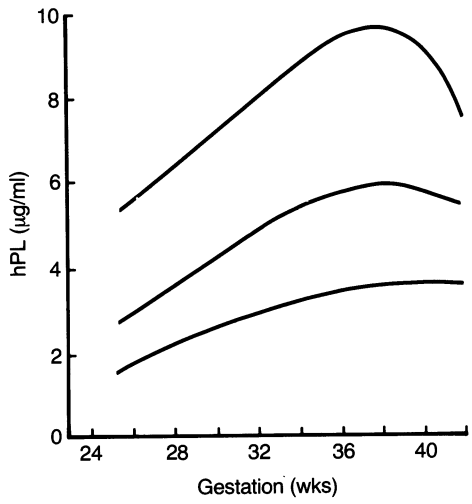

Figure 5.10 The normal range of circulating hPL levels in the mother from weeks 20–42 of gestation (200 subjects). Mean ± 2SD is shown. The distribution is skewed, the variation above the mean being greater than below it.

after the 35th week. This increase follows the sigmoid curve which characterizes all specific placental proteins and which closely parallels the growth of the placenta both in weight and in DNA content. The levels are higher in twin than in singleton pregnancies (Kazer *et al.*, 1991). The levels do not change at the onset of labour and the absolute levels are not related to the time of onset of labour (Gillard *et al.*, 1973).

The normal range of hPL levels in the later part of pregnancy is shown in Figure 5.10.

In common with most other biochemical parameters the variation around the mean shows a skewed distribution; the range of variation is greater above the mean than that below it. Thus, a better approximation to the true mean and standard deviations is obtained after logarithmic transformation of the data. Alternatively, the results are expressed as medians and centiles. In the early first trimester, hPL levels have been used to estimate the stage of gestation (Whittaker *et al.*, 1983), though others have questioned the value of this (Thomson *et al.*, 1988).

(b) Maternal levels of hPL in complications of early pregnancy

Threatened abortion

It is generally agreed that low maternal hPL levels after the 8–10th week are characteristic of threatened abortion with an unsatisfactory outcome and thus provide a guide to prognosis in this condition (Genazzani *et al.*, 1969; Niven *et al.*, 1972; Gartside and Tindall, 1975; Biswas *et al.*, 1980; Hertz and Schultz-Larsen, 1983; Gerhard and Runnebaum, 1984). The low levels would appear to be secondary to death or of damage to the trophoblast, since all placental products are affected in an identical manner (Salem *et al.*, 1984b).

(c) Maternal levels of hPL in complications of late pregnancy

Low birth-weight

Placental lactogen levels are correlated with the weight of the placenta (Sciarra *et al.*, 1968; Saxena *et al.*, 1969; Cramer *et al.*, 1971; Lindberg and Nilsson, 1973; Boyce *et al.*, 1975; Morrison *et al.*, 1980), and of the fetus (Letchworth *et al.*, 1971; Lindberg and Nilsson, 1973; Boyce *et al.*, 1975; Bagga *et al.*, 1990).

The latter relationship is secondary to that between the weight of the placenta and fetus, but there is no doubt that hPL levels are an efficient guide to fetal growth and the prediction of delivery weight in an individual patient (Lindberg and Nilsson, 1973; Hensleigh *et al.*, 1977; MacDonald *et al.*, 1983; Pledger *et al.*, 1984; Westergaard *et al.*, 1985a,b; Laurin *et al.*, 1987), particularly in cases of maternal hypertension (Granat *et al.*, 1977; Sagen *et al.*, 1984). The sensitivity of the test (proportion of positive results in patients with the abnormality) ranges from 29 to 50% depending upon the chosen cut-off point between normal and abnormal (Lilford *et al.*, 1983). Serial levels have better predictive

value than isolated levels (Obiekwe and Chard, 1984). Placental lactogen levels appear to be lower when there is specific evidence of dysmaturity than in those pregnancies where the child is small but normal (Westergaard *et al.*, 1985a). Of the currently available biochemical tests of placental function, hPL is probably marginally superior to all others (Chard *et al.*, 1985).

Low levels of hPL are associated with gross fetal abnormality (Gau and Cadle, 1977). Increased levels occur in twin pregnancies (Garoff and Seppala, 1973; Batra *et al.*, 1978; Briet and Hoorn, 1982; Trapp *et al.*, 1986). The concentration in umbilical cord blood in light-for-dates infants has been reported as elevated (Taketani *et al.*, 1984), but these findings could not be confirmed in another study (Houghton *et al.*, 1984). Elevated levels in cord blood have also been associated with pre-eclampsia (Sprague *et al.*, 1973).

There is evidence that hPL levels in fetal growth retardation only become abnormal after 33 weeks' gestation (Daikoku *et al.*, 1979). Normal levels of hPL are found during mid-trimester in mothers who subsequently deliver a growth-retarded child (Salem *et al.*, 1981).

Pre-eclampsia and hypertension

Spellacy *et al.* (1971) described a 'fetal danger zone' for subjects with hypertension: levels of hPL less than 4 μg/ml after the 30th week indicated a fetal mortality of 24%. Many workers have confirmed the association between low hPL levels and fetal outcome in hypertensive pregnancies (Keller *et al.*, 1971; Lindberg and Nilsson, 1973; Christensen *et al.*, 1974). For example, Kelly *et al.* (1975) have shown a 75% morbidity risk (growth retardation or perinatal asphyxia) for patients developing hypertension after the 28th week and having low hPL levels.

Some confusion in the literature on the precise clinical value of hPL levels in pre-eclampsia can be attributed to three factors. First, the condition itself is very heterogeneous and often not clearly defined. Second, it is very common for authors not to distinguish between pre-eclampsia *per se* and the fetal risk arising from the pre-eclampsia. Thus, in pregnancies in which the only abnormality is hypertension, hPL levels are normal after 36 weeks (Westergaard *et al.*, 1985a,b). Third, studies have looked for low levels of hPL in pre-eclampsia, whereas the best current information suggests that in primigravidas with pre-eclampsia the levels of hPL are elevated (Letchworth and Chard, 1972a; Obiekwe *et al.*, 1984). Placental lactogen levels are generally reduced in cases of antepartum eclampsia (Salem *et al.*, 1983).

Diabetes mellitus

Diabetes mellitus is associated with a large placenta, and it is therefore not surprising that hPL is generally elevated in this condition (Selenkow *et al.*, 1969; M.Cohen *et al.*, 1973; Ursell *et al.*, 1973; Soler *et al.*, 1975; Hertogh *et al.*, 1976; Larinkari *et al.*, 1982; Pledger *et al.*, 1982) (Figure 5.11).

The levels are reduced in cases in which the fetal outcome is unsatisfactory. Thus, hPL levels in a diabetic pregnancy must be interpreted in relation to the elevated range for a 'normal diabetic' pregnancy.

Conflicting results in the literature on hPL levels in diabetes can be attributed to a number of factors, including the definition of the severity of the condition, the failure to appreciate that abnormality should be judged in relation to the general elevation of levels in this condition and the fact that perinatal death may occur due to metabolic dysfunction in the absence of notable placental deficiency. A 'problem' of recent studies is the fact that most diabetic pregnancies are now so well controlled that they are, for all clinical and biochemical purposes, effectively normal (e.g. M.O. Stewart *et al.*, 1989).

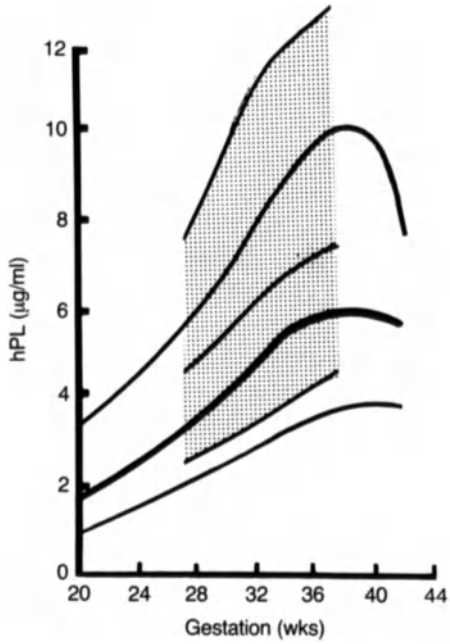

Figure 5.11 hPL levels in pregnancies complicated by diabetes mellitus in which there was no evidence of placental dysfunction (shaded area). Mean ± 2SD of the normal range is also shown.

Rhesus isoimmunization

Placental lactogen levels are generally increased in this condition. The levels are most elevated in cases in which the child is severely affected (Lindberg and Nilsson, 1973; Ward *et al.*, 1974). Prior to the 26th week, a value more than two standard deviations above the normal mean indicates a 90% likelihood that the case will be severe. Similar elevations are seen in amniotic fluid hPL (Niven *et al.*, 1974). The test has been advocated as an additional diagnostic aid at a stage when other parameters, such as liquor bilirubin, may be unhelpful.

Fetal death

Placental lactogen levels often fall before fetal death occurs (Ward *et al.*, 1974). This is compatible with the fact that in many stillbirths the cause is placental insufficiency, rather than a primary defect in the fetus itself. In a controlled study on patients with hypertension, Spellacy *et al.* (1975) showed that action based on hPL levels could lead to a substantial fall in perinatal mortality.

Fetal distress and neonatal asphyxia

Several authors have advocated hPL measurement as a general measure of 'fetal risk' (Letchworth and Chard, 1972b; England *et al.*, 1974; R.P. Edwards *et al.*, 1976; Grudzinskas *et al.*, 1982). There is little doubt that the main factor reflected by maternal hPL levels is fetal size and growth. Consequently, there has been some argument as to whether hPL determinations can predict acute fetal distress in labour, when the latter complication is analysed separately from growth retardation. However, there appears to be an association between abnormal hPL levels and an abnormal result of an oxytocin challenge test (OCT) (Spellacy *et al.*, 1979), and low hPL levels have been shown in association with fetal distress in babies of normal birth weight (Obiekwe and Chard, 1982b).

(d) Other factors which may affect hPL levels

The concentration of hPL tends to fall after 40 weeks' gestation (Lolis *et al.*, 1977). Maternal blood hPL levels are generally lower in smokers than in non-smokers (Moser *et al.*, 1974; Boyce *et al.*, 1975; Spellacy *et al.*, 1977). This is attributable to the associated growth retardation rather than to the smoking itself (J.N. Lee *et al.*, 1980). One study found higher levels of hPL associated with smoking (D'Souza *et al.*, 1988). hPL levels are lower in mothers exposed to continuous aircraft noise (Ando and Hattori, 1977), and elevated levels of hPL have been described in association with low implantation of the placenta (Nicolaides *et al.*, 1982). Low hPL levels may be associated with premature labour (Hercz *et*

al., 1987). Circulating levels of hPL are increased in pregnant renal transplanted women (Klebe *et al.*, 1990). Administration of iron supplements has no effect on hPL levels (Milman *et al.*, 1991).

(e) hPL deficiency

Several authors have described cases of apparent absence of hPL in otherwise uneventful pregnancies (Gaede *et al.*, 1978; Nielsen *et al.*, 1979; Borody and Carlton, 1981; Sideri *et al.*, 1983). Glucose tolerance appears to be normal in these subjects (Alexander *et al.*, 1982). The defects are isolated because other placental products have invariably proved normal in these cases. The deficiency is reflected by a deficiency of mRNA in the trophoblast (Hubert *et al.*, 1983). If both of the hPL genes are deleted there is a total absence of hPL, whereas if only one is deleted there is a relative deficiency, with circulating levels around one-quarter of those normally present (Parks *et al.*, 1985). Complex situations have been described in which there are different deletions on each chromosome (Simon *et al.*, 1986).

(f) Circulating levels of hPL in trophoblast tumours

Trophoblast tumours produce hPL but in smaller amounts than are found in a normal pregnancy (Samaan *et al.*, 1966; Saxena *et al.*, 1968; Goldstein, 1971). The maternal levels appear to be related to tumour differentiation; the greater the degree of malignancy, the lower the hPL value in relation to hCG (Saxena *et al.*, 1968; Goldstein, 1971). In some cases with active disease, hPL may disappear from the circulation while hCG remains detectable (Saxena *et al.*, 1968).

(g) Circulating levels of hPL in non-trophoblast tumours

There have been a number of reports of secretion of hPL by tumours of non-trophoblast origin, including carcinoma of the cervix (Das *et al.*, 1983), the stomach (Shinde *et al.*, 1981; Heyderman *et al.*, 1985) and the oesophagus (Burg-Kurland *et al.*, 1986). Entirely negative results have been reported in large series of cases of ovarian (Monteiro *et al.*, 1983) and breast cancer (Monteiro *et al.*, 1982). High levels have been found, together with hCG, in a case of ovarian dysgerminoma (Kofler and Spona, 1971). Although production of placental proteins (notably SPI and hCG) has been demonstrated in a number of human malignant cell lines *in vitro*, hPL has not been found under these circumstances (Rosen *et al.*, 1980a,b).

5.4.5 CLINICAL APPLICATIONS – THERAPY

(a) hPL as a fertility control vaccine

A high incidence of reproductive loss has been noted in animals immunized with hPL, including rabbits (El-Tomi *et al.*, 1971), rats (Gusdon, 1972) and mice (Yamini *et al.*, 1972). In the last case, it was suggested that the mode of action was an antigen–antibody reaction at the placental site, leading to complement fixation and tissue damage. The possibility of active or passive immunization with hPL to achieve fertility control in humans has not been explored.

NORMAL AND ABNORMAL EMBRYO–FETAL DEVELOPMENT IN MAMMALS

6

J.P. Hearn, A.G. Hendrickx, G.E. Webley and P.E. Peterson

6.1 Introduction 527
6.2 Embryo–maternal interactions 538
6.2.1 General 538
6.2.2 Species differences 540
(a) Reproductive biology 540
(b) Morphology 540
(c) The factors affecting the timing of embryonic development and survival 541
6.2.3 Embryonic signals at implantation 546
(a) *In vivo* 547
(b) *In vitro* 548
6.2.4 Embryonic signals before implantation 550
6.2.5 Maternal signals during the peri-implantation period 552
6.3 Regulation of the corpus luteum 553
6.3.1 Corpus luteum regression 554
(a) Prostaglandin $F_{2\alpha}$-induced luteolysis 554
(b) Other luteolytic mechanisms 555
6.3.2 Corpus luteum 'rescue' in early pregnancy 557
(a) Luteotrophic messages 557
(b) Anti-luteolytic messages 558
6.3.3 Timing of the embryo messages 560
6.4 Rates of development 562
6.4.1 Pre-implantation period 562
6.4.2 Organogenesis 564
6.4.3 Fetal period 564
6.4.4 Factors affecting prenatal growth 568
(a) Constitutive factors 568
(b) Genetic factors 569
(c) Hormones 569
(d) Growth factors 570
(e) Environmental factors 571
(f) Maternal size, age and parity 571
(g) Maternal nutrition and health 571
(h) Litter size and duration of pregnancy 572
(i) Placental size and function 573

6.5 Prenatal mortality 573
6.5.1 Human and non-human primates 574
(a) Incidence 574
(b) Aetiology 575
6.5.2 Domestic and laboratory species 581
(a) Incidence 581
(b) Aetiology 582
6.6 Development of the reproductive tract 586
6.6.1 Genetics of sex differentiation 586
(a) The Y chromosome 587
(b) The X chromosome 588
(c) Germ cell sex 590
6.6.2 Sexual differentiation of the central nervous system ('brain sex') 590
(a) Functional aspects of brain sex 591
(b) Structural aspects of brain sex 596
(c) Mechanisms of sexual differentiation of the central nervous system 598
(d) Female differentiation of the CNS: a default process? 602
6.6.3 Morphology of sexual differentiation 604
(a) Gonads 604
(b) Duct system 607
(c) Urogenital sinus 611
(d) External genitalia 612
6.6.4 Hormonal regulation 613
(a) Role of testosterone 614
(b) Role of Mullerian inhibiting substance 614
(c) Role of oestrogens 615
6.7 Abnormal development 615
6.7.1 Major malformations of the reproductive system 615
(a) Human pseudohermaphroditism 615
(b) Animal pseudohermaphroditism 618
(c) True hermaphroditism 620
(d) Testicular feminization 621
6.7.2 Experimental teratology 623
(a) Species 623
(b) Stage of prenatal development 623
(c) Dosage 626
(d) Route of administration 627
6.7.3 Teratogenicity of sex steroids 627
6.7.4 Teratogenicity of environmental agents 632
6.8 Concluding comments 636

6.1 INTRODUCTION

In this chapter we examine the first interactions between embryo and mother at the start of pregnancy: the biochemical messages that pass between them and the morphological links that are established. We consider the function of these biochemical signals in facilitating the process of implantation and the support of the corpus luteum of pregnancy. We review in some detail the growth and development of the embryo, the genetic basis for sexual differentiation and the aetiology of embryonic and fetal abnormality.

The past few years have seen considerable advances in our understanding of the establishment of pregnancy. Yet, because of the difficulties of accessibility *in situ* and the ethical constraints involved, it is not feasible to examine in much detail the process of implantation and corpus luteum rescue at a local, cellular level. This is particularly true for the primates, including man. The huge increase in research on pre-implantation development in man, associated with *in vitro* fertilization and related techniques, (Edwards, 1985) has shown the specificity of mechanisms operating in the primate and also our ignorance of the underlying cellular and molecular processes. Examples are the nutrient requirements for the embryo during its development from fertilization to implantation, the limits to potential in the regulation of blastomere, inner cell mass and trophoblast differentiation, the embryo maternal dialogue that results in the implantation of the fetal allograft, the genetic or other causes of abnormalities causing death or deformity of the embryo, and the flexibility possible in the embryo's growth rates and endocrine support.

Our main consideration here is the primates, including man. Where our knowledge on primates is insufficient, we develop our arguments with knowledge derived from other species. Throughout we refer to recent reviews in non-primate biology in order to provide leads for those readers who wish to pursue these questions further, but normal and abnormal embryo and fetal development in primates is our principal theme in this review.

In section 6.2 the two questions are:

1. What are the biochemical signals between embryo and mother at the start of pregnancy in primates?
2. How do these signals enhance (a) implantation and invasion of trophoblast, (b) nutritional and immunological security for the fetal allograft, (c) transformation of the corpus luteum (CL) to support pregnancy and (d) the differentiation of the early embryo through programmed gene activation?

During the past 15 years this field of research has moved from an emphasis on whole animals and systems towards a cellular and now towards a molecular level. We and others have developed *in vivo* and *in vitro* systems to explore cell–cell recognition and molecular mechanisms while retaining as far as possible the physiological validation of these findings in the whole animal. Where feasible, we have run parallel studies with human tissues, but the key questions stated above cannot be approached in detail on an experimental level using the human directly. In addition, there are fundamental differences between the primate and non-primate systems that ensure implantation and corpus luteum function. Consequently, while a vast amount of knowledge and technique developed on non-primate species has enabled studies to be carried out in primates, the results cannot often be interpreted across species. Indeed, there is considerable variation in the ways in which these processes have evolved even between primate species. Wimsatt (1975) has provided an excellent review of some comparative aspects of implantation. (See also Chapter 4.)

In section 6.3 we explore the development

of the embryo and the signals that it produces during the peri-implantation period. With the exception of chorionic gonadotrophin (CG) there is, as yet, little clear evidence for the physiological role of embryo-derived signals in primates, but there are several candidates whose function can be tested with the culture systems and molecular techniques now available. An example is the polymerase chain reaction (PCR), which allows amplification of message from small amounts of embryonic tissue. We do not discuss the biology of trophoblast or the placental proteins that are secreted well after implantation. There is a large amount of literature which can be followed up outside the scope of this chapter (for example: Schlafke and Enders, 1975; Loke and Whyte, 1983; Chapman *et al.*, 1988; and Chapter 5 of this volume).

Section 6.3 concerns the functions of embryonic signals at the site of implantation and the corpus luteum, together with the effects of immunological inhibition. We consider also the direct or indirect interactions and their timing between the embryo, corpus luteum and the hypothalamus. The rates of development of the embryo and fetus in a variety of mammalian species are considered in section 6.4. The constitutive and environmental factors which define the normal range of prenatal growth and birth weight, as well as the constraining influences that can result in embryo/fetal loss during pregnancy, have been observed in all mammals studied, although there are marked differences between species in the incidence and timing of prenatal death. Section 6.5 summarizes these rates of prenatal mortality at different periods during pregnancy in primate and non-primate species. Additionally, the species-specific genetic, maternal and environmental factors which contribute to prenatal loss are reviewed. Section 6.6 describes the genetic differentiation of the development of the reproductive tract and the sexual differentiation of both the reproductive tract and the brain. Sexual dimorphism of brain function as well as critical time periods for hormone action in sexual differentiation and morphology are also covered, particularly in relation to understanding abnormal development, which is dealt with in section 6.7. We emphasize in this section the major malformations of the reproductive system of animals and man and the ways in which experimental teratology can advance our knowledge of embryonic and fetal abnormalities. The teratogenic role of sex steroids and environmental agents receives special attention because of the current and future concerns regarding these compounds in abnormal development.

Finally, in section 6.8 we note briefly some of the more strategic and applied dimensions in this field of research concerning its application towards transfer and storage of gametes, the regulation of fertility either to stimulate or to inhibit reproduction in the human and the potential for the accelerated breeding and conservation of endangered species.

6.2 EMBRYO–MATERNAL INTERACTIONS

6.2.1 GENERAL

In all primates, ovulation occurs after a distinct follicular phase that does not overlap, in terms of oocyte maturation, with the previous luteal phase. This contrasts with the sheep and other non-primate species in which follicular maturation is in a late stage of preparation by the end of the luteal phase (Baird *et al.*, 1975). Ovulation takes place 12–36 h after the mid-cycle surge of LH and the oocyte continues to mature as it enters the Fallopian tube, with fertilization occurring 12–24 h later.

After fertilization, the embryo proceeds through cleavage stages that vary in timing according to species (McLaren, 1985; Chapter 2 of this volume). The timing of developmental stages in primates is shown in Table 6.1.

The embryo reaches the uterus on days 3–4

Table 6.1 The principal stages of implantation and their approximate timing (days) after ovulation in the human, baboon, rhesus monkey and marmoset monkey

Stage	*Human*	*Baboon*	*Rhesus*	*Marmoset*
Embryo enters uterus	3–4	4	4	4
Zona pellucida shed	5–6	7–8	7–8	9–10
Attachment	6–7?	8–10	8–10	11–12
Trophoblast differentiates (previous stages)	7–12	10–25	10–30	12–40
Tertiary villi	16–17	23–25	23–25	40+
Decidual reaction	12+	Local oedema (11–14)	Plaque (11–14)	Epithelial 20+ Stromal 30+
Implantation type	Interstitial	Superficial	Superficial	Superficial

of pregnancy when it is at the morula stage. Development to blastocyst, hatching from the blastocyst and attachment to the maternal endometrium take place between days 7 and 12 after ovulation depending on the species. Figure 6.1 shows the principal factors involved in the establishment of a dialogue between embryo, endometrium and corpus luteum at the start of pregnancy in primates.

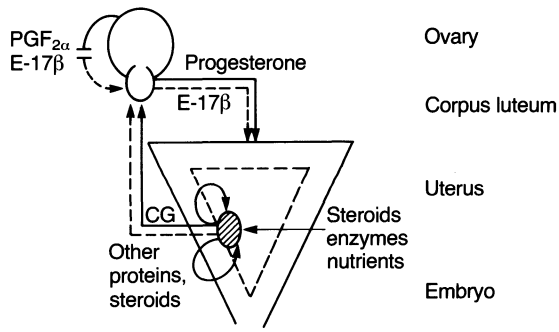

Figure 6.1 The embryo–maternal dialogue during implantation in primates. Pregnancy depends on progesterone from the corpus luteum and oestradiol may have a facilitatory role in stimulating endometrial support of the conceptus. The effects of ovarian prostaglandins or oestradiol-17β in terminating the lifespan of the corpus luteum need clarification. The embryo secretes CG to support the corpus luteum, and other proteins and steroids whose precise functions are not determined. Local actions of CG on embryo and trophoblast differentiation at implantation are conjectural.

It is at the time of attachment that CG is first secreted in measurable quantities, but this hormone, which is the first clear endocrine signal of the presence of an embryo, cannot be measured in the peripheral circulation for a further 2–3 days (as summarized in Table 6.2).

This vital attachment of embryonic to maternal tissue (see Figure 6.1), followed by rapid differentiation of trophoblast and invasion of the endometrial epithelium, must be completed efficiently in order to allow the establishment of vascular connections that ensure nutrient exchange to the embryo. Just as essential for the survival of the embryo is the rapid establishment of contacts whereby CG is conveyed to the corpus luteum to prevent its regression at the end of the cycle.

Table 6.2 The first detection (approximate days after ovulation) of CG in peripheral plasma for five primate species

Species	*Embryo attachment*	*CG first detected*
Human	7–9?	10
Chimpanzee	7–9	11
Baboon	8–10	12
Rhesus	8–10	12
Marmoset	11–12	14

Table 6.3 Factors affecting reproductive capacity in selected primate species (data for non-human primates are from captive colonies)

Species	*Ovarian cycle (days)*	*Gestation (days)*	*Average no. of young born/year*	*Sexual maturity (years)*	*Generation interval (years)*	*Seasonal breeding*[a]
Common marmoset (*Callithrix jacchus*)	28	144	5	1·5	2	No
Owl monkey (*Aotus trivirgatus*)	16	133?	1	1·5–2·0	2–3	No?
Squirrel monkey (*Saimiri sciureus*)	9	150	1	3	3–4	No?
Rhesus monkey (*Macaca mulatta*)	27	168	1	3–5	4–6	Yes
Baboon (*Papio cynocephalus*)	33	184	0·8	5–7	6–10	No?
Chimpanzee (*Pan troglodytes*)	37	235	<0·5	7–10	7–15	No
Man (*Homo sapiens*)	30	280	<0·5	15+	20+	No

[a]Of the species listed, the rhesus has a definite breeding season which may be extended but not abolished in captivity. Births will occur throughout the year in captive owl monkeys, squirrel monkeys and baboons, but there are probably seasonal changes in fecundity.

Within the general pattern summarized previously, there are considerable species differences among primates. These include the timing of attachment, the rates and degree of trophoblast invasion and the attainment of fetoplacental autonomy when the embryo and the extraembryonic membranes no longer require the presence of the corpus luteum for pregnancy to continue.

6.2.2 SPECIES DIFFERENCES

(a) Reproductive biology

Table 6.3 shows some factors affecting the basic reproductive biology and fecundity of selected primate species.

From these data we can see that studies of embryonic development are virtually impossible in some species, and not easy in any. The great apes are all threatened or endangered species and there are very few centres where it is possible to study their embryology in any detail. In contrast, there are now a number of centres in developed and less developed countries where the capacity exists for studies of simian species, both New and Old World.

(b) Morphology

In the human, the chimpanzee and presumably in the other ape species, the embryo and trophoblast sink well under the uterine epithelium, becoming surrounded quickly by endometrial tissue and maternal vasculature. In the simian species studied to date, the degree of invasion of trophoblast is less marked, the early endometrial hyperplasia is less evident and the embryo does not sink under the uterine epithelium although this layer is penetrated over a wide area by trophoblast (J.P. Hill, 1932; Wislocki and Streeter, 1938; Hertig *et al.*, 1959; J.D. Boyd and Hamilton, 1970; Hendrickx, 1971; O'Rahilly, 1973; Luckett, 1978). Figure 6.2 gives a diagrammatic comparison of the differences seen.

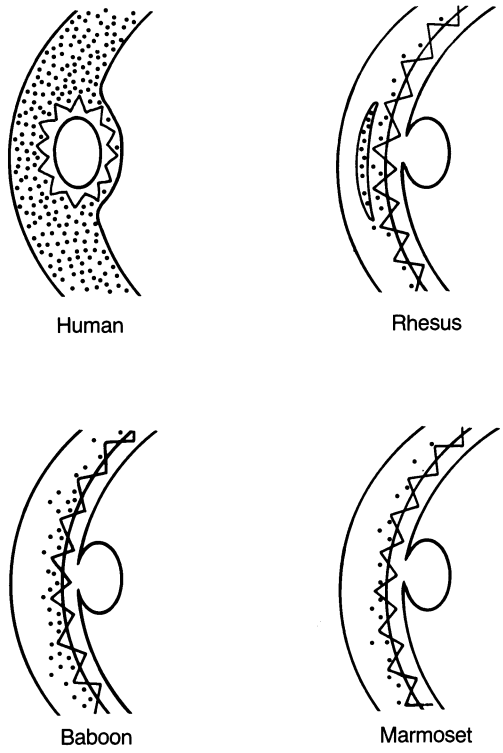

Figure 6.2 Implantation in primates, which requires further definition from ultrastructural investigations. The human trophoblast sinks under the endometrial epithelium and there is a massive endometrial reaction. In the monkeys studied to date, implantation is superficial, although rapid contact is made with the maternal vasculature. The degree of endometrial response varies in intensity and timing according to the species. Endometrial response; trophoblast–maternal interface; e.p. = epithelial plaque.

There have been more detailed accounts of the process of embryo implantation in the baboon and rhesus monkey (Hendrickx and Enders, 1980; Enders *et al.*, 1983) and in the marmoset monkey (H.D.M. Moore *et al.*, 1985; Smith *et al.*, 1987). From these studies it is clear that the stages of early embryonic development after embryo attachment occur relatively slowly in the marmoset when compared with the human and other primates. This may be due to the rather complex formation of early embryonic membranes in the marmoset, related to the chimaerism seen in this species (Figure 6.3).

The essential differences between the morphology of attachment and implantation in the hominoid and simian primates are perhaps academic in that after the first few days of implantation the degrees of embryo–maternal tissue apposition and exchange are similar whether the form of implantation is interstitial or superficial.

(c) The factors affecting the timing of embryonic development and survival

A comparison in selected species of the day of embryo attachment and the first day when CG is measurable in the peripheral circulation is presented in Table 6.2. Further comparisons on the rates of development of primate embryos are shown in section 6.4.

A major obstacle in obtaining data of this nature is that, until recently, it was almost impossible to provide a precise timing of the stage of development related to the time of ovulation. It is only since the wider use of radioimmunoassays in the 1970s and their application in monitoring the endocrine events of early pregnancy that a relatively non-invasive way of estimating the chronology of peri-implantation events has become feasible. This trend is continuing now with application of high-precision ultrasonography, which makes it possible to determine the day of embryo attachment through study of the size of the uterine lumen. Comparisons of embryo events based on the classic work of Hertig *et al.* (1956) and others depended on a very few samples from the human. Timing was related to the start of the previous menstrual period, so it is remarkable how much has been learned from this material. Definition of embryonic timing for the baboon can be achieved with greater precision because of the cyclical changes in sex skin exhibited in this species (Hendrickx, 1971). In other simians, including the rhesus monkey (Atkinson *et al.*, 1975), cynomologus

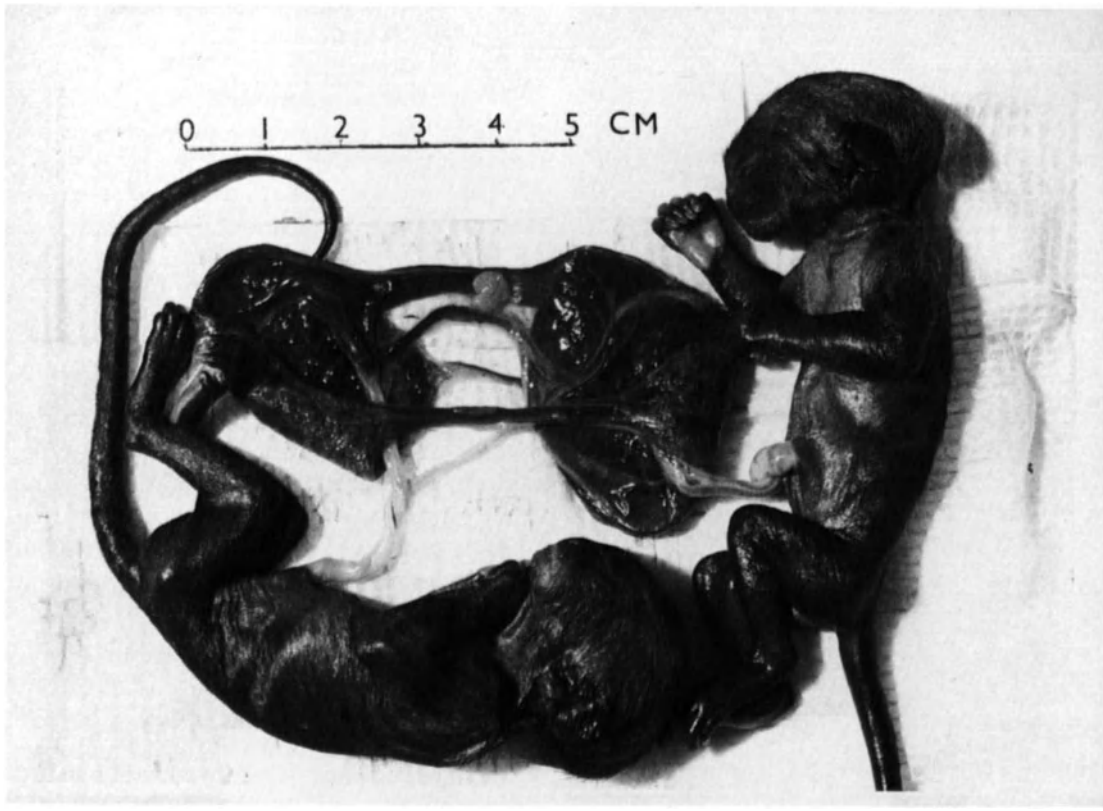

Figure 6.3 The anastomoses and vascular connections between triplet fetuses and placental discs in the common marmoset.

monkey (Dukelow, 1983) and marmoset (Hearn, 1983; Harlow *et al.*, 1984), daily monitoring of endocrine changes is necessary.

All of the above primate species have attributes and advantages depending on the questions being investigated. None of them are perfect models with homology to the human, but all share analogous attributes with the human in a general primate pattern. With regard to timing of the start of pregnancy, the marmoset has a particular advantage in that the end of the luteal phase can be synchronized by the administration of 0.5 μg of exogenous prostaglandin $F_{2\alpha}$ (Summers *et al.*, 1985). This permits collection and examination of embryos at precise stages of pregnancy as well as embryo transfer to synchronized recipients. This sensitivity of the corpus luteum and its possible evolutionary implications are noted further in section 6.3. Aspects of the evolution of the corpus luteum are discussed in Hearn *et al.* (1977).

The stage of embryonic development and the location of the embryo in the reproductive tract during the first 12 days of pregnancy in the marmoset monkey are shown in Table 6.4. As noted previously, the day of attachment of the embryo to the endometrial epithelium varies considerably between primate species (Table 6.1). Because of the obstacles in obtaining precise timing, it is likely that we may have to review our previous estimates of timing of human embryo attachment and implantation. Data from Lenton and Woodward (1988) can be interpreted to suggest that embryo attachment occurs on

days 8–9, rather than the days 6–7 suggested by earlier investigations based on imprecise immunological assays that may not have distinguished fully between CG and LH (Saxena *et al.*, 1974). On the other hand, the highly invasive mode of implantation in the human may enable a quicker establishment of vascular connections, proving the earlier estimates correct. If the recent data are confirmed, it would unify the timing of implantation of Old World species, with attachment occurring on days 8–9 in the human as well as in the rhesus monkey and baboon.

The timing of implantation in New World species has been worked out in detail only in the marmoset, occurring on days 12–13 after ovulation (H.D.M. Moore *et al.*, 1985). It may be significant that the luteal phase of the marmoset at 19 days (Hearn, 1983; Harlow *et al.*, 1984) is also longer than the 14–15 days seen in most Old World species. On a superficial assessment, the day of embryo attachment in New World species may be quite flexible since the owl monkey (*Aotus trivirgatus*) has an ovarian cycle of 16 days with a luteal phase of approximately 10 days (Dixson, 1983); the cebus monkey (*Cebus apella*) 21 and 12 days respectively (Nagle and Denari, 1983); the tamarins (for example, *Saguinus oedipus*) 16 and 10 days; and the squirrel monkey is reported to have a complete cycle within 8–10 days (Dukelow, 1983).

Another factor that affects the timing of early embryonic development in the marmoset monkey is the absence of post-partum lactational amenorrhoea. The marmoset can become pregnant within 10 days of a previous birth. While this greatly increases the fecundity and the productivity of the marmoset, it results in an overlap between the first 80 days of pregnancy and the suckling of twin infants (Hearn, 1983, 1984). This double physiological load may explain in part why the first 80 days of marmoset embryonic development are relatively slow compared with the rates of development in the human, rhesus monkey and baboon (Chambers and Hearn, 1985). Figure 6.4 and Table 6.5 show the comparison between these four species. In all other primate species that have been studied in detail to date, there is a lactational amenorrhoea during which ovarian cyclicity is suspended.

A further limiting factor to fecundity

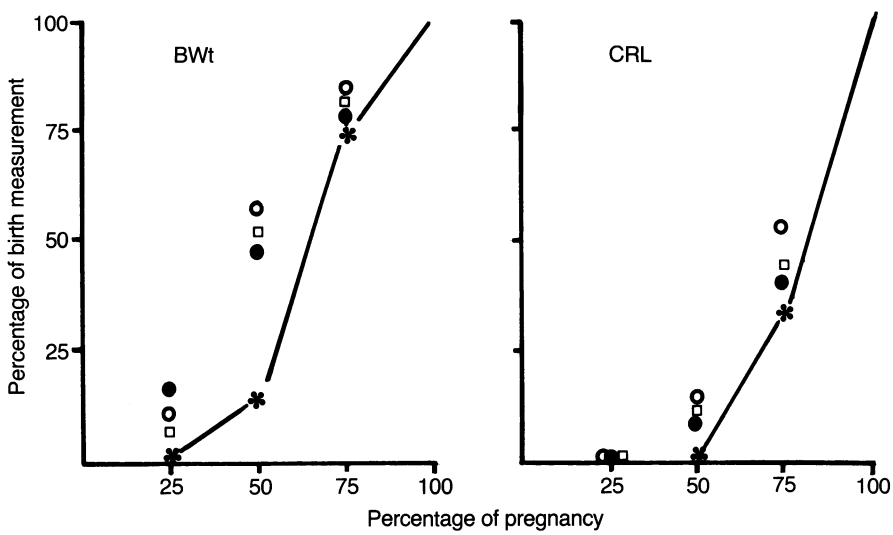

Figure 6.4 The percentage of the birth body weight (BWt) and the birth crown–rump length (CRL) achieved 25, 50 and 75% through gestation. Man (□), rhesus (●), baboon (○) and marmoset (*).

that will have shaped the evolution of reproductive strategies is that of seasonal breeding. Those primates, for example the marmoset and cynomologus monkeys, that show no seasonal periodicity in their reproduction are not constrained in their gestation length and lactation periods. Those that are tied to strict seasonal breeding, such as the rhesus monkey, need to complete a full gestation and lactation over 1 year if they are to breed when the next season starts. If, through adverse conditions of climate or diet, pregnancy starts too late in one season or lactation is prolonged beyond the start of the next, there is a negative effect on productivity. The infant–maternal interactions at weaning and the way in which these are related to reproductive productivity and the relative dominance of females in groups of baboons were studied by Nicolson (1981) and are reviewed by Lee (1987).

Embryonic loss is a significant factor affecting fertility and productivity in primates. Studies from non-primate species show that this is a phenomenon in many domesticated animals (Wilmut *et al.*, 1986). Estimates in the human vary from 20% to 50% loss of embryos as a normal, natural phenomenon (R.V. Short, 1979). Recent studies of the phenomenon related to the more controlled albeit less natural procedures of *in vitro* fertilization (IVF) and embryo transfer show that premenstrual pregnancy loss is significant in the human (Lenton *et al.*, 1988). The potential causes of embryonic loss are explored in more detail in section 6.4. It is difficult to obtain precise figures for normal embryonic loss during pre-implantation stages in the human, but it is likely that an estimate of 40% would not be far off reality. An understanding of the causes of this loss and the degree to which it is caused by genetic abnormality or by accidental failure of synchrony in the embryo–maternal dialogue could provide new initiatives in the treatment of human infertility, the regulation of human fecundity and the accelerated breeding of threatened and endangered species.

The current debate concerning the ethics of research on early embryos has a significant bearing on all of the above questions. The success of IVF procedures in some laboratories is now approaching the efficiency of natural embryonic survival. Further improvement for the human and extension of this knowledge to endangered primates depends on a greatly improved understanding of early embryonic development. At present, most of these questions can only be approached through experimental research over the peri-implantation period. The status of the embryo and the philosophical validity of the concept of a pre-embryo to describe the embryo's condition up to the 14th day of pregnancy needs further definition in drawing the boundaries of permitted research on the human embryo (McLaren, 1984, 1988; N. Ford, 1988).

Table 6.5 A comparison of the early embryonic development of the human, rhesus, baboon and marmoset showing the relative days of gestation in non-human species related to the same embryonic stage in the human

Species	*Implantation*	*Primitive streak*	*29–31-day human embryo*	*50-day human embryo*
Human	6–7	18	29–31	50
Rhesus	8–9	17	24	45
Baboon	8–9	17	27	46
Marmoset	12	30	60	80

6.2.3 EMBRYONIC SIGNALS AT IMPLANTATION

The first well-defined secretion of the early embryo that is known to be essential for its survival is chorionic gonadotrophin (CG). This glycoprotein, gonadotrophin hormone, is composed of α- and β-subunits, as are the other gonadotrophins and TSH (see this volume, Chapter 5). The biological activity of the gonadotrophins resides in their β-subunits, and a comparison of the CG and LH molecules shows the two to be virtually identical except that CG has an additional C-terminal chain of 32 amino acids (Canfield *et al.*, 1971; Morgan *et al.*, 1973).

The corpus luteum is supported by LH during the luteal phase and declines if monkeys are treated with antagonist to LHRH (Fraser *et al.*, 1985, 1986; Hodges *et al.*, 1988). There is a brief period in early pregnancy when the embryo must attach, activate the secretion of CG and maintain the production by the corpus luteum of essential progesterone and facilitatory oestrogen if pregnancy is to continue. The primate system therefore appears relatively simple in that a viable embryo controls its own survival from a very early stage by secreting sufficient CG to replace the luteotrophic effects of LH. It is likely that the secretion of CG also causes a reduction in LH secretion from the pituitary (Lenton and Woodward, 1988).

In the 20 years since the subunit structure of CG was established (Canfield *et al.*, 1971; Pierce *et al.*, 1971), thereby explaining the lack of specificity between antisera raised against the entire gonadotrophin hormones, there have been major advances in the precision of diagnostic applications related to pregnancy and to CG-secreting cancers. The availability of the amino acid and therefore the DNA sequence for human CG has enabled far more detailed study of its function. An understanding of the physiological significance of CG in pregnancy has been possible for many years at a peripheral, systemic level, but the studies at a cellular and molecular level that elucidate the local role of CG are only beginning to appear. This is not surprising since the availability of primate embryonic material is very limited; the capacity to study dynamic questions *in vivo* is hindered by the poor accessibility of the implantation site and of the corpus luteum; and *in vitro* culture of primate embryos through the whole peri-implantation process, together with the measurement of CG secretion, has only been achieved recently for the human (Fischel *et al.*, 1984), the baboon (Pope *et al.*, 1982) and the marmoset (Hearn, 1983; Hearn *et al.*, 1988c). The results of these and other studies are now posing leading workers to question whether CG's role is restricted to the traditional one of support of the corpus luteum until the end of the luteoplacental shift (Csapo *et al.*, 1972; Hearn, 1979; Ross, 1979). There is now a growing body of circumstantial evidence to suggest that CG may have a local role at the implantation site (Hearn, 1986), within the embryo itself (Hearn *et al.*, 1987, 1988a,b) or on early sexual differentiation of the primate gonad (Jost, 1970; Muller *et al.*, 1978a).

The profile of the secretion of CG through human pregnancy (Figure 6.5) might suggest that there are other functions for this hormone, since its secretion is still at relatively low levels by week 7 of pregnancy when its function of supporting the CL can be taken over completely through the secretion of progesterone by the placenta (Csapo *et al.*, 1972).

The specificity of CG to primate pregnancy has been challenged over many years. It is clear that this hormone is secreted by various cancerous tissues and that it can be used as in diagnostic and monitoring techniques in these cases. However, it now seems clear that CG is restricted to primates, since this order is the only one with the multiple gene system for control of CG, with one gene for the α-subunit and six or seven genes for the β-subunit (Talmadge *et al.*, 1984a,b; Policastro *et al.*, 1986). Consequently, the many claims

that have been made for CG secretion by embryos from species as diverse as the rat (Haour *et al.*, 1976) to the hyrax (Gombe *et al.*, 1980) may require re-examination. The other species in which a CG is expressed, the equids, do not actually express a specific placental gene since the protein synthesized by the cells of the chorionic girdle is identical to amino acid sequence in both its α- (H.J. Stewart *et al.*, 1987) and β-subunits (Bousfield *et al.*, 1987; Sugino *et al.*, 1987).

Chorionic gonadotrophin-β may be used as a trophoblast marker. Its expression in the embryo is thought to be limited to the syncytiotrophoblast cells of the chorionic villi, but the embryonic transcriptional activity of the genes may be observed much earlier since there is expression of hCG-β RNA at the six to eight-cell stage, before differentiation between trophectoderm and inner cell mass. This RNA is thought to be the product of *de novo* transcription from the embryonic genome since transcripts are observed only in embryos at least 2 days after fertilization (Bonduelle *et al.*, 1988).

In our own studies, we have concentrated on examining the role of CG *in vivo* and *in vitro* in the marmoset monkey. This has required the development and detailed validation of gonadotrophin and steroid assays in order to measure hormones in plasma, urine, tissues, cells and culture fluids. It was necessary to develop protocols for the synchronization of early pregnancy events using $PGF_{2\alpha}$ and hCG to stimulate ovulation; surgical and ultrasound procedures for the monitoring of follicular development and implantation, recovery, storage and transfer of embryos (Hearn, 1980, 1983; Summers *et al.*, 1985, 1988); morphological confirmation of the stages of implantation at light and electron microscopic levels (H.D.M. Moore *et al.*, 1985; Smith *et al.*, 1987); *in vitro* embryo manipulation and culture systems (Hearn *et al.*, 1988a; Summers *et al.*, 1988); and systems for microcannulation of the corpus luteum *in vivo* (Hearn and Webley, 1987; Webley and Hearn, 1987) as well as *in vitro* culture of marmoset and human granulosa and luteal cells (Webley *et al.*, 1988, 1989a).

Once the above systems had been developed and tested, we could ask questions about embryo–maternal interactions during the peri-implantation period at the levels of the whole animal, the cell recognition systems and now at the molecular level. These investigations could determine some of the factors regulating the secretion of CG, and the functions of this hormone, through its immunological neutralization. A summary of studies *in vivo* and *in vitro* is provided below, with reference to the work of other investigators.

(a) *In vivo*

Figure 6.5 shows the measurement of CG in the peripheral plasma of the marmoset during early pregnancy. In keeping with the results shown in Table 6.2, there is a period of 2–3 days after embryo attachment before a significant rise in peripheral levels can be detected, and it is not possible to deduce exactly, *in vivo*, when CG starts to be secreted by the embryo. Active or passive immunization of marmosets during early pregnancy against CG will inhibit implantation and terminate the pregnancy, suggesting that this hormone is necessary for successful implantation and survival of the embryo (Hearn, 1975, 1976, 1978, 1979; Hearn *et al.*, 1976).

Similar results were reported for active immunization in the baboon (V.C. Stevens, 1976) and the rhesus monkey (Talwar *et al.*, 1976). These results formed the basis for a research programme carried out by WHO and the Population Council to explore the feasibility of a vaccine against CG β-subunit or synthetic fragments of the C-terminal polypeptide chain as a long-term contragestational agent in the human. The research is currently being extended to phase II clinical trials in India and Australia.

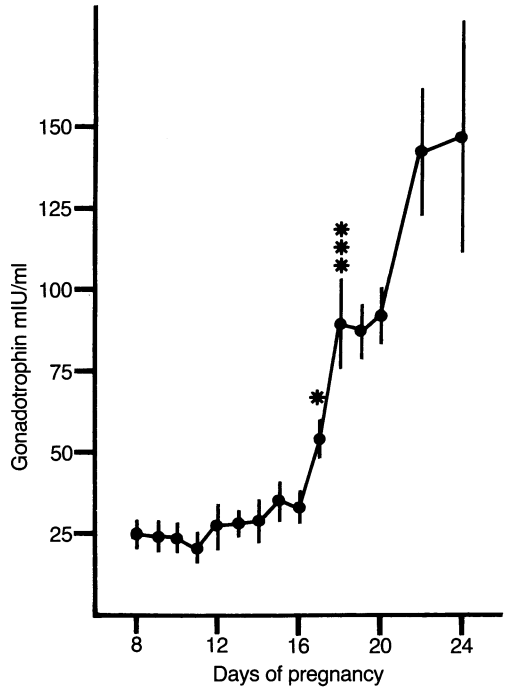

Figure 6.5 Concentrations (mean ± SEM) of CG in peripheral plasma of marmoset monkeys (n=10) during the first 24 days of pregnancy (after ovulation).

(b) *In vitro*

Figure 6.6 shows the production of CG by marmoset embryos cultured *in vitro* on a layer of marmoset fibroblasts (Hearn, 1983; Hearn *et al.*, 1988a).

The results indicate that CG secretion is not switched on or detectable, external to the embryo, until the time when the embryo attaches to the feeder layer and starts to differentiate into embryo proper, yolk sac and trophoblast. This is analogous to the time of attachment at the start of implantation *in vivo* (Figure 6.7). This conclusion was tested more rigorously by separation of inner cell mass and trophoblast in bisected embryos, suggesting that the inner cell mass is necessary for the efficient initiation of CG secretion (Hearn *et al.*, 1988b,c). Once again CG secretion was not detectable in culture fluids until after embryonic attachment. The intraembryonic role of CG requires further examination, as does its potential role in early embryonic differentiation and establishment of the implantation site (Hearn *et al.*, 1987). Summers *et al.* (1987) were able to establish a trophoblast cell line derived from the inner cell mass, subcultures of which have continued to produce CG for over 5 years. The prospects for working with primate embryonic cell lines and stem cells using this system are of great interest.

In a preliminary experiment with limited material, embryos cultured from the blastocyst through the *in vitro* 'implantation' system noted above were prevented from successful attachment if culture fluids contained marmoset anti-hCG-β antiserum at levels calculated to be similar to those that were effective in blocking implantation *in vivo* (Hearn *et al.*, 1988b). Although tentative, the results suggested that CG may be necessary for the process of attachment itself. We have yet to examine the expression of CG on the embryo surface immediately before attachment, since in spite of considerable effort we have yet to achieve a fully purified marmoset CG-β. It would be no surprise to find such expression since transcriptional activity of the encoding gene is thought to be present in the human embryo by the six to eight-cell stage (Bonduelle *et al.*, 1988). Fishel *et al.* (1984) and Lachtan-Hay and Lopata (1988) imply that the human pre-implantation embryo is capable of secreting CG into culture fluid, but it is not clear whether some contamination with LH might have been possible.

Although the studies we report in the marmoset do not show clear secretion of CG before attachment, recent studies in the rhesus monkey (Seshagiri and Hearn, 1993; Seshagiri *et al.*, 1993) and human (Hay and Lopata, 1990; Dokras *et al.*, 1991) have shown low levels of CG to be secreted before attachment, with an exponential increase commencing immediately after attachment. In addition, we have tested the hypothesis that

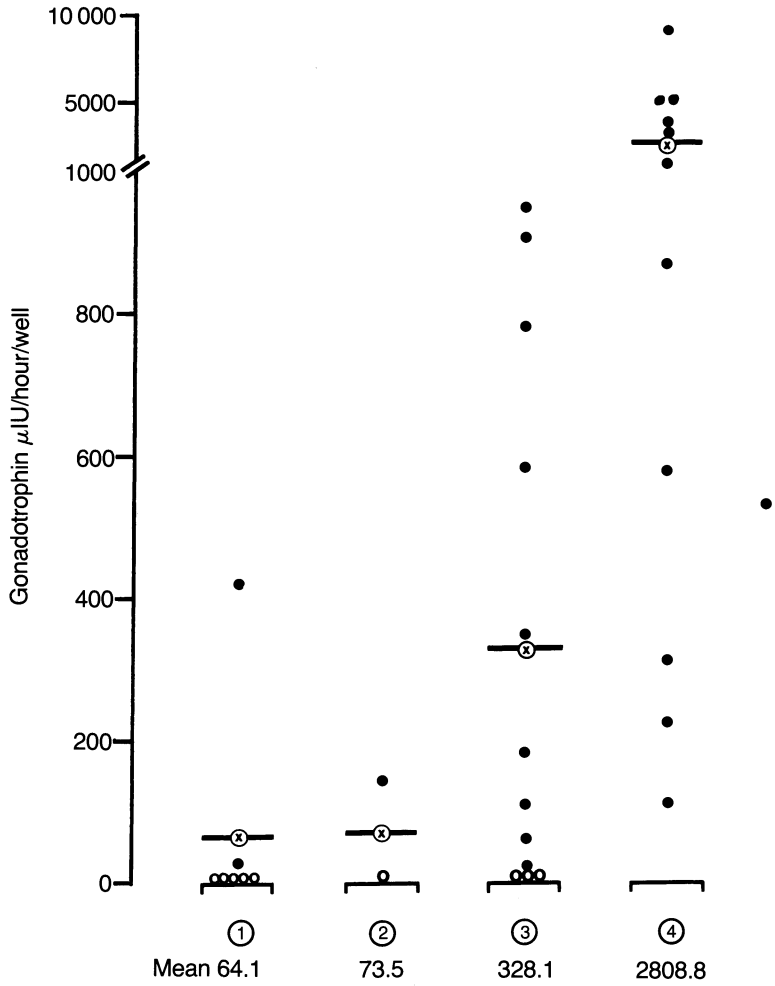

Figure 6.6 The secretion of CG by marmoset embryos cultured *in vitro*. Embryos were cultured for periods of 2–10 days. The sampling times are (1) blastocyst – hatched blastocyst; (2) hatched blastocyst–attachment; (3) attached blastocyst–48 h after attachment; and (4) 48 h after attachment–120 h after attachment.

CG in the preattachment embryo may be regulated by intraembryonic gonadotrophin-releasing hormone (GnRH) in a system analogous to the hypothalamo-pituitary regulation of gonadotrophins. Our results show for the first time that GnRH is expressed and secreted by the pre-implantation primate embryo, in a close association with the timing and secretion of CG. We are currently testing the causal linkage between these two hormones (Seshagiri and Hearn, 1993, unpublished). If confirmed, a GnRH–CG regulatory system in the primate embryo may permit new approaches to our understanding of embryo loss and to the regulation of fertility. As far as we know, it is only the primates that have adopted this mechanism into the embryo at this early stage of pregnancy, raising interesting questions about the evolution of the physiological mechanisms involved in the

maternal recognition of pregnancy and the support of the corpus luteum (Hearn *et al.*, 1991).

We conclude from the above studies and from others that CG is an essential requirement for implantation, that this hormone is necessary for the rescue of the corpus luteum and that further work is required to confirm a local role within the embryo, at the embryo–maternal interface and in embryonic gonadal differentiation. These questions have been intriguing developmental biologists and now it looks as though the cellular and molecular tools of sufficient precision to provide answers are becoming available.

6.2.4 EMBRYONIC SIGNALS BEFORE IMPLANTATION

The studies summarized so far prompt one to ask whether any embryonic signals are necessary before implantation. The beautiful simplicity of a system in which the embryo produces its own gonadotrophin and therefore takes command of the corpus luteum and perhaps of its own differentiation within days of the start of pregnancy leaves little room for improvement.

There are a number of candidates as pre-implantation signals in mammals. In the pig it was shown clearly that oestrogen-17β secreted by the blastocyst is necessary before implantation (Perry *et al.*, 1973) but a comparative study showed that this steroid was apparently not so important in a range of other species (Gadsby *et al.*, 1980). In the sheep and cow the conceptus secretes a protein prior to attachment, called ovine or bovine trophoblast protein 1, which prevents luteal regression and shows homology with α – interferons (Imakawa *et al.*, 1987, 1989; H.J. Stewart *et al.*, 1987; Charpigny *et al.*, 1988).

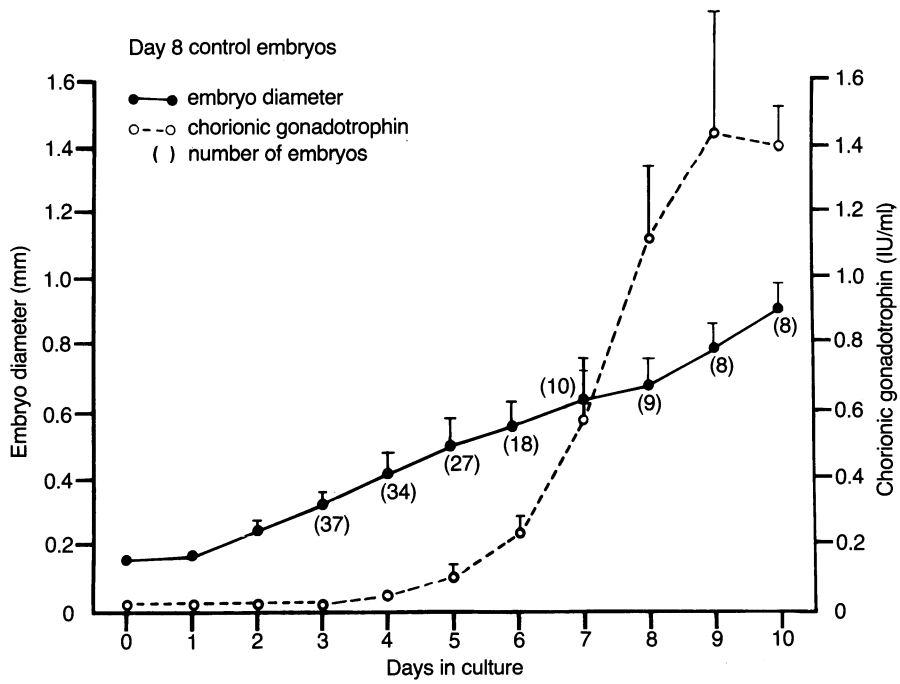

Figure 6.7 The growth in embryo diameter and the onset of secretion of CG in embryos recovered on day 8 after ovulation (blastocyst) and cultured for 10 days *in vitro*. Values are mean ± SEM for the number of embryos in parentheses.

Three further candidates, each claimed to be expressed soon after fertilization, include early pregnancy factor (EPF) for a range of mammalian species including mouse and man (Morton *et al.*, 1983), platelet-activating factor (PAF) as a phospholipid implicated in the establishment of pregnancy (O'Neill, 1985) and an embryo-derived histamine-releasing factor (Cocchiara *et al.*, 1987). No doubt there will be many more claims over the next few years for a range of growth factors, proteins or steroids, and it will be a challenge to tease out those that play an essential role, those that are facilitatory and those that have minor relevance. The same is likely to be true for secretions of the oviduct and uterus, for which there must be some significant factors, but their physiological actions in the embryo–maternal dialogue are too subtle for us to define with current technology. It is necessary to keep an open mind, while avoiding going on fishing trips without bait.

For example, when it was shown by Marston *et al.* (1977) that binucleate embryos could be transferred to the uterus of the rhesus monkey and implantation could proceed, some concluded that the oviduct was merely a tube and its secretions not essential. It was also concluded correctly that a precise synchronization of embryonic development during passage down the Fallopian tube in primates was not as necessary as in non-primates. The primate appears to be far more flexible than the rodent in this regard. This flexibility has been confirmed since by a great deal of the work in embryo transfer associated with human IVF (Edwards *et al.*, 1985) and also in primates such as the marmoset (Summers *et al.*, 1987). One result caused in part by Marston's finding was that there was a marked drop in funding for studies attempting to regulate fertility by interfering with the rate of passage of the embryo through the oviduct. This was at a time when Ortiz and Croxatto (1979) were obtaining some fascinating data about the early stages of embryonic development in the human and the timing of differentiation events. Their studies *in vivo* and those of Edwards, Trounson and others at the time, and the whole field of IVF subsequently, have given us a more considerable amount of knowledge in the human about pre-implantation stages of development than has been achieved for any other primate species. To that extent the human is now the model species for other primates.

The efficiency of embryo growth *in vitro* is relatively poor. In contrast to the successful media that have been developed for rodent embryo culture (Biggers, 1983; Balmaceda *et al.*, 1986; Bavister, 1987; Bavister and Boatman, 1989), culture systems for primate embryos give low embryonic survival to implantation if they are maintained for more than 2–3 days (reviewed by Bavister, 1987). Some findings indicate that co-culture of non-primate embryos with a monolayer of oviductal cells greatly increases the stability of the system and the viability of the embryo (Gandolfi and Moor, 1987; C. Polge, personal communication, 1989). These results suggest that the oviduct does have a role to play in facilitating embryonic development. The factors affecting formation and function of oviduct fluid are now becoming more apparent and may be found in a useful review by Leese (1988). This knowledge is vital if we are to understand the requirements for media for the culture of primate embryos. How these factors are involved in the embryo–maternal dialogue, as essential or subordinate, and whether they are a necessary stage in preparation of the uterus for implantation, remains to be seen.

The very obvious advantages that could be exploited both scientifically and commercially if any pre-implantation signal was defined have exerted considerable pressure to generate rapid results in this area of enquiry. A signal that could be utilized as a very early diagnosis of pregnancy, as a monitor of embryo health and viability or as the basis of an

inhibitory contragestational approach to fertility control, would be ideal in an area in which development of concepts has occasionally outstripped the realities of fully controlled experimental results.

The effects of bidirectional signals during pre-implantation life are now becoming apparent in several non-primate species (reviewed by Heap *et al.*, 1988). PAF and EPF are claimed to be present in addition in the human. O'Neill *et al.* (1985) showed that a transient thrombocytopenia could be induced in association with PAF, with chemical and physiological similarities to an acetylated choline ether lipid, the effects of which are evident within 6 h of fertilization and extend through pre-implantation development. This lipid shows many characteristics of a mediator and is ubiquitous in its production by cells, with receptors in many tissues, having a role as an intercellular messenger. PAF can exert a local effect and it does not normally enter the peripheral circulation. The studies reported by O'Neill (reviewed by O'Neill, 1987) are quite clear-cut, but as yet attempts to extend this system have proved ambiguous. Our own studies in the marmoset monkey, referred to in Hearn *et al.* (1988b,c), showed a reduction in the numbers of circulating platelets during the pre-implantation phase, but there was considerable intra- and inter-individual variation that was too high to allow us to use this system as a diagnostic or to inspire confidence in the feasibility or precision of a laborious methodology. The variations reported by three observers using the same methods with the same samples was not acceptable. We concluded that there was an association between thrombocytopenia and pre-implantation stages of pregnancy in the marmoset monkey but that the current methodology is too imprecise to allow any interpretation of cause and effect, at least in our hands. When there is a robust assay, we look forward to testing the assertion further (Hearn *et al.*, 1988b,c). A link between PAF and EPF was shown by Orozco *et al.* (1986), the former inducing expression of the latter within 1 h after injection. The potential of EPF and many hypotheses concerning its subunit structure and function have been explored enthusiastically in the literature over the past 15 years. It is fair to say that at the end of this period the prospects remain just as intriguing and just as much a mirage. The detection of EPF depends on a delicate *in vitro* test involving a small population of T lymphocytes in circulation to bind heterologous red cells in the presence of complement, this being inhibited by antibody (Morton *et al.*, 1980; Heap and McRae, 1988). Once again the rigorous testing of hypotheses must await the development of far more robust and precise assays.

The peri-implantation period is clearly a time when many genes are activated, but it is more difficult to assign physiological function to the gene products when they are expressed. Considerable amount of circumstantial evidence supporting a pre-implantation embryo–maternal dialogue will require confirmation at a molecular level as well as definition of the functions. In primates this is extremely difficult because of the minuscule amounts of embryonic material that are available. Advances in technology, including the PCR reaction, will make such studies feasible in the next few years.

6.2.5 MATERNAL SIGNALS DURING THE PERI-IMPLANTATION PERIOD

During its passage down the Fallopian tube and the establishment of vascular connections with the endometrium, the embryo requires nutrients that are provided by the oviduct and uterus. These nutrients and other factors are controlled through the secretion of progesterone and oestrogen by the corpus luteum. In primates, the dominant of these hormones is progesterone, and pregnancy will proceed if the corpus luteum is removed and adequate exogenous progesterone is provided in the rhesus monkey

and in women (Finn, 1985, and this volume, Chapter 3). It would be surprising if oestrogens did not facilitate the process of implantation in primates, but in rodents oestrogen is essential for implantation to occur (Finn, 1985).

Active and passive immunization against progesterone and oestrogen has been carried out during early pregnancy in a wide range of species, causing either partial or complete disruption (Hillier and Cameron, 1976). In recent times the approach has become far more precise, with Heap and his colleagues showing that passive immunization of mice with a monoclonal antibody against progesterone will block implantation and may inhibit embryo growth during the pre-implantation phase (Wright *et al.*, 1982; Ellis *et al.*, 1988). In addition, mouse monoclonal anti-progesterone IgG1 antibody can be seen, using rabbit polyclonal anti-idiotype in indirect immunofluorescence, on the surface of uterine luminal and glandular epithelia. This suggests that anti-progesterone antibody binds to an antigen that is associated with the uterine surface and that inhibits locally the uterine uptake of progesterone. Antisera to progesterone have provided similar results in rats and ferrets (Rider and Heap, 1986) but have yet to be extended to primates. A most useful summary of the maternal reactions affecting early embryogenesis and implantation in non-primate species, including reference to growth factors, angiogenesis and maternal cellular reactions, is provided in Heap *et al.* (1988). This topic is also dealt with extensively by Finn in this volume in Chapter 3.

There are a number of other putative embryonic or maternal signals found in various species that are thought to be involved in implantation (for reviews see Bazer *et al.*, 1986; Heap *et al.*, 1988; Hearn *et al.*, 1988b,c). These include 'purple protein' in the rabbit (Chen *et al.*, 1975) and proteins secreted by the endometrium during peri-implantation stages in the sheep (Findlay *et al.*, 1979). There are also the many pregnancy-associated proteins that are derived from trophoblast or maternal tissue and whose regulation and physiological functions are uncertain (reviewed in Chapman *et al.*, 1988). We do not propose to go into any further detail here.

It is likely that in the next few years we will see a multiplication of the factors with a potential role in implantation. This will be a consequence of the ever more precise molecular technology available, resulting in a long list of gene products that appear and disappear during this crucial period in embryonic differentiation. The prospects for advancing our understanding of the fundamental control processes of embryogenesis are most exciting. We must ensure, however, that we also develop adequate *in vivo* and *in vitro* test systems to make physiological sense of these potential signals or much time and resources will be wasted in chasing signals of minor importance.

6.3 REGULATION OF THE CORPUS LUTEUM

The corpus luteum is a highly vascularized structure which is formed in the ovary after release of the egg at ovulation. Its main function is in the secretion of progesterone, and also oestradiol in the primate, which act on the endometrium to provide a uterine environment which can receive and support the developing embryo. The lifespan of the corpus luteum is dependent on the presence of the embryo within the uterus. In the absence of fertilization, the corpus luteum undergoes regression and progesterone production decreases. The length of the luteal phase in the non-conception cycle varies between species. In the primate the mean cycle length ranges from 8.70 ± 3 days in the squirrel monkey (*Saimiri sciureus*) (R.C. Wolf *et al.*, 1977; Dukelow, 1983) to 30.1 ± 3.8 days in the marmoset monkey (*Callithrix jacchus*) (Chambers and Hearn, 1979; R.D. Harding *et al.*, 1982; Harlow *et al.*, 1983) both New World

primates, with cycle lengths for Old World primates of 27 ± 1 days in the rhesus monkey (*Macaca mulatta*) (Monroe *et al.*, 1970) and 30.3 ± 3.1 days for the baboon (*Papio anubis*) (C.V. Stevens *et al.*, 1970). However, following fertilization in a conception cycle the levels of progesterone do not fall either in women (Corker *et al.*, 1976) or monkeys (Knobil, 1973) and the corpus luteum is maintained. The extension of the lifespan of the corpus luteum is essential in early pregnancy for the continued production of progesterone and maintenance of the uterus. It is achieved in the human and non-human primate by the action of chorionic gonadotrophin secreted by the implanting embryo (Knobil, 1973; D.T. Baird, 1985).

6.3.1 CORPUS LUTEUM REGRESSION

The mechanisms of luteal regression are not completely understood in primate species. This is in contrast to the mechanisms adopted by a number of other species which have been well characterized. In the following paragraphs the mechanisms of luteolysis will be reviewed and compared with results obtained to date in the human and non-human primate.

(a) Prostaglandin $F_{2\alpha}$-induced luteolysis

In many species, including the sheep and cow, luteolysis is induced by the action of prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$) released from the uterus (McCracken *et al.*, 1970; Flint and Hillier, 1975). Hysterectomy in these species prolongs the life of the corpus luteum (CL), as does immunization against $PGF_{2\alpha}$ (Fairclough *et al.*, 1981). $PGF_{2\alpha}$, secreted by the uterus, reaches the ovary via a countercurrent system in the ovarian pedicle (McCracken *et al.*, 1971, 1981; Bazer and First, 1983) and by local transfer from uterine lymphatic vessels to the adjacent ovarian vein (Heap *et al.*, 1985). $PGF_{2\alpha}$ is most effective in causing luteolysis when released from the uterus in an episodic manner (Thorburn *et al.*, 1973). The release of $PGF_{2\alpha}$ appears to be under the control of circulating oxytocin, secreted by the ovary and interacting with receptors in the uterine endometrium (Wathes and Swann, 1982; Sheldrick and Flint, 1985, Flint and Sheldrick, 1986).

In the primate, $PGF_{2\alpha}$ secreted by the uterus does not appear to initiate luteolysis since hysterectomy has no effect on cycle length. This has been demonstrated both in the rhesus monkey (Neill *et al.*, 1969) and in women (Beling *et al.*, 1970). Although a countercurrent system between the ovary and uterus has been described in women (Bendz *et al.*, 1979; Einer-Jensen *et al.*, 1985), it does not appear to be of major importance at the time of luteal regression.

Intraovarian production of $PGF_{2\alpha}$ has been postulated as the source of $PGF_{2\alpha}$ for the induction of luteolysis in the primate (Rothchild, 1981). Evidence for this is provided by the ability of luteal tissue, from the rhesus monkey and women, to synthesize prostaglandins (Swanston *et al.*, 1977; Valenzuela *et al.*, 1983). A luteolytic action of $PGF_{2\alpha}$ on human ovarian cells *in vitro* has been described (McNatty *et al.*, 1975; Dennefors *et al.*, 1982), intraluteal administration of $PGF_{2\alpha}$ to the rhesus monkey results in luteolysis (Auletta *et al.*, 1984a) and perfusion of $PGF_{2\alpha}$ through the corpus luteum of the marmoset monkey *in vivo* was associated with a decrease in progesterone production (Hearn and Webley, 1987).

Systemically administered $PGF_{2\alpha}$ causes luteolysis in many species (Horton and Poyser, 1976) but there are variable reports of the effect of $PGF_{2\alpha}$ given systemically to the primate. A single intramuscular injection (0.5 μg) of a $PGF_{2\alpha}$ analogue (cloprostenol) to the marmoset monkey, a New World species, is luteolytic when given after day 8 of the luteal phase or during pregnancy (Summers *et al.*, 1985). In contrast, similar dose/weight injections of cloprostenol to the baboon, an Old World monkey, are not luteolytic at any

stage of the cycle or pregnancy (Eley *et al.*, 1987). $PGF_{2\alpha}$ is only transient in effect when administered systemically to women (Wentz and Jones, 1973).

A proposed mechanism through which $PGF_{2\alpha}$ can cause luteolysis is by blocking cAMP-dependent LH stimulation of progesterone secretion. This action of $PGF_{2\alpha}$ has been demonstrated after short-term tissue incubations and long-term culture of luteal cells in sheep (Fletcher and Niswender, 1982), cow (Pate and Condon, 1984) and rat (J.P. Thomas *et al.*, 1978). $PGF_{2\alpha}$ has also been shown to block the uptake of labelled hCG by luteal tissue *in vivo* in the rat (Behrman and Hichens, 1976). A similar luteolytic mechanism for $PGF_{2\alpha}$ has been demonstrated in the primate. In women, using both granulosa cells luteinized *in vitro* (McNatty *et al.*, 1975) and incubated luteal tissue pieces (Hamberger *et al.*, 1980), $PGF_{2\alpha}$ blocked LH/hCG-stimulated progesterone production. In the marmoset monkey perfusion of the corpus luteum *in vivo* with $PGF_{2\alpha}$ prevented the stimulatory action of hCG perfused subsequently (Hearn and Webley, 1987) and, after short-term incubation of tissue pieces, $PGF_{2\alpha}$ prevented stimulation of progesterone secretion by hCG (Webley *et al.*, 1989b).

Not all studies have demonstrated a luteolytic action for $PGF_{2\alpha}$. Indeed, $PGF_{2\alpha}$ stimulates progesterone production by incubated dispersed luteal cells from the cow (Alila *et al.*, 1988). A similar action has been demonstrated in the primate. $PGF_{2\alpha}$ stimulated progesterone secretion by mid-luteal phase cells from the rhesus monkey (Stouffer *et al.*, 1979), by incubated human luteal cells (Richardson and Masson, 1980) and by luteal cells taken in the mid-luteal phase and early pregnancy from the marmoset monkey (Webley *et al.*, 1989a). As $PGF_{2\alpha}$ can inhibit LH/hCG-stimulated progesterone production by incubated tissue pieces from the human (Hamberger *et al.*, 1980) and marmoset monkey (Webley *et al.*, 1989b), this suggests the necessity for tissue integrity for the luteolytic action of $PGF_{2\alpha}$ to be evident, which is lost after cell dispersion. Also, the contribution of different cell types in the CL may be of importance, as has been shown in the bovine CL; $PGF_{2\alpha}$ stimulated progesterone production by small luteal cells but inhibited LH-stimulated progesterone secretion by large luteal cells (Alila *et al.*, 1988). Cell contribution may vary with cycle stage as the early CL is resistant to $PGF_{2\alpha}$-induced luteolysis in the sheep (Hearnshaw *et al.*, 1973) and pig (Bazer *et al.*, 1982) and also in women (Dennefors *et al.*, 1982), the rhesus monkey (Stouffer *et al.*, 1979) and the marmoset monkey (Summers *et al.*, 1985). Alternatively, $PGF_{2\alpha}$ in the human may require neural innervation of the CL for its luteolytic action, this innervation not being sufficiently developed in the early luteal phase (Dennefors *et al.*, 1982).

(b) Other luteolytic mechanisms

While other luteolytic agents have been postulated in the primate, their role has not been fully established. One such candidate is oestradiol, which has a variable effect on luteal function in different species (see Richardson, 1986). Oestrogens are produced by the primate CL and their role as the endogenous luteolysins has been suggested (Knobil, 1973; Auletta and Flint, 1988). Luteolysis was induced in the rhesus monkey after systemic administration of oestradiol in the later half of the luteal phase (Schoonmaker *et al.*, 1982). This probably resulted from an action both at the pituitary, to increase negative feedback on LH release, and at the ovary, but oestradiol can induce luteolysis in the rhesus monkey when administered directly into the corpus luteum without an associated decrease in LH concentrations (Auletta *et al.*, 1985). Oestradiol has also been shown to decrease basal and LH/hCG-stimulated progesterone production *in vitro* by luteal cells and tissue from the human (Richardson and Masson, 1981; Laherty *et al.*, 1985; Hahlin *et*

al., 1986) and rhesus monkey (Stouffer *et al.*, 1977). The effect was evident at high doses of oestradiol and, although these doses may correspond to the levels found within the CL (Swanston *et al.*, 1977), an increase in the luteal concentration of oestradiol was not recorded at the time of luteolysis. One suggestion is that oestradiol may cause luteolysis by stimulating intraluteal production of $PGF_{2\alpha}$ (Auletta *et al.*, 1978), although in human luteal cells indomethacin, an inhibitor of PG, did not inhibit the action of oestradiol (Thibier *et al.*, 1980). Another suggestion is that oestradiol may act by inhibiting the action of 3β hydroxysteroid dehydrogenase, the enzyme which converts pregnenolone to progesterone (Williams *et al.*, 1979). However, a clear role for oestradiol in the control of luteolysis in the primate remains uncertain, particularly since studies have demonstrated that administration of anti-oestrogens fails to prevent luteolysis (Westfahl and Kling, 1982; Westfahl and Resko, 1983) and additionally oestradiol receptors have not been detected in any cells in the macaque CL throughout the luteal phase (Stouffer *et al.*, 1989).

Another candidate for a luteolytic agent in the primate is oxytocin. However, the presence of and a role for oxytocin in the human CL has been disputed, as recently discussed by Auletta *et al.* (1988). While there are reports of the presence of oxytocin in the human (Wathes *et al.*, 1982; Dawood and Khan-Dawood, 1986), cynomologus monkey (Khan-Dawood *et al.*, 1984) and baboon (Khan-Dawood, 1986) CL, others have not been able to demonstrate the presence of oxytocin in either the human (Richardson, 1986), rhesus monkey or marmoset monkey (Auletta *et al.*, 1988). Also disputed is the action of oxytocin. Tan *et al.* (1982) showed that low doses of oxytocin (4 μg/ml) stimulated progesterone production by dispersed human luteal cells, whereas high doses (40 μg/ml) inhibited both basal and hCG-stimulated progesterone production, an effect confirmed by Bennegard *et al.* (1987) with intact human luteal tissue. Oxytocin is also luteolytic when infused directly into the corpus luteum of the rhesus monkey (Auletta *et al.*, 1984b). In contrast, Richardson and Masson (1985) did not observe any change in basal or hCG-stimulated progesterone production when dispersed human luteal cells were incubated with oxytocin. Wilks (1983) also failed to see any major effect of oxytocin after *in vivo* administration in the rhesus monkey.

GnRH or its analogues have been shown to directly inhibit gonadotrophin-stimulated progesterone production by rat luteal cells (Clayton *et al.*, 1979; Harwood *et al.*, 1980). Consistent with the response was the demonstration of specific binding sites (Clayton *et al.*, 1979; see Richardson, 1986). Specific binding sites for GnRH have been demonstrated also in the primate CL (Bramley *et al.*, 1985), but the effect of GnRH on steroid production by luteal tissue in the primate is unclear. In one study progesterone production was inhibited *in vitro* by a long-acting LHRH analogue (Tureck *et al.*, 1982), whereas in another neither GnRH nor its analogue appeared to influence steroidogenic function of human granulosa cells (Casper *et al.*, 1982). Since hypothalamic GnRH is unlikely to reach the ovary in sufficient quantities, a direct action for GnRH at the primate CL awaits identification of an LHRH-like peptide in the primate ovary.

Another mechanism whereby luteolysis could be induced in the primate would be to remove luteotrophic support. It has now been clearly demonstrated, using the effects of LHRH antagonists during the luteal phase, that the primate CL depends on support provided by pituitary LH (Fraser *et al.*, 1985, 1986; Hodges *et al.*, 1988). In both women and the rhesus monkey, studies have described a decrease in the pulse frequency and amplitude of LH at the end of the luteal phase, associated with reduced pulses of progesterone (Ellinwood *et al.*, 1984; Filicori *et*

al., 1984). However, it does not appear that a decrease in LH is the cause of luteolysis since induced reduction of LH pulses in rhesus monkeys, which have hypothalamic–pituitary lesions, had no effect on the length or function of the luteal phase. The possibility of a decrease in the binding of LH at the CL inducing luteolysis also appears unlikely as a decrease in LH receptors does not necessarily precede or associate with the decrease in progesterone at luteolysis (Cameron and Stouffer, 1982). The pattern of LH/hCG receptors follows the pattern of progesterone in the human luteal phase, reaching a peak in the mid-luteal phase and falling at the end of the luteal phase (Yeko *et al.*, 1989).

To conclude on the data obtained so far on the control of luteolysis in the primate, it is probably appropriate to conclude that the mechanism is still unclear. The intraluteal production of $PGF_{2\alpha}$ causing luteolysis is a likely candidate, however there are several discrepancies, including the absence of an increase in intraluteal concentrations of $PGF_{2\alpha}$ before the onset of luteal regression (D.T. Baird, 1985), the absence of an effect of indomethacin on the lifespan of the corpus luteum (Manaugh and Novy, 1976) and the absence of an effect of *in vivo*, administered $PGF_{2\alpha}$ in some primates (Eley *et al.*, 1987). In addition, a PG synthesis inhibitor, sodium meclofenamate, infused into the CL of rhesus monkeys caused premature luteolysis rather than extending the life of the CL, indicating luteotrophic rather than luteolytic actions for PGs (Sargent *et al.*, 1988). A paper on human luteal function (Fisch *et al.*, 1989) considered it unnecessary to evoke an active luteolytic mechanism. Instead it suggested that luteolysis is preprogrammed at the time of ovulation and is only reversed by hCG secreted by the implanting embryo in pregnancy. As the CL becomes increasingly dependent on LH support in the late luteal phase (Fillicori *et al.*, 1984) it is difficult to understand how the CL would retain its ability to respond to hCG but not LH when the receptors are similar. As previously stated, a decrease in pulsatile LH does not precede luteolysis. We would suggest from our studies on the human and marmoset monkey that there is an intraluteal luteolytic agent, probably $PGF_{2\alpha}$, to which the CL becomes increasingly susceptible as the luteal phase progresses. Recent evidence in the marmoset monkey (Michael and Webley, 1993) and rhesus monkey (Houmard *et al.*, 1992) suggests that the changing response of second-messenger systems to $PGF_{2\alpha}$ may determine the timing of luteolysis. The luteolytic agent acts to inhibit LH support, which is increasingly necessary for the function of the CL. It is not able to inhibit the luteotrophic action of hCG because of the larger size of the hCG molecule and the extent of LH/hCG receptor occupancy, which is >90% in early pregnancy as compared with 10–30% in the late luteal phase (Bramley *et al.*, 1987).

6.3.2 CORPUS LUTEUM 'RESCUE' IN EARLY PREGNANCY

In early pregnancy a message is secreted by the embryo which prevents luteolysis and enables the life of the CL to be extended for the continued production of progesterone. A variety of messages produced by the embryos of different species have been identified; these include proteins, steroids and prostaglandins. The mechanisms by which these messages prolong the life of the CL varies between species and will be discussed in the following paragraphs in relation to the information available in the primate.

(a) Luteotrophic messages

As described previously, the first clearly defined message to be secreted by the primate embryo is CG. CG has a direct luteotrophic action, stimulating the production of increasing amounts of progesterone from the CL, prolonging its life beyond that of the luteal

phase and transforming it into the CL of pregnancy (Knobil, 1973). Administration of exogenous CG can prolong the life of the CL in the rhesus monkey (Wilks and Nobile, 1983) and in women (Van de Wiele *et al.*, 1970). Immunization against CG prevents the establishment of pregnancy and 'rescue' of the CL in the marmoset monkey (Hearn, 1979) and rhesus monkey (Moudgal *et al.*, 1971). In early pregnancy, during luteal rescue, CG concentrations in the peripheral circulation double every 2–4 days in the marmoset monkey (Hearn *et al.*, 1988a), rhesus monkey (Atkinson *et al.*, 1975) and in women (Braustein *et al.*, 1973). The ability of CG to stimulate progesterone production by luteal cells *in vitro* has been demonstrated in the marmoset monkey (Webley *et al.*, 1989a), rhesus monkey (Stouffer *et al.*, 1977) and human (Richardson and Masson, 1980) and after perfusion of the marmoset CL *in vivo* (Hearn and Webley, 1987; Webley and Hearn, 1987).

The bovine embryo also secrets a luteotrophic message. It was first identified when plasma progesterone concentrations were found to be considerably higher on day 10 of pregnancy, rather than day 10 of the cycle (Lukaszewska and Hansel, 1980; Hansel, 1981). *In vitro* studies have shown that homogenates from day 18 embryos stimulate progesterone production by bovine luteal cells (Beal *et al.*, 1981), and day 14 embryos in culture secrete a substance which stimulates progesterone production by rat granulosa cells (Plante *et al.*, 1987). The substance with the luteotrophic activity was found to have a molecular weight of <10 000 and be heat-labile and absorbed by dextran-coated charcoal (Hickey and Hansel, 1987). In a more recent report (Hansel *et al.*, 1989), it was suggested that the substance was like platelet-activating factor. As described previously, PAF has also been identified as an embryo message in women (O'Neill, 1985), but the report that PAF may have a luteotrophic action in women, since it increases progesterone production by human granulosa cells in culture (O'Neill, 1987), has yet to be confirmed.

PGE_2 and PGI_2, secreted by the embryo, have been suggested as possible luteotrophic agents in the sheep (Pratt *et al.*, 1977; Bazer *et al.*, 1981; Silvia *et al.*, 1984). PGE_2 dramatically increases in the uterine plasma of ewes on days 13 – 14 of pregnancy (Silvia *et al.*, 1984). In a review, Bazer *et al.* (1986), question the necessity for a luteotrophic agent in the pig as the CL can be maintained after hysterectomy as long as basal LH is available. However, since two or more embryos are required for the establishment of pregnancy, they suggest that in the pig, and also possibly in the cow, PGE_2 may play a role in luteostasis.

(b) Anti-luteolytic messages

Rather than a luteotrophic message, the embryos of the sheep, cow and pig secrete messages which are anti-luteolytic. That is they prevent $PGF_{2\alpha}$, secreted by the uterus, from reaching the corpus luteum and causing luteolysis.

In the pig, it has been proposed that oestrogens secreted by the blastocyst are responsible for the prevention of luteal regression and the establishment of pregnancy. Oestrogens are secreted by the pig blastocyst from day 10 of gestation (Flint *et al.*, 1979; Gadsby *et al.*, 1980; Stoner *et al.*, 1981; Bazer *et al.*, 1986) and the CL can be maintained in pseudopregnancy by injections of oestradiol. It would appear that blastocyst oestrogens do not inhibit uterine production of $PGF_{2\alpha}$ but instead cause a redirection of the release of $PGF_{2\alpha}$ by the uterus so that the amount released into the uterine vein is reduced (Bazer *et al.*, 1982).

In the sheep, the blastocyst secretes a variety of proteins during *in vitro* culture, but two-dimensional polyacrylamide gel electrophoresis (PAGE) showed one major product of interest. This was subsequently purified and termed 'trophoblastin' (Martal *et al.*, 1979), then ovine trophoblast protein 1 (OTP-

1) (Godkin *et al.*, 1982), but is now termed trophoblast interferon (tIFN) (H.J. Stewart *et al.*, 1987; R.M. Roberts *et al.*, 1992). Its antiluteolytic ability to extend the lifespan of the CL was demonstrated by infusing tIFN (or conceptus secretory proteins) from a day 16 embryo into the uterus of non-pregnant ewes and extending the inter-oestrus interval (Godkin *et al.*, 1984; Vallet *et al.*, 1988). Trophoblast interferons have been shown to act directly at the endometrium rather than at the CL and prevent luteal regression by inhibiting the ability of oxytocin and oestradiol to induce $PGF_{2\alpha}$ production (Bazer *et al.*, 1986; Vallet *et al.*, 1988). Both ovine conceptus secretory proteins and recombinant bovine α_1-interferon decrease endometrial oxytocin receptor concentration and suppress $PGF_{2\alpha}$ release following treatment with oxytocin in cyclic ewes and inhibit the formation of endometrial oxytocin receptors in progesterone-treated ovariectomized ewes (Vallet and Lamming, 1991). In recent studies, homology between OTP-1 and α-interferons has been described (Imakawa *et al.*, 1987; H.J. Stewart *et al.*, 1987; Charpigny *et al.*, 1988; Flint *et al.*, 1988) and the characteristics of these compounds compared. This has shown that, in addition to its antiluteolytic action, trophoblast interferons have potent antiviral activity (Pontzer *et al.*, 1988), which may be important in early pregnancy. That ovine tIFN acts locally was shown by measuring antiviral activity and endometrial oxytocin receptor concentrations in ewes made unilaterally pregnant by previously transecting and isolating one uterine horn from the remaining horn and body of the uterus. Under these conditions, tIFN concentrations were high and oxytocin receptor concentrations low in the pregnant horn, whereas the reverse occurred in the non-pregnant horn (Lamming *et al.*, 1991). Thus, by inhibiting endometrial receptor formation, second-messenger responses to oxytocin are precluded, preventing the luteolytic pulses of $PGF_{2\alpha}$ (Flint *et al.*, 1992). Further studies with unilaterally pregnant sheep showed that, while basal $PGF_{2\alpha}$ levels were high in blood draining the pregnant horn, there was little $PGF_{2\alpha}$ response to a bolus injection of oxytocin, whereas in the non-pregnant horn, luteolytic type $PGF_{2\alpha}$ pulses occurred (Payne and Lamming, 1992). This demonstrates the local action of trophoblast interferon in the pregnant horn, which does not require a change in systemic levels of ovarian steroid hormones. The administration of recombinant bovine α_1-interferon to cyclic ewes by both systemic and intrauterine routes inhibits prostaglandin $F_{2\alpha}$ secretion and extends CL lifespan (Parkinson *et al.*, 1992).

In the cow, oxytocin- and oestradiol-induced $PGF_{2\alpha}$ production is also inhibited by the presence of the conceptus (see Thatcher *et al.*, 1985). Proteins secreted by the cow embryo in culture extend the life of the CL (Knickerbocker *et al.*, 1986; Helmer *et al.*, 1989a,b). The protein, termed bovine trophoblast protein 1 (BTP-1) is similar immunologically to OTP-1. The two proteins may be biologically active in both species as interspecies transfer of trophoblastic vesicles altered the lifespan of the CL of the recipient species (Heyman *et al.*, 1984; Martal *et al.*, 1984). BTP-1 has been shown to prevent luteolysis by acting at the endometrium to inhibit the production of prostaglandin by inducing synthesis of an intracellular inhibitor of $PGF_{2\alpha}$ synthesis (Helmer *et al.*, 1989b). Infusion of bovine α-interferon into the uterus of cyclic cows delayed luteolysis suggesting that, as in the sheep, an interferon-like molecule may be important in the establishment of pregnancy (Plante *et al.*, 1988).

It can be suggested that CG secreted by the primate embryo should also be termed an anti-luteolytic as well as or rather than a luteotrophic message. If CG is able to maintain the life of the CL in early pregnancy by preventing the luteolytic action of $PGF_{2\alpha}$ (Knobil, 1973; D.T. Baird, 1985; Hearn and Webley, 1987) or, alternatively, its pro-

duction, then the only difference in the required action for the embryo message, between the primate and the above species, is the source of the luteolytic agent.

6.3.3 TIMING OF THE EMBRYO MESSAGES

The timing of events is, however, rather different between primate and non-primate species, although in all species the timing of release of the embryo message is critical. In the primate, CG is secreted at the time of implantation. Implantation begins on days 8–9 in women (Lenton and Woodward, 1988), the rhesus monkey and baboon (Hendrickx and Enders, 1980) and rather later on days 11–12 in the marmoset monkey (Hearn, 1980; H.D.M. Moore *et al.*, 1985; Smith *et al.*, 1987). Although CG cannot usually be detected in the peripheral circulation until some 3 days later (Hearn, 1986), culture of embryos *in vitro* shows a clear secretion of CG from the time of attachment in the human (Fishel *et al.*, 1984) and marmoset monkey (Hearn *et al.*, 1988a).

Comparison of progesterone production by luteal cells from the marmoset monkey during short-term incubation *in vitro* showed differences between cells taken from pregnant and non-pregnant animals on day 14 after ovulation (Webley *et al.*, 1989a). Progesterone production by luteal cells from non-pregnant animals responded to stimulation by luteotrophic agents, whereas the luteal cells from pregnant animals were unresponsive; control production of progesterone was high and already equivalent to the levels stimulated by the treatments (Figure 6.8).

This suggested that on day 14 (just 2 days after implantation, which occurs on days 11–12) a message secreted by the embryo may have affected the CL, providing an endogenous stimulus. In the marmoset, the secretion of CG begins at the time of attachment of embryos in culture, although measurement of CG in the peripheral circulation does not rise above background levels until day 17 (Hearn *et al.*, 1988a). If CG is not detectable for 3–4 days after embryo attachment is it CG or another message received by the CL within 2 days of attachment? In women, using very sensitive assays for hCG and accurate extrapolation of the hCG curve, an increase in levels could be detected within 2 days (Lenton and Woodward, 1988).

If CG is secreted into the peripheral circulation at the time of implantation, in sufficient quantities to reach the CL, there may be no need to postulate a role for other embryo messages in the rescue of the CL during early pregnancy in the primate. Indeed the ability of a pre-implantation embryo message to reach the CL via the peripheral circulation is questionable. However, while administration of exogenous CG can extend the life of the CL, it can do so for only a few days (diZerega and Hodgen, 1980; Ottobre *et al.*, 1984). This could result from the CL becoming desensitized to repeated injections of hCG or the involvement of another luteotrophic agent in the rescue of the CL (discussed by Moudgal, 1984; Richardson, 1986). In the marmoset monkey, luteal cells taken from pregnant animals on day 20 after ovulation had a lower basal production of progesterone than luteal cells from day 14 pregnant animals and the cells responded to stimulation by luteotrophic agents, whereas the day 14 luteal cells did not (Webley *et al.*, 1989a). CG concentrations in the peripheral circulation of the marmoset are undetectable on day 14 whereas on day 20 levels are detectable and rising rapidly (Hearn *et al.*, 1988a). Consequently, if CG could influence the CL before it was detectable in the peripheral circulation the luteal cell response must alter between days 14 and 20 or pregnancy when the CL of pregnancy is established. Alternatively, the embryo may secrete a different message to 'rescue' the CL before CG reaches sufficient concentration in the circulation to take over the luteotrophic role.

In the sheep, the embryo secretes the anti-

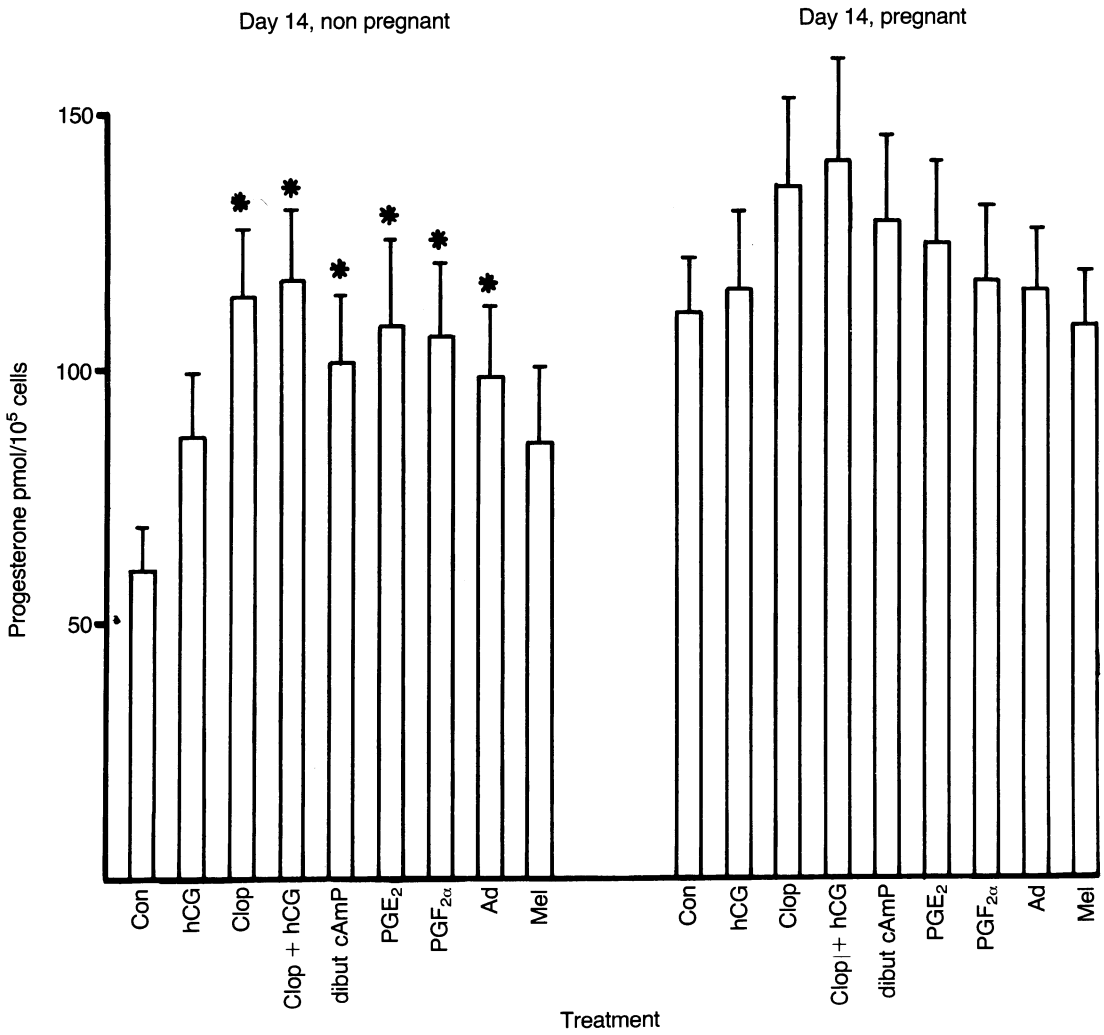

Figure 6.8 Progesterone concentrations (mean ± SEM) produced by dispersed luteal cells from non-pregnant and pregnant marmoset monkeys on day 14 after ovulation after incubation for 2 h with hCG, cloprostenol (Cp) ± hCG, dibutyrl cAMP (db), PGE_2 (E_2), $PGF_{2\alpha}$ ($F2_{2\alpha}$), adrenaline (Ad) and melatonin (mel). C=control. *$P<0.05$ compared with control values (Duncan's multiple range test).

luteolytic protein OTP-1 for a short period at the beginning of pregnancy between days 12 and 21 (Godkin *et al.*, 1982). It must be produced by day 12/13 as the CL begins to regress at this time; if an embryo is transferred to a non-pregnant ewe on day 15 it is too late and luteal regression occurs (Moor and Rowson, 1966). Once luteolysis has been prevented, the life of the CL continues after day 21 when the embryo stops secreting OTP-1. In the cow, the embryo also secretes BTP-1 for a limited period from days 16–24 of pregnancy. Proteins secreted by the bovine embryo in culture on days 16 to 18 extended the life of the CL and inter-oestrus interval when administered into the uterine lumen of cyclic cattle on days 15–21 after oestrus (Knickerbocker *et al.*, 1986).

Primates differ from the domestic species in the timing of secretion of the embryo mess-

Table 6.6 Comparative rates of pre-implantation development in mammals

[a]Days after fertilization (from the literature).

age. In primates, CG is secreted at the time of implantation, whereas in domestic species the embryo signals are sent to the mother before there is intimate contact at implantation. In the pig, oestrogens are secreted by the blastocyst from day 10, production is decreased between days 13 and 14 then increases between days 15 and 25–30, while attachment of the embryo occurs on day 18 (Gadsby *et al.*, 1980; Bazer *et al.*, 1986). In the sheep, OTP-1 is secreted from day 12 (Godkin *et al.*, 1982), whereas attachment occurs on day 16 and in the cow BTP-1 is secreted from day 15 (Knickerbocker *et al.*, 1986) and attachment occurs between days 25 and 30. The difference between primates and domestic species is that the primate embryo message must reach the ovary via the circulation, whereas the embryo messages secreted by the embryo of domestic species acts at the uterus to prevent release of uterine $PGF_{2\alpha}$, so close contact between the embryo and the maternal circulation may not be required.

This part finishes the discussion of interrelationships between embryo and mother. The signal for pregnancy has been established. It is now important to discuss how the embryo and fetus develop within the maternal organism.

6.4 RATES OF DEVELOPMENT

6.4.1 PRE-IMPLANTATION PERIOD

Prenatal development includes the period from fertilization to birth and is characterized by a series of external and internal morphological changes that are similar in many mammalian species. However, the time course of cleavage, organ formation and fetal growth vary both within and between different species. Following fertilization, the embryo undergoes cleavage, the process of cellular division without cellular growth. Cleavage continues until implantation. At this time cell size has been reduced to the approximate size of the normal somatic cells characteristic of the species. In general, the laboratory species have shorter gestation periods than domestic species and slightly greater rates of cleavage (Davies and Hesseldahl, 1971; Brinster, 1974; McLaren, 1974) (Table 6.6).

In most species, the embryo undergoes cleavage while in the oviduct and does not pass into the uterus until the late morula to early blastocyst stage. The oviductal transport of the embryo during this period prior to implantation is a complex process exhibiting marked species variability. Muscular activity, ciliary movements and tubal fluid currents contribute to the propulsion of the embryo to varying degrees. Passage of the embryos through the oviduct takes 3–4 days in most mammals (Wimsatt, 1975), but it can be as short as 24 h (opossum, Hartman, 1928) or 48 h (pig, Hunter, 1974) or as long as 8–10 days (dog, Holst and Phemister, 1971) (Table 6.6).

Blastocysts undergoing cleavage move through different portions of the oviduct at variable rates. Rabbit oocytes (or ova) reach the junction of the ampulla and isthmus as quickly as 6 min after ovulation, but the remainder of the time in the oviduct is spent in slow transport through the isthmus prior to entry into the uterus (Bodkhe and Harper, 1973). In contrast, the ova of mice and rats are transported rapidly through the ampulla and then detained at the isthmoampullar junction for 24 h. Transport through the isthmus is again rapid with a 30-h delay at the uterotubal junction (Humphrey and Martin, 1969). This pattern of rapid movement to the isthmoampullar junction, a delay at the site of fertilization, then rapid movement to the tubouterine junction with a second delay, appears to predominate in most mammals (D.H. Anderson, 1927; Blandau, 1961). A third type of oviductal transport is exhibited by pig and cow ova, which spend most of the time above the isthmo ampullar junction and then move rapidly through the isthmus into the uterus (Aref and Hafez, 1973; Blandau, 1973). Studies in human (Croxatto and Ortiz, 1975) and non-human primates (Eddy *et al.*, 1975) indicate that tubal transport in these species is similar to the third mechanism.

The first overt sign of cellular differentiation occurs with the development of the blastocoele, which usually coincides with the arrival of the embryo in the uterus. During the blastocyst stage, the zona pellucida is lost and the embryo breaks free (hatches). There is a marked increase in the total size and often a change in shape of the embryo during this stage, mainly due to the enlargement of the blastocoele. Considerable species variability is observed in both the rate and magnitude of blastocyst expansion following blastocoele formation. While marked distension of the blastocyst is common to the primate, rabbit, dog, cat and most livestock species (Brinster, 1974; G.B. Anderson, 1977; Noden and deLahunta, 1985), minimal expansion takes place in the mouse, rat and guinea pig (Hafez, 1972).

Essentially two cell types become recognizable in the blastocyst. Those that accumulate at one pole become slightly larger and constitute the embryonic disc (inner cell mass, blastodisk), from which the embryo will develop. The cells on the periphery of the blastocyst are trophoblast cells, which facilitate the absorption of nutrients early in development and later participate in the formation of extraembryonic membranes, which contribute to the formation of the placenta. In domestic animals the trophoblast cells overlying the embryonic disc degenerate or shift peripherally and the blastodisc becomes exposed on the surface of the blastocyst. In most primates the embryonic disc remains beneath the trophoblastic cover and is referred to as the inner cell mass (Noden and deLahunta, 1985).

Implantation is a transitional stage in early pregnancy during which the blastocyst assumes a fixed position within the uterus. The steps involved are species dependent but usually include apposition and adhesion of the blastocyst to the surface of the uterine epithelium followed by penetration of the epithelium by the blastocyst (Boving, 1963; Enders, 1972). The loss of the zona pellucida in relation to the time of implantation varies with the species and mechanism of implan-

tation. In animals in which implantation is eccentric (rat, mouse, hamster) or interstitial (bats and primates), the zona is lost before implantation is initiated. The blastocysts of animals with centric implantation (rabbit, pig, sheep, cow, horse, dog and cat) expand and implant with the extracellular coat(s) surrounding the trophoblast still intact (Wimsatt, 1975). Detailed morphological descriptions of implantation have been provided for a few non-human primate species, including the rhesus monkey (Enders *et al.*, 1983), baboon (Tarara *et al.*, 1987) and marmoset (Smith *et al.*, 1987); in contrast, the availability of comparable human material for evaluation is limited to the study of Hertig *et al.* (1956).

6.4.2 ORGANOGENESIS

Organogenesis encompasses the period of embryonic development from the establishment of the primitive streak, which marks the future longitudinal axis of the embryo, until palate closure and ossification of the humerus. During this time the three germ layers are reshaped to form the embryo proper by a process combining growth with cell and tissue movements. The major changes during the period of organogenesis are elongation of the body, subdivision of the body into head, trunk and tail, development of the appendages, and separation of the embryo from the extraembryonic structures. By the end of this period the shape of the embryo has changed greatly and the major features of the external body form are recognizable. The morphological features of human embryos during organogenesis have been well described (see O'Rahilly and Müller, 1987). A number of non-human primate species have also been the subject of developmental staging, which utilizes size and age criteria, in addition to morphology, to define this period of prenatal growth (Hendrickx, 1971; Gribnau and Geijsberts, 1981; Butler, 1983; Binkerd and Hendrickx, 1984). While the rudiments of the various organ systems conform to generalized, basic plans in the embryos of all vertebrate species, the temporal aspects of organ formation are species specific (Table 6.7).

Studies in mice have shown that up to the time of primitive streak formation cell proliferation in the embryo remains very slow. Measurements of tissue and cell volume in mouse embryos (at 6.5 days) show a cell population of only 500–600 cells (Snow, 1976). With the onset of gastrulation (primitive streak formation) the number of cells has increased to 15 000 within a 24-h period, requiring a doubling of the previous proliferation rate (Snow, 1977). In other species there is also an acceleration in growth rate during primitive streak formation. It has been estimated that human (Boyd and Hamilton, 1964; Langman, 1975; K.L. Moore, 1977) and pig (Patten, 1953) embryos increase some 40-fold in size in 4 days, while the baboon (Hendrickx, 1971) increases about 16-fold in 3 days. If this change in volume is produced entirely by an increase in cell number (rather than changes in cell volume or intercellular spaces), then cell proliferation rate has accelerated to about the same extent as in the mouse, i.e. doubled (Snow, 1981).

From the neural plate stages through organogenesis, various regions of the embryo establish their own growth profiles characteristic of the organs into which they will develop. In the mouse, the high cell proliferation rate of gastrulation stages is not maintained throughout the embryo during this period (Snow, 1986). Although more attention has been devoted to fetal growth in humans, a considerable body of information has recently been accumulated on the corresponding age, stage and length as well as the growth of a few organ systems in the human (O'Rahilly and Müller, 1986).

6.4.3 FETAL PERIOD

The fetal period is characterized by maximum growth and further development of the

Table 6.7 Comparative times of development during organogenesis (days)

[a]Day of mating is considered as day 0 of gestation. (From the literature.)

organs and systems established during the embryonic stage. Absolute prenatal growth continues throughout gestation while relative growth (percentage increment change) begins to decrease about midway in gestation. Fetal crown–rump length and weight are the indices most consistently correlated with gestational age in growth assessment studies. While crown–rump length reflects the growth of the head and vertebral column, weight is determined mainly by the developing muscles and other soft tissues (Bergin *et al.*, 1967).

Figure 6.9 shows the growth curves for length and weight for a normally developing human fetus.

There is a steep linear relationship between fetal length and gestational age after the second month with an average increase in sitting height (crown–rump) of 1.5 mm/day (Patten, 1968). Maximal linear growth during gestation occurs in the sixth and seventh months and decelerates during the last 2 months of the fetal period (Scammon and Calkins, 1929). The relationship between weight and gestational age is more curvilinear; from the time of fertilization to birth the increase in weight is approximately 6 billion times (Lowrey, 1978). The 'shape' of the growth curves for several species, including the pig (Ullrey *et al.*, 1965), rhesus monkey (van Wagenen and Catchpole, 1965), baboon (Hendrickx, 1971), cow (Evans and Sack, 1973; Eley *et al.*, 1978) and rat (Angulo and Gonzalez, 1932), is similar to that of the human.

Intraspecies comparisons of fetal growth have been made by quantitative descriptions of these two parameters as a function of gestational age. Haase's rule describes the linear

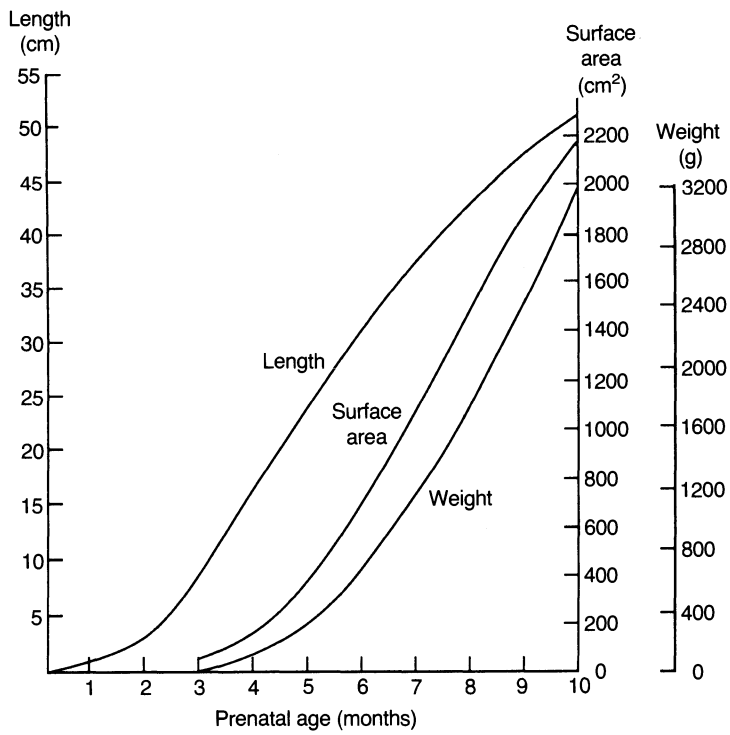

Figure 6.9 Prenatal growth curves for the human fetus from time of conception to birth, length (cm, crown–heel), surface area of the body (cm^2) and weight (g).

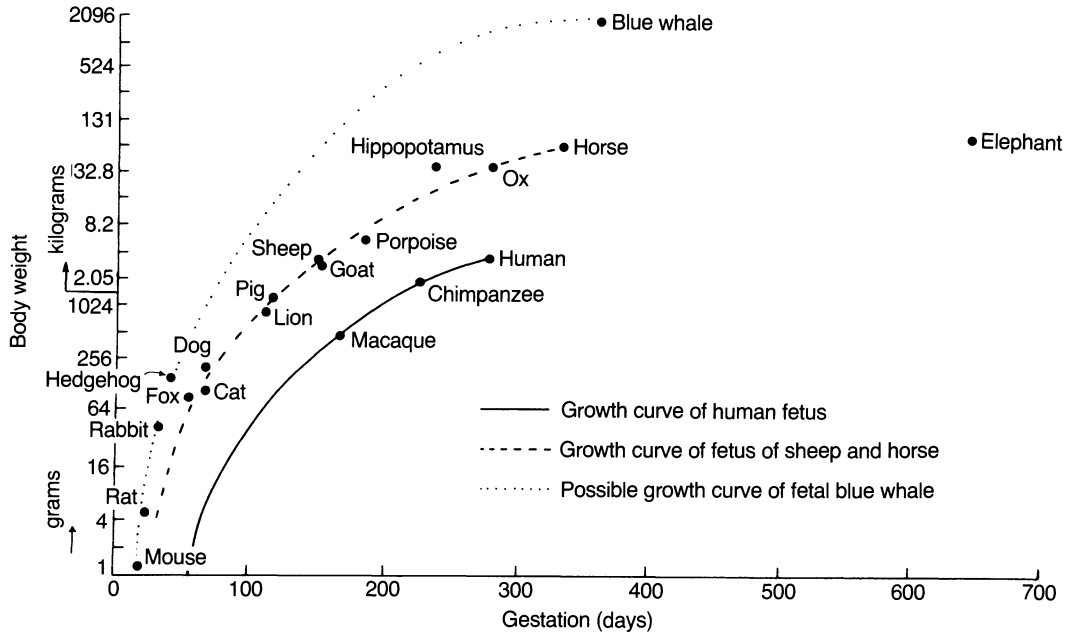

Figure 6.10 Birth weights of 20 species and their lengths of gestation. The curves show that the species can be classified into those that grow very fast (. . .), fast (- - -) and slow (——). (Reproduced with permission from McCance & Widdowson, 1986.)

relationship between the length of the fetus of many species and gestational age during the second half of pregnancy (Spencer and Coulombe, 1965). It has been determined that the fetal weight of many species is a cubic function of time after the appearance of the primitive streak (corresponding to the time when placental function becomes established). The equation is $W = a(t-t')^3$ where W is the weight of the fetus on any given gestational day, a is a constant expressing the rate of supply of nutrients per unit of fetal surface area, t is the length of gestation, and t' is the lag period of growth prior to placental function (Page *et al.*, 1981). For man the value of a is 0.24×10^6 and for large mammals the value is considerably larger (e.g. 16 times as great in the cow). The rate of growth for most mammals is enormous initially and progressively slows as pregnancy progresses. For example, in the first month after fertilization, the human zygote increases a million times in weight, whereas in the last month of gestation the rate of increase is 0.3. A decrease in the value of a toward the end of gestation will result in intrauterine growth retardation (Page *et al.*, 1981).

The rate of growth soon after conception sets the pace for the subsequent growth *in utero* and thus the weights at birth for similar lengths of gestation. The size at birth is the product of the rate and duration of growth. The relationship between these variables is different among mammals, some achieving final size quickly by rapid growth, others at a slower pace for a longer period *in utero*. Figure 6.10 shows the weights at birth of 20 species plotted against their length of gestation.

The points appear to fall on three curves which describe three classes of mammals: very fast, fast and slow growers (McCance and Widdowson, 1986). As seen in this

figure, the small rodents (mouse, rat) and the rabbit as well as the fetal whale grow extremely rapidly throughout gestation. In contrast, man, the macaque and the elephant grow more slowly in the early stages, which results in lower weights after similar times in the uterus. An intermediate growth rate is exhibited by the cat, pig, dog, guinea pig, goat, ox, sheep, porpoise, hippopotamus and horse. These differential growth rates and gestational lengths result in different sizes at birth. Thus, the newborn hippopotamus is larger than the newborn human baby because it grows faster. The human fetus grows much larger than the rat before it is born because it stays in the uterus longer (McCance and Widdowson, 1986).

The prenatal growth period is characterized by a progressive alteration of form and proportions, both externally and internally. Diversity of form is acquired through differential rates of growth operating in various regions of the fetus and in definite directions. While the absolute rates may vary among individuals of any species, the ratios existing between the growth rates of different parts of the body in that species are relatively constant. The emergence of limbs from initial bud-like swellings and the early form changes during the development of the brain are visual examples of the progressive modelling of external and internal form by differential growth (Arey, 1974).

Assessment of intrauterine growth in humans using radiographic, anthropometric and ultrasonic methods has made a major contribution to a better understanding of the principle of fetal growth in relationship to gestational age (P.R.M. Jones *et al.*, 1986; Meire, 1986). The establishment of growth curves generated by clinical ultrasound observations and measurements of various fetal dimensions provides information on gestational staging, somatic growth and functional maturity in addition to diagnosis and management of fetal growth disorders including intrauterine growth retardation (Birnholz, 1986; Bowie, 1988; Reece *et al.*, 1989). Assessment of intrauterine growth in non-human primates has also been advanced by the recent use of ultrasonography in monitoring pregnancy in rhesus and cynomologus monkeys (Tarantal and Hendrickx, 1988a).

In humans, the skeleton and musculature grow rather slowly until the last two fetal months, during which time they each show accelerated growth to constitute from 15 to 25% of the total body weight of the newborn. The central nervous system, on the other hand, makes up a larger portion of the body weight in the young embryo (25% in the second month) than at birth (15%). As a whole, the viscera decrease slowly and steadily in relative weight after the first two embryonic months. In the second prenatal month these organs constitute about 15% of the total body weight, which is reduced to approximately 9% at birth (Arey, 1974). Although each fetal organ has its characteristic growth curve, the individual organs generally increase rapidly to a maximum relative size during the early fetal period and then decrease with age even to maturity (Arey, 1974). Recent growth curves for the spleen, kidney and liver as well as foot length in human fetuses have been correlated to fetal parameters of maturity, including gestational age, crown–rump length/weight (Ferreira *et al.*, 1990, 1992; Mandarim-de-Lacerda, 1990; Sampaio and Aragao, 1990).

6.4.4 FACTORS AFFECTING PRENATAL GROWTH

Fetal growth rate and size at birth are affected by a combination of constitutive and environmental factors.

(a) Constitutive factors

While the fetal and maternal genomes dictate the growth potential of the fetus, adequate amounts and successful transfer of substrate are needed to achieve this potential. The ulti-

mate definition of fetal size during normal pregnancy is a result of regulation of this genetic and environmental blueprint by hormones and growth factors.

(b) Genetic factors

Genetic factors have an important influence in determining fetal growth rates characteristic of different species and contribute to the normal biological variation in size within a species. Non-chromosomal instructions appear to be especially important in the earliest stages of development immediately after fertilization, which are heavily influenced by the maternal genotype through the cytoplasmic genetic information. At fertilization the sperm is only made up of chromosomes with negligible amounts of other material, whereas the maternal contribution embodies the full cytoplasmic material as well as chromosomes (D.F. Roberts, 1981). Thereafter, differentiation and development proceed as a complex of gene-controlled synthetic processes resulting largely from switching on and off the activity of particular fetal genes at specific times.

The existence of genetic influence on human fetal growth is evidenced by the fact that infant birth weight is grossly affected by genetic disease, both single gene and chromosomal (Rimoin and Graham, 1989). Infants with fibrocystic disease and galactosaemia as well as those with Down's syndrome, trisomy 13 and Turner's syndrome, for example, are of reduced mean birth weight. Since only the XO aberration is consistently associated with reduced growth rate in humans, the genetic control of intrauterine growth is believed to involve loci widely distributed through the autosomes (D.F. Roberts, 1981).

Fetal genotype has been estimated to account for approximately 20% of birth weight variation in humans (Polani, 1974). Male genotype is associated with increased birth weight, with males averaging 150–200 g more than females at term (H.C. Miller and Merritt, 1979). This difference in fetal size is not apparent in early gestation, but rather appears to be dependent on increased growth in the third trimester (Thomson *et al.*, 1968). Clearly, genetic influences play a part in some of the variation noted in birth weights among different ethnic groups. Although some of these differences may be explained by environmental factors, a number of studies describe striking ethnic differences in birth weight, irrespective of socioeconomic status (Barron and Vessey, 1966).

Thus, the contribution of the fetus's own genes in determining its size at birth is small compared with the contribution of maternal factors – both environmental and genetic. While in early pregnancy fetal genetic control is dominant and determines relatively narrow limits of variability in patterns of fetal growth, maternal and placental constraints as well as hormonal and growth factor stimuli assume increasing importance and give rise to greater variability in fetal growth later in pregnancy (Liggins, 1982). After birth such strong prenatal influences upon growth are gradually neutralized. The individual's own genes begin to reassert their influence, and post-natal growth moves firmly in a direction determined genotypically (R.S. Wilson, 1976).

(c) Hormones

The translation of genetic information to actual growth requires regulation by fetal hormones which mediate utilization of available substrate. Insulin plays a significant role in this regulation of fetal growth. Human fetuses either deficient in insulin due to infant diabetes or pancreatic agenesis or resistant to insulin, as in leprechaun syndrome, are small in size (D'Ercole and Underwood, 1986). The level of serum insulin in the human fetus is thought to reflect autonomous fetal pancreatic insulin secretion, since the

placenta is impermeable to insulin throughout pregnancy (H. Wolf *et al.*, 1969). Various clinical syndromes associated with excessive fetal growth, such as diabetes, Beckwith–Wiedemann syndrome, nesidioblastosis, insulinoma and erythroblastosis, have associated hyperinsulinism (D.E. Hill, 1976). Although the mechanism of action of insulin in the induction of overgrowth is uncertain, some evidence suggests that it can enhance insulin-like growth factor 1 (IGF-1) secretion (Gluckman, 1989).

A number of animal models support this growth-promoting role for insulin. Rat fetuses injected near term with subcutaneous insulin showed evidence of macrosomia and increased glucose utilization (Picon, 1967). Surgical removal of the pancreas in lambs (D.E. Hill, 1976), alloxan injection into fetal rabbits (P.G.R. Harding *et al.*, 1975) and streptozotocin injection into fetal monkeys (Cheek and Hill, 1975) have all resulted in hypoinsulinaemic, growth-retarded fetuses. *In vivo* and *in vitro* animal studies suggest that insulin is permissive for fetal growth and that its growth-stimulatory actions in the fetus are mediated by its effects on carbohydrate, protein and fat metabolism, rather than through direct stimulation of cellular proliferation (D'Ercole and Underwood 1986).

The effect of growth hormone on fetal development is not well understood. Human infants with familial isolated growth hormone deficiencies and those with high levels of inactive growth hormone are generally of normal weight, although their length may be diminished at birth (Laron and Pertzelan, 1969). That growth hormone may not be crucial in humans is also supported by the fact that newborn infants with anencephaly and congenital absence of the pituitary are not small in size (D'Ercole and Underwood, 1986). The effect of interference with hypothalamic and pituitary development and function seems to be species specific, i.e. fetal decapitation *in utero* has minimal effect on fetal size in the rat, mouse, hamster, pig and rabbit, while in the calf and lamb significant differences were seen following both naturally occurring absence of and surgical destruction of the fetal pituitary (Liggins, 1974; Jost, 1979). Neuronal growth in rats appears to be enhanced by administration of exogenous growth hormone (Honnebier and Swaab, 1974), although somatic growth is unaffected.

There are conflicting results with respect to the direct effect on somatic growth of the adrenal steroids. An increasing number of studies in humans (Taeusch, 1975) and experimental animals (de Lemos, 1976; Frank and Roberts, 1979) have demonstrated that exogenous glucocorticoids have a negative effect on fetal growth. Experimentally adrenalectomized lambs (Drost and Holm, 1968), rats (Jacquot, 1959) and monkeys (Mueller-Heubach *et al.*, 1972) have birth weights within normal limits. However, in some cases of idiopathic adrenal hypoplasia in humans, birth weights are slightly reduced (Liggins, 1974). Depending on the cell type, glucocorticoids either inhibit or stimulate the proliferation of fetal cells in culture (Jimenez de Asva *et al.*, 1977). The role of thyroid hormone appears to vary in different species. Fetal hypothyroidism is associated with growth retardation in some species, but not in others, including man. Experiments in sheep with placental lactogen raise the possibility that this hormone is also involved in the regulation of fetal growth; however, its role in human pregnancy remains uncertain (Gluckman, 1989).

(d) Growth factors

A number of biologically active substances that stimulate mitosis and/or differentiation have been thought to be important in fetal growth (see reviews by Rizzino, 1987; Mercola and Stiles, 1988). Among the peptides that have been purified, sequenced and studied for their effects on *in utero* growth are nerve growth factor (NGF) (Springer, 1988), epidermal growth factor (EGF) (Burgess,

1989; Marti *et al.*, 1989) and the somatomedins (SMs) (Heyner *et al.*, 1989). Although there is no direct proof of the effects of these factors on fetal growth, they have been implicated in human or animal fetal development by one or more lines of evidence:

1. stimulation of proliferation and/or differentiation of cultured embryonic and fetal cells;
2. identification of growth factor receptors in fetal tissues;
3. synthesis of growth factors by fetal tissues; and
4. circulation of growth factors in fetal blood.

Other factors which have also been well studied include haemopoietic growth factor (Gabrilove, 1989) fibroblast growth factor (FGF) (A. Baird and Walicke, 1989) and transforming growth factors (TGFs) (Rizzino, 1988).

It has been postulated that growth factors exert their effects on fetal development by mediating the actions of classic hormones on target tissues (D'Ercole and Underwood, 1986). There is evidence that EGF and NGF are dependent on thyroid hormones and SM might be dependent on prolactin, placental lactogen, insulin or growth hormone. The effect that growth factors have on embryonic and fetal development is probably a result of local tissue action via autocrine or paracrine mechanisms. The regulatory mechanisms by which these factors influence cell growth and differentiation will be facilitated by future studies of embryos cultured in serum-free media (Rizzino, 1987).

(e) Environmental factors

The major environmental factors which affect prenatal growth in mammals include size, age, parity, nutrition and health of the mother, litter size, duration of pregnancy and placental size and function.

(f) Maternal size, age and parity

The size of the mother is positively correlated with prenatal growth rate in most mammalian species. This effect is much more pronounced than the father's size and is most obvious in animals with long gestation periods and singleton pregnancies. The influence of maternal size is obscured by litter size in polytocous animals (Hendrickx and Houston, 1970).

Although the effect of maternal age on fetal size has not been fully investigated, young mothers tend to have smaller offspring, partially because they continue to grow during pregnancy and they compete with the fetus for available nutrients (Hafez, 1968).

Studies in humans have shown that parity may affect size at time of delivery. The average birth weight increases with increasing order, i.e. the birth weight and dimensions of the firstborn are less than those of subsequent infants (Lowrey, 1978). In lower species, parity primarily affects the level of prenatal mortality rather than fetal growth rates. Experiments in mice and rats indicate a decrease in the size of litters with each successive pregnancy and, hence, with age. This decrease has been attributed largely to higher embryonic loss in older animals since the number of shed ova remains fairly constant after the first pregnancy (Hollander and Strong, 1950).

(g) Maternal nutrition and health

In most polytocous animals in which the total weight of the litter is large relative to the weight of the mother, undernutrition has some effect on birth weight. However, studies in rats and rabbits indicate that restriction of maternal food intake has to be extreme before fetal birth weight is markedly decreased (Campbell *et al.*, 1953; Dawes, 1973). The effect of maternal nutrition is noted only to a minor degree in the higher primate species, including the human. Since

nutrient requirements for the fetus follow a similar trend to fetal growth (very low in early pregnancy and increasing markedly in the last trimester), the effects of maternal over- or undernutrition on fetal growth in all species are operative only in about the last one-sixth of gestation (Rattray, 1977; Page *et al.*, 1981).

The effects of maternal health on fetal growth have largely been provided by the medical literature. The most common identifiable cause of intrauterine growth retardation is maternal vascular disease, such as pre-eclampsia, chronic essential hypertension, collagen vascular diseases and neuropathies, including diabetic neuropathy (Oppe *et al.*, 1957). Vascular disease is thought to lead to a decrease in fetal growth by interfering with uteroplacental blood flow (J.C. Browne and Veall, 1953). Other conditions, including chronic antepartum haemorrhage, diminished cardiac output, cyanotic congenital heart disease and various haemoglobinopathies presumably lead to decreased fetal growth because of decreased ability to transport substrate to the fetus or a decreased availability of oxygen in the maternal vascular component (Resnik, 1978).

Intrauterine infections, including rubella, cytomegalovirus, varicella and herpes infections, have also been associated with growth retardation in the fetus (Nahmias and Visintine, 1976; Young, 1976; Knox, 1978). There is increasing evidence that certain environmental factors (i.e. smoking, alcohol, drugs) also affect intrauterine growth. The adverse effects of maternal smoking on fetal growth have been partially attributed to the impairment of uteroplacental circulation as a result of the vasoconstricting effects of nicotine. Low birth weights and lengths are also associated with prenatal exposure to alcohol, which readily accumulates in, but is slowly eliminated from, the fetus. Recent studies suggest that maternal use of cocaine adversely affects fetal growth through impairing fetal oxygenation by catecholamine-induced vasoconstriction of the uterine arteries (Kretchmer *et al.*, 1989).

(h) Litter size and duration of pregnancy

In nearly all polytocous species which have been examined, increases in litter size reduce the rate of prenatal growth and thus birth weight. The influence of litter size on fetal size is manifested through a 'local effect' and a 'general effect' (Eckstein *et al.*, 1955). The effect of other nearby fetuses in the same uterine horn is the 'local effect' and that of any fetus anywhere in the uterus is the 'general effect'. The ratio of each factor varies with the species. Studies in guinea pigs, mice, rabbits and humans support a haemodynamic explanation for this phenomenon, i.e. retardation of growth is due to restriction of the channel (i.e. placental exchange) which links mother and fetus rather than to a limitation of maternal nutritional substances or uterine space (McKeown *et al.*, 1976).

The weight of the entire litter relative to maternal weight shows an inverse relationship, with the smaller mammals having rapidly growing, relatively heavier litters as compared with larger mammalian species. Two extreme examples of this are the guinea pig, which has a litter weight of more than 50% of maternal weight, and the polar bear fetus, which weighs 0.3% of mean maternal weight (Gewolb and Warshaw, 1983). Fetal genes may contribute to these interspecies differences in fetal growth rate, i.e. those species reaching maturity earlier in post-natal life are genetically programmed for a rapid rate of prenatal growth, while other mammals, including humans, have a correspondingly lower fetal growth rate and hence a lower fetal–maternal weight ratio (McKeown *et al.*, 1976).

These litter effects are determined in part by the duration of pregnancy. In placental mammals, the length of gestation (G) is demonstrated to be related to body weight (W) by the equation $G = a \times W^b$, where a

varies with the type of placenta and *b* is approximately the same (0.17) for all terrestrial animals, but significantly smaller (0.04) for aquatic animals (Kihlstrom, 1972). Prolongation of gestation for most mammals is associated as a rule with reduction in litter size and increase in maturity at birth. In certain mammals, including most of the large ones, natural selection has resulted in increased maturity at birth. The increase in maturity has been associated with, and perhaps may require, prolongation of pregnancy and reduction in the number of young, since large litters are incompatible with long gestations. In these circumstances, an increase in litter size above the norm for which a species is adapted is associated with retardation of fetal growth (McKeown *et al.*, 1976).

(i) Placental size and function

There is a close relationship between placental size and embryo size which has been observed in many mammalian species. The weight of the fetus increases with increasing weight of the placenta in guinea pigs, rabbits, pigs, sheep and mice (Dawes, 1973). Although numerous investigators (Abramovich, 1969; Gellen and Gyori, 1969) have found a positive correlation between fetal and placental size in humans, no differences have been found between normal and large or small for gestational age infants when fetal–placental ratios have been corrected for gestational age (Molteni *et al.*, 1978). This observation emphasizes the importance of placental function rather than placental size. Specifically, uterine and umbilical blood flow, intraplacental metabolism and hormonal control and substrate flux determine fetal growth. Although large babies almost always have large placentas, the converse is not always true. Certain clinical conditions such as high altitude (Kruger and Arias-Stella, 1970), placental haemangiomata and some chromosomal anomalies (Polani, 1974) are characterized by large non-oedematous placentas and growth-retarded fetuses.

Placental blood flow is clearly crucial in regulating the transfer of substrate (e.g. glucose, amino acids, fatty acids; Kretchmer *et al.*, 1989) to both placenta and fetus (Kretchmer *et al.*, 1989). Numerous studies in animals have utilized either ligation or embolization of uterine vessels or surgical reduction of placental area to induce intrauterine growth retardation (Dawes, 1976; Cassady, 1981). Clinical conditions presumably associated with diminished placental blood flow, such as maternal toxaemia, severe diabetes and long-standing hypertension, also result in an increased incidence of small for gestational age babies (Gewolb and Warshaw, 1983).

Placental metabolism is an important variable in determining fetal growth, since it accounts for about half of the apparent utilization of glucose delivered to the placental circulation (Morriss, 1981). Placental production of various polypeptide hormones (human chorionic gonadotrophin, placental adenyl cyclase, human placental lactogen) and steroids (oestrogen and progestins) may be involved in the regulation of substrate flow to the fetus (Chatterjee and Munro, 1977; Mulay *et al.*, 1980).

The growth of the fetus may be adversely affected by one or more conditions leading to placental restriction:

1. reduction in placental size due to abnormal differentiation or limitation of maternal nutrition;
2. diminished uterine blood flow due to various pathological conditions;
3. abnormal development of placental membranes which adversely affects membrane transport properties; and
4. disorders in fetal placental circulation.

6.5 PRENATAL MORTALITY

Spontaneous prenatal mortality is a widespread phenomenon, which occurs in all

species and strains of otherwise normal and fertile domestic and laboratory animals as well as human and non-human primates. Termination of pregnancy may occur at several stages: (a) between fertilization and implantation; (b) during the time of implantation; or (c) after implantation at various stages of embryo or fetal development.

6.5.1 HUMAN AND NON-HUMAN PRIMATES

(a) Incidence

Human fecundability, i.e. the probability of producing a full-term infant per menstrual cycle during which intercourse occurs, is very low when compared with the fertility of domestic animals. Demographic studies have shown that fecundability ranges from 21 to 28% between the age of 20 and 30 years (R.V. Short, 1979). Prenatal mortality at different stages in gestation contributes markedly to this low fertility rate. The estimated frequency of losses after clinical recognition of pregnancy is 10–25%, depending on the epidemiological approach. It has been estimated from the results of studies using different methodological approaches (Hertig *et al.*, 1959; French and Bierman, 1962; Hertig, 1967; Leridon, 1977; J.F. Miller *et al.*, 1980; Rolfe, 1982; Shiota *et al.*, 1987) that a much greater rate of loss of fertilized ova occurs preclinically, i.e. before or during the implantation period (Kline and Stein, 1985). Figure 6.11 graphically illustrates the probability of spontaneous abortion during human pregnancy based on this analysis of the literature.

Prenatal mortality occurs throughout gestation in non-human primates, but the level is particularly high during the early embryonic stages when pregnancy confirmation may be uncertain and/or unreliable. Assessment of the magnitude of early embryonic mortality is additionally complicated by the occurrence of 'placental bleeding', which is frequently seen in macaques during the second and third weeks of normal pregnancy (Hendrickx and Binkerd, 1980). Information on embryonic death during the peri-implantation period has been provided by morphological examination of normal and abnormal embryos in the rhesus monkey (Heuser and Streeter, 1941), baboon (Hendrickx and Binkerd, 1980) and chimpanzee (Heuser, 1940). These studies indicate pre-implantation losses of 26.3% and 25.0% for rhesus monkeys and baboons respectively. Histological features of abnormal embryos at this stage are similar to those described for human embryos and include cell and nuclear fragmentation, organellar aggregation and irregularity in blastomere size and shape (Enders *et al.*, 1982). Corresponding values during the post-implantation period (approximately gestational days 10–22) have been estimated at 14.3% in baboons, 28% in rhesus monkeys and 50% in chimpanzees. Characteristics of embryos lost at this stage, i.e. embryonic degeneration, retardation and asymmetry of the embryonic disc, and abnormalities of the extraembryonic membranes, also parallel observations in defective human embryos.

During the subsequent period of organogenesis (approximately days 20–50), the incidence of embryonic loss is significantly lower for several non-human primates than in the peri-implantation period. Microscopic examination of embryos of five Old World species indicate embryonic mortality rates of 2.4–18.2% during organogenesis (Hendrickx and Binkerd, 1980). The increased frequency of prenatal loss during the early stages of pregnancy has also been well demonstrated in a marmoset breeding colony (Heger *et al.*, 1988). Following a 30% implantation failure rate (including missed fertilization and pre-implantation losses), 28% of implantations failed prior to organogenesis. Lower loss rates occurred during organogenesis (20%) and the fetal period (4%) in this study.

Reported figures for the incidence of stillbirths among 11 species of indoor-housed primate colonies, including the green mon-

key, mangabey, baboon, langur and five species of macaques, range from 5.9% to 20% (Hendrickx and Binkerd, 1980). These rates are markedly higher than the 2.7% figure reported for free-ranging rhesus monkeys (Koford, 1965) and may be attributable to the artificial housing conditions.

(b) Aetiology

The primary factors which have been implicated in prenatal mortality in human and non-human primates are abnormalities of embryonic development, adverse maternal factors and external embryolethal influences (see Rushton, 1985, and Kochenour, 1987, for reviews).

Genetic factors

There is considerable information on the large contribution of an abnormal fetal karyotype to spontaneous abortions in humans (Carr, 1967; J. Boué *et al.* 1975; A. Boué *et al.* 1985; Jacobs, 1982; Warburton, 1987). In most, but not all studies, the proportion of chromosomal anomalies tends to be low (14–26%) in abortions before 8 weeks, highest (40–65%) in losses at 8 – 15 weeks and

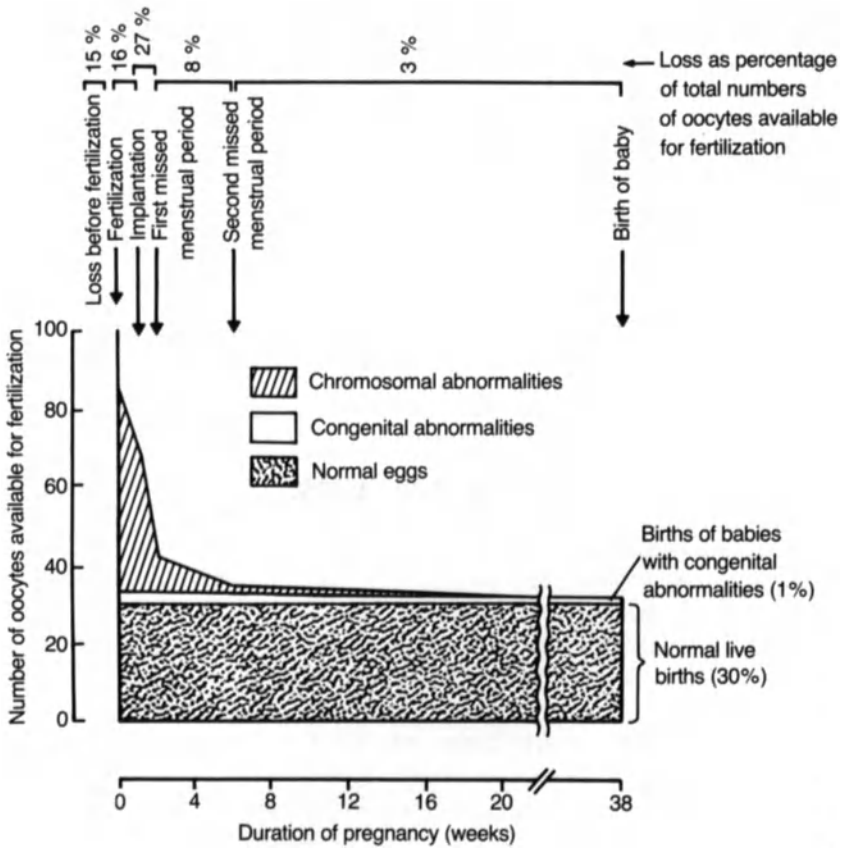

Figure 6.11 The probability of spontaneous abortion during human pregnancy based on the current literature. From these studies it has been estimated that 75% of all fertilizations will result in embryonic or fetal death. The largest proportion of losses occurs in early pregnancy, i.e. 30% prior to implantation, 18% after implantation and the remaining 27% after day 14 of gestation. (Reproduced with permission from Begley *et al.*, 1980.)

decreasing to about 5–10% in abortions after the 20th week of gestation (Leridon, 1977; Warburton *et al.*, 1980). It should be noted that the rate of chromosome anomaly during early pregnancy may be artificially low because of the difficulty in documenting these defects in very early spontaneous abortions (i.e. at less than 4 weeks' gestation). Among chromosomally abnormal spontaneous abortions, approximately one-half are trisomic for one or more chromosomes, 15% are triploid and 20% are monosomy X. The remainder consist of a variety of post-fertilization errors (tetraploidy, hypertetraploidy, hypertriploidy, mosaicism), structural anomalies and double anomalies (Warburton *et al.*, 1980). Both the prevalence and types of chromosomal anomalies observed among recognized spontaneous abortions are considerably greater than those observed among stillbirths and livebirths. This reflects the fact that the majority of chromosomal anomalies (e.g. trisomies, triploidies, monosomy X) are incompatible, or rarely compatible, with survival to birth (Kline and Stein, 1987; J.L. Simpson, 1990). Hormonal imbalance in women, intrafollicular over maturity of ova and the ageing of gamete in the female reproductive tract before gamete fusion have been cited as the most plausible reasons for the high frequency of spontaneous chromosomal aberrations (Dyban and Baranov, 1987). Although chromosomal abnormalities remain the most common single finding associated with abortion, a simple cause-and-effect relationship has not been established between karyotype and abortion in humans (Rushton, 1987). Insufficient data are available to confirm a similarly high contribution of genetic abnormalities to the incidence of abortion in non-human primates.

Maternal factors

Age, parity The association of spontaneous abortion with maternal age in humans has been attributed to two independent causes:

1. the association of trisomic conceptions with age; and
2. the risk of abortion of euploid conceptions with age.

The risk of trisomy at conception, as observed in abortions, rises with maternal age. Some trisomies (e.g. 7, 10, 17, 18, 20–22) contribute more to the increasing risk with age than others (e.g. 2, 8, 9, 16) (Stein *et al.*, 1980). Several studies have shown that the risk of abortion, particularly first abortions (Warburton and Fraser, 1964), rises with increasing maternal age (Naylor, 1974; Selvin and Garfinkel, 1976; Harlap *et al.*, 1980), paternal age (Selvin and Garfinkel, 1976) and parity (Warburton and Fraser, 1964; Naylor, 1974; Harlap *et al.*, 1980). Possible explanations for a non-genetic maternal age effect are cumulative exposure to toxins, greater opportunity to acquire chronic infection, diminished luteal response and poorly vascularized endometrium (J.L. Simpson, 1990). There is little evidence that the increasing difficulty in maintaining pregnancy in older women is due to primary changes in the uterus (Talbert, 1968). Age and parity have also been cited as possible maternal causes of reproductive failure in macaques (see Small, 1982).

Nutrition Although the relationship between nutritional deprivation and reproductive outcome in humans has not been clearly established, it appears that significant restriction of maternal nutrition affects fetal growth, birth weight and post-natal mortality, rather than intrauterine mortality (Kohrs *et al.*, 1976; Susser and Stein, 1980). Studies carried out in rhesus monkeys indicate that normal prenatal growth is maintained on a protein-deficient diet owing to the ability of the gravid primate uterus to adapt to such nutritional restriction (Riopelle, 1985). However, severe protein deprivation during pregnancy has been found to result in maternal as well as fetal mortality in these species (Kohrs *et al.*, 1976).

Health Several medical illnesses have been implicated in causing habitual abortions in women. It has been speculated that the higher rate of fetal wastage associated with systemic lupus erythematosus (Fraga *et al.*, 1973) may be due to immune complex deposition on trophoblastic basement membrane (Grennan *et al.*, 1978) and fetal cardiac anomalies (Chameides *et al.*, 1977). The abnormally high rates of fetal loss (>50%) in women with congenital cardiac disease may be attributable to deficits in the supply of well-oxygenated blood to the developing fetus (McAnulty *et al.*, 1982). Severe maternal illnesses which have also been associated with increased prenatal mortality are Wilson's disease, phenylketonuria, haematological disorders (e.g. haemoglobinopathies, aplastic anaemia), poorly controlled type 1 diabetes mellitus and renal disease with associated hypertension (Felding, 1968; J.L. Simpson, 1990).

Studies have been undertaken in rhesus monkeys to examine the effects of experimentally induced diabetes mellitus on fetal metabolism and growth (Mintz *et al.*, 1972). Administration of the pancreatic beta-cell cytotoxin, streptozotocin, before conception and during the first trimester of pregnancy is associated with a 27% mortality rate during the second and third trimesters. The drug effects included fetal hyperinsulinaemia, enhanced pancreatic islet cell responsiveness, enlarged placentas and polyhydramnios.

Infections Abortion, intrauterine growth retardation, congenital anomalies or severe disease of the newborn may be a result of certain maternal infections. Several reviews of this topic provide information on the major clinical features as well as the fetal risk of infections that have been implicated in obstetric pathology (Sever, 1980; Remington and Klein, 1983; Persaud *et al.*, 1985; Benirschke and Robb, 1987). Intrauterine infection as an aetiological agent for recurrent pregnancy wastage remains a highly controversial clinical question because of the difficulty in separating the adverse effect of an infection on the developing fetus from its effect on the mother (Rushton, 1985).

The following micro-organisms and viruses have been associated with early spontaneous abortion: congenital rubella and rubeola viruses, *Treponema pallidum* (syphilis) (Sever, 1980), smallpox virus (Lynch, 1932), vaccinia (M.M. Levine *et al.*, 1974), *Salmonella typhosa* (Hicks and French, 1905), *Vibrio fetus* (Eden, 1966), *Plasmodium* (Preston, 1942), *Chlamydia* (Schachter, 1967), cytomegalovirus (Kriel *et al.*, 1970; Sever, 1980), *Candida* (Ho and Aterman, 1970), *Brucella* (Sarram *et al.*, 1974), herpesvirus (Nahmias *et al.*, 1971; Sever, 1980), *Toxoplasma* (Zighelboim *et al.*, 1968; Kimball *et al.*, 1971; Sever, 1980) and *Mycoplasma* (Kundsin *et al.*, 1967).

Both spontaneous and experimentally induced maternal infections have been shown to be important factors in reproductive failure in some species of non-human primates. The following infections have been implicated as causative agents in the observed high level of abortions or stillbirths in non-human primates: Chagas' disease (*Trypanosoma cruzi*-like) in marmosets (Lushbaugh *et al.*, 1969); T-strain mycoplasmas in talapoins (*Miopethecas talapoin*) and patas monkeys (*Erythrocebus patas*) (Kundsin *et al.*, 1975); measles virus in rhesus monkeys (Hertig *et al.*, 1971); rubella virus in crab-eating monkeys and baboons and mumps virus in rhesus monkeys (Hendrickx, 1966; Delahunt and Rieser, 1967; London *et al.*, 1971).

Stress Although several clinical studies have shown an association between psychological disturbances and habitual abortion, evidence demonstrating a cause-and-effect relationship is lacking (Weil and Tupper, 1960; Grimm, 1962). Among the psychological stresses related to an adverse pregnancy outcome are bereavement (Kaij *et al.*, 1969;

Mandell and Wolfe, 1974) and neurotic illnesses (Mandelbrote and Monro, 1964). Although difficult to substantiate, physical stress (e.g. heavy lifting and physical effort) has also been implicated as a risk factor in spontaneous abortions (Goulet and Theriault, 1987). The physiological mechanism remains unclear; however, fetal hyperthermia and changes in circulating maternal hormone levels leading to uterine contractility have been proposed.

Observations in rhesus monkey colonies indicate that maternal psychological factors may be as important as maternal physiological conditions during pregnancy for fetal viability. The high level of abortion (50–70%) in pregnant animals captured in a native environment and shipped to the USA for experimental purposes may be partially attributable to the high degree of stress associated with handling techniques (Myers, 1972). Experiments carried out in rhesus monkeys to study the effect of maternal stress on pregnancy indicate that excitability and pain associated with labour and delivery may have deleterious effects on the fetus. Brief episodes of experimentally induced stress in near-term rhesus monkeys cause fetal deterioration in the form of fetal bradycardia and decreased arterial oxygenation (Morishima *et al.*, 1978) or fetal asphyxia and concomitant disturbances in acid–base balance (Myers, 1975) as a result of impaired uteroplacental circulation. Boot *et al.* (1985) have also demonstrated that housing conditions (i.e. cage size and density) can adversely affect pregnancy outcome which may be related to stress in cynomolgus monkeys.

Immunological abnormalities Disturbances in the maternal immune system which normally allows the fetus to survive within the uterus without being rejected may play a role in early abortion. Evidence suggests that immunological aberrations, rather than genetic factors, may have a greater contribution to repeated pregnancy failure (J.R. Scott *et al.*, 1987). Although the mechanisms are unclear, the increased rate of fetal death associated with autoimmune disease may be related to uteroplacental vascular lesions (Branch, 1987). Potential alloimmune mechanisms in pregnancy wastage include:

1. absence of serum blocking antibodies which are normally produced by the maternal immune system as an initial response to the implantation of the blastocyst (Rocklin *et al.*, 1976);
2. homozygosity of histocompatibility locus antigens (HLA) between partners which may result in a failure of the maternal immune system to produce blocking antibodies (Komlos *et al.*, 1977; Beer *et al.*, 1981);
3. reduction in early pregnancy factor (EPF), which normally suppresses maternal lymphocyte activity and immune response to the fetal allograft during early pregnancy (Smart *et al.*, 1981);
4. ABO blood group incompatibility between the father and mother (Lauritsen *et al.*, 1976);
5. the existence of antisperm antibodies in the mother which may cross-react with cleaving embryos (W.R. Jones, 1976);
6. the aberrant expression of transplantation antigens on the placental surface (T.J. Gill, 1990); and
7. the presence of anti-phospholipid antibodies in the mother (H.L. Brown, 1991).

Endocrine

It is uncertain whether the majority of endocrine disturbances reported in association with spontaneous abortion reflect the failure of the pregnancy rather than the cause of that failure (Rushton, 1985). Although still controversial, it has been suggested that progesterone deficiency may play a role in some cases of infertility. The incidence of luteal phase deficiency (LPD) has been reported to range from 3.7% (G.S. Jones and Pourmand, 1962)

to 10.7% (Gillam, 1955) in infertile patients and to be 35% in habitual aborters (G.E.S. Jones and Delfs, 1951).

Uterine factors

A variety of congenital anomalies of the uterus have been implicated as causative factors in reproductive wastage in humans. These Mullerian fusion anomalies include unicornuate, didelphic, septate and bicornuate uteri (Rock and Jones, 1977; Rock and Zacur, 1983). An increased rate of early spontaneous abortion has also been associated with congenital alterations in uterine blood supply, which may result in poor placental growth and development (Burchell *et al.*, 1978).

Habitual abortion has been noted in 14% (238 of 1973) of patients with uterine adhesions reviewed in the literature (Schenker and Margalioth, 1982). Early pregnancy loss may be due to the decreased dimension of the uterine cavity and absence of sufficient endometrium for fetal growth or defective vascularization of scanty endometrium (Polishuk *et al.*, 1977; Rock and Zacur, 1983). Uterine leiomyomas responsible for repetitive pregnancy loss have been estimated at approximately 18% (Robins, 1972). Alterations in endometrial stroma or vasculature leading to abnormal implantation or decreased blood supply to the developing placenta and fetus may be causes of fetal wastage associated with fibromyomas (Farrer-Brown *et al.*, 1971). Although it is difficult to document dystocia in non-human primates due to the high incidence of night births, contributing causes may include cephalopelvic disproportion, positional abnormalities, uterine malformation and inertia, uncontrolled haemorrhage and toxaemia (Hendrickx and Binkerd, 1980). Adverse pregnancy outcome (i.e. stillbirth) has also been associated with breech rather than cephalic presentation in term pregnancies of cynomolgus (Cho *et al.*, 1985) and pig-tailed (Goodlin and Sackett, 1983) macaques.

Various types of placental insufficiency have been associated with high rates of fetal mortality in the human population as well as in some non-human primate species. These include infections of the placenta (placentitis), impaired placental circulation (infarctions and abruptio placenta) and abnormal placental location (placenta praevia).

Placental infections in humans are often responsible for fetal death and sometimes associated with maternal morbidity and mortality. Infections reach the placenta by ascent from the lower genital tract, by contiguity with endomyometrial lesions, transtubally and via the maternal circulation. While bacteria are the most common pathogens to the placenta, fungal, viral and parasitic infections also contribute to this type of placental pathology (Benirschke and Driscoll, 1967; Rushton, 1985).

In a histological study of stillborn fetuses from a variety of non-human primate species, necropsy examination confirmed placentitis in seven of eight cases as the primary cause of fetal demise. The most commonly isolated organisms which were responsible for ascending genital infections leading to placentitis and subsequent fetal anoxia were group D streptococci and β-haemolytic, coagulase-positive *Staphylococcus aureus*. Infection of the placenta was accompanied by infiltration of inflammatory cells, oedema, necrosis and haemorrhage which interfered with fetal oxygenation (Andrews, 1974). Gram-positive cocci, especially α-haemolytic *Streptococcus viridans*, were implicated in 11 of 17 cases of abortions and stillbirths in rhesus monkeys (Swindle *et al.*, 1982). Acute placentitis and fetal bronchopneumonia were the most consistent histopathological findings in these cases.

Abruptio placenta, a premature separation of the placenta from the endometrial surface, is a serious obstetric complication which occurs in 1–2% of human pregnancies. This condition accounts for 1% of maternal mortality and 15% of all perinatal mortalities. The

mortality rate for infants of abruption ranges from 30–50% (Berstein, 1981). The reported incidence of abruptio placenta in 1200 rhesus monkey pregnancies was 0.6% and was also associated with a high degree of fetal death (Myers, 1972). The recent use of ultrasonography in primate breeding colonies has considerably reduced the mortality associated with this condition. Of nine concealed abruptions detected over a 4-year period (1% incidence), no maternal deaths occurred as all animals were scheduled for hysterotomies upon ultrasonic detection of retroplacental or subchorionic haemorrhage (Tarantal and Hendrickx, 1988b).

Placenta praevia, which is characterized by partial or complete placental localization over the cervical outlet, may be associated with a high risk of bleeding and an increased hazard of ascending infection during pregnancy. The clinical frequency of this condition averages approximately one in 250 births (0.4%) (Green, 1984) and the risk of recurrent placenta praevia is as high as 8% (Kelly and Iffy, 1981). Perinatal survival associated with this problem is critically dependent on the gestational age at delivery. Seventy-three per cent of all perinatal deaths are attributable to praevia deliveries prior to 32 weeks' gestation, which occur in 20% of affected women (Cotton *et al.*, 1980). This condition also leads to an increased level of fetal loss in rhesus monkeys, in which the reported incidence has been estimated at 0.5% among 1200 cases (Myers, 1972; Hendrickx and Binkerd, 1980).

Environmental factors

Intrauterine death is the most common result of a teratogenic insult early in embryonic development when the undifferentiated embryonic cells are more refractory to teratogenesis. After the initiation of organogenesis, malformations of specific organs or systems, in addition to variable degrees of embryolethality and growth retardation, are the primary manifestations of hazardous environmental factors. Interference with development during the subsequent periods of histogenesis and functional maturation would be expected to result primarily in growth retardation and functional disturbances.

The relationship between intrauterine death and malformations following exposure to a teratogenic insult has not been clearly established. Some authorities view death and abnormal development as simply different degrees of reaction to the same stimuli, with the rate of mortality and the rate and severity of malformations increasing in roughly parallel fashion as dosage is increased (Beck and Lloyd, 1963; J.G. Wilson, 1959). Other investigators (Gebhardt, 1970; Tuchmann-Duplessis, 1970) cite a distinction between embryolethality and teratogenicity as unrelated responses. This issue is a critical one in the interpretation of teratological evaluations and may reflect interspecies differences in sensitivity to environmental toxins. These could be attributed to differences in genetic make-up as well as species-specific reproductive features, particularly length of gestation (Schardein, 1976).

It has been suggested that the characteristics of the agent itself may determine the pattern of response, i.e. environmental teratogens can be divided into those that cause non-specific fetal death and those that cause malformations which result in fetal death. It may be possible that one agent, under different circumstances (e.g. dose and time of exposure), may exhibit both these properties (Kalter, 1980).

In a recent tabulation of potential human developmental toxicants, the primary manifestation of adverse outcome was fetal/neonatal death. Among the agents associated with pregnancy loss were cigarette smoking and alcohol in addition to drugs (e.g. retinoic acid) and environmental chemicals (e.g. lead, organic mercury) (Schardein and Keller, 1989).

Several agents have been shown to cause embryolethality in the absence of malforma-

tions as the primary manifestation of developmental toxicity in the rhesus, cynomolgus and pig-tailed macaques. These include a variety of natural and synthetic sex steroids in addition to antineoplastic agents (methotrexate, 5-fluorouracil), therapeutic drugs (norfloxacin, diphenylhydantoin, acetazolamide) and alcohol (Binkerd *et al.*, 1988). A number of additional agents (e.g. valproic acid, triamcinolone acetonide, retinoic acid) are associated with malformations and/or intrauterine growth retardation in addition to prenatal mortality in a variety of primate species (Hendrickx and Binkerd, 1990).

6.5.2 DOMESTIC AND LABORATORY SPECIES

(a) Incidence

The methods used to demonstrate the existence and extent of prenatal death are variable depending on the species and the period of gestation in question. In cattle, estimates of early pregnancy loss are made by calculation of the fertilization rate and the number of fertilized ova that fail to continue development following slaughter at different intervals after mating (Laing, 1949). Although less reliable, calculation of the return to oestrus interval following mating has also been used as a reflection of the extent of embryonic death (D.L. Stewart, 1952). Information on prenatal death occurring during the late embryonic and fetal periods has been obtained by comparison of the results of pregnancy diagnosis by rectal palpation at 30–40 days with subsequent pregnancy diagnosis or with calving rate (Hanly, 1961).

In the pig, since total loss of pregnancy is apparently uncommon, the effect of prenatal death takes the form of a reduction in litter size (R.F. Wilson *et al.*, 1949) and information is obtained by comparison of the number of corpora lutea with the number of surviving embryos or with litter size (King and Young, 1957). In sheep, the methods based on slaughter and on delay in oestrous return interval have been used (Hanly, 1961).

In most domestic animals the highest rate of prenatal mortality occurs during the first 4 weeks of gestation which coincides with the period of rapid growth and differentiation of the embryo and the extraembryonic membranes. In cattle, which are usually monotocous, fertilization failure rates of 15% have been reported (H. Boyd *et al.*, 1969) and estimates of embryonic mortality range from 15–34% during the first 6 weeks of gestation (Robinson, 1957; R.V. Short, 1979). The subsequent losses before term are low and range from 3–5% (Ulberg, 1962). Egg transfer studies indicate that asynchrony between the endocrine state of the uterus and the stage of development of the fertilized egg results in embryonic death (Betteridge and Mitchell, 1974). Proximity to another embryo also reduces the chances of survival, as shown by a doubling of the chance of twins when one egg is shed from each ovary as compared with both from one (Gordon *et al.*, 1962) or when one is transferred to each uterine horn (Rowson *et al.*, 1971). Infectious agents have been reported to account for approximately 23% of abortions and stillbirths in cattle in the USA (Hubbert *et al.*, 1973).

In sheep, which are usually polytocous, there is a high fertilization rate of 90–100%, but 20–30% of these fertilized ova fail to develop to full-term lambs, with most of the losses occurring before day 18 of pregnancy (Quinlivan *et al.*, 1966; Edey, 1976). Infectious agents rank high as the primary cause of early embryonic loss in this species (W.J. Scott, 1978). Additional contributing factors include high ambient temperature, nutritional extremes and genetic abnormalities. The stillbirth rate in sheep has been estimated at 2–13% (Terrill, 1962).

The pig is another polytocous species with a high fertilization rate (95–100%) which experiences the greatest level of embryo loss, 25–50%, during the first 25 days of pregnancy (Scofield, 1975; Selby, 1978). While most

abortions result from infectious diseases, other causes include systemic diseases, high ambient temperature, physical injuries and chemicals or drugs with abortifacient actions (e.g. oestrogens). The estimated 6% stillbirth rate in this species has been attributed to maternal dystocia, nutrition, age and health as well as hereditary factors (Day, 1962).

The average abortion rate is lower in horses, i.e. approximately 10%. Some reports indicate that the mares are endocrinologically most susceptible to abortions during the fifth month owing to hormonal deficiencies that can result when the placenta takes over progesterone synthesis from the ovary. Decreased progesterone production during the 10th gestational month also accounts for the higher frequency of fetal death during this period (Nishikawa and Hafez, 1962).

Prenatal mortality in laboratory species also occurs to the greatest degree during early pregnancy. The estimation of pre-implantation embryo loss is most commonly based on a comparison of the number of corpora lutea with the number of implantation sites. However, the accuracy of this method is limited since it makes no allowance for failed fertilization (J.G. Wilson, 1978). Further, the number of corpora lutea may not correspond to the number of ova released because of the occurrence of polyovular follicles and anovular corpora lutea that have been reported for some species (Kent, 1962; Horowitz, 1967). Post-implantation loss is more accurately assessed by comparing the number of live fetuses at term with the number of implantation sites in those species with short gestation periods that have recognizable signs of endometrial decidualization at term, e.g. rats and other rodents (J.G. Wilson, 1978).

In the rabbit, there is an estimated 10–11% loss prior to implantation and 15–18% after implantation (Adams, 1960; Palmer, 1978). In addition to such extraneous causes as disease, poor nutrition and treatment with embryotoxic agents, variability in prenatal mortality is largely genetically determined. While asynchrony between embryo development and endometrial stage accounts for a large part of the pre-implantation mortality (Noyes and Dickman, 1960), deficiency in placental development or inadequacy of endometrial vascular supply contributes to post-implantation losses (Hafez and Tsutsumi, 1966).

In laboratory rats pre-implantation loss ranges from 6–8% and post-implantation loss between 5% and 7% (J.G. Wilson, 1978). The corresponding overall prenatal loss in wild rats is 25% (Perry, 1945). In ferrets the pre- and post-implantation loss has been estimated at 15% (Marston and Kelly, 1969). Only post-implantation losses have been reported in guinea pigs (5–7%) (Hoar, 1978; Shenefelt, 1978) and golden hamsters (7% average) (Shenefelt, 1978). Reported values for prenatal loss in wild and laboratory mice are 31–36% and 24–36% respectively (Berry, 1981). Very little information is available on the level of prenatal mortality in dogs and cats. However, a 5% rate of resorptions on day 60 (Earl, 1978) and a 7% rate of stillbirths (Bowden *et al.*, 1963) has been reported for dogs.

(b) Aetiology

Prenatal mortality in domestic and laboratory animals can be due to genetic factors, maternal factors or adverse environmental conditions (Wilmut *et al.*, 1986).

Genetic factors

The frequency of embryonic loss in domestic animals is partially determined by the genetic make-up of the sire (Perry, 1960) and the dam (L.N. Baker *et al.*, 1958) as well as the breeding system. In swine (Squiers *et al.*, 1952), cows (Hawk *et al.*, 1955; Mares *et al.*, 1958) and rabbits (Palmer, 1978) inbreeding increases and cross-breeding reduces the

embryonic mortality rate. Breed differences in sheep affect the level of prenatal death, i.e. some breeds are more susceptible to embryonic loss than others (Foote *et al.*, 1959).

The effect of semen characteristics on embryonic mortality is pronounced, especially where artificial insemination is practised. In the pig (Dziuk and Henshaw, 1958) and the sheep (Dutt and Simpson, 1957), the quality of semen used for artificial insemination by donor (AID) has a direct effect on embryo survival. Knudsen (1956) has correlated abnormal chromosome make-up in bull sperm with increased embryonic death, presumably as a result of an unbalanced genetic constitution of the embryo.

There appears to be great variability between species, breeds, strains and families in the incidence and types of aberration causing embryonic mortality (Gustavsson, 1980). Spontaneous chromosome aberrations have been estimated to occur in embryos in frequencies of 1–8% in the rabbit (Hofsaess and Meachan, 1971; Martin and Shaver, 1972; Fechheimer and Beatty, 1974) and 12.5% in the pig (McFeely, 1967). The predominant aberrant karyotypes are triploids, and it has been shown that at least in species such as the pregnant rabbit they survive until mid-term (Bomsel-Helmreich, 1965). Haploidy, pure heteroploidy and pure polyploidy are rarely observed in domestic animals born at full-term since most affected fetuses probably die early in gestation (Gustavsson, 1980). Embryonic studies have demonstrated the occurrence of polyploidy in pig blastocysts (Moon *et al.*, 1975), tetraploidy in cattle embryos (McFeely and Rajakoski, 1968) and trisomy in cleavage-stage sheep embryos (Long and Williams, 1978). Unbalanced karyotypes and autosomal trisomy in particular, are much less common in laboratory rats and mice than in humans. The most common chromosome aberration in these rodents is triploidy, which is inevitably lethal by mid-gestation (Dyban and Baranov, 1987). In both species, the presence of major histocompatablity (MHC)-linked recessive lethal genes is associated with *in utero* death at different stages of development.

Maternal factors

Age It has been well established that the mean litter size at birth decreases with advancing maternal age in many polytocous species, including the rat (Ingram *et al.*, 1958), mouse (E.C. Jones and Krohn, 1961), pig (Perry, 1954) and hamster (Soderwall *et al.*, 1960). This decrease is well correlated with increasing levels of prenatal mortality (Hollander and Strong, 1950; Finn, 1962; Connors *et al.*, 1972; Kalter, 1975) rather than with exhaustion of oocytes in many mammalian species (E.C. Jones and Krohn, 1961; Talbert, 1978). In contrast, lower levels of embryonic mortality associated with increasing age have been reported in cattle (Erb and Holtz, 1958). The relative importance of ageing of ova and the uterus as factors in the decline of reproductive capacity appears to vary considerably from one species to another. Data presently available indicate that this age change in the mouse is almost exclusively the result of a decline in the ability of the uterus to support pregnancy (Talbert and Krohn, 1966; Gosden, 1975), whereas in the hamster (Blaha, 1964), and to a lesser degree in the rabbit (Adams, 1970; Maurer and Foote, 1971), degenerative changes in the ovum and in the uterus both promote reproductive decline.

Nutrition There is considerable evidence that specific nutrients, level of feeding and/or body condition may influence conception rates and embryonic survival in most species of domestic and laboratory mammals (Rattray, 1977). In swine (Self *et al.*, 1955; Haines *et al.*, 1959) and sheep (El-Sheikh *et al.*, 1955; Foote *et al.*, 1959), high caloric intake or continuous unlimited feeding increases ovulation rate as well as embryonic mortality up

to the time of implantation. The effect of caloric intake on prenatal death in cattle is controversial (Hafez, 1967; Rattray, 1977).

Studies in rats (Nelson and Evans, 1953; Berg, 1967) have verified the requirement for an adequate protein source in the earliest stages of placental and fetal development. A high level of early resorption in this species results when animals receive a severely protein-restricted diet during early pregnancy. Experimental studies in mice have shown that decidual hemorrhage and necrosis accompanied by embryonic mortality can be induced by short-term fasting (McClure, 1959, 1961).

Infections Infectious abortions account for a significant portion of the reported reproductive failure in several domestic animals (Hubbert *et al.*, 1973; W.J. Scott, 1978; Holter and Andrews, 1979). Table 6.8 lists the major infectious diseases and organisms which have been identified in the aetiology of prenatal mortality in cattle, sheep, swine, goats, dogs, cats and horses.

Overcrowding in utero

Transuterine migration of embryos is of special physiological significance in certain polytocous species for equal distribution of conceptuses between the two uterine horns. In swine there is a high incidence of embryonic mortality in the absence of migration (Smidt, 1962). Embryo transfer experiments in cattle have demonstrated a greater degree of embryonic loss in cows which had received two transferred embryos in a single uterine horn, presumably because of overcrowding and intrauterine competition for nutrients (Rowson *et al.*, 1971). In rabbits (Hafez, 1964) and guinea pigs (Eckstein *et al.*, 1955), as the number of implantations rise, the vascular supply to each site is reduced, which restricts placental development and causes increased levels of *in utero* death.

Environmental factors

Surveys of veterinary diagnostic laboratory data in the USA have verified the following environmental toxins as causative factors in non-infectious abortions in cattle and swine: mycotoxicoses, nitrate–nitrite compounds, carbon monoxide, selenium deficiency, lead poisoning, chlorinated naphthalene, locoweed, pine needle and perennial broomwood (Stuart and Oehme, 1982).

Increased embryonic mortality occurs in a number of species following exposure of the female to elevated ambient temperature (Ulberg, 1958; Dutt, 1960). High summer temperature has been shown to have a detrimental effect on spermatogenic activity in rams, which causes decreased fertilization as well as increased embryonic mortality rates (Dutt and Simpson, 1957). In the rabbit, transfer of fertilized ova following culture at 40°C results in increased levels of post-implantation mortality (Alliston *et al.*, 1965). Reciprocal ova transplantation experiments in this species have shown that elevated temperatures have adverse effects on the maternal tissues rather than on the embryo (Shah, 1956). Experimentally induced thermal stress in cattle (Ragsdale *et al.*, 1948), pigs (Tompkins *et al.*, 1967) and rats (Hsu, 1948) results in a high proportion of embryonic mortality.

Studies carried out in laboratory species to develop animal models for potential human teratogens have demonstrated a strong relationship between fetal wastage and exposure to potential human teratogens for several substances. Several agents are known, when given at sensitive times in gestation, to produce mainly or only embryolethal effects in test species, e.g. chloramphenicol, actinomycin D and other antibacterial agents, most folate antagonists, inhibitors of protein synthesis and many post-coital anti-fertility drugs (Wilson, 1980). Other agents which produce increased levels of prenatal death in addition to malformations include: alcohol

Table 6.8 Infectious diseases affecting reproduction in domestic animals (Reproduced with permission from Osebold, 1977)

Disease	*Species*	*Aetiology*	*Reproductive effect*
Bacterial infections			
Brucellosis	Cattle	*Brucella abortus*	Late abortion, sterility in bulls
	Sheep, goats	*Brucella melitensis*	Abortion
	Swine	*Brucella suis*	Abortion, weak pigs
	Dogs	*Brucella canis*	Abortion
Vibrosis	Cattle	*Campylobacter fetus*, subspecies *fetus*	Infertility, early abortion
	Sheep	*Campylobacter fetus*, subspecies *intestinalis*	Abortion in last trimester
Leptospirosis	Cattle	*Leptospira pomona*	Abortion in last trimester
	Swine	*Leptospira pomona*	Late abortion, weak pigs
	Horses	*Leptospira pomona*	Late abortion
Listeriosis	Cattle, sheep	*Listeria monocytogenes*	Abortion – second half gestation
Epididymitis in rams	Sheep	*Brucella ovis*	Infertility in rams, late abortion
Viral infections			
Equine virus abortion	Horses	Equine herpesvirus I	Abortion in last trimester
Equine viral arteritis	Horses	Equine arteritis virus	Abortion – second half gestation
Infectious bovine rhinotracheitis or pustular vulvovaginitis	Cattle	IBR-IPV virus	Abortion – second half gestation temporary infertility in cows and bulls, and fetal infection
Bovine viral diarrhoea	Cattle	BVD-MD virus	Abortion in first trimester, fetal deformities
Epizootic bovine abortion	Cattle	Virus?	Abortion in last trimester
Enzootic abortion of ewes	Sheep	*Chlamydia psittaci*	Late abortion
Blue tongue	Sheep	Modified live virus vaccine	Fetal deformities
Hog cholera	Swine	Modified live virus vaccine	Fetal deformities
Protozoan infections			
Trichomoniasis	Cattle	*Trichomonas fetus*	Abortion in first trimester, sterility in cows
Toxoplasmosis	Cattle, sheep, swine, dogs, cats	*Toxoplasma gondii*	Abortion, stillbirths, premature births, fetal abnormalities

(Kronick, 1976; G.F. Chernoff, 1977; Randall *et al.*, 1977) and nicotine (Nishimura and Nakai, 1958) in mice; methotrexate (J.G. Wilson, 1978), ionizing radiation (Brent, 1977) and alcohol (Tze and Lee, 1975; Abel and Dintcheff, 1978) in rats; nitrates and nitrites (Sleight and Atallah, 1968), norethynodrel (Foote *et al.*, 1968), thalidomide (Arbab-Zadeh, 1965) and vitamin C (Neuweiler, 1951) in guinea pigs; nitrogen mustard in ferrets (Beck, 1978) and glucocorticoids (Howarth and Hawk, 1968; Fylling *et al.*, 1973) and colchicine (Edey, 1967) in sheep.

6.6 DEVELOPMENT OF THE REPRODUCTIVE TRACT

6.6.1 GENETICS OF SEX DIFFERENTIATION

The development of an animal into a male or a female depends on a switch mechanism which is under environmental (e.g. alligators), chromosomal (e.g. *Drosophila*) or genetic control (e.g. mammals). In the last case, the TDF (testis-determining factor) gene on the Y chromosome is responsible for male development (McLaren, 1990). Since it is likely that many different genes are required for both maleness and femaleness, studying the mode of action of one or more of these genes is essential to our understanding of the genetic controls in mammalian sexual development.

The primary development of the mammalian bipotential gonad toward a male or female identity is genetically determined, while the subsequent development of secondary sexual characters is under endocrine control. In most mammalian species, including humans, the female is homogametic and has two isomorphic sex chromosomes (the X chromosomes), while the male has one X and one Y chromosome. It is the presence of a Y chromosome, not the number of X chromosomes, that distinguishes male from female: abnormal individuals with an XO chromosomal constitution are female while XXY genotypes are phenotypically male. Genetic sex is determined at fertilization when either an X- or Y-bearing sperm unites with the X-bearing ovum.

Largely through cases of abnormal sexual differentiation, we have learned that this XX/XY system is not as simple as it first appears. Several genes on each sex chromosome, as well as genes on the autosomes, are known to influence sexual determination and differentiation. The gene products of these loci have not been identified, and the mechanisms by which they steer developmental processes – e.g. as cell recognition markers (L. Singh *et al.*, 1984) or by setting the timing and rate of such processes (Mittwoch, 1983) – are still not understood, although significant advances are being made (Eicher, 1988; Jost and Magre, 1988).

Furthermore, while the XX/XY system characterizes most mammalian species, there are several exceptions or variations on this theme. In some mongooses (genera *Herpestes*, Fredga, 1972; and *Atilax*, Pathak and Stock, 1976) there are apparently no Y chromosomes, so males are determined by the XO configuration. Y to autosome translocations have been postulated based on cytogenetic evidence (*Aotus*) and the observation of trivalents at meiosis including the X chromosome and two homologous autosomes, one of which presumably carries not only the male-determining part of the Y but also the Y–X pairing region (*Herpestes*) (Austin *et al.*, 1981).

A number of mammalian species have multiple sex chromosome mechanisms for sex determination in which more than one type of X or Y chromosome is present (Austin *et al.*, 1981). The general principle that the presence of one or more Y chromosomes corresponds with male sexual differentiation while their absence is associated with female differentiation also holds in these systems.

(a) The Y chromosome

Gonadal determination

H-Y antigen Individuals from highly inbred strains of mice are typically able to accept tissue grafts from members of the same strain. In 1955, however, Eichwald and Silmser reported that females of certain inbred strains gradually rejected skin grafts from syngeneic males, while male-to-female and within-sex grafts were successful. These results suggested the existence of a minor histocompatibility (H) antigen whose presence on male skin cells is controlled by the Y chromosome (hence the name H-Y). Subsequent investigation revealed that H-Y antigen is present on the surface of all nucleated male cells in many mammalian tissues (D.L. Gasser and Silvers, 1972) and that it shows extreme evolutionary conservation, not only within mammals (Wachtel *et al.*, 1974; Nagai and Ohno, 1977; Selden and Wachtel, 1977) but also between different vertebrate classes where its presence is associated with the heterogametic sex (Wachtel *et al.*, 1975a).

Wachtel *et al.* (1975b) proposed that the H-Y antigen was the product of testis-determining genes normally found on the Y chromosome. A number of *in vitro* studies support this hypothesis (Ohno *et al.*, 1978; Zenzes *et al.*, 1978a,b; Muller and Urban, 1981) and several do not (R.V. Short, 1979; Muller and Urban, 1981; Goldberg, 1988). Nonetheless, an association between H-Y and the development of testicular structure seems clear. Evidence that H-Y also directs functional development of the testis comes from the fact that rat ovarian cells reaggregated in the presence of H-Y developed LH/hCG (luteinizing hormone/human chorionic gonadotrophin) receptors, which are characteristic of newborn testes but not ovaries (Muller *et al.*, 1978b). The reaggregation of ovarian cells into testosterone-producing bodies, however, has not been achieved.

There are two kinds of receptors for H-Y antigen. One is associated with the major histocompatibility complex–β2-microglobulin dimers on the plasma membrane and seems to be unable to bind exogenous H-Y. In mouse and human male somatic cells, however, there is an association between H-Y and this dimer (review in Meck, 1984). The second receptor is gonad specific and is able to bind exogenous H-Y both in males and in females (Muller *et al.*, 1978a). Muller *et al.* (1978a) and Russell *et al.* (1982) have suggested that the former receptor sites bind H-Y exerting the histocompatibility function, whereas the gonad-specific receptors, picking up H-Y in solution, are necessary for testis induction. Thus, primary sexual differentiation of the gonad would depend on both the production and reception of H-Y: the receptor is essential.

The genetics of H-Y antigen has been investigated by measuring H-Y titres in individuals with varying chromosomal constitutions. In all but a few reported cases, H-Y was present whenever there were testes (E. Simpson, 1982; Gore-Langton *et al.*, 1983; Goodfellow, 1986). However, H-Y can also be present in the absence of testicular tissue and therefore is clearly not the only determinant of gonadal sex (McLaren *et al.*, 1984; E. Simpson *et al.*, 1984, 1986; Goldberg, 1988). There is also recent evidence that the H-Y antigen may be more involved in spermatogenesis than sexual differentiation (McLaren *et al.*, 1984; Burgoyne *et al.*, 1986; Burgoyne, 1988).

Before leaving the topic of H-Y antigen, we should briefly consider where on the Y chromosome the testis-determining gene is located. Previous studies of Y structural anomalies suggest that the critical locus is on the short arm of the Y near the centromere (reviewed in Davis, 1981). Promising evidence for a more specific location of the testis determining region has recently appeared. Sinclair *et al.* (1990) have located TDF on 35 kilobases of segment 1A1 of the short arm of

the human Y chromosome and is Y specific for a number of mammals, and has been called SRY (sex-determining region of the Y).

Bkm sequences

Bkm sequences are minor satellite DNA sequences, interspersed with other more complex sequences. In the mouse, Bkm sequences are located on the Y chromosome, where they are especially concentrated at the proximal tip and Sxr locus (L. Singh and Jones, 1982), on two regions of the X chromosome and on the autosomes (Kiel-Metzger and Erickson, 1984), including one locus where deletions can lead to hermaphroditism (Kiel-Metzger *et al.*, 1985).

The discovery that Bkm sequences in humans are virtually absent from the Y, while they are concentrated only on the X and two autosomes (Drumm *et al.*, 1985; Kiel-Metzger *et al.*, 1985), necessitates rethinking about the relationship between Bkm sequences and sex determination (Kiel-Metzger *et al.*, 1985). The higher concentration of Bkm sequences found on some heterogametic sex chromosomes is evidently not required for determination of the heterogametic sex. Either Bkm sequences and sex determination are not related, or there are small but important sex differences in the Bkm sequences on the homogametic sex chromosome or autosomes and these sequences are able to fulfil the sex-determining function.

The Y chromosome and spermatogenesis

In man, small deletions of the euchromatic part of the Y chromosome long arm have been associated with azoospermia and suggest that certain Y loci are needed for normal spermatogenesis. Some possibly contradictory cases in which Y deletions coincided with normal fertility have also been described (Davis, 1981).

Further evidence of Y involvement in spermatogenesis comes from XO Sxr (sex reversed) male mice. These animals are believed to have the testis-determining sequence (normally found on the Y chromosome) transferred to the X chromosome. However, although their germ cells do undergo meiosis, these males are ultimately sterile because the spermatozoa are morphologically abnormal (Lyon *et al.*, 1981). Perhaps the lack of a Y chromosome in the germ cells causes their abnormality. Alternatively, it may result from the X's inability to pair with a homologue during meiosis (McLaren, 1983).

While one Y chromosome is evidently required for normal spermatogenesis, more than one Y disturbs this process. XYY humans and mice have testes, but many tubules show arrested spermatogenesis. Normal spermatogenesis is sometimes possible if the second Y chromosome is lost from the germ cell line (R.V. Short, 1982). A disorderly meiosis may again be the cause of the problem.

The Y chromosome and oogenesis

It is unlikely that the Y chromosome prevents oogenesis (McLaren, 1983). In XX/XY mosaic mice, XY germ cells can develop as oocytes, though this very rarely occurs (C.E. Ford *et al.*, 1975; Evans *et al.*, 1977). XX oocytes predominate in such chimaeras, but this is probably because of the advantage of having a second X (see below).

(b) The X chromosome

Gonadal determination

The X chromosome appears to have a repressing effect on the action of the Y chromosome, hence inhibiting organization of the testis. Evidence comes from the study of XY females whose sex reversal is familial and X-linked. The best known of such cases is the Scandinavian wood lemming, *Myopus schisticolor*, which received attention because some females produce only female offspring.

In this species, as well as in the Alaskan lemming *Dicrostonyx torquatus* (Gileva and Chebotac, 1979), some fully fertile females have an XY genotype, though they produce only XX oogonia (Fredga *et al.*, 1976). These females receive normal Y chromosomes from their fathers, so an X-linked locus (X*) must lead to sex reversal. The X* chromosome is slightly shorter than a wild-type X, owing to deletion and structural rearrangements in the short arm (E.W. Herbst *et al.*, 1978). Although the exact mechanism of sex reversal is unclear, females carrying X* transmit it to their XY offspring who consequently develop as females.

Further evidence that the X* chromosome has lost genes necessary for male sexual development comes from X*XY sterile males, which occur occasionally as a result of failure of the double non-disjunction which typifies X*Y meiosis. Schempp *et al.* (1985) determined that when the wild-type X chromosome was inactivated X*XY individuals were fertile females. When the mutant X* was inactivated, X*XYs were males which were sterile owing to the presence of two X's.

Cases of familial XY gonadal dysgenesis (X-linked recessive) are also known in humans (Sternberg *et al.*, 1968; German *et al.*, 1978; J.L. Simpson *et al.*, 1981). XY females, who have small streak gonads like those of XO females, can be H-Y negative or positive (U. Wolf, 1979; Wachtel *et al.*, 1980; review in Meck, 1984), so that female differentiation may be due to a lack of expression of H-Y in the former case, and to H-Y receptor deficiencies in the latter (Wachtel *et al.*, 1980). There are clear parallels with the wood lemming case (Ohno, 1979), except that human XY females are sterile while wood lemmings are not.

A different kind of sex reversal (Sxr) occurs in mice, in which XX and XO individuals develop into sterile males whose germ cells have disappeared by adulthood (Lyon *et al.*, 1981). Mouse Sxr is inherited via a non-reciprocal transfer of the testis-determining locus on the tip of the Y chromosome to the distal part of the X chromosome during meiosis (Cattanach, 1985).

Familial XX sex reversal, which appears to be inherited as an autosomal dominant, occurs in humans (de la Chapelle, 1981), and Cattanach (1985) has argued that a genetic mechanism like the one operating in XXSxr mice may apply to humans as well. In isolated cases of XX sex reversal in man, patterns of inheritance (de la Chapelle *et al.*, 1984) and direct biochemical evidence (Guellaen *et al.*, 1984) do suggest that X–Y interchange occurs during meiosis, and that the amount of chromatin transferred may be variable (Cattanach, 1985).

The X chromosome and oogenesis

Two X chromosomes seem to be required for normal oogenesis in most mammals. One X can sustain development of the ovary, but is insufficient for its sustenance into adulthood and for oogenesis. XO females are usually infertile: in humans, for example, the streak gonads of such individuals are devoid of germ cells at adulthood (Carr *et al.*, 1968). In mice, XO females are fertile, but germ cells age unusually quickly (Carr *et al.*, 1968). Muller (1984) has related this difference to the different patterns of X chromosome inactivation in man and mouse. He suggests that X-linked genes promoting (or allowing) ovarian differentiation are among those that escape inactivation in man, in whom they must operate in double dosage, while mice require only one dosage. The need for double dosage in man evidently begins at meiosis, since only one X is active during oogonial proliferation (Vandeberg, 1983).

The X chromosome and spermatogenesis

The presence of two X chromosomes appears to block spermatogenesis. No fertile XX males have been reported in any mammal (Wachtel, 1986). XX germ cells in a testicu-

lar environment degenerate post-natally (McLaren, 1983). Germ cells with one X chromosome, however, may survive in a testis, as occurs in normal males. Even XO germ cells can survive in the testis of an XXSxr mouse (Lyon *et al.*, 1981). In XX/XY chimeric mice, XSxrO and XY germ cells even enter spermatogenesis, whereas XX germ cells are lost after birth (McLaren, 1983).

(c) Germ cell sex

In most normally developing individuals, the genotypes of germ cells and somatic cells are identical. There are reasons, however, for considering germ cell sex and gonadal sex separately. In females, germ cells, unlike XX somatic cells, do not undergo X inactivation during meiosis (McLaren, 1983). In males, germ cells, but not somatic cells, undergo X inactivation during meiosis. Furthermore, only male somatic cells express H-Y antigen, while germ cells do not. Finally, in some mammals, germ cell and somatic cell sex is regularly different. In the creeping vole (*Microtus oregoni*), for example, XY males produce only OY spermatogonia, while XO females produce only XX oogonia by non-disjunction and selective atresia. This example suggests that the Y chromosome serves a critical function only in the germ cells, where we have seen that it induces testicular organization.

Germ cells evidently do not contribute to the early organization of the gonad. If they are reduced in number or eliminated before arrival at the genital ridge, there is no effect on gonadal differentiation (review in Wachtel and Koo, 1981; Haseltine, 1983). Later, however, their presence may be required for normal gonadal differentiation: ovaries without oogonia do not develop normally (Wachtel and Koo, 1981).

There is evidence that the gonadal environment contributes to the sexual orientation of the germ cells. Zamboni and Upadhyay (1983) have argued that primordial germ cells are basically female: XX **and** XY mouse germ cells growing ectopically in the adrenal gland until 3 weeks post partum all differentiated into oocytes, closely following a typical mouse ovarian timetable. Thus, a testicular environment is necessary for XY germ cells to differentiate into spermatocytes.

A similar gonadal influence can operate on XO germ cells in mice. Normal XO mice are fertile females, though the oogonia undergo more rapid atresia than XX oogonia. XO sex-reversed mice, on the other hand, have testes, and their XO germ cells enter spermatogenesis (McLaren, 1983).

The degree to which the gonadal environment can influence germ cell differentiation is limited. In general, gonadal and germ cell sex must be compatible for normal development to occur (R.V. Short, 1982). No cases have been reported of XX germ cells successfully differentiating into testes in a testicular environment. In fact, in XXSxr mice there is evidence that they begin differentiation into oocytes which die before sexual maturity (McLaren, 1980).

6.6.2 SEXUAL DIFFERENTIATION OF THE CENTRAL NERVOUS SYSTEM ('BRAIN SEX')

While the genes direct the initial determination of the gonads in early mammalian development, steroid hormones produced by these organs act later to influence the differentiation of secondary sexual characters such as behaviour. The fact that hormone manipulation around the time of birth can effect permanent changes in adult sexual behaviour, regardless of genotype and adult hormone treatments, suggests that such hormones have an organizing effect on the tissues mediating that behaviour, i.e. on the brain (Phoenix *et al.*, 1959). Such an effect differs from an activating effect, in that the presence or absence of certain hormones coincides with behavioural changes that are reversed when those hormones are removed or restored.

Table 6.9 Relation between the length of gestation and the timing of developmental critical periods for CNS-sexual differentiation (reproduced with permission from MacLusky and Naftolin, 1981)

Animal	*Gestation (days)*	*Critical period (after conception)*
Rat	20 to 22	18–27 days
Mouse	19 to 20	Post-natal
Hamster	16	Post-natal
Guinea pig	63 to 70	30–37 days
Ferret	42	Post-natal
Dog	58 to 63	Prenatal and post-natal
Sheep	145 to 155	~30–90 days
Rhesus monkey	146 to 180	~40–60 days

The organizing effects of early hormone exposure were first demonstrated on functional brain responses such as behaviour and the feedback system of pituitary hormones. More recent work has centred on the morphological correlates of hormone-mediated organization. Steroid-induced differences have been found in numerous areas of the brain, and the nature of the sex differences (e.g. neurone size, number and connectivity) is variable. The cellular mechanisms by which hormones cause morphological changes is currently an area of active research.

(a) Functional aspects of brain sex

Critical periods for hormone action

Studies of development of both brain function and structure have shown that there are limited critical periods for sexual differentiation of the brain. During these periods, brain structures and functions (that may appear later) are maximally susceptible to the permanent organizing effects of hormones, and these effects cannot be reversed by treatment at a later time. The timing of critical periods relative to birth varies between species (Table 6.9) but precedes eye opening in all cases that have been studied to date (Goy and McEwen, 1980).

Variation is due to the fact that birth occurs at various developmental stages in different species. Thus, in rats and guinea pigs, the critical period for hormone action spans a few days before and after birth, while in the relatively precocious rhesus monkey, the equivalent critical period spans several weeks during the first trimester of pregnancy (Goy and McEwen, 1980, Handa *et al.*, 1988; Sholl *et al.*, 1989). The temporal relationship between the critical periods of CNS development and gonad development is known only for a few rodents in which the critical CNS development seems to follow differentiation of the Leydig cells and onset of testosterone secretion.

The timing of critical periods also varies depending on the functional and structural parameters in question (Gorski, 1984). In guinea pig females treated with testosterone, for example, masculinization precedes defeminization, and the critical period for masculinizing behaviour begins sooner than that for masculinizing gonadotrophin regulation (Goy and McEwen, 1980). In the species studied so far, all of these reproductive functions, as well as brain structures, seem to have their critical periods of development before or around the time of birth, but sensitivity to

exogenous factors does not appear to be limited to this period (Gorski, 1986). However, organization of some non-reproductive sexually dimorphic brain functions (McEwen, 1983), such as taste preference in rats, occurs considerably later, i.e. at puberty (Shapiro and Goldman, 1981).

Sexual dimorphism of brain function

In normal female mammals, rising oestrogen levels trigger the cyclic release of gonadotrophin-releasing hormones from the hypothalamus and these, in turn, stimulate the release of two gonadotrophins, luteinizing hormone (LH) and follicle-stimulating hormone (FSH), from the pituitary gland. LH and FSH stimulate ovarian maturation and trigger ovulation. The positive feedback of oestrogen on gonadotrophin release is absent in normal males. However, males will not release LH or FSH in response to rising oestrogen or testosterone levels. Thus, the hormonal response of the pituitary and hypothalamus to oestrogen challenge is sexually dimorphic.

Sexual dimorphism is also apparent in the sexual behaviour of normal males and females (Goy and McEwen, 1980; Goy *et al.*, 1988). In rodents, the most frequently studied response by females to male mounting attempts is a concave arching of the back in the lordosis posture (Figure 6.12).

Lordosis is not part of the normal male's behavioural repertoire. They will, however, mount receptive females with thrusting while females typically do not perform this behaviour. In other mammals, the behaviour of receptive females takes different forms, while typical male behaviour usually includes mounting of receptive females. Other non-mating behaviour patterns are sometimes sexually dimorphic (e.g. urination in dogs, flehmen in sheep, taste preference in mice, various social situations in primates) and these have also been used as assays of functional organization of the brain (Quadagno *et al.*, 1977; Goy and McEwen, 1980; Pomerantz *et al.*, 1988). The degree to which sexually dimorphic behaviour is strictly sex specific varies from species to species (Goy and McEwen, 1980; J.J. Ford and D'Occhio, 1989).

Figure 6.12 Sexually dimorphic behaviour: lordosis in the female rat. Normal males do not perform this behaviour.

When sexual dimorphism involves different forms of a particular behaviour, rather than the absence or presence of the behaviour, it is useful to distinguish the masculinizing (or feminizing) effects of early hormone exposure from the defeminizing (or demasculinizing) effects (Beach *et al.*, 1972). As we shall see, the expression of typical female behaviour need not preclude male behaviour patterns, and vice versa (for review see Gorski, 1985a).

Effects of early exposure to hormones on development of sexually dimorphic brain functions

The response of both the developing and mature nervous system to hormones, particularly those secreted by the gonadal and adrenal glands, is related to the presence of receptor sites which mediate hormonal action at the level of gene expression (McEwen, 1988). When abnormal amounts of hormones are secreted, when they are secreted at the wrong time, or when exogenous hormones or

pseudohormones are ingested or absorbed, the nervous system may respond in abnormal ways. This may lead to permanent functional and structural changes in the brain which are associated with deviation or dysfunctions in reproductive function. These effects are generally more severe when experienced by the developing fetus than by the adult.

One of the important consequences of the developmental action of gonadal steroid is the programming of the male and female brain to respond differently to the same hormone (McEwan, 1988). Thus, the brain will respond differently to exogenous drugs and endogenous neurotransmitter depending on the individual's sex as well as the type of hormone present. The developing brain–pituitary–gonadal axis in both males and females is sensitive to abnormal concentrations of hormones or pseudohormones at critical developmental periods. For example, medroxyprogesterone acetate (MPA), a synthetic progestin, produces paradoxical genital abnormalities in cynomolgus monkeys, i.e. the external genitalia of female fetuses are masculinized and those of male fetuses are feminized (Prahalada *et al.*, 1985a). Adverse effects on psychosexual identity and other aspects of personality have also been associated with prenatal exposure to this drug in humans (Ehrhardt and Money, 1967; Reinisch, 1977). Thus, a basic understanding of the complex events that occur during normal sexual differentiation of the nervous system is a prerequisite to understanding the mechanisms which result in perturbed sexual development.

In rodents such as the rat and hamster, exposure to steroid hormones in late fetal life and in the first week of post-natal life plays a critical role in determining functional responses of the brain in adulthood. Exposure to androgen during this period leads to the development of masculinized behaviour and non-cyclic pituitary function. In the absence of androgen, female sexual behaviour patterns and cyclic gonadotrophin release occurs (review in Goy and McEwen, 1980; McEwen, 1983).

Because masculinization occurs prenatally, female rats from litters in which several littermates are male are much more likely to show mounting behaviour than females from litters with 0–1 male. The masculinization of female behaviour is greatest in those individuals located closest to males *in utero*, where androgen concentration is highest (Clemens and Coniglio, 1971; Clemens, 1974; Goy and McEwen, 1980; vom Saal, 1989). Similarly, females injected with androgens prenatally show masculinized behaviour (Ward, 1969).

Treatment with anti-androgens before birth blocks normal masculinization of males (Ward and Renz, 1972). There is some evidence that dihydrotestosterone (DHT) as well testosterone (T) is involved in masculinization (McEwen, 1983).

Defeminization of behaviour by androgens in rats follows masculinization and occurs during the first week after birth. This is also when androgens exert their strongest effect on gonadotrophin secretion (Arnold and Gorski, 1984). Female rats injected with testosterone propionate (TP) shortly after birth lose the lordosis response and do not show cyclic gonadotrophin release, while males castrated neonatally can show lordosis and do respond positively with gonadotrophin-releasing hormone after stimulation with oestrogen as adults (Dohler *et al.*, 1984a).

While these results appear to highlight the role of testosterone in perinatal organization of the rat brain, it has been found that oestradiol has similar effects, and is in fact more effective (per unit weight administered) than testosterone in preventing feminization of gonadotrophin release and behaviour (Gorski and Wagner, 1965; Sutherland and Gorski, 1972).

Non-aromatizable androgens such as DHT, on the other hand, are not effective in stimulating a male pattern of brain organization. A widely held hypothesis holds that testoster-

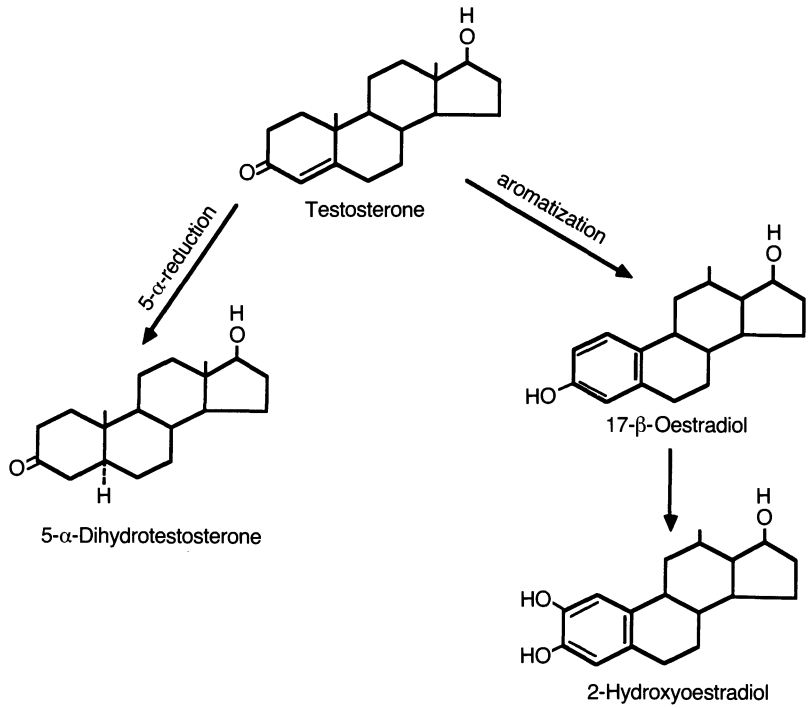

Figure 6.13 Transformations of testosterone that can occur in brain tissue.

one is converted in the brain via aromatization to the oestrogens oestrone and oestradiol, and that these are the active molecules (Figure 6.13) (MacLusky and Naftolin, 1981).
