Since DHT cannot be transformed into oestrogen in the brain, it is ineffective in inducing male brain organization. This hypothesis is supported by the following observations: (i) androgen-to-oestrogen conversion does occur in the brain; (ii) anti-oestrogens block both testosterone- and oestrogen-induced masculinization; (iii) aromatase inhibitors block masculinization by testosterone; (iv) anti-oestrogens attenuate defeminization of females by testosterone; (v) in Tfm males, who lack androgen receptors, normal defeminization occurs in response to testosterone produced by the testes; and (vi) in cell cultures of mouse hypothalamus, neuritic outgrowth, which is typical of males, occurs only in cells whose oestrogen receptors are intact (Goy and McEwen, 1980; MacLusky and Naftolin, 1981; McEwen, 1983; Toran-Allerand, 1984a).

It is then necessary to explain why female rats are not masculinized by ovarian oestrogens which occur at high titres post-natally. It has been suggested that alpha-fetoprotein protects the developing female rat brain cells from excess oestrogens by binding them and thus keeping them in the circulation and out of the brain (Soloff *et al.*, 1972; Arnold and Gorski, 1984). Alpha-fetoprotein is present in large amounts only during gestation and immediately after birth, following the time course of neural differentiation (Toran-Allerand, 1984b). In rats and mice, it has a high affinity for oestrogen, but does not bind testosterone. As would be expected under the protection hypothesis, synthetic oestrogens which do not bind to alpha-fetoprotein

as well as oestradiol are more effective than oestradiol in inducing masculinization of the female rat brain (Goy and McEwen, 1980).

However, the alpha-fetoprotein protection hypothesis has been questioned. This high affinity of alpha-fetoprotein for oestrogen is not found in other species such as the guinea pig and human (MacLusky and Naftolin, 1981). Even in the mouse and rat, alpha-fetoprotein has been found within brain cells (Benno and Williams, 1978; Toran-Allerand, 1984b), though it is not made there in mice (Schachter and Toran-Allerand, 1982). Thus, alpha-fetoprotein may have other functions, including transport of oestrogen into the brain (Dohler *et al.*, 1984a; Toran-Allerand, 1984b). Other possible mechanisms for protection from oestrogen may exist, including placental barriers and progesterone-mediated anti-oestrogen action (McEwen, 1983).

Sex differences in fetal and neonatal testosterone titres are small or non-existent (Weisz and Ward, 1980); however, on days 18–21 post conception, titres are higher in males. Although these 4 days do not encompass the entire period of hormonal organizing action, the sex difference in testosterone levels during this time appears to be critical to sexual differentiation (Goy and McEwen, 1980). The higher testosterone levels in male fetuses at this time may exert a priming effect so that males are more sensitive to circulating testosterone later. The mechanism of priming could involve induction of the aromatizing enzyme system or of nuclear oestrogen receptors (Goy and McEwen, 1980; Toran-Allerand, 1984b; Goy *et al.*, 1988).

Androgenic induction of male functional brain organization has been most thoroughly studied in the rat, but this species is not typical (Table 6.10).

While masculinization and defeminization of brain function are distinct events occurring at different times and under the influence of different hormones in rats, defeminization has not been shown in ferrets, rhesus monkeys or humans. In these species, females treated with androgens during development have masculinized behaviour in addition to the normal female repertoire later in life, and cyclic gonadotrophin release with ovulation is retained (McEwen, 1983). Another primate, the marmoset, may show a reduction in female reproductive behaviour patterns when females are androgenized prenatally (Abbott and Hearn, 1979).

There is also variation among mammals in the pathway of androgen metabolism followed to produce the active molecule which induces masculinization or defeminization. In rats, both testosterone (or oestrogen) and DHT appear to be involved (McEwen, 1983). In guinea pigs and rhesus monkeys, however, prenatal treatment with DHT alone can organize some aspects of masculine sexual behaviour as effectively as does T (Goldfoot and van der Werff ten Bosch, 1975; Goy and McEwen, 1980). Why these interspecies differences exist is not known. Even the generalization that organizational and activational pathways are the same within a given species is not entirely correct, since some elements of male sexual behaviour in ham-

sters may be activated by non-aromatizable androgens which are not effective during development (McEwen, 1983).

(b) Structural aspects of brain sex

The study of anatomical measures of steroid hormone action began well after the studies of brain function (Arnold and Gorski, 1984). In a seminal paper, Raisman and Field (1973) documented a sex difference in the type of dendritic synapses in the preoptic area of the rat that could be reversed by manipulating neonatal androgen levels. Since then, there have been numerous reports of sex differences in central nervous system (CNS) anatomy, and perinatal exposure to steroids has been shown to affect axonal growth, dendritic connectivity (arborization), synapse formation, regional nuclear volumes and neuronal numbers in the hypothalamus, preoptic area, septum, amygdala and spinal cord (McEwen, 1983; Toran-Allerand, 1984a; L.S. Allen *et al.*, 1989), as well as a number of biochemical properties (McEwen, 1983) (Table 6.11).

For the most part, the functional significance of anatomical markers is not known, but they may provide useful models for understanding the mechanisms of hormone action on brain function.

Whereas many sexually dimorphic anatomical markers were discovered by direct inspection of brain tissue, localization of the circuitry for steroid-dependent organization of brain function has been investigated more indirectly as well. For example, by varying the site of oestrogen implants in newborn female rat brains, Nordeen and Yahr (1982) showed not only that masculinizing and feminizing implants must be placed in the preoptic area and ventromedial nucleus respectively, but also that behavioural masculinization results from implants in the right side of the hypothalamus, while defeminization of behaviour and gonadotrophin release follows implantation in the left side.

The sexually dimorphic nucleus of the preoptic area

A particularly well-studied sexually dimorphic brain structure, which is known to respond to early hormone exposure, is the sexually dimorphic nucleus (SDN) of the preoptic area (POA) of rats (Arnold and Gorski, 1984, Gorski, 1984). In males, this area of high- density neurones is about five times larger than in females (Figure 6.14).

Neuronal density is the same in both sexes, so the size difference must reflect a difference in cell number. Homologues for this area are also found in gerbils, ferrets and guinea pigs (Gorski, 1984). The exact function of the SDN-POA is not known, but the POA appears to play a complex role in many integrative processes. In rats, the POA appears to be critical for male copulatory behaviour. It is also involved in cyclic endocrine regulation in females (Gorski, 1984). In primates, on the other hand, the POA is not necessary for cyclic gonadotrophin release (Ayoub *et al.*, 1983).

A change in SDN-POA volume occurs simultaneously with functional masculinization of the brain in rats, though the volume does not correlate with the degree of expression of brain function (Gorski, 1984). SDN-POA size is not affected by gonadal steroids in adulthood. The size dimorphism develops within the first 10 days of life, when the adult SDN-POA size is achieved. It is hormones acting at this stage of development which influence SDN-POA size. In males castrated 1 day after birth, SDN-POA size is substantially reduced (Tarttelin and Gorski, 1988). If such males are treated with TP a day after castration, however, adult SDN-POA volume matches that of normal males. Female neonates injected once with testosterone propionate or oestradiol benzoate show increased SDN-POA volume as adults. If TP administration is prolonged, adult SDN-POA volume of females may be fully sex reversed (Gorski, 1984).

Table 6.11 Sex differences in the brains of infrahuman mammals (Reproduced with permission from McEwen, 1983)

Description	*Region*[a]	*Species*	*Org?*[b]
Morphological			
1. Size of nerve cell nuclei and nucleoli	Hyp, POA, Hippo, cortex, Hab	Rat	Yes
2. Size of nerve cell nuclei	Hyp, POA	Rat	Yes
3. Size of nerve cell nuclei	Amygd	Squirrel monkey	?
4. Size of pyramidal neurones	Cortex	Rat	?
5. Ratio of synaptic 'types'	POA	Rat	Yes
6. Dendritic distribution	POA	Hamster	Yes
7. Size of neuroanatomical 'nucleus'	POA	Rat	Yes
8. Size of neuroanatomical 'nucleus'	Spinal cord	Rat	Yes
9. Dendritic branching	POA	Macaque monkey	?
10. Synaptic 'type'	Hyp	Rat	Yes
11. Synaptic 'type'	Amygd	Rat	Yes
12. Bungarotoxin-binding region	Amygd	Mouse	Yes
13. Vasopressin neurones	Septum, Hab	Rat	?
14. Response to septal damage	Hippo	Rat	Yes
15. Neurovascular contact surface	Hyp	Rat	?
16. Lateralization of 2-deoxyglucose uptake	Many areas of brain	Rat	?
17. Lateralization of cortical thickness	Cortex	Rat	Yes
Biochemical			
18. Hypothalamic peptidases	Hyp	Rat	Yes
19. Cholinergic enzymes	POA	Rat	Yes
20. Cholinergic enzymes	POA, Amygd	Rat	?
21. Monoamine oxidase	Hyp, Amygd	Rat	?
22. Noradrenaline, dopamine levels	Many areas	Rat	?
23. Dopamine levels	Hyp, POA	Rat	Yes
24. Neurotransmitter enzymes	Many areas	Rat	?
25. Trace element levels	Hyp, pit	Rat	?
26. Glutathione-*S*-transferase activity	Whole brain	Rat	?
27. Muscarinic receptors	POA, pit	Rat	?
28. Glucocorticoid receptors	Hippo	Rat	?
29. Serotonin level in early development	Whole brain	Rat	Yes*
30. Monoamine oxidase activity in early development	Hyp	Rat	Yes*
31. Serotonin synthesis on post-natal day 2	Whole brain	Rat	?
32. Serotonin synthesis in early development	Whole brain	Rat	Yes*
33. Serotonin, noradrenaline levels in early development	Various areas	Rat	Yes*
Functional			
34. Amygdala projections to preoptic area (electrophysiology)	Amygd, POA	Rat	Yes
35. Release of dopamine, noradrenaline *in vitro*	Caudate, Hyp	Rat	?
36. Amphetamine-elicited rotational behaviour		Rat	?

It appears that SDN-POA size is actually determined by oestrogen, rather than by testosterone. Thus SDN-POA size is the same in Tfm rats which lack androgen receptors as in normal males. Also, diethylstilboestrol, which does not bind to alpha-fetoprotein, can cause complete sex reversal of SDN-POA size in females if administered throughout the perinatal period, just as does TP (Dohler *et al.*, 1984b).

The spinal nucleus of the bulbocavernosus muscle

A second well-studied sexually dimorphic part of the central nervous system that responds to perinatal gonadal hormones is the spinal nucleus of the bulbocavernosus muscle (SNB) in rats (Arnold and Gorski, 1984, Breedlove, 1984).

In males, this nucleus is an easily visible compact structure, while in females it contains only a third as many motoneurones, which are smaller (Figures 6.15 and 6.16).

The SNB system has an advantage over the SDN-POA system in that the functional correlates of the morphological dimorphism are known. The SNB, located in the spinal cord, consists of motoneurones innervating the levator ani (LA) and bulbocavernosus (BC) muscles in males. In rodents, these muscles occur only in males, where they attach to the base of the penis and mediate penile reflexes important in copulatory plug formation, which ensures effective copulation (Breedlove, 1984).

Unlike the SDN-POA, sexual dimorphism of the SNB in rats is mediated by androgens and not by oestrogens. This clearly indicates that sexual differentiation of brain morphology occurs by different mechanisms depending on the particular structure. SNB motoneurones are unable to accumulate oestrogens, but do accumulate DHT and testosterone. However, only the accumulation of testosterone is sexually dimorphic. In addition, there are androgen receptors in the levator ani muscle (Jung and Baulieu, 1972), so that the muscles themselves must be considered as a potential site of hormone action, along with or instead of the motoneurones (Breedlove, 1984).

Tfm males lacking androgen receptors have female-type SNBs and lack the levator ani and bulbocavernosus muscles. Similarly, when normal males are treated with antiandrogens prenatally and castrated as neonates, their adult SNB system is completely sex reversed. If females are treated with testosterone propionate or DHT propionate (DHTP) perinatally, the SNB system is masculinized. However, masculinization does not occur if oestrogen is used, even in higher doses (Breedlove, 1984).

(c) Mechanisms of sexual differentiation of the central nervous system

The discovery of hormone-sensitive morphological parallels of sexually dimorphic brain functions has focused attention on cellular mechanisms of sexual differentiation which affect the structure of neural circuits and, thus, ultimately lead to dimorphic brain function. Experimental manipulations have shown that hormonal action of CNS sexual differentiation depends both on the time course of exposure to hormones (see next section on critical periods below) and on the dose of hormone administered (Toran-Allerand, 1984a; Handa *et al.*, 1985; Sholl *et al.*, 1989).

Morphological dimorphism could result from hormonal effects on the rate or period of neurogenesis, on the pattern of neuronal differentiation, on cell migration patterns, or on cell survival. These effects may be direct, in that hormones act on the dimorphic neurones themselves, and/or indirect, in that the targets and afferents of those neurones are affected (Arnold and Gorski, 1984). Gonadal hormones may influence several developmental processes directly, or may trigger one such process which affects many others in a cascading manner (Figure 6.17)

Table 6.11 *continued*

Description	*Region*[a]	*Species*	*Org?*[b]
37. Electrical stimulation of rotational behaviour		Rat	?
38. Lateralization of dopamine levels	Caudate	Rat	?

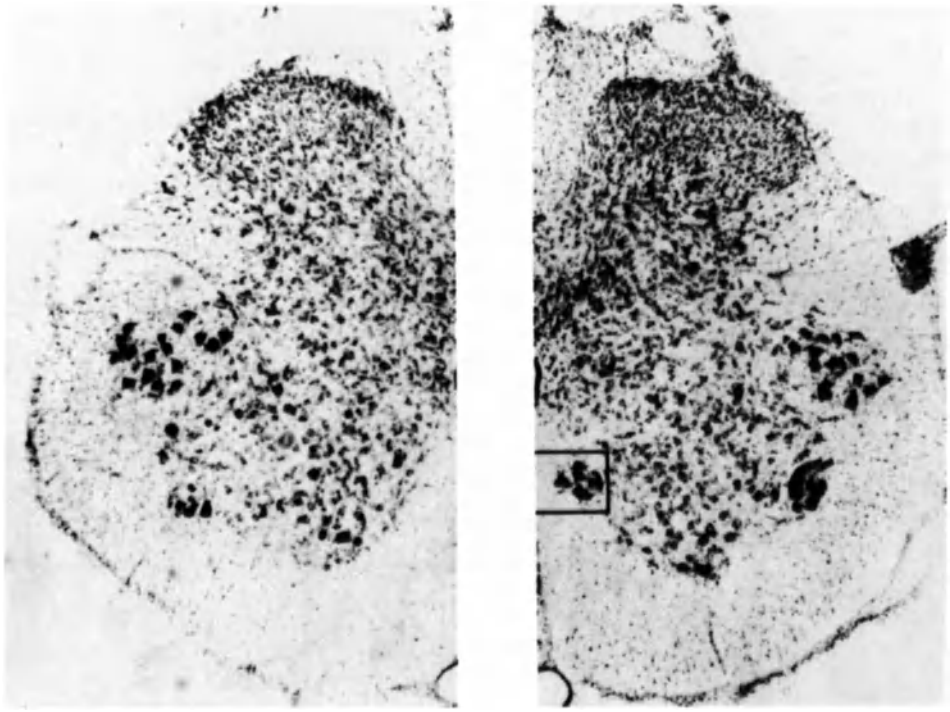

Figure 6.15 Photomicrographs of the fifth lumbar segment of the spinal cord of a female (left) and male rat. The spinal nucleus of the bulbocavernosus (SNB) is an easily recognized, discrete nucleus in the male only. The arrows indicate the anatomical limits of the SNB in males (right). This region, 200–400 mm ventral to the central canal and within 250 mm of the midline, was examined in male and female fifth and sixth lumbar spinal segments, within which all densely staining cells were designated SNB cells for comparison between treatment groups and the two sexes. (Reproduced with permission from Breedlove, 1984).

(Arnold and Gorski, 1984; Toran-Allerand, 1984b).

Data on the development of the SDN-POA and SNB suggest that the first hypothesis, differential neurogenesis, is unlikely since neurogenesis stops before the hormones are present and can exert their effects (Breedlove, 1984; Gorski, 1984). The possibility that hormones act to redifferentiate neurones has also been discounted for SNB development since labelling experiments show that motoneuronal differentiation occurs before androgen-induced SNB formation (Breedlove, 1984). Hormonal influence on migration patterns has been proposed to account for sexually dimorphic SDN-POA development, and current evidence suggests that this is a possible explanation: for example, steroid hormones may influence neuronal death before neurones finish their migration to the SDN-POA (Gorski, 1984). The hypothesis that hormones mediate cell death is perhaps the most widely favoured, although evidence is circumstantial. It is generally accepted that

more neurones are produced than survive development, that survival depends on the establishment of appropriate connections, and that the growth of neuronal processes can be stimulated by oestrogen (Gorski, 1984). Thus, hormonal mediation of cell death would occur indirectly via the effects of hormones on neuronal development. Supporting this hypothesis is the observation that the time course of (non-SNB) motoneurone cell death coincides with sexual differentiation of the SNB. Studies are currently under way in which the incidence of dying (pyknotic) SNB cells in relation to SNB development is examined.

Steroid hormones may act on biochemical features of neurones as well as morphological ones (McEwen, 1983). For example, the expression and concentration of neurotransmitters may differ between the sexes. Such biochemical differences may lead to differential sensitivity of male and female neural tissue and enzyme systems to hormones later in life.

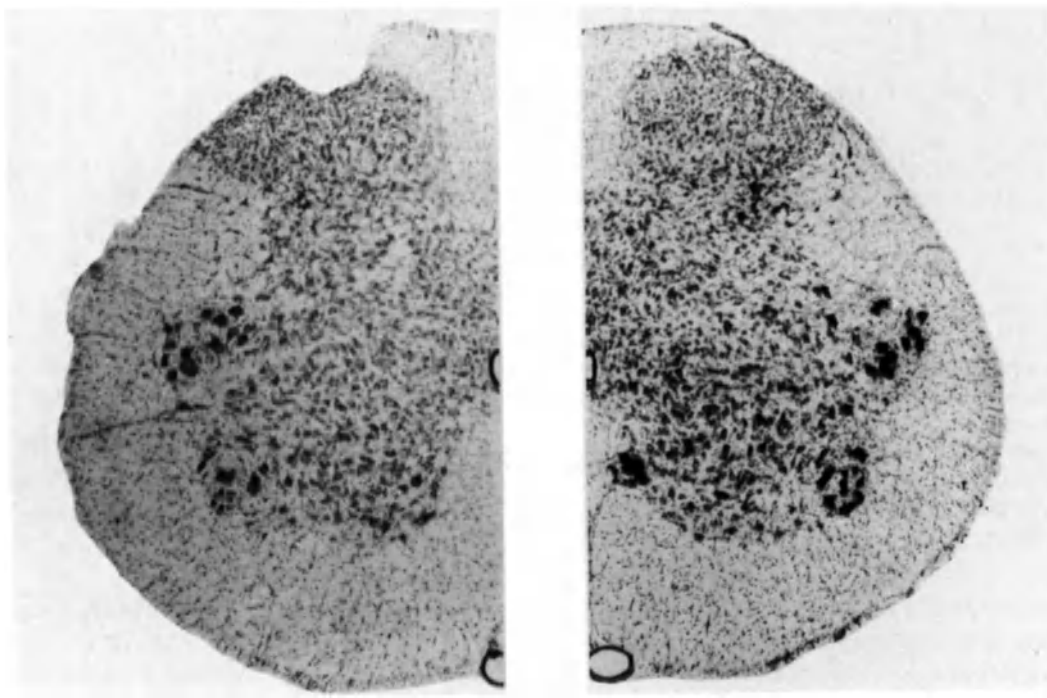

Figure 6.16 Photomicrographs of transverse sections of the fifth lumbar spinal segment from a male (left) and female rat. The arrows point out the anatomical region occupied by the SNB in normal male rats. The spinal cord on the left lacks a coherent nucleus because this male was treated prenatally with an anti-androgen and was then castrated at birth. The spinal morphology is within the range of normal female rats in this male which, like females, does not possess the SNB target muscles BC/LA. The spinal cord on the right is from a female which was injected with 1 mg of DHTP on days 1, 3 and 5 of life. In adulthood, this female possesses an SNB which innervates the muscles BC/LA. (Reproduced with permission from Breedlove, 1984.)

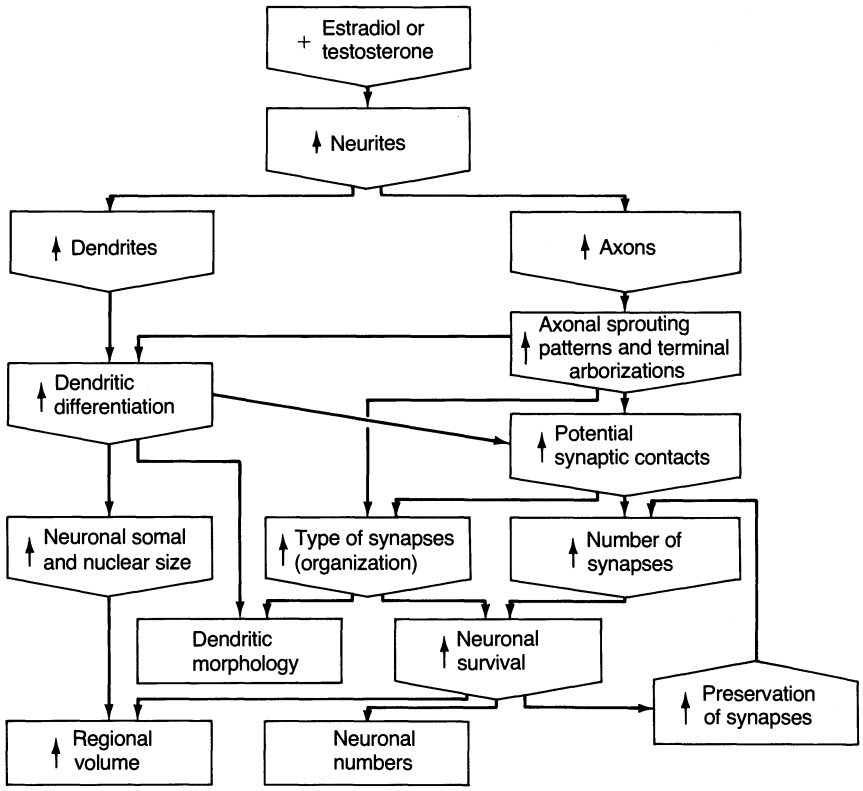

Figure 6.17 The cascade hypothesis. Morphogenetic consequences of early stimulation of neuritic growth by steroid could elicit a cascade of cellular events affecting subsequent aspects of target neural differentiation to result in the sexual dimorphism of brain structures. Different scenarios are also possible (Arnold and Gorski, 1984). (Reproduced with permission from Toran-Allerand, 1984b.)

Regardless of exactly which changes in neural anatomy and biochemistry are affected by steroid hormones in development, it is clear that the hormone receptors are a critical component of the system. The identity and concentration of these receptors in early development varies with time, location in the brain and sex (i.e. exposure to hormones) (Figure 6.18) (McEwen, 1983; Sholl *et al.*, 1989).

Furthermore, dimorphic receptor profiles in adults, which may lead to dimorphic brain function, have been shown to depend on perinatal exposure to particular hormones at particular times (Rainbow *et al.*, 1982; Weiland and Barraclough, 1984; Gorski, 1985b).

(d) Female differentiation of the CNS: a default process?

Although female organization of the CNS is often assumed to occur in the absence of stimulation of male differentiation, there is evidence that the organization of the female brain is also an active process requiring exposure to steroid hormones. Roles for testosterone (Gorski, 1984) and progesterone (Shapiro and Goldman, 1981) have been suggested, but most emphasis has been

placed on the role of oestrogen (Dohler *et al.*, 1984a; Toran-Allerand, 1984b). Dohler *et al.* (1984a) have criticized the assumptions on which the 'female by default' hypothesis was based. According to these authors, and contrary to what is widely assumed, oestrogen is available to the developing nervous system of female rats, either from the reservoir bound by alpha-fetoprotein (which can be found within brain cells) or from the mother. In addition, large numbers of oestrogen receptors are present in certain CNS regions where aromatizing enzymes are absent (Toran-Allerand, 1984b).

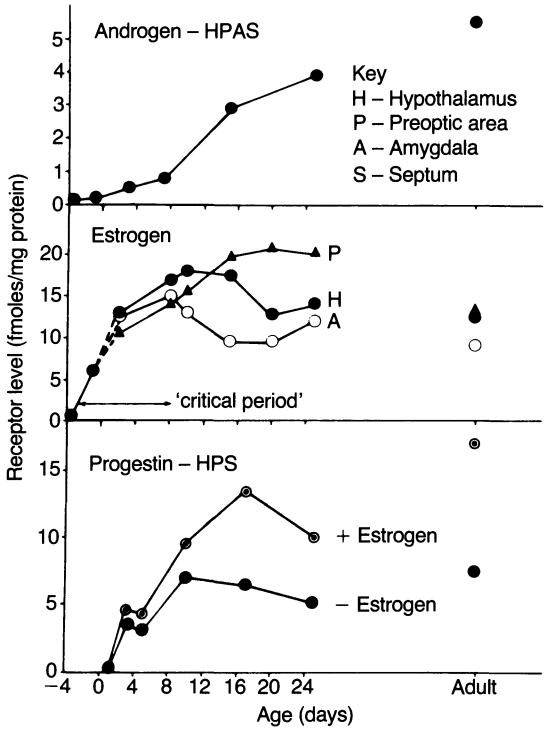

Figure 6.18 Developmental time course of gonadal steroid receptors in female rat brains. Receptor levels are expressed as fmol per mg of cytosol protein, are plotted against age in days before or after birth. Brain structures are denoted by letters (see key); note that they were studied individually (oestradiol) or as tissue pools (e.g. hypothalamus-preoptic area-septum-amygdala (HPAS) and hypothalamus-preoptic area-septum (HPS)). Androgen receptors were measured with [^{3}H]testosterone and were isolated by DNA–cellulose chromatography. Oestrogen receptors were measured with [^{3}H]R-2858 (moxestrol) by the Sephadex LH-20 gel filtration method. Progestin receptors were measured with [^{3}H]R-5020 by the LH-20 method. Arrows denote critical period for defeminization. (Reproduced with permission from McEwen, 1982.)

Direct evidence supporting the role of oestrogen *per se* comes from cases where oestrogen levels during development were experimentally reduced (Dohler *et al.*, 1984a; Toran-Allerand, 1984b):

1. Females treated post-natally with tamoxifen, an oestrogen antagonist, develop permanent anovulatory sterility, without masculine behaviour.
2. The presence of ovaries post-natally is known to influence feminization of receptive behaviour later in life.
3. Ovariectomy of neonatal females, but not adult females, changes the asymmetry in the cerebral cortex to a typical male pattern.
4. Neonatally gonadectomized males and females develop female-type non-reproductive behaviour when treated with small (sub-masculinizing) amounts of oestrogen.
5. Cultured female hypothalamic cells show abnormally reduced neuritic development when the culture medium lacks oestrogen.

If oestrogen does play an active role in female differentiation of the brain, the question remains how this one hormone can induce both feminization and masculinization. Dohler *et al.* (1984a) have proposed a quantitative effect which states that moderate levels of oestrogen, provided by maternal and placental tissues and bound to alpha-fetoprotein, cause female development of the brain. High levels of oestrogen, derived from aromatization of androgen (and perhaps acting synergistically with androgen), induce masculinization. An even higher threshold must be met for defe-

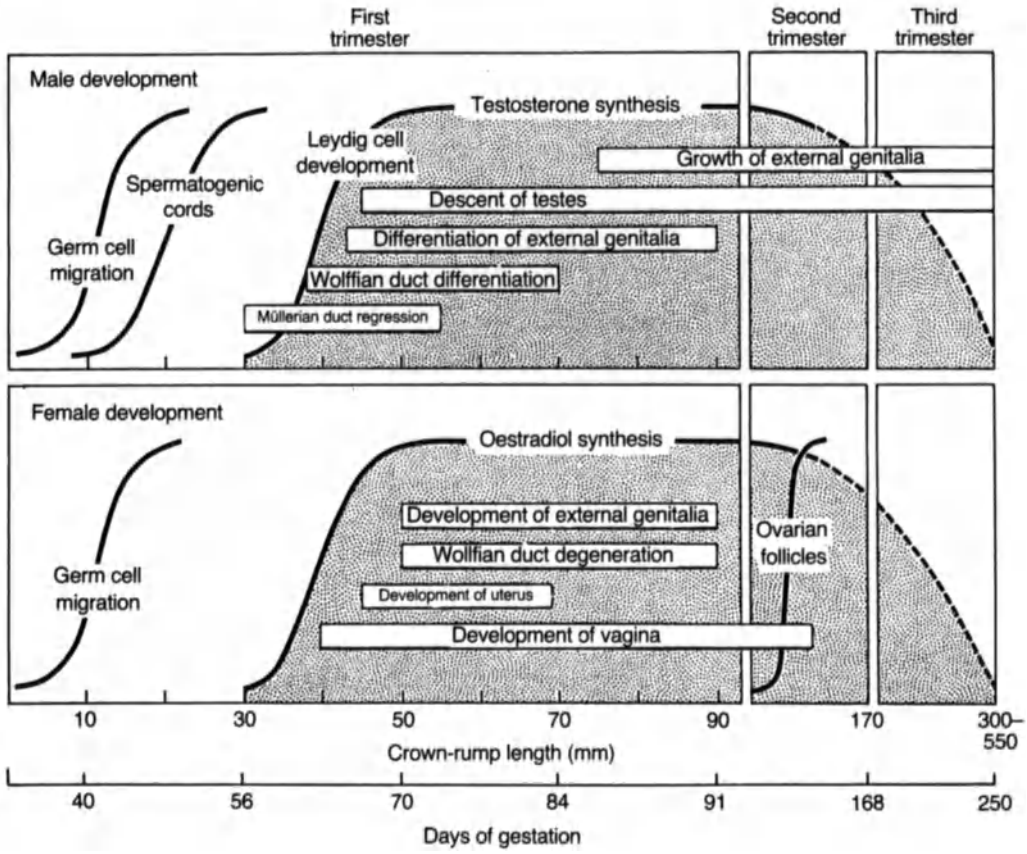

Figure 6.19 Relation between differentiation of the gonads and the anatomical differentiation of human male and female embryos. (Reproduced with permission from J.D. Wilson *et al.*, 1981.)

minization. This quantitative effect would depend not only on the titre of oestrogen at any one time, but also on the duration of its presence during critical periods of development.

6.6.3 MORPHOLOGY OF SEXUAL DIFFERENTIATION

In most instances, differentiation of the genital tract proceeds craniocaudally, thus affecting the gonads and the ducts first and the external genitalia last. One notable exception to this is in the bovine fetus, where the onset of penile development is the first sign of male differentiation (Vigier *et al.*, 1976). Figure 6.19 summarizes some of the morphologic features of the developing reproductive system in the human.

(a) Gonads

Even though the genetic sex of an individual is determined at fertilization, the reproductive systems of both sexes go through an early indifferent stage of development during which time the gonads remain morphologically indistinguishable until testicular differentiation occurs (Gondos, 1985). It is generally accepted that the indifferent gonad is a consortium of somatic and germinal cells composed of primordial germ cells, which (according to most human embryology textbooks) migrated from the yolk sac to the future gonadal ridge (Witschi, 1963). More

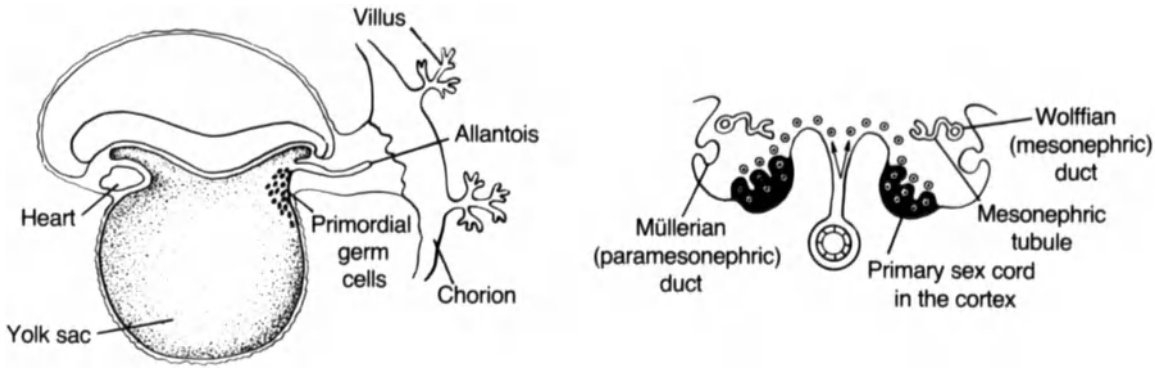

Figure 6.20 Schematic drawing of a 3-week human embryo (left) showing the primordial germ cells in the wall of the yolk sac, close to the attachment of the allantois. Schematic drawing of a transverse section through a 6-week human embryo (right) showing the primary sex cords and the developing mesonephric and paramesonephric ducts.

recent evidence from the mouse indicates that the primordial germ cells are derived from the epiblast, at the posterior end of the primitive streak (McLaren, 1992). Here they intermix with epithelial cells and underlying mesenchymal cells of mesodermal origin (Figure 6.20).

The origin and lineage of somatic cells contributing to the development of the gonad remained a point of interest and controversy for many years (Jost, 1985; Wartenberg, 1985). There is a large body of data that supports the view that epithelial cells are derived from the coelomic epithelium,which forms a layer of cells over the gonadal ridge (K.L. Moore, 1982; Sadler, 1985; Yoshinaga *et al.*, 1988). However, there are several studies in the mouse, rabbit and sheep which indicate that the blastema cells of the gonad have a nephric origin (Fraedrich, 1979; Kinsky, 1979; Upadhyay *et al.*, 1979; Wartenberg, 1979, 1981; Zamboni *et al.*, 1979).

The primordial germ cells are large, spherical to ovoid cells that can be identified histochemically by their high alkaline phosphatase and glycogen content. The presence of the primordial germ cells in the newly formed gonadal ridge stimulates the coelomic epithelium to multiply and invade the developing gonad. Cords of cells, called the sex cords, containing epithelial cells and primordial germ cells, form and give rise to the testis and ovary.

In the male gonadal ridge, under the influence of the Y chromosome, the contact between the primordial germ cells and somatic cells occurs earlier than in the female gonadal ridge and leads to formation of seminiferous tubules rather than follicles (Jirasek, 1976, 1977; Ohno, 1979). This occurs between 42 and 52 days of gestation or developmental stages 18–20 (O'Rahilly, 1983) and is thought to be mediated by the H-Y antigen, a gene product of the Y chromosome. It coincides with the acquisition of anti-Mullerian activity of the male gonad (Tran *et al.*, 1977). The process of gonadal differentiation and reproductive tract development has been studied most extensively in the human. More limited studies in several other species, i.e. dog, mouse, rat, rabbit, sheep, suggest that the basic processes are similar in mammals.

Male

In the human, during the seventh week of development, the presence of the male sex chromosome causes the genital ridge to se-

crete testosterone, which induces testicular development as well as development of other internal and external reproductive organs (Saenger, 1984; Gondos, 1985). At the same time, the development of the female genital organs is suppressed. Because of the proliferation of the mesenchyme the sex cords of the genital ridge become separated from the adjacent coelomic epithelium. The tunica albuginea, a fibrous layer located between the coelomic epithelium and the sex cords, forms from a condensation of the newly formed mesenchyme. During the fourth month in the human the U-shaped sex cords form the seminiferous tubules. The free ends of these tubules, the straight tubules, join together to become the rete testis. After canalization, the tubules join with the remnants of the mesonephric tubules, the future efferent ductules of the testis. The remaining part of the internal duct system, the epididymis, the vas deferens, the seminal vesicles and the ejaculatory ducts are formed from the mesonephric duct.

The primordial sex cells in the seminiferous tubules form the spermatogonia and the sex cord cells give rise to the Sertoli cells (Tran *et al.*, 1977). Both H-Y antigen and anti-Mullerian hormones are secreted by the Sertoli cells. Initially, groups of primordial germ cells and differentiating Sertoli cells become surrounded by a basal lamina within the fetal testis. At this time the germ cells are randomly distributed among the numerous Sertoli cells (Gondos and Hobel, 1971). The interstitial cells or Leydig cells, which are already secreting testosterone, are mesenchymal in origin. Leydig cells first appear at about 60 days of gestation, and by 14–18 weeks make up more than half the volume of the testis (Pelliniemi and Niemi, 1969). Seminiferous tubules remain as solid cords until puberty; at that time, in response to stimulation by the pituitary gonadotropic hormone, there is a proliferation of spermatogonia, an increase in size of the Sertoli cells and a lumen is formed in the tubules.

Jost (1972) and Jost *et al.* (1973) found that the first event to occur in the differentiation of the rat testes was the emergence of the primordial Sertoli cells, which then aggregated into seminiferous cords. This process of aggregation occurred in a period of a few hours, between 13 days 7 hours and 13 days 23 hours. Both electron microscopic and *in vitro* studies confirmed this initial observation (Magre and Jost, 1980, 1984; Magre *et al.*, 1981; Agelopoulou *et al.*, 1984). A similar process of seminiferous cord formation occurs in rabbits (Jost *et al.*, 1985).

Female

In the female the absence of testosterone from the fetal testes induces the development of the ovary and other female genital organs. The female gonad differentiates later than that of the male (Figure 6.19); the first morphological signs of ovarian differentiation occur in the human in the eighth gestational week. The sex cords are broken up into cell clusters by the proliferating mesenchyme. However, a thick tunica albuginea does not form as in the male. The primordial germ cells differentiate into oogonia, which undergo mitotic division to form primary oocytes beginning in the third month of pregnancy. The primary oocytes are surrounded by a single layer of cells, the granulosa cells, which are derived from the epithelial cells of the sex cords. The primary oocytes, together with the surrounding granulosa cells, are known as primordial follicles. It is believed by some authorities that many of the primordial follicles are killed and that a secondary proliferation of sex cords from the coelomic epithelium occurs. These sex cord cells again become associated with pre-existing primordial germ cells, and additional primordial follicles are formed. The ovarian stroma is derived from the mesenchyme surrounding the follicles.

The morphologic development of the human fetal ovary is much slower than that

of the testis. By 20 weeks of fetal age, more than 3 months after the start of testicular development, the ovarian germ cell population reaches a peak of approximately seven million cells. This population then decreases to two million cells at term as a result of atresia and of cessation of mitotic activity (T.G. Baker, 1963).

The mechanisms responsible for gonadal sex differentiation are still unknown (J.D. Wilson *et al.*, 1981; Saenger, 1984; Gondos, 1985). Since testicular differentiation precedes ovarian differentiation in all mammalian species studied so far, a specific inductive factor in the male may be responsible. However, the identity of such a factor, or factors, has not been determined, although there is evidence that Sertoli cells may trigger testicular development without further development of the Y chromosome (Burgoyne, 1988)

(b) Duct system

In the undifferentiated state two sets of paired ducts, the Wolffian and Mullerian ducts, are present in all embryos of either sex, and will give rise to major portions of the male and female reproductive tracts (Figure 6.21).

Male

Differentiation of the duct system in the male is characterized by regression of the Mullerian ducts, retention of the Wolffian ducts and their subsequent differentiation. The primordia for male sex accessory organs, particularly the Wolffian ducts, originate from the embryonic kidney, the mesonephros. The contribution from the mesonephros is incorporated into the genital system after the definitive kidney, the metanephros, develops.

In the human, the Wolffian ducts develop dorsolateral to the pronephric blastema, the forerunner of the mesonephros, and lateral to somites 8–13 (Torrey, 1954). They grow caudally, reaching the hindgut (cloaca) in human embryos at 28–30 gestational days (GD). The mesonephric nephrons and caudal tubules degenerate but the cranial mesonephric tubules are retained as the vasa efferentia, which connect the rete testis to the epididymis. The portion of the Wolffian duct that becomes the epididymis undergoes extensive lengthening and convolution. Later the distal segment of the Wolffian duct develops a thick muscular layer and becomes the ductus (vas) deferens (Figure 6.21).

Only limited information on the cellular differentiation of the male reproductive system is available. At the ultrastructural level, in the differentiating rat epididymis, cisternae of the granular endoplasmic reticulum form numerous specializations resembling intracytoplasmic confronting cisternae (Flickinger, 1969). The apical cell surfaces form numerous cylindrical microvilli, separated by areas covered by a thickened plasma membrane and dense material applied to its cytoplasmic side. Agranular endoplasmic reticulum increases in the apical region of the cell. In the sheep embryo, cilia appear in the epididymis near term and maturation is marked by an increase in the size of the Golgi complex and in the glycogen content of the cells. Lysosomes are also very common (Tiedemann, 1971). Mucus secretion from the epididymis is evident in the human fetus from 25 weeks of gestation onwards (Zondek and Zondek, 1965).

The seminal vesicle originates as a dilation of the terminal portion of the vas deferens in 70-day human fetuses (Jirasek, 1971) and in 18- to 19-day-old rat fetuses (Flickinger, 1970). The part of each Wolffian duct between the seminal vesicle and the urethra becomes the ejaculatory duct. In the rodent, development of the seminal vesicle is completed post-natally and is characterized by the appearance of primary and secondary epithelial cell branching and the abundant deposition of glycosaminoglycan cell matrix

in the cell membrane between the branches (Cunha and Lung, 1979).

The fine structure of the undifferentiated Wolffian duct has been described in the rat (Flickinger, 1969), the mouse (Dyche, 1979) and the sheep (Tiedemann, 1971) and more recently in the human (Lawrence *et al.*, 1992). The columnar cells, which make up the duct walls, contain moderate amounts of granular endoplasmic reticulum, sparse agranular endoplasmic reticulum and many dense bodies and lysosomes.

The onset of Mullerian duct degeneration in the male embryo begins at the end of the bisexual stage of development. In the human embryo, at 55–56 gestational days (GD), the first signs of regression appear in the area where the ducts are closest to the caudal pole

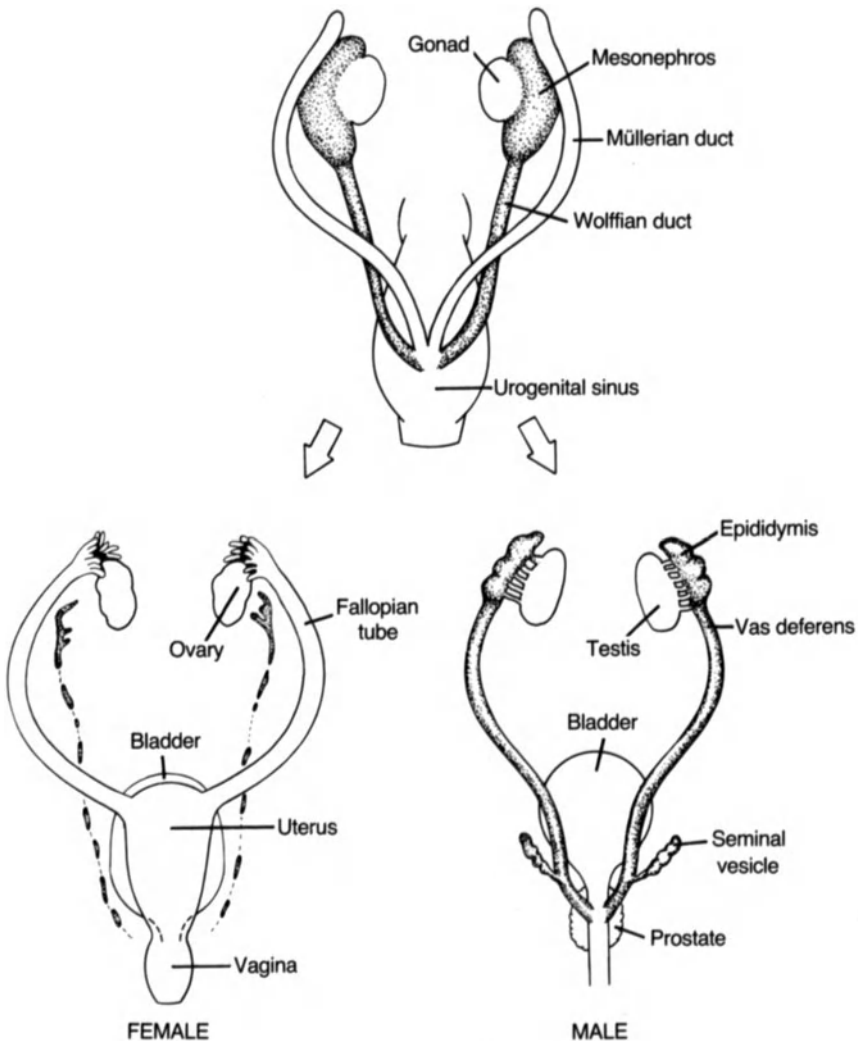

Figure 6.21 Development of the male and female internal genitalia from the Mullerian and Wolffian ducts of the indifferent stage. In the male, the prostate is an outgrowth of the urogenital sinus and is not derived from the Wolffian duct. In the female, the lower part of the vagina is formed from the urogenital sinus.

of the testis and cross the caudal ligament. This ligament is invaded by an acid mucopolysaccharide substance secreted by the fetal testis (Jirasek, 1977). Regression progresses in a craniocaudal sequence, sparing only the cranial portion, which persists to form the appendix testis, and the caudal tips, which remain as vestigial structures, the prostatic utricle (Figure 6.22).

In the human embryo the Mullerian duct is completely regressed in embryos 60–62 GD and in the rat by GD 20. While it is recognized that extensive cytolysis is a normal feature of both Mullerian and Wolffian duct development, the extrusion of whole degenerated cells from the duct early in regression appears to be unique to the involution of the Mullerian duct. Involution may also induce a process called 'puffing' in the periductal mesenchymal cells, which become joined by junctions resembling desmosomes. Their morphology is different from those mesenchymal cells surrounding the duct earlier in gestation.

Female

Female sex differentiation lags behind that of the male (Figure 6.19), although sex determination occurs at the same time in both sexes. Major events affecting the function of the female reproductive organs occur during fetal development. For example, 8-week-old human female Mullerian ducts, which are nearly fully formed, no longer respond to anti-Mullerian hormone. It is at this exact time that the Wolffian ducts begin to degenerate in female embryos (Josso *et al.*, 1977). Similar responses are observed in the 15-day rat fetus (Picon, 1969). The Wolffian ducts contribute mesenchymal tissue to the uterine wall (Witschi, 1970) and the lower portions contribute to vaginal formation (Forsberg, 1965).

Female genital development in mammals is characterized by retention of the Mullerian ducts and their subsequent differentiation into Fallopian tubes, uterus and upper vagina (Figure 6.21). In the 37–40 GD human embryo, Mullerian or paramesonephric ducts first appear as clefts lined by coelomic epithelium lateral and parallel to the Wolffian ducts. Caudal to this cleft, a solid bud of epithelial cells burrows progressively into the mesenchyme in a caudal direction. By the eighth week in the human the solid tip of the Mullerian ducts lies in the pelvis and has crossed ventral to the Wolffian ducts to assume a medial position. As the epithelial bud increases in length, a lumen first appears in its cranial-most end, where it is continuous with the coelomic cavity, and gradually extends caudally until the paired ducts reach the urogenital sinus. For a short time two lumina persist but the medial septum, under normal conditions, disappears shortly after fusion. The unfused cranial portions of the Mullerian ducts become the paired Fallopian tubes and the fused portions become the uterus and upper vagina. The caudal tips of the Mullerian ducts, the Mullerian tubercle, cause an elevation of the dorsal wall of the urogenital sinus and give rise to sinusal tissue. Mullerian ducts do not open into the urogenital sinus until much later in development, when canalization of the vagina occurs. In the rat, at the end of the indifferent stage, the Mullerian duct is formed of tightly packed, wedge-shaped columnar cells with basal nuclei, many free ribosomes and a supranuclear Golgi apparatus (J.M. Price *et al.*, 1977).

Fallopian tube differentiation includes formation of fimbriae, folding in the ampullary region and acquisition of cilia and secretory capability by the epithelial cells. The fallopian tubes differentiate from the cranial portions of the Mullerian ducts and the caudal portions give rise to the uterovaginal canal (Figure 6.21). The uterotubal junction is demarcated by a dramatic increase in diameter of the uterine segment. The oviduct of the human and guinea pig is well developed at term, but in laboratory rodents tubal differ-

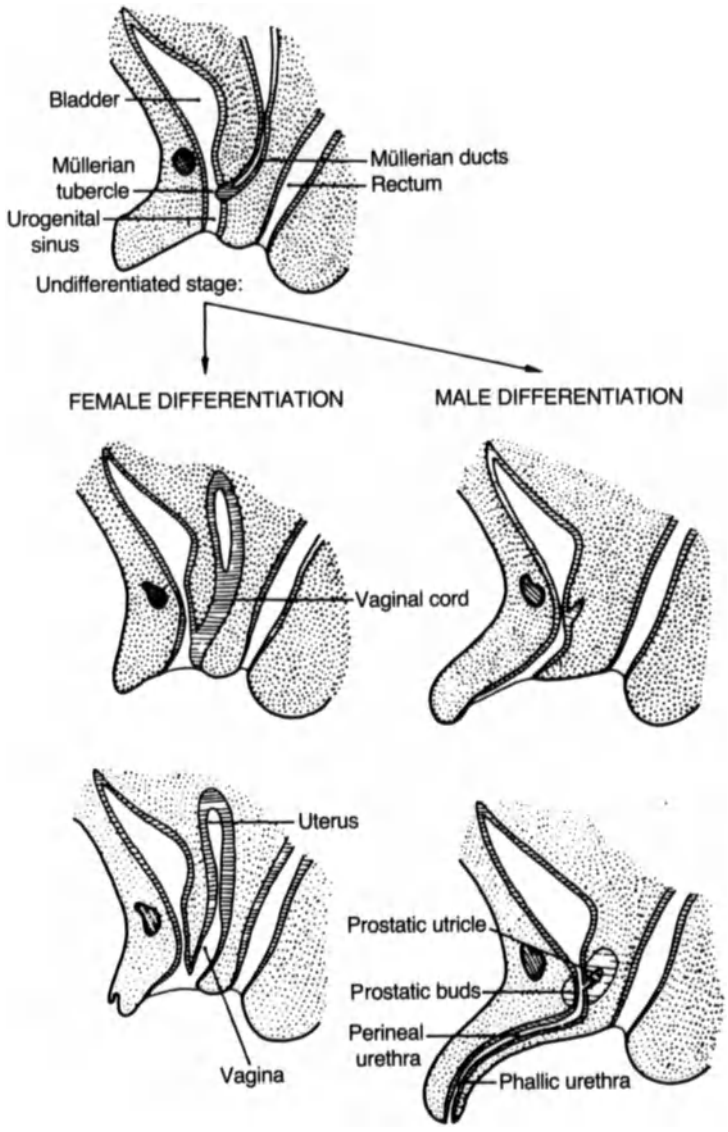

Figure 6.22 Differentiation of the urogenital sinus in male and female fetuses. In females, the vaginal cord develops between the urogenital sinus and the Mullerian ducts, and gains direct access to the perineum. In males, the utricular cord cavitates, to form the prostatic utricle, the male equivalent of the vagina, which opens between the vasa deferentia, just beneath the neck of the bladder. (Reproduced with permission from Josso, 1981.)

entiation is completed after birth (D. Price *et al.*, 1968).

Fusion of the Mullerian ducts to form the uterovaginal canal is complete by 66–68 GD in the human fetus (O'Rahilly, 1977). The cervix makes up the distal two-thirds of the fetal uterus with a slight curvature developing between the future cervical and fundic parts of the uterus at mid-gestation and the future ostium appearing by 100 GD (Bulmer, 1957). The endometrial and endocervical linings are derived from Mullerian duct epithelium and the adjacent mesenchyme contributes to the formation of the uterine muscular and connective tissue layers (Witschi, 1970). The basic structure of the uterus is established early in development. The cervical portion is larger than the body throughout fetal development. The proportions characteristic of the adult do not appear until the post-natal period. Mucin secretion in the endocervical canal occurs as early as 25 weeks of gestation and functional changes occur at this time resembling those elicited by oestrogen stimulation in the adult uterus.

The development of the vagina, and especially the origin of its epithelium, has been debated extensively in the embryological literature. There is still no general agreement regarding the relative contributions of these sources (O'Rahilly, 1977; J.G. Wilson, 1978). The current views are that the upper vagina and ectocervix develop from the Mullerian duct system as the caudal portion of the uterovaginal canal. The lower portion of the vagina is derived from the urogenital sinus.

During early development of the uterovaginal canal, the vaginal plate, a cord-like separation, forms between its lower portion and the cranial portion of the urogenital sinus (Figure 6.22). The hymen delineates the border between the vagina and urogenital sinus. By the fifth month of pregnancy, the fetal uterovaginal canal is patent and there is access to the exterior (O'Rahilly, 1977).

The epithelial lining of the vagina undergoes changes as it differentiates. During the time of vaginal plate formation, the cephalic portion is lined by a cuboidal epithelium. After differentiation of the vaginal plate, this epithelium, believed to be of Mullerian origin, degenerates and is replaced by a glycogen-rich, enzyme-poor, stratified squamous epithelium from the urogenital sinus, which joins with the columnar epithelium of the uterus just outside its external os (Bulmer, 1957; Forsberg, 1965; Gondos, 1985). This process begins late in the first trimester of pregnancy and is not completed until late in the fetal period. The dual origin of the vagina is exemplified by the abnormalities observed in patients with atresia of either Mullerian ducts or the distal vagina (Ulfedder and Robboy, 1976). There has been a renewed interest in the normal sequence of vaginal differentiation with the induction of vaginal abnormalities after prenatal exposure to diethylstilbestrol (A. Herbst *et al.*, 1971; Robboy *et al.*, 1977; R.F. Gasser, 1985).

(c) Urogenital sinus

The urogenital sinus is separated from the rectum when a transverse septum, the urorectal septum, divides the cloaca into the rectum dorsally and the urogenital sinus ventrally. The division of the cloaca begins in human embryos at 35–38 GD and is completed by 51–53 GD (Jirasek, 1971). After it is established, the urogenital sinus is divided into an upper pelvic portion and a lower phallic portion, which is in close association with the genital tubercle. The fused tips of the Mullerian ducts are separated from the dorsal wall of the urogenital sinus by a solid mass which may receive contributions from Mullerian, Wolffian and sinusal epithelium, although there is still considerable controversy regarding this point (Bulmer, 1957; Glenister, 1962; Forsberg, 1965; O'Rahilly, 1977).

In the male, the external genitalia arise in relation to the phallic portion of the definitive urogenital sinus (Gondos, 1985). The prostate

gland also develops in conjunction with the pelvic portion of the urogenital sinus with contributions from the primitive urethra. The prostate gland first appears as epithelial buds, extending laterally from the urogenital sinus near the Mullerian tubercle in human fetuses 61–63 GD (Figure 6.21) (Glenister, 1962). Mesenchymal differentiation precedes bud development, forming solid branching cords which develop a lumen followed by formation of tubules and alveoli. Ultrastructurally, the prostatic cells first resemble those of the stratified urethral epithelium. After lumen formation some apical cells become structurally polarized and the appearance of floccular material in the apical cytoplasmic granules indicates the onset of prostatic secretory activity (Kellokumpu-Lehtinen *et al.*, 1979).

Prostatic maturation in the rat is not far advanced at birth and most acini are still solid (Flickinger, 1970). The rat fetal prostatic and sinusal cells look similar and are characterized by confronting cisternae in the granular endoplasmic reticulum. Masculinization of the urogenital sinus involves regression and lack of descent of the vaginal anlage, closure of the urogenital folds, growth of the phallus and formation of the penile urethra (Figure 6.22).

In the female, the urogenital sinus gives rise to the lower two-thirds of the vagina, including the endodermal portion of the vaginal epithelium (Cunha, 1975; O'Rahilly, 1977). The urethral and the bulbourethral glands are also derived from the epithelium of the urogenital sinus. The lower part of the urogenital sinus forms the vestibule.

(d) External genitalia

At the indifferent stage of development the genital tubercle, a midline elevation, and the laterally located genital folds surround the urogenital membrane. The urogenital membrane ruptures, allowing the urogenital sinus to open onto the surface. An additional pair of swellings, the genital swellings, appear lateral to the genital folds (Figure 6.23).

Male

Lengthening of the anogenital distance marks the beginning of masculinization of the external genital organs in humans (Jirasek, 1971) and probably in other mammals as well. By the end of the first trimester the genital tubercle becomes elongated and is transformed into the cylindrical-shaped penis. The genital swellings develop into rounded scrotal folds which migrate caudally and then fuse below the base of the penis (Figure 6.23). The definitive urethral groove extends forward on the ventral aspect of the penis. The lining of the penile urethra is derived mainly from the endodermal portion of the urogenital sinus. The perineal raphe results from fusion of the urethral folds. The prepuce forms from a fold of skin at the base of the glans and the bulbourethral glands arise from the penile urethra as endodermal derivatives. The erectile tissue, the corpus spongiosum and the corpus cavernosa, develops within the mesenchymal core of the penis. Formation of the penis is completed by 100 GD in the human, but no appreciable difference exists between the penis and clitoris until the 16th gestational week (Feldman and Smith, 1975). Paradoxically, penile growth occurs mainly between 20 weeks' gestation and term, a time when serum testosterone levels are declining.

Female

The changes in the female are less extensive than in the male, and development of the external genitalia begins in the 8-week-old fetus. The genital tubercle does not continue to enlarge as in the male and is bent caudally, forming the clitoris. The lateral portions of the genital (labioscrotal) swellings enlarge to form the labia majora, and the urethral folds

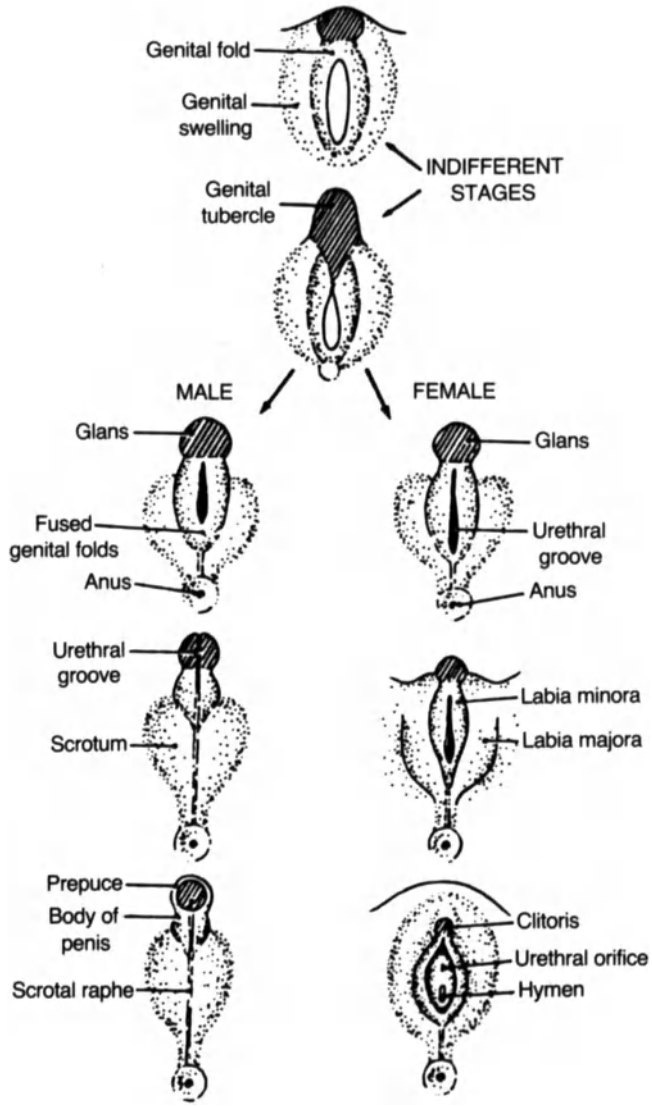

Figure 6.23 Differentiation of the external genitalia in males and females from identical primordia. (Reproduced with permission from J.D. Wilson *et al.*, 1981.)

which flank the urogenital orifice persist as the labia minora (Figure 6.23).

6.6.4 HORMONAL REGULATION

Jost (1947, 1953) was the first to elucidate the fundamental mechanism of sexual differentiation. No stimulation is known to be required for female differentiation while differentiation of the male genital tract is controlled by the fetal testis; in the absence of the fetal testis feminization occurs passively. Jost (1972) established that the castrated mammalian embryo of either sex develops as a

female, while male development is induced only in the presence of specific signals from the fetal testis.

The sexual differentiation of most mammals is thought to be hormonally mediated as a consequence of the genetic determination of gonadal sex. There is recent evidence that a marsupial mammal (*Macropus eugenii*) undergoes extensive sexual dimorphism preceding any form of gonadal morphological differentiation (Wai-Sum *et al.*, 1988). Thus, the conventional view that all somatic sexual dimorphisms in mammals are a consequence of gonadal hormone secretion requires further study, especially the effects of sex-linked genes (Jost and Magre, 1988).

(a) Role of testosterone

In the rabbit and human fetal testis, testosterone synthesis begins shortly after the onset of histological differentiation of the seminiferous tubules and at the time the Leydig cells appear (J.D. Wilson and Siiteri, 1973; Siiteri and Wilson, 1974). Testosterone, the main androgen produced by the male fetal testis (J.D. Wilson and Siiteri, 1973), has two known functions in the developing embryo. In the testis it has a local function promoting maturation of the seminiferous tubules. Systemically, after it is secreted into the fetal circulation, it has an essential function in Wolffian duct virilization and differentiation of the male genital tract. Five different genetic defects have been identified in man which illustrate the essential role of testosterone in the embryological development of the male genital tract (Bongiovanni, 1978; J.G. Wilson, 1978; Saenger, 1984). These defects are discussed later (section 6.7) under abnormal development of the genital tract.

There is considerable experimental evidence to demonstrate the role of the fetal testis in Wolffian duct development. If rabbit male fetuses are castrated, removing the source of testosterone, the Wolffian ducts regress unless testosterone is implanted (Jost, 1947). A similar response occurs *in vitro* in both rabbit and rats (Josso, 1970). Under similar circumstances female Wolffian ducts can be induced to persist, but only within their 'critical period' for sex differentiation.

In rabbits, rats and man the undifferentiated Wolffian ducts lack 5α-reductase, an enzyme which enables conversion of testicular testosterone into its 17-hydroxylated derivative, dihydrotestosterone (DHT) (J.D. Wilson and Lasnitzki, 1971; Siiteri and Wilson, 1974). After sexual differentiation, 5α-reductase levels rise as a consequence of androgen-mediated differentiation. The conversion of testosterone to dihydrotestosterone leads to masculinization of the urogenital sinus and external genital organs by means of DHT–androgen receptor protein interactions. Androgen receptors from fetal rat Wolffian ducts bind more readily with DHT than testosterone (Gupta and Block, 1976); this is also true of androgen receptors elsewhere in the body. In 14.5-day male and female rat fetuses the number of binding sites is similar but later increases in males. The presence of functional androgen receptors is now considered to be an absolute requirement for male sexual differentiation (Mowszowicz *et al.*, 1989).

At present there is considerable knowledge regarding the mechanisms of androgen action in the post-natal period. However, very little is known about what happens in the embryo because of its small size, which makes it difficult to study (J.D. Wilson *et al.*, 1981). Studies of single-gene mutations in animals and humans that cause resistance to androgen action and inhibition of male genital system development indicate that androgens act similarly during pre- and post-natal life (Griffin and Wilson, 1977, 1980).

(b) Role of Mullerian inhibiting substance

In addition to a stimulatory effect on the Wolffian duct system, the fetal testis has an inhibitory effect on Mullerian duct develop-

ment. This was first demonstrated in mammals by Jost (1947) in the rabbit fetus. He found that Mullerian ducts were refractory to high levels of testosterone and produced a specific inhibitor of the Mullerian duct which differed from testosterone. Since this initial critical observation, Picard *et al.* (1978) have demonstrated that the fetal testis contains an incompletely characterized glycoprotein with anti-Mullerian properties. This substance, or factor, is known as the anti-Mullerian hormone (AMH) or the Mullerian inhibiting factor and acts in the male to cause regression of the Mullerian ducts. AMH is formed by the Sertoli cells in the seminiferous tubules and is about 70 000 molecular weight (Blanchard and Josso, 1974; Donahoe *et al.*, 1977). Mullerian duct regression begins soon after differentiation of the seminiferous tubule. The formation of this inhibiting substance constitutes the first endocrine function of the embryonic testis (J.D. Wilson *et al.*, 1981). Although the mechanism by which AMH acts is unknown, recent evidence suggests that it may play a role in germ cell maturation (Hirobe *et al.*, 1992). Support for the concept that Mullerian regression is an active process comes from the human genetic disease (persistent Mullerian duct syndrome) in which genetic and phenotypic males have Fallopian tubes and a uterus, and the male Wolffian ducts are also present (Sloan and Walsh, 1976). This disease is inherited as a recessive trait, either autosomal or X-linked, and results from either a failure to produce AMH or an inability of the tissue to respond to the hormone. One of the main features of this disease is the failure of the testis to descend, particularly the transabdominal movement of the testis. This suggests that AMH plays an important role in testicular descent (J.D. Wilson *et al.*, 1981; J.D. Wilson, 1989).

(c) Role of oestrogens

The embryo is exposed to a wide array of hormones as it develops in the uterus. In contrast to androgens, the role of oestrogens, especially in the development of the genital system, is largely unknown. Oestrogen synthesis occurs in both male and female embryos prior to implantation, and this oestrogen may be essential to the process of implantation itself. Between 6 and 8 weeks of gestation both the ovaries and the testes of human embryos initiate characteristic endocrine function. Thus, the ovary acquires the capacity to secrete hormones at the same time as the testes (George and Wilson, 1978). If the synthesis or response to oestrogens is blocked, normal implantation may be prevented, resulting in early embryonic death. As yet no mutations have been characterized that result in either deficient oestrogen synthesis or unresponsiveness to its action (J.D. Wilson *et al.*, 1981). Later in pregnancy, oestradiol formation is initiated in the embryonic or early fetal ovary before its histological differentiation occurs. Oestrogen has also been shown to modify the Mullerian duct system experimentally, and oestrogen receptors have been demonstrated in Mullerian ducts of fetal rats and guinea pigs late in gestation. However, normal development occurs in castrated females, indicating that it is not an oestrogen-dependent process. The local action of oestradiol may play a role in the histological differentiation of the ovary, and exposure to diethylstilboestrol (DES), an exogenous oestrogen, alters sexual differentiation (McLachlan and Newbold, 1987). Aside from this, the role that oestrogen plays in the development of either sex is not yet known.

6.7 ABNORMAL DEVELOPMENT

6.7.1 MAJOR MALFORMATIONS OF THE REPRODUCTIVE SYSTEM

(a) Human pseudohermaphroditism

Female pseudohermaphroditism (FPH) is a form of phenotypic sex reversal. Human fe-

Table 6.12 Critical periods of organogenesis in animals (Reproduced with permission from Schardein, 1976)

Species	*Mean duration of gestation (days)*	*Critical period*[a] *(days)*
Hamster, golden	16	4–14
Mouse	19	7–16
Rat	21	9–17
Rabbit	31	8–21
Ferret	43	8–28
Cat	63	5–58; 5–15 (most favourable)
Dog	63	1–48; 8–20 (estimated)
Guinea pig	68	11–20
Pig	114	12–34
Sheep	150	14–36
Monkey, rhesus	168	20–45; 22–30 (most susceptible)
Monkey, baboon	175	22–47
Armadillo	225	1–30
Human	278	20–55
Cow	284	8–25
Horse	336	?

[a] Period of embryological organogenesis or period of known susceptibility to teratogens.

male pseudohermaphrodites are genetic, XX karyotype and gonadal females with normally developed but hypoplastic internal genitalia (Table 6.13).

The genitalia are ambiguous, i.e. male or female sex cannot be determined, or they are masculinized to a variable degree. A female fetus becomes masculinized if exposed to excessive androgens *in utero*. The androgens may be derived from the fetus itself, from a maternal source or from an external source operating via the mother (Polani, 1981a). The degree of masculinization is time dependent. If androgen exposure occurs before the 12th week of gestation the degree of masculinization may be so great that the urethral opening is penile. On the other hand, if androgen exposure occurs after the 12th week of gestation, when the vagina has already been separated from the urethra, only hypertrophy of the clitoris will occur (Saenger, 1984; Reindollar *et al.*, 1987). These individuals may be fertile and bear young once the source of the androgens has been removed.

Congenital adrenal hyperplasia is the most common cause of female pseudohermaphroditism, causing variable degrees of virilization of the external genitalia. Female pseudohermaphroditism is caused by three different forms of congenital adrenal hyperplasia, 3β-hydroxylated dehydrogenase deficiency, 2l-hydroxylase deficiency and 11-hydroxylase deficiency (New *et al.*, 1981). The external genitalia are normal in male fetuses exposed to excess testosterone from congenital adrenal hyperplasia. The female fetus with congenital adrenal hyperplasia is born with a normal uterus and Fallopian tubes because it does not possess a testis. Anti-Mullerian hormone is not produced. Thus, female genital abnormalities are present only in the external genitalia which is androgen responsive. The fact that the Wolffian duct undergoes complete involution in these cases

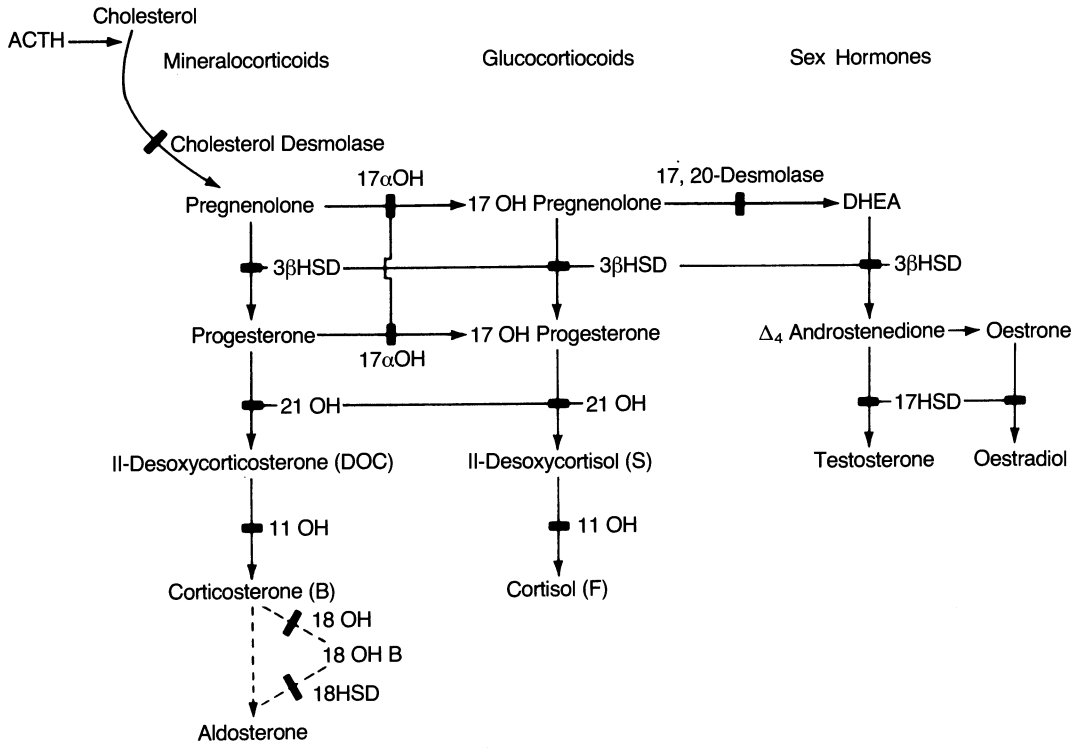

Figure 6.24 Synthesis of mineralocorticoids, glucocorticoids and sex steroids. (Reproduced with permission from Saenger, 1984.)

suggests that for normal Wolffian duct development the level of androgen is higher than that produced in congenital adrenal hyperplasia.

In cases of male pseudohermaphroditism (MPH) the individual with a 46XY karyotype has testes and possesses ambiguous external and internal genitalia or the genitalia resemble a female. Male pseudohermaphroditism can result from abnormalities in testosterone synthesis, testosterone metabolism or androgen action (Saenger, 1984; Reindollar *et al.*, 1987). Five distinct autosomal recessive disorders have been identified that result in reduced testosterone synthesis, caused by a deficiency in one of the five enzymes required for conversion of cholesterol to testosterone (Figure 6.24).

In three of these disorders, which involve deficiencies of cholesterol desmolase (Kirkland *et al.*, 1973; Bongiovanni, 1978), 3β-hydroxysteroid dehydrogenase (Bongiovanni, 1962; Schneider *et al.*, 1975; Pang *et al.*, 1983) and 17α-hydroxylase (New, 1970; Tourniaire *et al.*, 1976), cortisol as well as testosterone is deficient.

The clinical appearance of patients with these enzyme deficiencies is quite variable (C.R. King and Pernoll, 1984). The phenotypes range from the male with mild hypospadias to an apparent female with marked ambiguity. The Mullerian system is absent in these males because embryonic production of anti-Mullerian hormone is not affected by errors in androgen synthesis. The Wolffian system and the external genitalia are virilized to a variable degree.

In two of the disorders there are enzyme defects involving deficiencies of 17,20-desmolase (Zachmann *et al.*, 1972; Goebelsmann

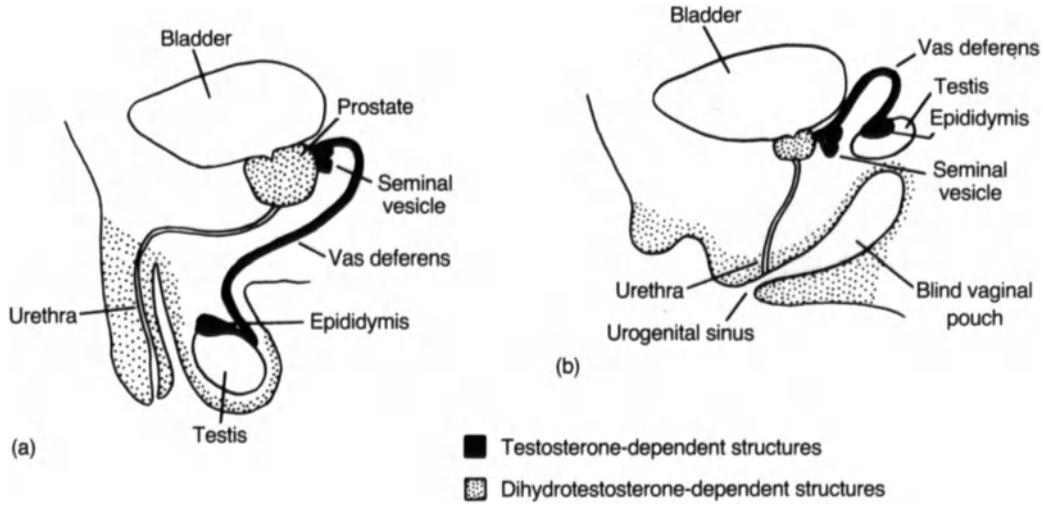

Figure 6.25 (A) Suggested selective roles of testosterone and dihydrotestosterone in normal male sexual differentiation. (B) Findings in males with inability to convert testosterone to dihydrotestosterone due to 5 α-reductase deficiency. Testosterone-dependent structures are normal, although testes are not descended and dihydrotestosterone-dependent structures are not developed. A blind vaginal pouch is frequently present. (Reproduced with permission from Saenger, 1984.)

et al., 1976; Zachmann *et al.*, 1982) and 17-hydroxysteroid dehydrogenase (Goebelsmann *et al.*, 1973; Givens *et al.*, 1974; Virdis *et al.*, 1978; Levine *et al.*, 1980) that primarily affect testosterone synthesis by the testes. Patients with 17-α-hydroxysteroid dehydrogenase deficiency are thought to be normal prior to puberty, however a blind-ending vaginal pouch without Mullerian derivatives is usually present (Goebelsmann *et al.*, 1973). Inguinal testes are usually present and gynaecomastia may develop from the peripheral conversion of weak androgens to oestrogens.

Male pseudohermaphroditism resulting from abnormal testosterone metabolism involves a deficiency of 5α-reductase and is the first inherited abnormality of steroid metabolism to be recognized in which the defect resides in target tissues (Imperato-McGinley *et al.*, 1974). The deficiency is an autosomal recessive defect, and causes abnormally low conversion of testosterone to DHT, the androgen responsible for masculinizing the external genitalia of the male fetus (Figure 6.25). Deficiency in 5α-reductase leads to pseudohermaphroditism in males who are born with ambiguous genitalia (Saenger, 1984). The clitoris is enlarged and often has a ventral urethral groove. A urogenital sinus is present and either a single orifice or separate urethral and vaginal orifices are present, depending upon the degree of masculinization. At puberty, the clitoris and the testes enlarge and the testes descend into the labioscrotal folds. A male phenotype develops, the voice deepens, and frequent erections occur. Because DHT does not play a role in female sexual differentiation or pubertal maturation homozygous females have a normal phenotype and are fertile (R.E. Peterson *et al.*, 1977). See Table 6.13.

(b) Animal pseudohermaphroditism

The spontaneous incidence of this condition has been reported only occasionally for animals, especially when compared with con-

Table 6.13 Classification of disorders (malformations) of sexual differentiation

Diagnosis	*Karyotype*	*External genitalia*	*Gonads*	*Internal ducts*	*Comments*
Female pseudohermaphroditism					
Congenital adrenal hyperplasia	46,XX	Ambiguous	Ovary	Mullerian	Female genital abnormalities are present only in the androgen-responsive external genitalia.
Maternal ingestion of androgens and synthetic progestins	46,XX	Ambiguous or male	Ovary	Mullerian	Exposure before 12 weeks causes formation of urogenital sinus; after that causes only clitoral enlargement
Male pseudohermaphroditism					
Abnormal testosterone synthesis	46,XY	Ambiguous, hypospadic male or female	Testis	Ambiguous or Wolffian	Enzyme defects affecting synthesis of testosterone and cortico-steroids (variants of congenital adrenal hyperplasia)
Abnormal testosterone metabolism	46,XY	Ambiguous	Testis	Wolffian	Defects in testosterone metabol-ism by peripheral tissues (5α-reductase deficiency).
True hermaphroditism	46,XX or 46,XY or mosaics	Variable but usually ambiguous	Testis + ovary or ovotestis	Mullerian + Wolffian	Cause is unclear; 46, XY karyotype; There is probably undetected chimerism or mosaicism and 46, XX sex chromosome mosaicism may occur
Testicular feminization	46,XY	Female	Testis	Wolffian	Phenotypic females because there is no response to testosterone or DHT because of receptor defect

ditions such as freemartinism, which are much more common (Benirschke, 1981). Both male and female pseudohermaphroditism have been observed in dogs (Phillips *et al.*, 1939; Fralick and Murray, 1948; Schultz, 1962; Curtis and Grant, 1964; McFeely and Biggers, 1965; Murti *et al.*, 1966; McFeely *et al.*, 1967) and are apparently more common in cocker spaniels. In 48 cases of canine intersex, 16 were found in cocker spaniels (Hare, 1976). Of these, nine were male pseudohermaphrodites with either scrotal or inguinal testes with ambiguous genitalia and 78XX karyotypes. Rieck (1973) reported on a female pseudohermaphroditic cow with atrophic ovaries. Bruere *et al.* (1969) identified a male pseudohermaphrodite with normal 54XY chromosomes. The external genitalia were female and testes were present in the ovarian positions but no uterus was present. Although intersex is common in goats (Koch, 1961) only a small number of pseudohermaphrodites have been reported (Basrur and Coubrough, 1964). The caprine male pseudohermaphrodite is an example of an animal in which testes develop in an XX individual lacking a Y chromosome (N.W. King, 1978). The presence of the homozygous autosomal dominant gene for polledness (absence of horns) in genetic female goats also results in male pseudohermaphroditism, or, sometimes, true hermaphroditism (Eaton, 1943; Soller *et al.*, 1969). The European roe deer has a relatively high incidence of both pseudo- and true hermaphroditism (Koch, 1961). Benirschke (1981) examined the autopsy reports of 3000 mammals from the San Diego Zoo and found only three intersex states. All three animals, a Nubian goat, a Himalayan goat and a Uganda kob, possessed characteristics of male pseudohermaphrodites with testes and external genitalia which were ambiguous or female.

(c) True hermaphroditism

This is a relatively rare condition in humans. Abnormal differentiation of both external and internal genitalia also occurs and the gonads are usually classified as ovary–testis or ovotestes–ovary (Van Niekirk, 1981). In the true hermaphrodite ovarian and testicular tissue coexist. Approximately 80% of individuals studied have 46XX karyotypes, 10% have 46XY and 10% have mosaicism. Assigning sex may be difficult except where ovarian and testicular tissues are aligned end-to-end; in these individuals differentiation is straightforward (Saenger, 1984; Reindollar *et al.*, 1987). In true hermaphrodites the fetal testis may inhibit Fallopian tube development but development of the uterus is not suppressed. The testicular tissue is defective in secreting androgens and the anti-Mullerian factor. This deficiency in testicular function leads to inadequate virilization of the external genitalia and the failure to inhibit Mullerian duct development.

The cause of true hermaphroditism is still unclear. In those cases with a 46XY karyotype, there may be chimerism or mosaicism which is undetected; in 46XX sex chromosome mosaicism, Y–X interchange, Y–autosome translocation and single-gene mutation are possible causes (Wachtel *et al.*, 1976). In patients with 46XX the immunological detection of H-Y antigen suggests that in many individuals X–Y interchange or a Y–autosome translocation may, in fact, take place. Additional support for this theory comes from two patients with a minute additional band on the short arm of one of the X chromosomes. The involvement of a Y–chromosome translocation that is too small for cytological detection may account for testicular differentiation in true hermaphrodites with a 46XX karyotype (Saenger *et al.*, 1976; Wachtel *et al.*, 1976).

Clinically, sex designation should be based on the appearance of the external genitalia (Saenger, 1984). With regard to surgical cor-

rection, in patients with an end-to-end arrangement of the ovary and testis, the ovarian tissue may be saved but in those individuals with an ovotestis the entire structure must be removed (Van Niekirk, 1974). Breast development and virilization may occur at puberty if the ovotestis is left in place. Menstruation occurs in two-thirds of the patients with a uterus (J.L. Simpson, 1976).

Only two true hermaphrodites have been reported in primates. Sullivan and Drobeck (1966) reported that the external and internal organs in a female rhesus monkey were normal except for the presence of bilateral typical ovotestes. The cortex of the ovaries contained primordial ova and the central portions contained closely packed tubules and some interstitial tissue. Sex chromatin-positive cells were also identified. Much earlier Harlan (1826) described a 2-year-old Bornean orang-utan, though his description of hair colour suggests that this animal was in fact a gibbon (Ruch, 1959). The penis had a hypospadic groove, and a vulva, vagina and a bifid scrotum were present. The testes were undescended, the epididymis was present but the seminal vesicles were absent. A normal uterus, uterine tubes and ovaries were present. Ruch (1959) states that this animal was mistakenly reported as hermaphrodite and was probably a normal female. The long pendulous nature of the clitoral skin in spider monkeys, a normal feature of the external genitalia in this species, is misleading and intersexuality is often erroneously suspected.

True hermaphrodites have been observed in cats but at a low incidence (Centerwall and Benirschke, 1973; Benirschke, 1981). In the dog, true hermaphrodites are more commonly reported but only a few cases have been documented chromosomally (Benirschke, 1981). True hermaphrodites have been reported in beagles, terriers, setters, cocker spaniels and in unspecified breeds (N.W. King and Garvin, 1964; Vandevelde, 1965; McFeely *et al.*, 1967; Gerneke *et al.*, 1968; Pullen, 1970; Selden *et al.*, 1978; Dain and Walker, 1979). The most common chromosomal complement observed in these studies was XX and a smaller number of XXY cells. True hermaphrodites are also rare in cattle (McFeely *et al.*, 1967; Dunn *et al.*, 1968, 1970) and great care must be taken to distinguish them from freemartins by employing genetic techniques.

True hermaphrodites have not been reported in horses but a variety of aneuploid states, mainly, the 63XO condition, is relatively common (Benirschke, 1981). A review by Giovanni and Cribiu (1978) on chromosomal and sex anomalies in horses included a total of 23 cases reported in the literature. True hermaphroditism, with ovotestis or unilateral testis as well as uteri and Barr bodies, has been reported in pigs (Johnston *et al.*, 1958). Basrur and Kanagawa (1971) found one of three true hermaphrodites to be an XX/XY whole-body chimaera. The two others had bilateral ovotestes, uterus and female external genitalia and were 38XX. Maik (1969) found XX lymphocytes in 25 intersex pigs, including many who were true hermaphrodites. True hermaphroditism among goats is uncommon (Koch, 1961). This is somewhat surprising since the frequency of genital defects is common (Benirschke, 1981). Genital anomalies in artiodactyla have been occasionally observed (Benirschke, 1981).

True hermaphrodites are uncommon in rats, hamsters and guinea pigs. In the rat at least one ovotestes was observed in those reported as true hermaphrodites (D.C. Johnson, 1966; Kikuchi *et al.*, 1977; N.W. King, 1978), and only one true hermaphrodite has been reported in the rabbit (Sheppard, 1943). A few spontaneous true hermaphrodites have been observed in other strains of mice (Lyon, 1969; N.W. King, 1978).

(d) Testicular feminization

Testicular feminization (TF) is a form of male pseudohermaphroditism in which the

gonads are testes and are frequently found in the inguinal canal, and the external genitalia are those of a normal female. In testicular feminization the karyotype is 46XY. Under the influence of the Y chromosome, the gonads differentiate as testes and secrete testosterone and dihydrotestosterone (DHT). The condition is rare, inherited and is determined by a recessive gene. There is no response to testosterone or DHT because of a receptor defect caused by a gene mutation on the X chromosome (Migeon *et al.*, 1981a; Brown and Migeon, 1986) and phenotypic females develop. In these female fetuses the testis secretes an anti-Mullerian hormone and there is a suppression in development of the Fallopian tubes, uterus, and upper third of the vagina (Migeon *et al.*, 1981b).

Testicular feminization may be detected at birth by the presence of inguinal hernia or after puberty by primary amenorrhoea. At puberty, the external genitalia are unambiguously female, the clitoris is normal in size and the breasts are normally developed. The vagina usually ends blindly, and may be shortened, depending on the relative contribution of the Mullerian ducts and the urogenital sinus to its formation (Migeon *et al.*, 1981b). Typical of prolonged cryptorchidism, spermatogenesis does not occur.

Androgen production in these cases is normal or may be higher than normal (Griffin and Wilson, 1980). The higher levels of androgen are probably secondary to elevated levels of luteinizing hormone, which may be due to a deficient feedback regulation caused by resistance to androgen at the hypothalamic–pituitary level. Higher levels of androgen result in the testes producing more oestrogen, which contributes to the appearance of normal female secondary sex characteristics at puberty. The resistance to androgen is caused by abnormalities of the androgen receptor. At least two genetic variants exist; the receptor-negative variant is characterized by undetectable DHT binding to the cytosol of fibroblasts and is caused by absence of the receptor protein or by changes in the structure of the receptor, resulting in a temperature-dependent loss of affinity for the steroid. The presence of unstable receptors has been observed in both complete and incomplete testicular feminization. The receptor-positive variant has both normal cytoplasmic and nuclear binding of DHT. It may represent a defect that is distal to the receptor, i.e. the generation site of specific messenger RNA in the nucleus (Amrhein *et al.*, 1976; Griffin, 1979). These two variants are important, especially in patients with incomplete testicular feminization. An infant with XY karyotype and inguinal testes and complete female external genitalia with undetectable androgen binding may be expected to feminize spontaneously at puberty. On the other hand, an infant with normal androgen binding may not be completely insensitive to androgens and may virilize at puberty (Saenger *et al.*, 1980).

Testicular feminization is less common in most animal species (Benirschke, 1981). Nes (1966) described a form of testicular feminization in cattle. Shaver (1967) described two female intersexes in rabbits with apparently normal XY karyotypes. They possessed testes containing spermatogonia but the seminiferous tubules lacked lumina. The Mullerian ducts were absent and the vaginas ended blindly, thus they can be interpreted to represent cases of testicular feminization. This syndrome has been characterized in the rat (Bardin *et al.*, 1970) and in the mouse (Lyon and Hawkes, 1970) with male pseudohermaphroditism. King-Holtzman rats also have features resembling testicular feminization with normal male karyotypes (Allison *et al.*, 1965). The pattern of inheritance in the rat is the same as that for man (Benirschke, 1981). It affects males only and is transferred as an X-linked recessive character or possibly as a sex-limited autosomal dominant trait (Stanley and Gumbrech, 1964). In these cases the scrotum does not form, the testes are in the inguinal position and spermatogonia are present.

The affected rats resemble some human cases of testicular feminization in that they show some resistance to androgen (Lyon *et al.*, 1981). In mice with testicular feminization the karyotype is XY and they are positive for H-Y (Lyon and Hawkes, 1970). The mice have blind vaginas, no uteri and the epididymides and vasa deferentia are small or absent. The testes, located in the inguinal region, contain spermatogonia and the trait is X linked.

Freemartinism, the most common form of sex differentiation altered by hormones, occurs most often in cattle and, much less commonly, in sheep, goats and pigs (Noden and deLahunta, 1985). The gonad of the sterile intersex female twinned to a normal male displays various forms of testicular organization and has an XX karyotype. This condition results from an anastomosis of the extraembryonic chorioallantoic blood vessels of the twins about a week before gonadal differentiation and allows for passage of fetal hormones and blood cells from one twin to another. Primary germ cells may also pass between twins and localize in the gonad but their fate is unknown. The gonadal sex reversal of freemartins is due to the passage of a substance promoting testicular development, presumably H-Y antigen, from the developing male twin to the female twin (Noden and deLahunta, 1985). Even though seminiferous tubules develop in the genetically female testes, spermatogenesis does not occur, probably because XX germ cells cannot form spermatocytes. Inhibition of the paramesonephric duct and differentiation of the mesonephric duct are variable. Male duct differentiation is most advanced in the region most proximal to the gonad as a result of production of androgens from the sex-reversed freemartin gonad. The external genitalia of the freemartin calf are predominantly female, although there is usually some evidence of virilization due to the circulating androgens. It is of interest to note that, even though twin marmoset monkey fetuses of opposite sex often share a common circulation as a result of placental blood vessel fusion, the normal development of the female fetus is unimpaired.

Both chimaeric and mosaic animals offer interesting opportunities for the study of more than one genotype within one organism. In a mosaic animal, because of mitotic non-disjunction or chromosomal loss, all genotypes originate from a single zygotic genotype. The expression of trisomy and the accompanying abnormalities depend on when during cleavage non-disjunction occurs and where the affected cells are located.

Chimaeric animals also have more than one genotype but they are derived from two or more zygotic genotypes and they can be produced by transplanting tissue or blastomeres from one animal to another. Chimaeric animals are valuable models for the study of placental function and maternal–fetal interactions. The most common naturally occurring chimaeras are believed to be due to fusion of zygotes with fertilized polar bodies or by the fusion of two cleavage-stage embryos (Noden and deLahunta, 1985). Numerous other disorders of sexual development occur in animals and man but they are beyond the scope of this book (Benirschke, 1981; Polani, 1981a,b).

6.7.2 EXPERIMENTAL TERATOLOGY

General conditions for the occurrence of malformations have become evident from the numerous studies that have been conducted in laboratory animals as experimental models or for the purpose of testing the safety of drugs and chemicals for human use or exposure. From these studies principles of the science of teratology have been formulated (J.G. Wilson, 1973; J.G. Wilson and Fraser, 1977; Persaud *et al.*, 1985; Schardein, 1985) which provide useful guidelines in determining susceptibility to teratogenesis. Susceptibility to teratogenesis is dependent upon an interplay of the following: species, stage of prenatal development, dosage, route

of administration and teratogenic mechanisms.

(a) Species

All species are not equally sensitive to teratogenesis by a given teratogen. Some of these species differences are due to genetic factors but such things as variability in litter response observed even in inbred animals is not attributed only to genetic factors. Observed species differences may also result from differences in the intrinsic sensitivities of the target tissues and pharmacokinetic differences that determine the crucial concentration–time relationships in the embryo. These include maternal absorption, distribution, protein binding, metabolism and excretion as well as placental transfer (Nau, 1987). Kalter (1968) reported that inter- and intra-species variability in teratogenic response may be manifested in the following ways:

1. An agent that is teratogenic in some species may have little or no teratogenic effect in others.
2. A teratogenic agent may produce similar defects in various species, but the defects will vary in frequency.
3. A teratogenic agent may induce certain defects in one species that are completely different from those induced in other species.

Numerous examples exist to amplify the point of inter- and intra-species variability. Man and higher primates are highly vulnerable to thalidomide, rabbits react in a somewhat similar fashion, but require a higher dosage; most other animals, including rats, are more resistant to thalidomide teratogenesis. Mice are generally susceptible to the induction of cleft palate by cortisone, hamsters and guinea pigs less so, and rats are usually refractory to this action. Aspirin at doses sufficient to induce cleft lip and other defects in mice have no effect in guinea pigs and monkeys (Trasler, 1965; Tanimura, 1972; Kromka and Hoar, 1973).

There are also genetic differences within given strains or breeds of the same species which influence teratogenesis. As an example, cortisone induced cleft palate 100% of the time in the A/J strain of mouse, while only 20% of the fetuses in the C57 B1/6J strain had cleft palate exposure to a similar dosing regimen (Kalter, 1968). Both the maternal and fetal genotypes play an important role in the response to cortisone through cleft palate induction. Other factors which are variables in strain susceptibility to teratogenic agents are maternal parity and weight, fetal weight, number of young, maternal basal metabolic rate, size and constitution of the placenta, intrauterine associations, fetal and maternal production of hormones and maternal utilization of vitamins and other essential substances (Schardein, 1976).

(b) Stage of prenatal development

It is generally accepted that drugs and chemicals must be administered during organogenesis in order to induce teratogenesis. The importance of this principle can be appreciated by the fact that in thalidomide teratogenesis it was the time of treatment rather than the dosage that was the decisive factor (J.G. Wilson, 1972). The organogenic period, the critical period for teratogenesis, varies among the species and is partly dependent upon the length of gestation (Table 6.12). It has been generally held that the conceptus is resistant to production of malformations during the predifferentiation period, i.e. the time from fertilization to the onset of organ differentiation (Figure 6.26).

However, there is growing evidence from studies in rodents that chemical exposure during preimplantation can cause subtle nonlethal mutations that result in shifts in the developmental programme of the embryo. The deleterious effects can range from intrauterine mortality to growth retardation

and frank malformations (see review by Iannaccone *et al.*, 1987). Additionally, exposure to developmental toxins (e.g. alcohol and hyperthermia) during the period of gastrulation has been associated with brain and facial anomalies in experimental animals and humans (Webster *et al.*, 1988).

The time of greatest teratogenic insult usually corresponds to the time when the embryo is undergoing marked morphological changes and a particular organ is developing most rapidly. In the human this occurs during the third and eighth weeks of gestation (Figure 6.27).

Ironically, the period of greatest susceptibility begins before pregnancy is usually diagnosed or is even suspected by many women. Following organogenesis, 9 weeks to term, the fetus becomes progressively less susceptible to teratogenesis. The most important

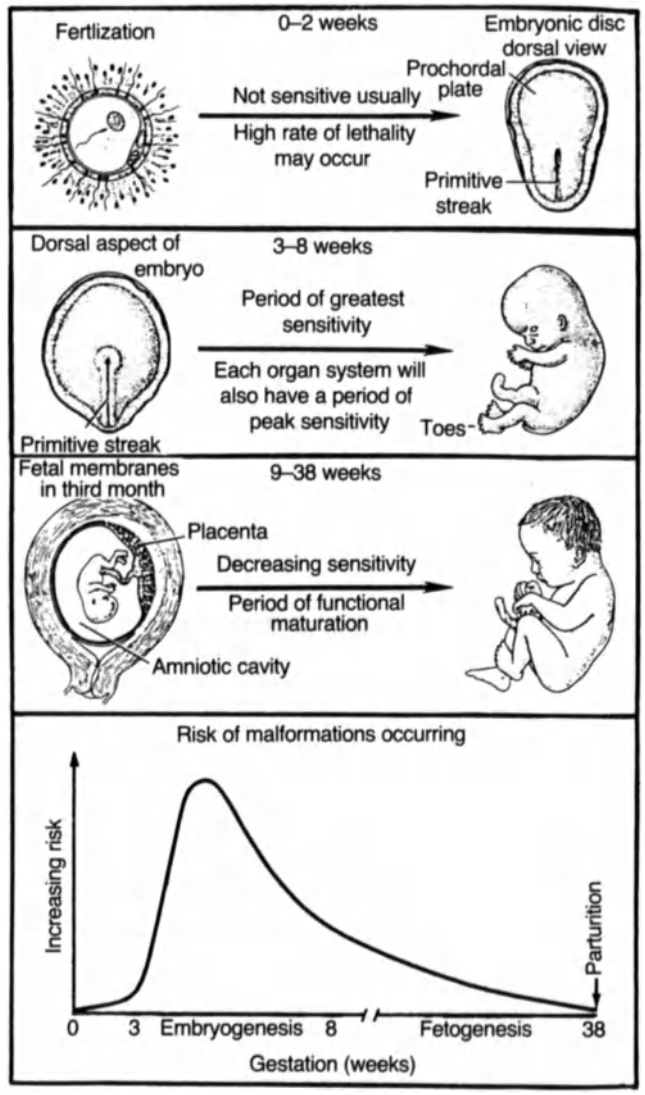

Figure 6.26 Periods of susceptibility to teratogenesis. (Reproduced with permission from Sadler, 1985.)

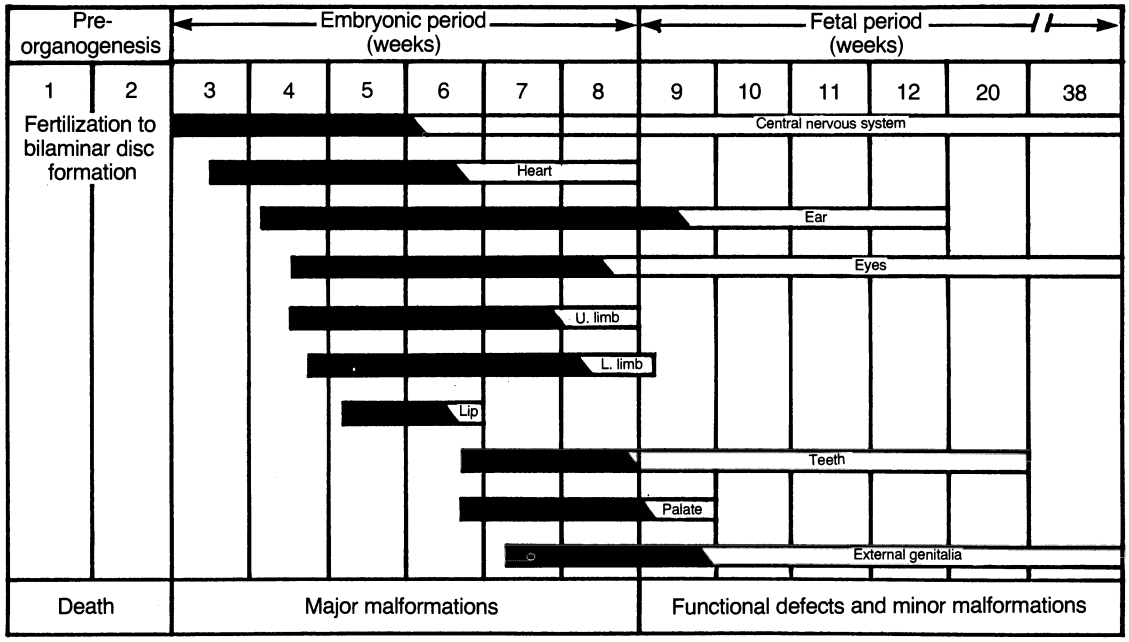

Figure 6.27 Susceptibility to teratogenesis for organ system (solid bar denotes highly sensitive periods). (Reproduced with permission from Sadler, 1985.)

features of the fetal period are marked histogenetic changes, rapid growth and functional maturation.

Administration of drugs that are dissolved, absorbed, metabolized and excreted rapidly can be confined to the period of organogenesis. This is the way most drugs are routinely tested. However, the activity of drugs that are absorbed or metabolized more slowly may occur outside the organogenic period and result in absence of a teratogenic effect. This factor explains why some drugs and chemicals administered outside (before or after) the critical period have shown teratogenic activity, and it also constitutes one of the common pitfalls in teratogenic testing.

(c) Dosage

The dosage of a potential teratogenic agent is very critical with regard to susceptibility to teratogenesis. In most instances the dosage of a teratogenic agent is within a narrow zone between that which will kill the fetus and that which has no discernible effect. It is only those doses that are sufficient to interfere with specific developmental events that are teratogenic, thus all doses are not teratogenic. The embryo is usually more susceptible to drugs than the adult; this is mainly because of the specific vulnerability of certain embryonic cells that is no longer present in the corresponding adult cells. Exposure of the embryo to greater concentrations of the drug than the adult is also possible. This may be due to the lack of development of the necessary enzymes in the embryo which are necessary for detoxification (Tuchmann-Duplessis, 1970).

There is considerable controversy concerning the relationship of embryolethality and malformation. Several authorities state that these two manifestations of abnormal development are different degrees of reaction to the same stimuli, with the rate of embryonic death and the rate and severity of malforma-

tions increasing in a somewhat parallel fashion as the dosage is increased (J.G. Wilson, 1959; Beck and Lloyd, 1963). These same authorities also state that the embryo has a threshold to dosage, above which irreparable alterations occur, resulting in malformation, or, secondarily, death. Other investigators claim that the correlation between embryolethality and malformation does not always exist, nor are these two manifestations of teratogenicity necessarily related (Tuchmann-Duplessis 1965, 1970; Gebhardt 1970; Kalter 1980; J.G. Wilson 1980).

In experimental settings, and probably in situations where accidental exposure to an environmental teratogen might occur, a suitable dosage of a teratogen usually results in the production of some normal offspring, some malformed offspring and some dead or resorbed offspring. Depending on the agent and the conditions of exposure, less common patterns of response may involve the production of intrauterine death in the absence of malformations (Neubert *et al.*, 1980) (see section 6.7.4, Teratogenicity of environemtnal agents) or vice versa. Experimentally, the selection of the proper dose level is, thus, of paramount importance. Teratogenicity, as in other toxicological studies, is governed by dose–response relationships. The response curve is usually quite steep and is of great significance in determining a true teratogenic effect. 'No effect' levels also have been shown for teratogens that have undergone realistic testing, however there is usually no relationship between teratogenicity and chemical structure or pharmacological properties of a drug.

(d) Route of administration

The route of administration of the teratogenic agent can influence the outcome of the experiment. For teratological testing it is usually recommended that the route (oral, parenteral, etc.) employed in human therapeutic use be used. The differences which occur in teratogenic response in many experimental studies are often due to the different routes of administration of the teratogenic agent. These responses are mostly related to differences in absorption and concentration of the drug, duration of exposure and speed of release, or to differences in metabolic fate and the nature of the metabolites reaching the embryo. As an example, hypervitaminosis A, a potent teratogenic procedure in animals, requires oily solutions of the vitamin to be effective orally.

To determine teratogenic mechanisms a number of unique methods of administering drugs have been employed. Turbow and Chamberlain (1968) used intra-amniotic injections to determine the direct effect of 6-aminonicotinamide on rat embryos. Wilk (1969) placed a millipore filter containing small amounts of chlorcyclizine directly on the amniotic sac or placenta of rats to demonstrate that the drug had a local action. W.J. Scott (1970) injected the diuretic drug acetazolamide into the yolk sac and/or decidua capsularis or into the exocoelom to produce the typical forelimb defect seen when given the drug orally.

6.7.3 TERATOGENICITY OF SEX STEROIDS

Little is known about the mechanisms of teratogenic action even though there is a wealth of information on the embryonic and fetal effects of drugs and chemicals in laboratory animals. J.G. Wilson (1973) has presented a sequence of metabolic and developmental events which may account for most abnormal development (Figure 6.28).

Hypothetically a sequence of molecular events occurs between the primary teratogenic insult and the final morphological defect; increased attention has been directed towards elucidating teratogenic mechanisms using a variety of experimental approaches, including *in vitro* culture and pharmacokinetics (McLachlan *et al.*, 1987, Welsch 1987). Beckman and Brent (1984) have summarized

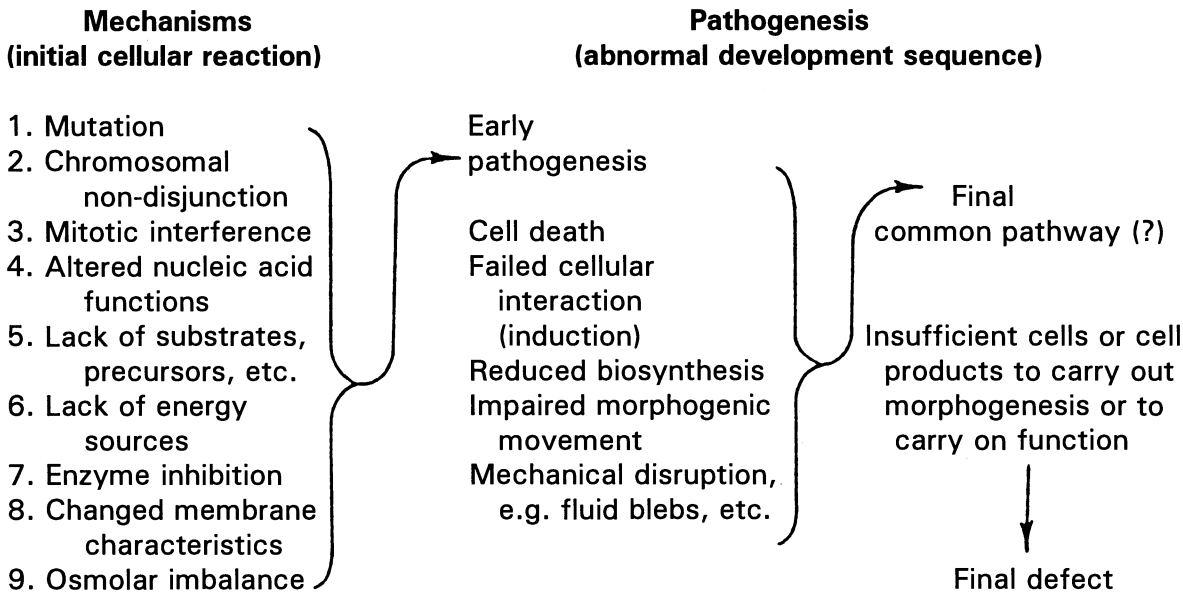

Figure 6.28 Schematic summary of initial cellular reactions and different types of pathogenesis converging into a final common pathway. (Reproduced with permission from J.G. Wilson, 1973.)

the mechanisms of action of known developmental toxins which may account for their embryopathy in humans.

Sex steroids

For the last several decades there has been much concern over the association between exogenous hormone therapy and a variety of birth defects. Worldwide clinical use of female sex hormones includes oral contraception, treatment for habitual or threatened abortion, management of dysmenorrhoea and dysfunctional uterine bleeding, antineoplastic therapy and, formerly, pregnancy testing.

Sex steroidal hormones, natural and synthetic, delivered singly or in combination, have been studied in several species of laboratory rodents, lagomorphs and non-human primates. Although there is a relatively wide range of embryotoxic effects reported for both the natural and synthetic oestrogens, there is no definable pattern; it appears that embryo or fetal death is common but teratogenicity very rare (Table 6.14).

These results reflect the known abortifacient effect of these compounds (McLean-Morris and van Wagenen, 1973; Neumann *et al.*, 1974). Genital tract abnormalities, including feminization of male fetuses and masculinization of female fetuses, have been reported in rodents exposed to some of these compounds during the period of sexual differentiation (Table 6.14).

Diethylstilboestrol (DES) has also been associated with genital tract anomalies in several test species. No one species precisely mimics the human response to *in utero* DES exposure which includes anatomical anomalies in the upper vagina, cervix and uterus, adenosis and clear cell adenocarcinoma in exposed females and oligospermia, variocoeles, epididymal cysts, cryptorchidism and testicular hypoplasia in exposed males (W.B. Gill, 1988; Rotmensch *et al.*, 1988). Similar reproductive anomalies in treated offspring of mice, rats, hamsters and rhesus monkeys have been observed (Khera, 1984; Walker, 1984; Hogan *et al.*, 1987).

While little or no teratogenicity has been reported in laboratory studies involving pre-

[a] N, no effect; E, embryolethality; GT, genital teratogenicity; NGT, non-genital teratogenicity.

Observed feminization effects include persistence of Mullerian ducts, hypospadias, cryptorchidism, testicular atrophy, arrested spermatogenesis and inhibition of prostate development in exposed males.

Studies using various sex steroid combinations have shown few or no teratogenic effects in non-genital organs and embryolethal effects only at the highest doses administered (Table 6.16).

Genital organ malformations (i.e. masculinization of female fetuses) have been observed at excessive doses of norethindrone and ethinyloestradiol administered to cynomolgus monkeys (Hendrickx *et al.*, 1987b).

In summary, the animal studies involving prenatal administration of natural or synthetic progestins and oestrogens alone, or in combination, have elicited embryolethality and malformations of the genital system with

no apparent effect on non-reproductive organs. The lack of clear association between exogenous hormone exposure during human pregnancy and non-genital teratogenicity (Schardein, 1980; J.G. Wilson and Brent, 1981; Wiseman and Dodds-Smith, 1984; Katz *et al.*, 1985) is supported by the animal data.

It is evident from the data presented above that a number of sex hormones (i.e. oestrogens, diethylstilboestrol and some synthetic progestins) interfere with normal genital system development. J.G. Wilson and Brent (1981) have attributed the alterations observed in both animal and human intersexes to the prenatal influence of hormones which are heterologous to the fetal genetic sex. Thus, intersexuality (masculinization or feminization) consists of partial or complete retention of duct derivatives and external genitalia characteristic of the opposite sex as well as some degree of suppression of normal reproductive organ development. This perturbation in the fetal hormone–target organ relationship is considered a specialized teratogenic response. Until recently, little consideration had been given to the effects of steroid hormones and brain development (McEwen, 1987). Rodent studies indicate that abnormal levels of systemic gonadal hormones during brain differentiation may lead to permanent functional and structural changes in the brain which are associated with reproduction dysfunction (Arai *et al.*, 1988). Future studies will expand our knowledge in this area, especially the action of environmental chemicals on brain development and behaviour.

Although the mechanism of hormonal-induced effects on prenatal sexual maturation is not well-understood, the possibilities include:

1. disruption of normal steroid synthesis and/or metabolism; and
2. interference with the normal steroid–receptor interaction.

Studies designed to explain the paradoxical effect of medroxyprogesterone acetate (MPA) on differentiating male and female external genitalia have shed some light on this topic. Three enzyme inhibition mechanisms have been proposed as possible mechanisms of MPA action:

1. inhibition of 3β-hydroxysteroid dehydrogenase, which results in an abnormal biosynthetic pathway leading to absence of androgen in male fetuses and production of weak androgens capable of virilizing the female fetus (Goldman and Bongiovanni, 1967);
2. blockage of 5α-reductase which is essential for conversion of testosterone to dihydrotestosterone (Voight and Hsia, 1973);
3. direct inhibitory action on testicular steroidogenesis (Rosenthal *et al.*, 1983).

That MPA might elicit its effects via interaction with receptors for sex steroids has also been proposed. Receptor studies in rats (Cupceancu and Neumann, 1969) indicate that MPA may have weak androgenic activity. This could result in the occupancy of androgen receptors and subsequent blocking of more potent endogenous androgens to produce an anti-androgenic (i.e. feminizing) effect in males. Conversely, a weak androgen receptor stimulation in females might be sufficient to produce virilization.

6.7.4 TERATOGENICITY OF ENVIRONMENTAL AGENTS

Drugs and other environmental chemicals have been studied in various animal species to determine their embryotoxic potential (see reviews by Hemminki and Vineis, 1985 and F.M. Sullivan and Barlow, 1985; Schardein and Keller, 1989). The focus of this section will be on a review of the data on embryotoxic effects of some of the environmental chemicals in animals and humans.

The toxic potential of metals is of special concern since these compounds may be bio-

concentrated and enter the food chain whether they occur naturally or are released into the environment as industrial contaminants. To date, mercury is the only environmental metal that has been firmly established as being teratogenic in humans. This compound was responsible for 'fetal Minamata disease' in Japanese infants born to mothers exposed to mercury-containing fish between 1954 and 1960. Similar incidences of fetal neurological dysfunction associated with maternal ingestion of methylmercury have been reported in the USA and Iraq (J.G. Wilson and Fraser, 1977). The developmental toxicity of various mercuric compounds has been confirmed in laboratory studies using rats, hamsters, mice and cats (Table 6.17).

While lead has been determined teratogenic in laboratory animals, its primary developmentally toxic effect in humans is fetal wastage rather than malformations. The risks are less well defined following exposure to other heavy metals during human pregnancy (Schardein, 1985). Studies in laboratory animals have shown variable embryotoxic responses to miscellaneous metallic compounds following treatment during organogenesis (Table 6.17).

Much attention has been directed to the potential toxicity of the widely used and chemically diverse group of pesticides used to control unwanted insects, fungi and plants in the environment. Studies in laboratory animals testing the embryotoxicity of various fungicides, insecticides and herbicides have produced different effects on intrauterine

development which may be related to the highly variable experimental parameters including route, level and duration of dosage. A small number of these studies is summarized in Table 6.18 and the reader is referred to Schardein (1985) for a more complete listing.

The embryotoxic potential of many pesticides is speculative since adverse effects in laboratory animals have often been produced at or near maternal toxic levels and considerably above likely environmental levels (J.G. Wilson and Fraser, 1977).

Despite the widespread concern over the potential embryotoxicity of dioxin-contaminated 2,4,5-trichlorophenoxyacetic acid (2,4,5-T) following its use as a defoliant in Vietnam between 1961 and 1969, repeated attempts to validate the teratogenicity of this herbicide in humans in various parts of the world have not been successful (J.G. Wilson and Fraser, 1977; Schardein, 1985). This compound has been tested for teratogenic potential in multiple studies and the results have not been clear-cut. This may be due, in large part, to the quantity of dioxin (TCDD) present as a contaminant in the manufactured chemical which is thought to impart much of the toxicity of 2,4,5-T (Schardein, 1985).

Polybrominated and polychlorinated biphenyls (PBBs and PCBs) are regarded as potentially important environmental contaminants because of their extensive use as lubricants and heat transfer agents as well as ingredients of paints, varnishes and synthetic resins. Studies in mice, rats and non-human primates have resulted in varying degrees of embryotoxicity with the major effects manifested as embryo or fetal death and intrauterine growth retardation (Table 6.18). A clear association between these compounds and malformation rates in humans is yet to be established.

Carbon monoxide (CO) is a major environmental pollutant due to air pollution from industrial complexes and vehicular traffic as well as to cigarette smoking. The most com-

mon embryotoxic effects that have been associated with CO poisoning during pregnancy are fetal death and adverse neurological signs in surviving offspring. Studies in laboratory animals have not shown consistent teratogenicity of this environmental agent (Table 6.18).

The possible embryotoxicity of solvents is of concern because of their widespread industrial and household use as well as their generally high rates of absorption via the skin, lungs and digestive tract. Although associations have been made between several industrial solvents, particularly benzene and chlorinated hydrocarbons, and birth defects, the data are too inconsistent to draw definitive conclusions regarding the teratogenicity of these compounds. However, the developmental toxicity of several solvents tested in laboratory animals (Table 6.19) is suggestive of their embryotoxic potential in humans. Most of the animal studies conducted testing agents used in the production of plastics (e.g. styrene and vinylidene chloride) have not verified their embryotoxicity (Table 6.19).

Careful analysis of the human data has not yet indicated a causal association of these agents with birth defects (Schardein, 1985).

In summary, the value of animal teratogenicity testing to reduce human exposure to hazardous agents during pregnancy is justified by the fact that all human teratogens also induce some form of developmental toxicity in at least one test species. The protocols originally established by the US Food and Drug Administration (FDA, 1966) and the World Health Organization (WHO, 1975) recommend two test species; the rat and the rabbit are most commonly used, although the mouse is often a substitute for either of these species. The role of the non-human primate in teratological research is particularly valu-

able where equivocal results are experienced in these commonly used laboratory species, when the drug/chemical is likely to be used during pregnancy and for human-derived biotechnical products which often are not bioactive in non-primate species (Hendrickx and Binkerd, 1990).

Although the practical aspects of current testing procedures do not require alteration, incorporation of pharmacokinetic and metabolism data is strongly advised in order to account for species differences in teratogenic susceptibility (N.A. Brown and Fabro, 1983). This information provides quantitative estimates of hazard in teratogenicity tests and facilitates risk extrapolation. Further, the evaluation of all manifestations of abnormal development in animal studies, i.e. malformations, embryolethality, growth retardation and functional alteration, is essential due to species-specific responses to prenatal insults (Schardein and Keller, 1989). The guidelines recently published by the US Environmental Protection Agency (1986) clearly address these four end-points in the assessment of developmental toxicity. The incorporation of maternal toxicity evaluation in test protocols has also received increased support, particularly with regard to the risk assessment process (Kimmel *et al.*, 1986). Thus, multiple factors must be taken into consideration when extrapolating the evidence of animal studies to the human situation.

6.8 CONCLUDING COMMENTS

In this chapter we have covered the maternal recognition of pregnancy during embryo implantation in primates, together with the regulation of the corpus luteum to the extent currently understood in primates. We then explored the normal and abnormal embryo fetal development in mammals, giving emphasis to primate systems, including the rates of development and the factors inducing abnormal differentiation. These factors may be genetically derived; may result from disorders at fertilization or synchronization of the embryo maternal dialogue during early pregnancy; or may be the consequences of teratogenic agents introduced inadvertently from therapy or environmental hazards. An experimental approach to understanding the effects of teratogens can help us to avoid their use and can also give us new probes that clarify the regulation of embronic and fetal development.

The term reproductive health normally covers the treatment of infertility and the regulation of fertility. In the broader context it covers also the maturation of gametes and the well-being of the embryo and fetus to birth together with the understanding of how these stages are perturbed by both intrinsic and extrinsic factors.

Our basic knowledge in this field requires considerable extension at present as a whole new dimension is opening up. The regulatory mechanisms of reproduction at molecular and cellular levels in real embryo–fetal time can now be approached. The new productive technologies, which include *in vitro* maturation of oocytes (R.M. Moore and Trounson, 1977), *in vitro* fertilization (Edwards, 1980), storage of games and embryos from a range of species by cryopreservation (Whittingham, 1971; Wilmut, 1972; Summers *et al.*, 1987), embryo transfer to the same or closely related species (Hearn and Summers, 1986) and the manipulation of embryos to produce twins, clonal products, transgenic cells or individuals through microinjection and stem cell transfer, open up new prospects for significant improvements to the reproductive health of animals and man.

The work of Surani (1986) and others is now opening up a greater appreciation of the interplay between maternal, paternal and embryonic genomes as well as the regulation of totipotency and pluripotency in embryos through a definition of cell lineage and the role of stem cells in rodents (Johnson *et al.*, 1986). At present we are still at the early stages of extending this knowledge to pri-

mate systems. Oocyte development and fertilization *in vitro* was reviewed by Boatman (1987), and there is now a range of species in which embryo culture, storage, transfer and successful development to birth have been achieved, for example the cynomolgus monkey (Balmaceda *et al.*, 1986), the baboon (Pope *et al.*, 1984), the rhesus monkey (Bavister, 1987) and the marmoset money (Summers *et al.*, 1987). Non-human primate systems will be essential for the future development of gene therapy or the cloning and accelerated production of new models for the disorders of early pregnancy.

More recently, our understanding of the genetic regulation of the maternal to embryo transition, the transcription, expression and secretion of embryo signals and of differentiation signals is being clarified. The prospects for gene injection, the repair of genetic deficiency and the precise isolation and transfer of genes are now real. The development of new cell and whole-animal analogues for human disease requires markers in *in vivo* and *in vitro* systems to increase the efficiency of monitoring and screening both the successful integration of genes and the physiological consequences of such manipulation.

Among the applications that will flow from such fundamental knowledge are novel diagnostics in molecular medicine, new developments in agriculture and animal science, including cloning of livestock (Fehilly *et al.*, 1984; reviewed by Polge, 1985), and the potential for industrial exploitation in high-value enzymes, reagents and biotechnological systems.

Looking to the future, a greater efficiency in our exploitation of the regulatory mechanisms of embryo–fetal development promises improved health and a greater choice in fertility regulation. The next 50 years will see a doubling of the human population from 5 to 10 billion, raising fundamental ethical and practical questions about genetic diversity and species survival. A balance in human and animal populations, with greater expectation of health, of which reproductive health is an important part, will be a vital need in achieving a solution.

7.1 INTRODUCTION

The earliest mammals were all small, nocturnal insectivorous creatures, and it appears that the basic mode of mammalian reproduction remained unchanged from the time of the origin of mammals in the late Triassic (about 200 million years ago) until the dispersal of the Gondwanan continents in the middle Cretaceous (95–110 million years ago). This meant that there was no land faunal communication between Africa and the Antarctic–Australia–India complex except via South America after the earliest Cretaceous (Lillegraven *et al.*, 1979). The major adaptive radiations of the advanced therian mammals occurred during the middle Cretaceous, so that by the late Cretaceous (75–80 million years ago) the Eutheria and Metatheria were already distinct and largely geographically isolated (Archer, 1984; Tyndale-Biscoe and Renfree, 1987). Whilst marsupials are true mammals in every sense, and in endocrine terms have the same range of hormones, these hormones are sometimes used in different ways (Amoroso *et al.*, 1980) – for example, prolactin inhibits the marsupial corpus luteum, whereas it is luteotrophic in some eutherian mammals. This communality of hormones but diversity of actions between the mammalian groups clearly demonstrates the validity of Medawar's (1953) aphorism that it is not hormones that have evolved, but rather the uses to which they are put.

There are about 250 living species of marsupials representing about 6% of the mammalian fauna (Kirsch, 1977), distributed widely in South America, Australia and New Guinea, but we have detailed endocrine knowledge of only a small number of these (Tyndale-Biscoe and Renfree, 1987). Most information on marsupial reproduction in the past has been based on wild-caught specimens, but the establishment of self-sustaining laboratory colonies of several species now makes possible more conventional laboratory studies (Renfree and Tyndale-Biscoe, 1978; Tyndale-Biscoe and Janssens, 1988; Hinds *et al.*, 1990a). Each family grouping of marsupials shares a common and distinctive reproductive pattern, with each species displaying modifications of the basic pattern in relation to its own constraints of size, diet and habitat (Tyndale-Biscoe, 1984; Lee and Cockburn, 1985). The majority of marsupials are polyoestrous, and, compared with eutherian mammals, have relatively uniform gestation periods that range between 12 and 36 days. This means that pregnancy is remarkably short even for the largest marsupials but since they have such a prolonged and sophisticated lactation, the young marsupial when weaned is as developed as any eutherian at the same stage.

There has recently been a great burgeoning of knowledge about marsupial reproduction, and the whole of marsupial reproductive physiology and development has been reviewed (Tyndale-Biscoe and Renfree, 1987). Several major reviews on various aspects of reproduction have also been published (Tyndale-Biscoe *et al.*, 1974, 1986; Renfree, 1982, 1983; Tyndale-Biscoe, 1984, 1986, 1989; Renfree *et al.*, 1987, 1989; Renfree and Short, 1988; Renfree 1992, 1993).

Two decades ago there was scarcely any knowledge about the endocrinology of marsupials, although it was recognized that the corpus luteum is of central importance, and that progesterone is present in red kangaroo, wallaroo and opossum corpora lutea (Lindner and Sharman, 1966; Cook and Nalbandov, 1968; and Short and Sharman, (unpublished observations) cited in J.G. Smith *et al.*, 1969). Plasma progesterone was measured subsequently in the possum (Thorburn *et al.*, 1971) and the tammar (Lemon, 1972). Today, most is known of the reproductive endocrinology of the tammar wallaby, *Macropus eugenii*, in which all of the major reproductive hormones have been

studied. In this chapter, endocrinology will provide the linking theme between pregnancy, parturition and lactation. Details of marsupial breeding biology, anatomy, development, male reproduction, seasonal breeding and the evolution of reproduction can all be found in Tyndale-Biscoe and Renfree (1987) and the excellent chapter in Volume 1 of this edition by Tyndale-Biscoe (1984).

7.2 PATTERNS OF REPRODUCTION

Most marsupials are seasonal breeders and produce relatively small young, ranging from the honey possum, *Tarsipes rostratus*, which delivers the smallest neonate weighing less than 5 mg at birth (Renfree, 1980a), to the largest, the kangaroos, which deliver neonates weighing around 800 mg. Although the maternal investment in **pregnancy** is very small and much less than that of eutherian mammals, this is more than made up for during the long **lactation**. Marsupials may be monoestrous or polyoestrous, and in most species lactation controls reproduction by preventing either ovulation or post-blastocyst development. In seasonally breeding marsupials the animals may become either anoestrous or reproductively quiescent at the end of the season, regardless of whether lactation continues. The shortest gestation period is 9.5 to 12 days in *Sminthopsis macroura* (Gemmell and Selwood, 1993), followed by 12½ days, as found in bandicoots (Lyne, 1974) and opossums (Hartman, 1923, 1928). The longest gestation periods so far described are amongst kangaroos, being 36 days in the grey kangaroo, *Macropus giganteus* (reviewed in Tyndale-Biscoe, 1984), and 44 days in Matchie's tree kangaroo, *Dendrolagus matschiei* (L.R. Collins, personal communication). In the macropodids pregnancy may be extended even further by embryonic diapause. Detailed tables of the breeding biology of marsupials have been provided extensively in Tyndale-Biscoe and Renfree (1987), and a summary table showing the gestation periods of some commonly studied species is given here (Table 7.1).

The oestrous cycle of marsupials is very similar to that of the Eutheria. The histological changes in the uterus and ovary during the follicular and luteal phases resemble those seen in many other mammals (see Pilton and Sharman, 1962; Sharman and Berger, 1969). The steroid hormones and gonadotrophins involved in reproduction in eutherian mammals have been measured in marsupials, though as we will see later particular features of their functions differ (Tyndale-Biscoe and Renfree, 1987). Ovulation is spontaneous in all marsupials and in most species occurs within 2 days of oestrus.

The marsupial oestrous cycle varies in mean length from 22 to 42 days, the average being 28 days (Tyndale-Biscoe, 1973) (see Table 7.1). However, in some didelphids, such as the woolly opossum, *Caluromys philander*, which has a cycle of 38 days (Perret and Atrementowicz, 1989), it may range up to 40 days (Godfrey, 1975; Fadem and Rayve, 1985). The life of the corpus luteum is not prolonged by the presence of a conceptus, although in the Peramelidae (bandicoots) the corpus luteum persists during lactation (Hughes, 1965; Gemmell, 1979). Because pregnancy is shorter than the oestrous cycle in all except the swamp wallaby, *Wallabia bicolor*, the histological changes of pregnancy and the oestrous cycle are similar (Figure 7.1), and the young are born, depending on the species, at different stages of the luteal and follicular cycle (Figure 7.2).

The timing of birth and oestrus can be altered experimentally, suggesting that gestation and oestrous cycle activity need not be closely linked (Clark, 1968). In the American opossums *Didelphis virginiana* and *Marmosa mitis*, as in many monovular and polyovular Australian species, the young are born towards the end of the luteal phase, and the mother's return to oestrus is suppressed by the sucking stimulus. By contrast, in the

Table 7.1 Duration of the oestrous cycle, gestation and litter size and occurrence of embryonic diapause for a few selected species of marsupial. (Condensed from Tyndale-Biscoe and Renfree, 1987)

N, no; Y, yes; RPY, removal of pouch young.

macropodids, the single-pouch young reaches the pouch at the end of the pro-oestrous phase, and ovulation and fertilization occur post-partum (Figure 7.2). In most of the Macropodoidea, the fertilized egg enters a dormant phase at the blastocyst stage at about the eighth day post coitum, and during this period of embryonic diapause both the blastocyst and the corpus luteum remain quiescent as long as the suckling pouch young is present. If the pouch young is removed (RPY), the quiescent blastocyst reactivates and pregnancy ensues. In *M. eugenii*, and in Bennett's wallaby, *M. rufogriseus rufogriseus*, photoperiodic influences maintain the diapause in the second half of the year after the winter solstice (see Figure 7.3), and reactivation occurs spontaneously after the longest day.

Marsupial reproductive strategies have

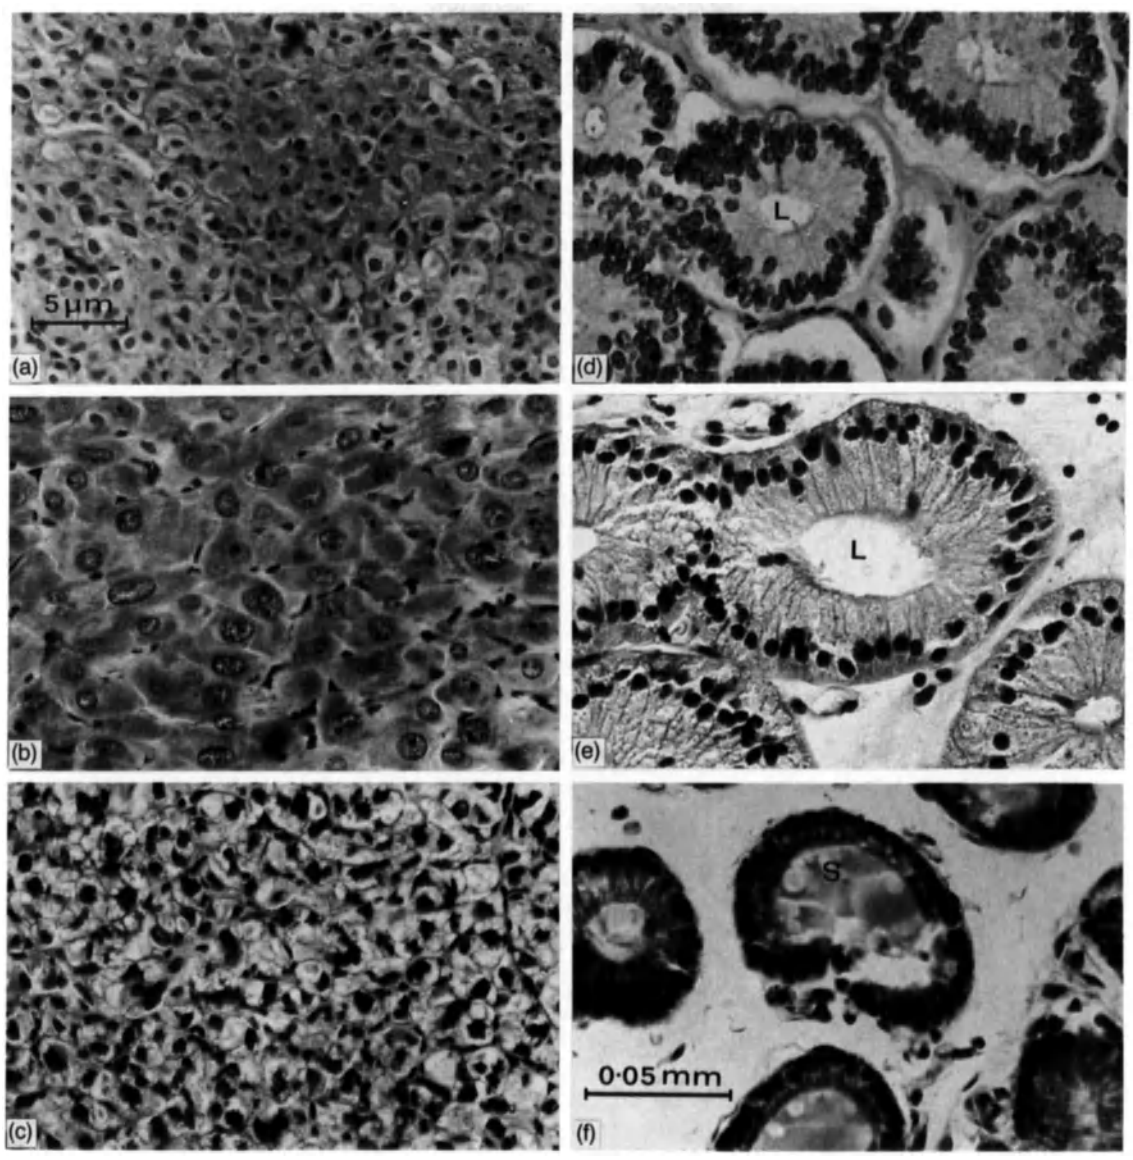

Figure 7.1 Histology of the corpus luteum and uterine endometrium of the tammar wallaby during gestation after removal of the pouch young (RPY). (a–c) Sections of the corpus luteum (all at same magnification: scale bar 5 µm) showing the hypertrophy and hyperplasia of luteal cells after RPY, and their subsequent degeneration with pyknotic nuclei by day 25 of the 26.5 days' gestation. (a) Day 2 RPY; (b) day 17 RPY; (c) day 25 RPY. (d–f) Sections of the endometrium (all at same magnification: scale bar 0.05 mm). (d) Uterine glands in endometrium on day 0 RPY. (e) Uterine glands on day 17 RPY and (f) on day 27 RPY. At mid-pregnancy, the uterine glands are noticeably expanded, with tall columnar epithelial cells surrounding the enlarged gland lumina (L). By day 27, immediately after birth, the cells have darkly staining, basal nuclei although the gland lumina contain residual secretion.

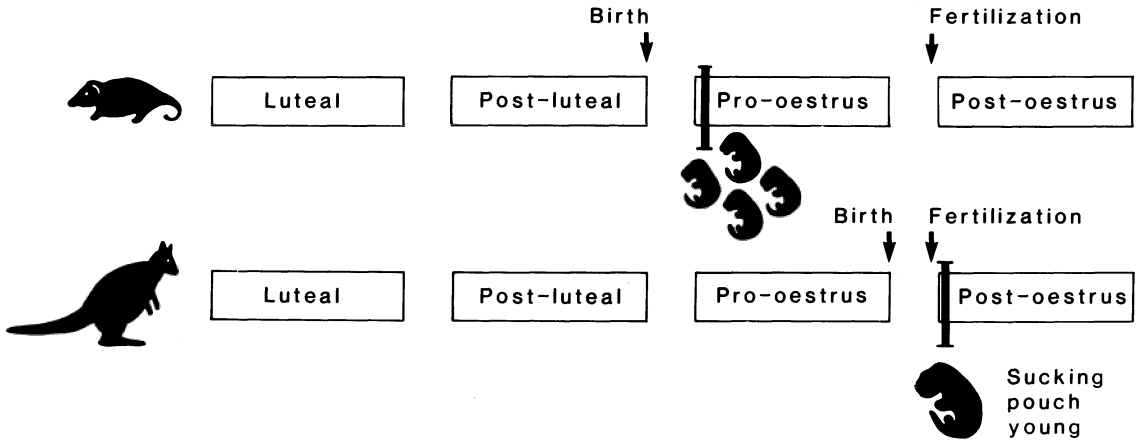

Figure 7.2 The relationship of marsupial oestrous cycles to pregnancy. In species such as the polyovular American opossum (*Didelphis virginiana*) (top) belonging to group 1 reproductive pattern (see text), birth occurs toward the end of the uterine secretory phase, and the presence of the numerous young in the pouch prevents the pro-oestrus phase (dark bar) and the development of any new follicles. Should the sucking young be lost, animals return to oestrus about 7 days later, with the subsequent pregnancy taking only 12.5 days. In the macropodids, such as the monovular tammar wallaby (*Macropus eugenii*) (bottom), with the group 3 reproductive pattern, gestation occupies the whole length of the oestrous cycle, and ovulation occurs within a day of the birth of the single young. Sucking of the pouch young prevents development of the new conceptus beyond the blastocyst stage (dark bar) (arrows show the relative times of ovulation and fertilization). (Redrawn from Renfree, 1980b.)

been divided into four categories by Tyndale-Biscoe and Renfree (1987). These are:

Group 1: Polyovular, polyoestrous species in which the gestation period is considerably shorter than the oestrous cycle and coincides with the luteal phase; post-partum oestrus and ovulation are suppressed during lactation. This pattern seems to be common to the possum families, Petauridae, Phalangeridae, and to the majority of the carnivorous groups, the Polyprotodonta as well. Tyndale-Biscoe (1984) concludes that it represents the basic marsupial pattern from which the other patterns have been derived. The evidence from carnivorous Dasyuridae suggests that the monoestrous pattern of the brown marsupial mouse *Antechinus* and *Phascogale* has been derived from a polyoestrous pattern as special adaptations of seasonal breeding.

Group 2: Polyoestrous, polyovular marsupials with an ultra-short gestation occupying less than the luteal phase, which is prolonged into lactation. In addition there is a well-developed chorioallantoic placenta (the bandicoot families Peramelidae, Thylacomyidae).

Group 3: Monovular, polyoestrous species in which the gestation period is almost the same length as the cycle and extends into the follicular phase so that post-partum oestrus and ovulation occur. During lactation further development is arrested, and if fertilization occurs the embryo remains as a unilaminar blastocyst of about 100 cells in embryonic diapause. Most of the kangaroo and wallaby family Macropodidae share this pattern, with the exceptions of *M. giganteus, M. fuliginosis, M. parma, M. parryi* and *D. matschiei*, which follow an essentially group 1 pattern. In two species, *M. eugenii* and *M. rufogriseus rufogriseus*, a photoperiodic seasonal control of diapause has been superimposed on the lactational one after the winter solstice.

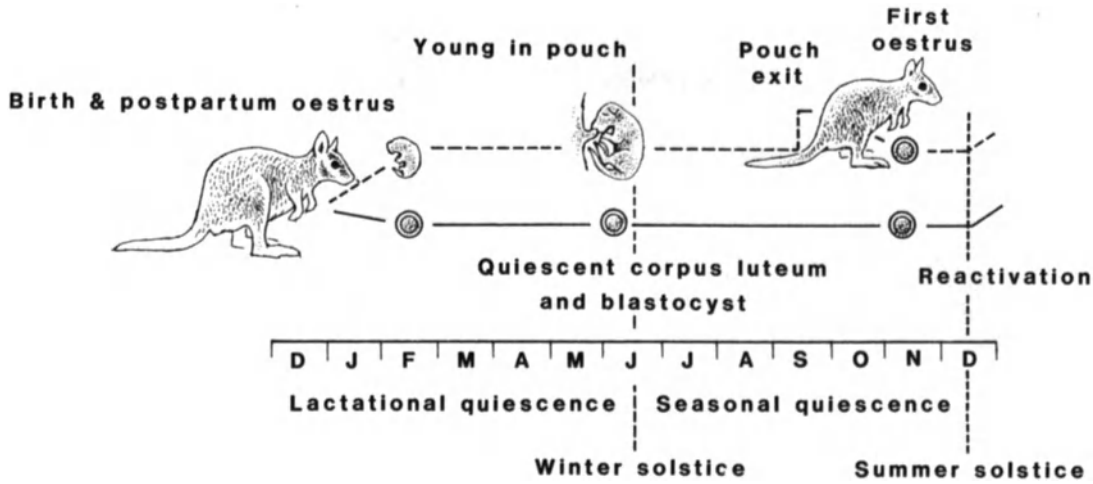

Figure 7.3 The annual cycle of reproduction in the tammar, in the southern hemisphere. Most females give birth towards the end of January or early February, a month or so after the summer solstice on December 21/22. Within 8 h of birth the females come into oestrus, mate and the fertilized egg develops into a 100-cell blastocyst. The blastocyst remains in diapause until the summer solstice. The pouch young leaves the pouch around October, and if it is a female may conceive shortly thereafter. The conceptus immediately enters diapause and the female does not go into active pregnancy until the following solstice. (From Tyndale-Biscoe and Renfree, 1987, with permission.)

Group 4: Polyoestrous, polyovular, with a very prolonged pre-luteal phase and gestation, which includes a long period of embryonic diapause after a post-partum oestrus. It is unclear as to whether diapause is controlled by lactation or is obligatory. The small possum families Burramyidae (except *Burramys* which has the group 1 pattern), Acrobatidae and Tarsipedidae fall into this group.

7.3 EARLY PREGNANCY: OVULATION, CLEAVAGE AND THE EARLY BLASTOCYST

Folliculogenesis overlaps with the last half of pregnancy in macropodid marsupials, and the sequence of events is best known for the tammar. The follicular cycle begins around mid-pregnancy, when progesterone concentration is high. Graafian follicles are evident in the ovary from about day 23 of pregnancy after removal of the pouch young (RPY), and reach their maximum size at post-partum oestrus (Harder *et al.*, 1984). The concentration of progesterone in the peripheral circulation and in the uterine branch of the ovarian vein draining the corpus luteum falls precipitously at birth, or more slowly after a non-pregnant cycle (Hinds and Tyndale-Biscoe, 1982a; Towers *et al.*, 1986), but oestradiol 17β peaks in the peripheral circulation and in the ovarian branch of the ovarian vein draining the ovary with the Graafian follicle (Harder *et al.*, 1984; Shaw and Renfree, 1984) about 8–10 h post-partum (Figures 7.4 and 7.5).

This peak of oestradiol coincides with behavioural oestrus, and removal of the Graafian follicle prevents oestrus and the luteinizing hormone (LH) pulse which follows the oestradiol rise by about 7 h (Harder *et al.*, 1985; Horn *et al.*, 1985). Similarly, interference with the LH pulse by immunization prevents folliculogenesis and the ovulation which usually occurs about 30 h post-partum (Short *et al.*, 1985). In the brush possum oestradiol is measurable on the day of oestrus but not at other times (Curlewis *et al.*, 1985),

and C.A. Horn (unpublished results) has found a transient LH pulse on this day. In the opossum, peak values of oestradiol are detected immediately and up to 4 days before oestrus (Harder and Fleming, 1981) (Figure 7.5). However, in the kowari *Dasyuroides byrnei*, ovulation occurs 4–6 days post-oestrus but there is a pulse of LH 12 days before oestrus (Fletcher, 1983).

Ovulation, which, as far as is known, is spontaneous in all marsupials, occurs in most marsupials 1–2 days after oestrus, though it occurs up to 10 days later in three dasyurids (Hill and O'Donoghue, 1913; Woolley, 1966; Selwood, 1980; Fletcher, 1983). Marsupial oocytes have no surrounding cumulus or corona cells but are covered by a thin zona pellucida of about 4 μm in the opossum *Didelphis virginiana* (Rodger and Bedford, 1982a) and 3 μm in the dunnart *Sminthopsis* (Breed and Leigh, 1988) (Figure 7.6).

Mucoid material is deposited around the zona soon after the egg enters the oviduct. This mucopolysaccharide layer, which increases in thickness as the egg moves down the oviduct, acts as a secondary block to

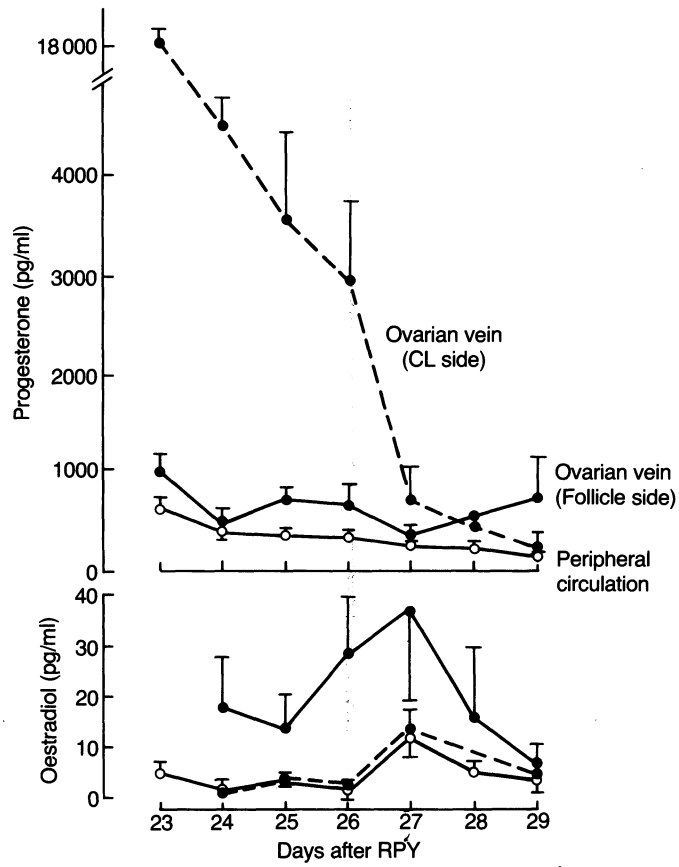

Figure 7.4 Concentrations (mean ± SEM) of progesterone and oestradiol-17β in the peripheral circulation (○ — ○), the ovarian vein draining the ovary with the corpus luteum (● - - - ●) and the ovarian vein draining the ovary bearing the Graafian follicle (● _ ●) through late pregnancy, parturition, and postpartum oestrus in the tammar wallaby. Data for oestradiol from Harder *et al.*, 1984. (Redrawn from Tyndale-Biscoe *et al.*, 1986.)

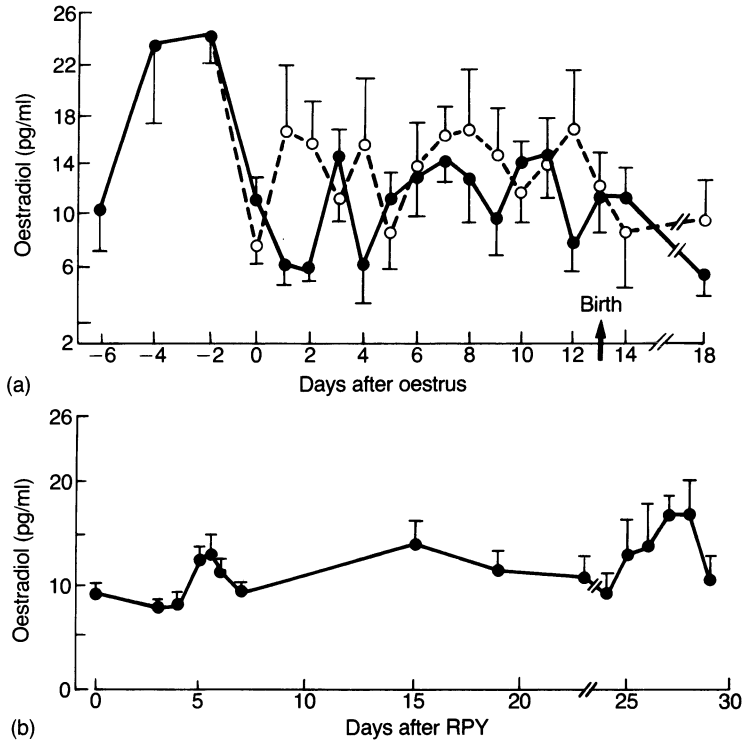

Figure 7.5 (a) Concentrations (mean ± SEM) of oestradiol and progesterone in the peripheral circulation of *Didelphis virginiana* during the oestrous cycle (● — ●) and gestation (○ — ○). Data from Harder and Fleming (1981). (b) Concentrations (mean ± SEM) of plasma oestradiol in *Macropus eugenii* between days 0 and 30 after removing pouch young. Note that, after day 24, the values are synchronized to the time of birth rather than to day after RPY. There are two significant rises in oestradiol: at day 5, coincident with the progesterone peak, and one day after birth, coincident with oestrus and mating. Data from Shaw and Renfree, 1984. (From Tyndale-Biscoe and Renfree, 1987, with permission).

polyspermy (Rodger and Bedford, 1982a; Selwood, 1982; Breed and Leigh, 1988; Breed *et al.*, 1989). The primary block to polyspermy may be due to a release of cortical granules beneath the vitelline membrane, as found in eutherians and observed in *Didelphis* (Rodger and Bedford, 1982a) and in an unfertilized *Sminthopsis* egg (Breed and Leigh, 1988). Fertilized *Sminthopsis* eggs lack these cortical granules but the block to polyspermy appears to be inefficient (Breed and Leigh, 1990). Fertilization can therefore only be effected by spermatozoa which have already reached the fimbria (Rodger and Bedford, 1982b; Rodger, 1990), and in the tammar they are at this location 24 h post coitum (p.c.) (Tyndale-Biscoe and Rodger, 1978). Oestrus must therefore precede ovulation by at least this time if fertilization is to occur before the mucin layer is too thick. Transport down the oviduct is also rapid, and all marsupial fertilized eggs are transported to the uterus in less than a day, while the keratinous shell membrane secreted by cells in the lower oviduct and utero-tubal region is laid down over the mucoid coat (Tyndale-Biscoe and Renfree, 1987). The first cleavage division usually takes place within the uterus between 30 and 40 h post-ovulation (Figures 7.6 and 7.7), and the six or seven cleavage divisions which lead to the blastocyst stage are complete by day 4 in the opossum *Didelphis*, day 5

in the brush-tailed possum *Trichosurus*, day 8 in the brown antechinus *Antechinus stuartii* and quoll *Dasyurus viverrinus* and day 8–9 in the tammar (Tyndale-Biscoe and Renfree, 1987).

In the common dunnart, *Sminthopsis macroura*, the time taken to reach the expanding complete unilaminar blastocyst of about 32 cells is just less than 4 days (Selwood, 1987). In this and in the fat-tailed dunnart, *S. crassicaudata*, there is an arrest of 24 h at the four cell stage, while in *Antechinus stuartii* cleavage is arrested for 4 days at the four cell stage (Selwood, 1980, 1981, 1986,

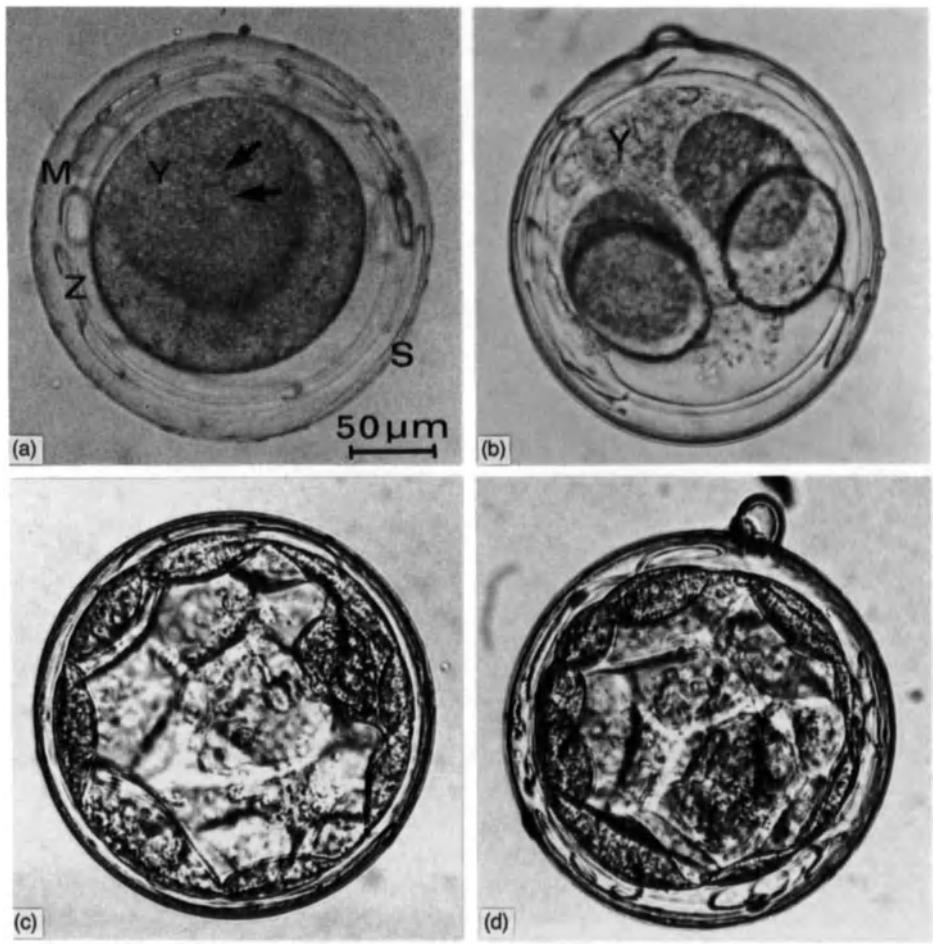

Figure 7.6 Cleavage stages and blastocyst formation in a dasyurid, *Sminthopsis crassicaudata*.
(a) The fertilized egg. The two pronuclei (arrows) can be seen through the yolk mass (Y) that has started to accumulate at one pole of the vitellus. Many sperm tails are visible in the mucoid layer (M). S, shell; Z, zona pellucida. (b) An embryo with four rounded blastomeres. The yolk mass (Y) lies at one pole of the embryo. An imperfection in shell deposition is found at this pole, which lies at the top of the figure. (c) An embryo at the 16-cell stage viewed from the non-yolky pole. The roof of the blastocyst is completely lined by cells over the transparent yolk mass, which is not in focus in the blastocoele. (d) An incomplete blastocyst of about 16 cells. The blastocyst is viewed from the open non-yolky hemisphere looking into the blastocoele. An imperfection in the shell deposition lies to one side of the embryo. (Photographs kindly provided by Dr Lynne Selwood.)

1987; Selwood and Young, 1983; Selwood and Santhananthan, 1988). Whilst these first cleavage events are occurring, there are no remarkable changes in the circulating steroids in the tammar, opossum, brush possum, brown antechinus or quoll (Harder and Fleming, 1981; Hinds and Tyndale-Biscoe, 1982a; Curlewis *et al.*, 1985; Hinds, 1989a; Hinds and Selwood, 1990), and indeed in *S. macroura* and *S. crassicaudata* addition of progesterone to the medium does not improve culture success of cleavage-stage eggs. As in eutherian mammals, the cleaving egg appears to be autonomous, and this is supported by evidence of blastocyst formation in quokkas, tammars and brush possums ovariectomized at the time of the first cleavage (Tyndale-Biscoe, 1963a, 1970; Sharman and Berger, 1969; Shorey and Hughes, 1973a), and by *in vitro* culture studies (Selwood, 1987).

In the majority of marsupials the concentrations of progesterone steadily increase during early pregnancy and, as noted above,

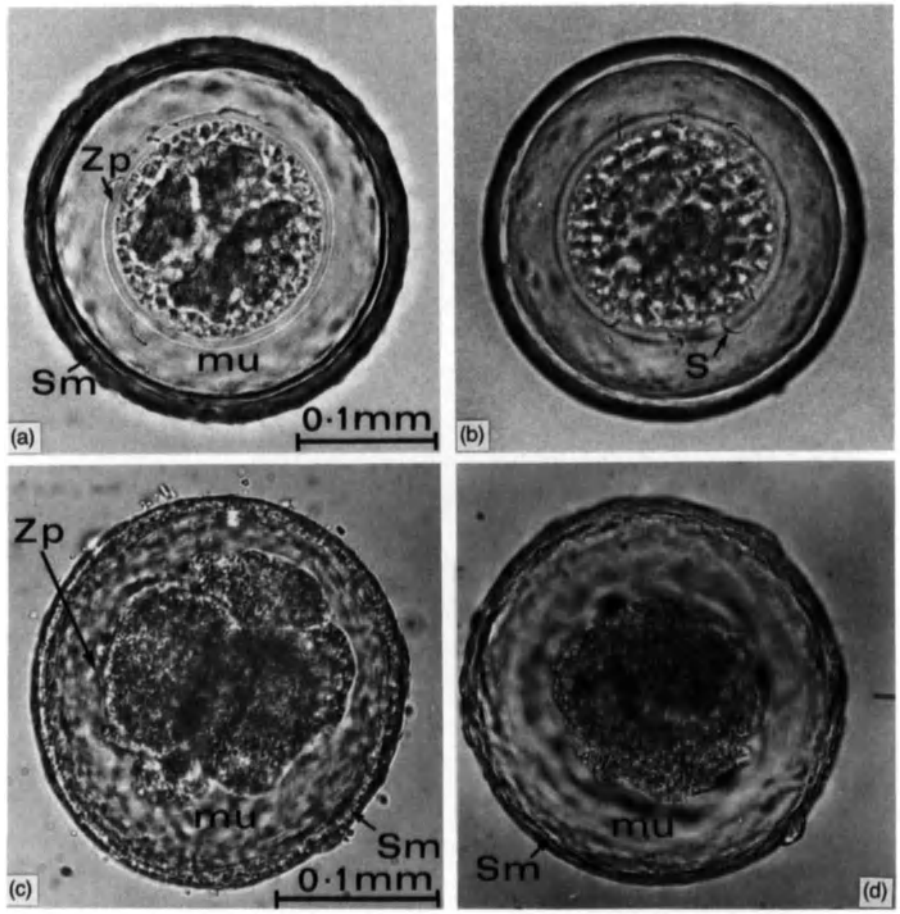

Figure 7.7 Early cleavage stages in an acrobatid, the feather-tailed glider, *Acrobates pygmaeus* (a and b), and a macropodid, the tammar wallaby, *Macropus eugenii* (c and d). (a, b and c) Four-cell embryos; (d) 20-cell embryo. Sm, shell membrane; mu, mucoid coat with embedded spermatozoa (s); and Zp, zona pellucida. In both species there is a considerably thicker mucoid layer than in the dasyurids (see Figure 7.6), and much less yolk. a and b to same scale; c and d to same scale.

formation of the blastocyst does not apparently require any specific stimulus. However, continued development and expansion of the blastocyst requires the continued secretion of progesterone at least to day 10 in the brush possum (Sharman, 1965a) and the opossum (Renfree, 1974), but only to day 8 in the quokka and tammar (Tyndale-Biscoe, 1963a, 1970). In these last two (macropodid) species, it is significant that this is after an early, transient pulse of progesterone which occurs at day 3–4 in the quokka and day 5–7 in the tammar (Cake *et al.*, 1980; Hinds and Tyndale-Biscoe, 1982a). This period also coincides with increased growth of the endometrium and increased uterine secretions, and will be discussed in detail in the section 'Maintenance of pregnancy'. In the absence of this transient pulse of progesterone, embryos at the blastocyst stage enter embryonic diapause.

7.4 EMBRYONIC DIAPAUSE

Blastocyst growth in mammals that do not have embryonic diapause occurs by rapid cell division and fluid accumulation. Although diapausing blastocysts can also accumulate fluid, there appears to be little or no mitotic activity and therefore little or no new cell proliferation (Daniel, 1970; Renfree, 1978). In mammalian blastocysts dormancy occurs when the embryo is 200–400 cells with the exception of the badger (900–2000), macropodid marsupials and rodents (80–100 cells) and tarsipedid, burramyid and acrobatid marsupials, in which the blastocysts are up to 2000 cells (Renfree, 1981a; S. Ward and Renfree, 1988; S. Ward, 1988). With the one exception of *M. fuliginosus*, all species of the two subfamilies of the Macropodidae that have been investigated exhibit the phenomenon of diapause (Tyndale-Biscoe *et al.*, 1974; Renfree, 1981a). During diapause the blastocyst size (shell diameter) varies from 0.25 to 0.33 mm (M.J. Smith, 1981) and the diameter of the trophoblast of four macropodid species varies little – from 0.20 to 0.25 mm (Tyndale-Biscoe, 1963b; Renfree and Tyndale-Biscoe, 1973; Tyndale-Biscoe and Renfree, 1987). The macropodid blastocyst in diapause is invariably unilaminar and consists of 70–100 uniform cells in which mitoses are never seen (Figures 7.8 and 7.9). Blastocysts in diapause are always associated with a quiescent corpus luteum.

The Macropodidae are monovular and polyoestrous marsupials, and gestation is longer than the oestrous cycle in all except *Wallabia bicolor*, the swamp wallaby (Tyndale-Biscoe and Renfree, 1987). Some species have long oestrous cycles, so that birth occurs before the pro-oestrous phase is initiated, and sucking prevents further development (see Figure 7.2). In these species (*M. giganteus, M. parma, M. parryi* and *Aepyprymnus rufescens*), diapause usually occurs after fertilization in late stages of pouch life (Calaby and Poole, 1971; Maynes, 1973; Tyndale-Biscoe, 1973; Moors, 1974; Poole and Catling, 1974; Tyndale-Biscoe *et al.*, 1974). *M. fuliginosus*, as mentioned above, does not ever have diapause since the lactational inhibition of ovarian activity is complete and the pro-oestrous phase of the cycle is suppressed throughout pouch life. If the suppression fails, as it occasionally does, the resulting conception can occur during lactation but there is no delay and the neonate is born into a pouch still occupied by a larger young and it dies within a few days (Poole, 1975). This supports Sharman's (1965a) idea that the prime importance of diapause in macropodids is to prevent occupation of the pouch by two young of different ages, an event that would occur regularly since oestrus and ovulation are not normally inhibited postpartum. This is equivalent to the prevention of superfetation by ovulation inhibition during pregnancy in eutherians.

In the remaining macropodids, gestation extends into the post-luteal and pro-oestrous phases without suppressing follicle growth, so that ovulation occurs a few days after par-

turition in these species (e.g. *Setonix brachyurus, Macropus eugenii, Macropus rufogriseus, Megaleia rufa, Bettongia lesueur, Thylogale billardierii,* and *Potorous tridactylus*; Tyndale-Biscoe and Renfree, 1987). Sucking prevents the full development of the corpus luteum, and if fertilization has occurred post-partum the embryo is retained as a unilaminar blastocyst in diapause (Sharman, 1955a,b; Hughes, 1962; Sharman, 1965b; Tyndale-Biscoe, 1963b, 1968; Calaby and Poole, 1971; Rose and McCartney, 1982; Figures 7.8 and 7.9).

In addition to the lactational inhibition of the blastocyst and corpus luteum, in at least two species, the tammar *Macropus eugenii* and the Bennett wallaby *Macropus r. rufogriseus*, the quiescent blastocyst and corpus luteum persist for several months after weaning (Sharman and Berger, 1969), and resume development after the summer solstice (Berger, 1966; Renfree and Tyndale-Biscoe, 1973; Tyndale-Biscoe *et al.*, 1974; Merchant and Calaby, 1981; Tyndale-Biscoe and Renfree, 1987).

Until recently, amongst marsupials diapause was thought to be restricted to the macropodids, but Tyndale-Biscoe (1973) was the first to suggest that Hill's (1900) observations on *Acrobates* were consistent with the occurrence of diapause. Confirmation has now been provided for three non-macropodid families: the Tarsipedidae, a monospecific family consisting only of *Tarsipes rostratus* (the honey possum) (Renfree, 1980a, 1981a; Renfree and Calaby, 1981; Wooller *et al.*, 1981); Burramyidae (the pygmy possums), *Cercartetus concinnus* (Clark, 1967); *Cercartetus nanus* and *C. lepidus* (Ward, 1988), and Acrobatidae, *Acrobates pygmeaus* (the feather-tailed glider) and *Distoechurus pennatus* (the feather-tailed possum) (S. Ward and Renfree, 1988; S.Ward, 1988). Graafian follicles are found in the ovaries of females with newborn young, and sperm from a post-partum oestrus mating are found in the reproductive tract (Figure 7.10).

In these small possums the diapause blastocyst is very large (1–2 mm) and consists of about 2000 cells in *Acrobates* and *Tarsipes* (Figure 7.11).

In contrast to the macropodids, there is a period of slow growth (for about 30 days) of both the blastocyst and corpus luteum early in the diapause (Renfree, 1981a; S. Ward and Renfree, 1988) (Figure 7.12).

Nothing is yet known of the endocrine control of diapause in these small possums but it does not appear to be under lactational control (Renfree *et al.*, 1984a; S. Ward and Renfree, 1988). It may be related to the birth of the previous offspring or to nutritional or ecological factors. Since these species have a seasonal pattern of reproduction, S.Ward (1988) has suggested that nutrition and availability of nectar and pollen-bearing flowers may be an important controlling factor.

7.5 INITIATION AND MAINTENANCE OF DIAPAUSE

Blastocysts in diapause are always associated with a quiescent corpus luteum, and in the quokka the blastocyst degenerates when the corpus luteum disappears from the ovary (Sharman and Berger, 1969) and when the peripheral plasma progesterone levels are

Figure 7.9 Transmission electron micrograph of one cell of a 100-cell quiescent tammar blastocyst taken from the uterus of a lactating female. The shell membrane has the characteristic three layers, with the mucin coat separating it from the zona pellucida. The individual trophoblast cells are flattened along the inner surface of the shell, with elongate nucleii. Convoluted tight junctions join adjacent trophoblast cells. No sperm fragments are seen in this micrograph (×5500). The scale bar shows the width of the shell membrane as 0.0085 mm. j, junctional complex; m, mitochondrion; n, nucleus; S, shell membrane; z, zona pellucida.

Section of the whole ovary of a female with a large Graafian follicle (Gf) and enclosed oocyte (Oc), together with a surface section of another follicle (F), numerous primary follicles and a mature corpus luteum (CL). Note the absence of obvious regions of interstitial tissue. (b) The honey possum, *Tarsipes rostratus*. Section of the whole ovary of a female with a follicular oocyte (Oc). Three Graafian follicles (Gf) and three secondary follicles are evident, but there appears to be relatively little discrete interstitial tissue. No corpora lutea are visible in this section. (c) The monitos del monte, *Dromiciops australis*. Section of the ovary showing several developing follicles and numerous primary follicles (P) in the cortex. No corpora lutea are visible and, as in (a) and (b), no discrete interstitial tissue is present. [c kindly provided by Dr P. Temple-Smith and the Corporacion Nacional Forestal (CONAF) Chilé, which gave him permission to collect *Dromiciops* specimens.]

very low (G.I. Wallace, personal communication). The corpus luteum, however, is not required to maintain diapause because blastocysts can remain apparently viable for at least 4 months after ovariectomy or luteotomy (Tyndale-Biscoe and Hearn, 1981). In the brush-tailed bettong it appears that the corpus luteum may have an inherent lifespan of about 80 days and is not influenced by either sucking or season (M.J. Smith, 1989).

As noted in the previous section, the corpus luteum is not necessary for entry into diapause, and its removal at day 2 p.c. allows the one-cell fertilized uterine egg to progress to the blastocyst stage (Sharman and Berger, 1969). Tyndale-Biscoe (1979) has shown that the 6–7 cell divisions required to reach the unilaminar blastocyst stage of 80–90 cells takes 6–8 days from fertilization, which is about 7 days from oestrus. This is twice as long as cleavage and blastocyst formation in the opossum and bandicoot (Hartman, 1928; Lyne and Hollis, 1976). Expansion of tammar blastocysts in non-lactating females has occurred by day 9 (Figure 7.13), and endometrial weights have also increased by this time, with a distinct change in endometrial proteins occurring at day 8 p.c. (Tyndale-Biscoe, 1979, 1986).

Thus the inhibitory influence of the sucking stimulus begins to take effect before day 8 p.c. This has been further investigated by removal of the sucking young at daily intervals from birth, and measuring the interval to the next birth (Tyndale-Biscoe, 1986). In non-lactating females, in which there is no dia-

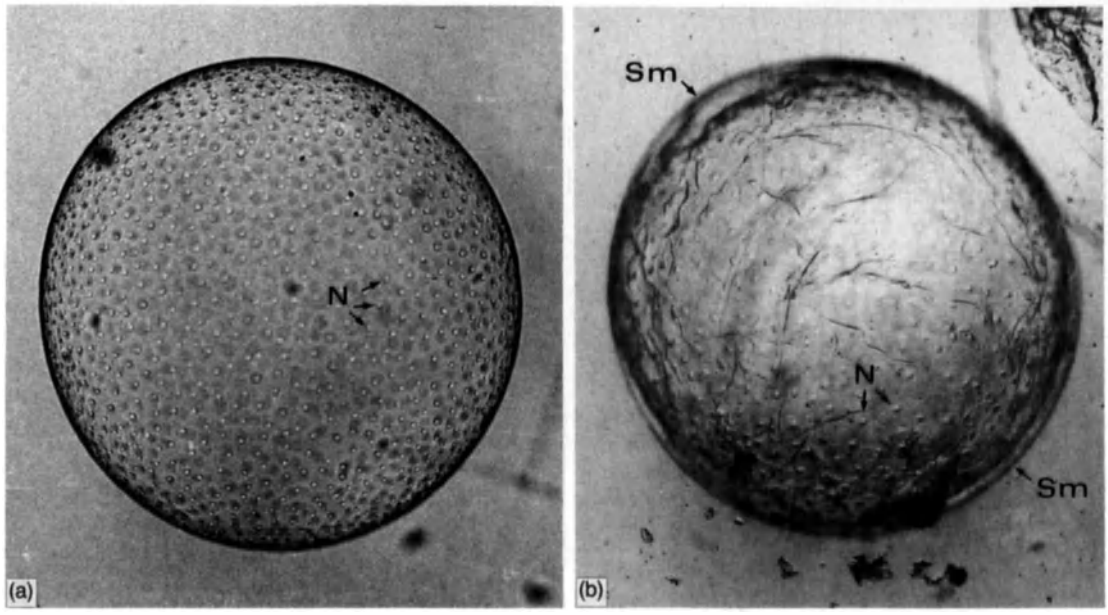

Figure 7.11 Diapause. Blastocysts of two small possums, the feather-tailed glider, *A. pygmaeus*, and the honey possum, *T. rostratus*. (a) Living 1.7-mm-diameter blastocyst from uterus of a lactating female *A. pygmaeus*, containing approximately 2000 cells. N, trophoblast nuclei. (b) Living 1.2-mm-diameter blastocyst from the uterus of a lactating female, *T. rostratus*. There can be variation in size between the 2–3 blastocysts in each uterus, but most have reached this size by day 30 of pouch life and undergo little further expansion until the end of lactation (see Figure 7.12). Sm, shell.

pause, the interval from oestrus to birth is 29 or 30 days, but the interval from RPY to birth remains constant at 26.4 days on day 4 or 5 after oestrus. The sucking inhibition thus begins on day 4 or 5 post oestrus. In the absence of any sucking stimulus, there is a transient pulse of progesterone on days 6 or 7 post oestrus (Hinds and Tyndale-Biscoe, 1982a). Two days after the progesterone pulse there is an increase in the weight of the endometrium and a change in the composition of the uterine secretions, and expansion of the blastocyst. The interval from the progesterone pulse to birth is relatively constant at 21–22 days, regardless of whether or not the female is lactating (Tyndale-Biscoe and Renfree, 1987) (see Figure 7.14).

One interesting variant on this general control mechanism for the entry into diapause occurs in the pubertal tammar (and, presumably, Bennett's) wallabies in which seasonal, photoperiodic influences can act directly without the presence of any sucking stimulus. Young females leaving the pouch in October and early November during seasonal quiescence may ovulate, mate and develop a conceptus to the 100-cell blastocyst stage (Andrewartha and Barker, 1969; Tyndale-Biscoe and Hawkins, 1977). This blastocyst then enters embryonic diapause and it remains quiescent until the subsequent summer solstice in late December (Berger and Sharman, 1969a).

7.6 REACTIVATION AFTER DIAPAUSE

7.6.1 THE ROLE OF THE SUCKING STIMULUS

It is clear from the studies summarized above that the influence of the sucking stimulus is all-important in the maintenance of lactational quiescence in all but pubertal animals, at

least amongst macropodids (Tyndale-Biscoe and Renfree, 1987). Not surprisingly, it is the neural stimuli from the teat that is of primary importance, and denervation of the mammary gland in the tammar causes immediate reactivation of the diapause blastocyst even though lactation continues (Renfree, 1979). However, development does not resume immediately on removal of the sucking stimulus, in that no changes can be seen in the blastocyst before day 8, and no change in the corpus luteum before day 4. Birth does not occur 21–22 days after RPY, which is the time taken from the early progesterone pulse in non-lactating females to birth. The actual time taken is around 5 days longer than this.

After removal of pouch young, there is a critical period after day 2 and before day 4 when ovariectomy or excision of the corpus luteum is followed by a resumption of blastocyst growth, but subsequent collapse, and by a failure of the endometrium to become secretory (Berger and Sharman, 1969b). Ovariectomy or lutectomy before this stage blocks reactivation, and after this stage allows fetal development to full term (Berger, 1970; Tyndale-Biscoe, 1970; I.R. Young and Renfree, 1979). Similarly, lutectomy at day 3 RPY results in a failure to produce a neonate but a new ovulation occurs instead 18–23 days after RPY (Fletcher and Renfree, 1988). When reactivation is stimulated by exogenous progesterone, which by-passes the corpus luteum, the fetus takes 3 days less to reach full term than after RPY (Figure 7.14) so it has been assumed that the corpus luteum takes 3 days to reactivate after sucking stimulus withdrawal (Renfree and Tyndale-Biscoe, 1973; Tyndale-Biscoe, 1979). Recently we have investigated the precise time for which

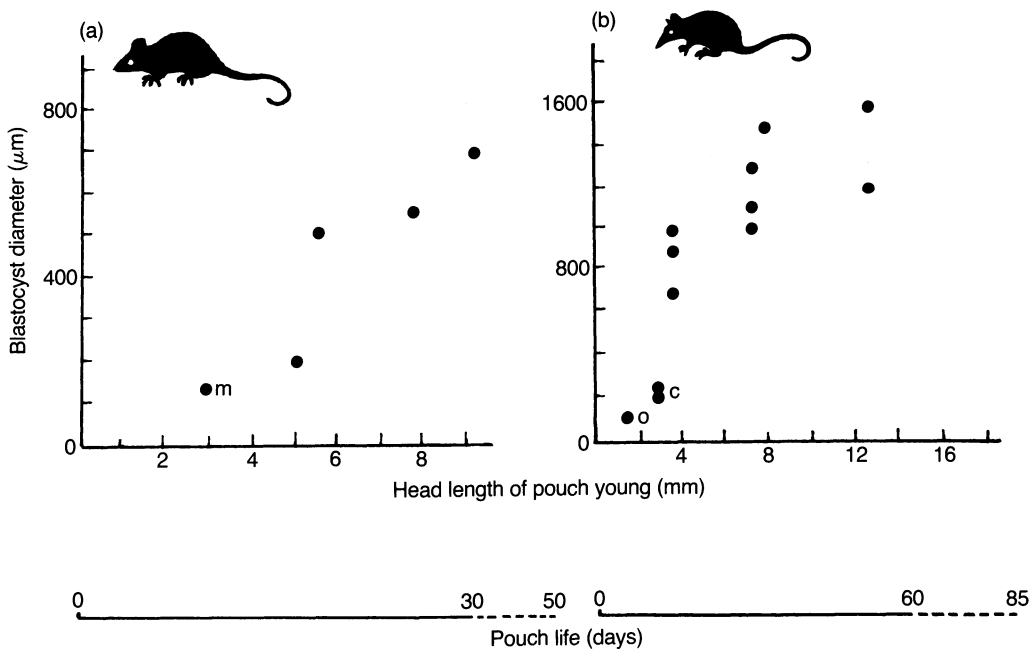

Figure 7.12 Blastocyst growth during lactation in (a) the pygmy possum, *Cercartetus concinnus*, and (b) the honey possum, *Tarsipes rostratus*, shown in relation to size of young in the pouch. Based on data from Bowley (1939), Clark (1967) and Renfree (1980a). The duration of pouch life (solid line) and suckling after pouch exit (broken line) are indicated below: o, oocyte in follicle; c, cleaving eggs; m = mitotic figures observed. (From Tyndale-Biscoe and Renfree, 1987, with permission.)

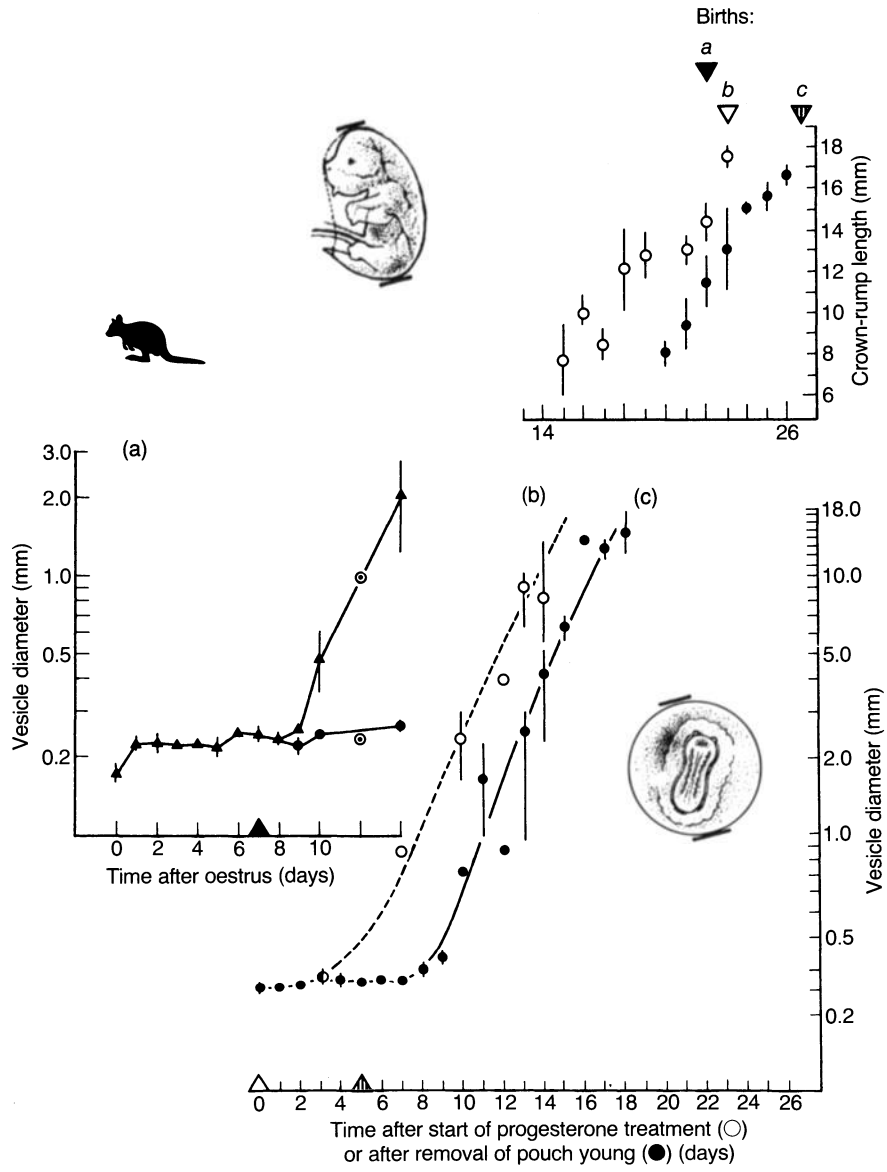

Figure 7.13 Growth of the embryo of *M. eugenii* before and after lactation. (a) Growth of the conceptus after oestrus uninhibited by the presence of (▲) a sucking pouch young compared with (•) lack of growth in the presence of a neonatal young. ▲ represents the mean day of transient pulse of progesterone in non-lactating animals; •, mean values for pregnant animals ovariectomized (lower point) or sham operated (higher point) on day 2 by Sharman and Berger (1969). (b) Growth of the diapausing blastocyst stimulated by 10 days of progesterone injection (○) or (c) after RPY (•). Δ, start of progesterone treatment: ⩓ , mean day of transient pulse of progesterone after RPY. Time of birth of treated animals shown in top panel a: ▼ (day 29 after oestrus), b: ▽ (day 23 after start of progesterone treatment) and c: ⩛ , (day 27 after RPY). Note the 3–4 day advance in time of birth after progesterone treatment compared with RPY. (From Tyndale-Biscoe and Renfree, 1987, with permission.)

the sucking stimulus must be withdrawn to reactivate the corpus luteum and, if present, the diapausing blastocyst, and have found once again that 3 days is required. The sucking stimulus must be absent for at least 72 h to allow the corpus luteum to escape inhibition (Gordon *et al.*, 1988). If the young is returned to the teat and reattaches after 72 h, reactivation is not inhibited and pregnancy proceeds concurrent with lactation. Collectively the evidence demonstrates that the corpus luteum must be present for 3 days if reactivation is to be initiated (see Figure 7.19), presumably to mediate the effects of the loss

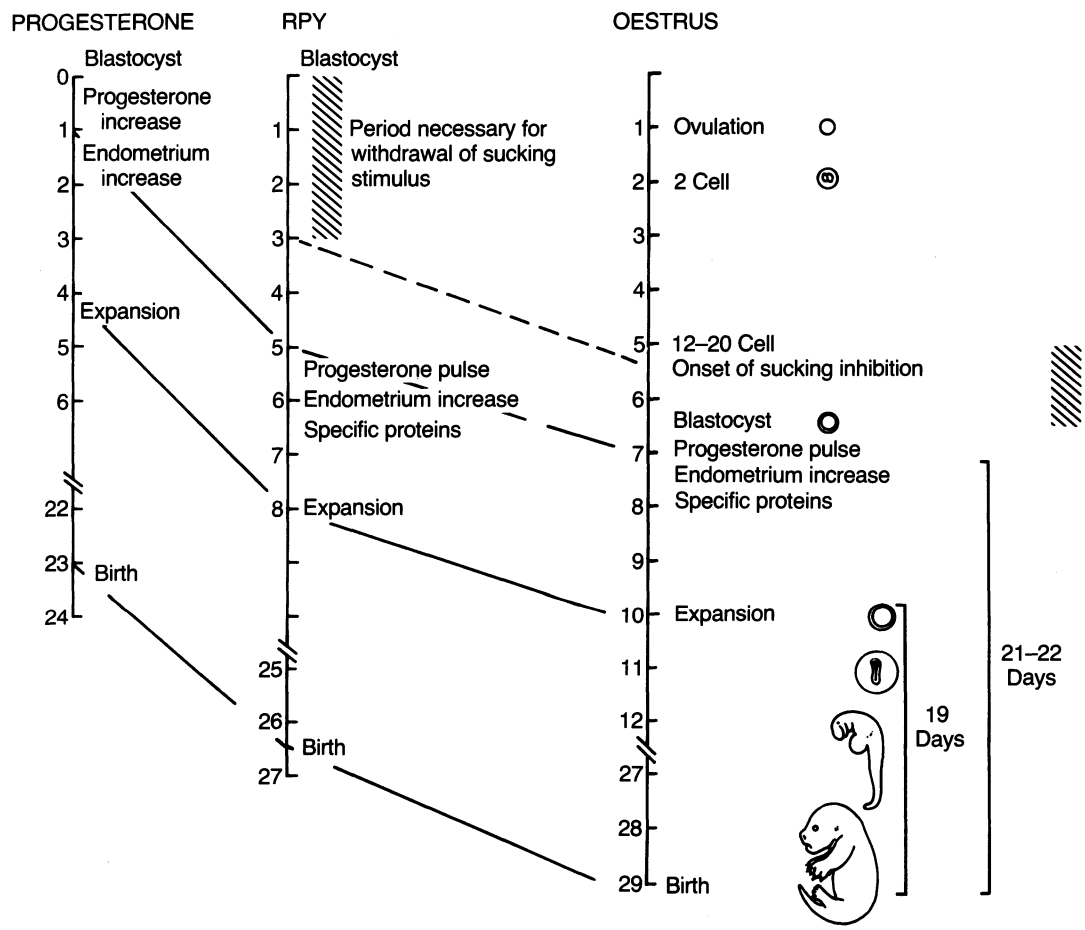

Figure 7.14 Intervals from either exogenous progesterone injection, removal of pouch young or oestrus to the withdrawal or onset of sucking inhibition, the early rise in progesterone (progesterone pulse), the increase in endometrial wet weight, the first measurable expansion of the blastocyst and birth. Although not shown, the progesterone pulse also coincides with an oestradiol-17β pulse after RPY. Note that, whilst the timing from injection, RPY or oestrus to the early progesterone pulse or to expansion is variable, the duration of pregnancy from the pulse is more or less constant and takes 21–22 days (Tyndale-Biscoe & Renfree 1987), and from expansion to birth 19 days. Compare also with Figure 7.19. Based on data in Renfree (1973a,b); Renfree and Tyndale-Biscoe (1973); Tyndale-Biscoe (1979, 1986); Hinds and Tyndale-Biscoe (1982a); Shaw and Renfree (1984); Fletcher and Renfree (1988); Gordon *et al.* (1988).

of the sucking stimulus. It also implies that nothing irreversible happens on day 1 and day 2 after RPY, but that the pituitary – hypothalamic axis must be sensitive to the lack of the sucking inhibition on three successive days. This will be discussed further below.

7.6.2 THE PITUITARY AND REACTIVATION

The marsupial corpus luteum does not depend on a luteotrophic stimulus for reactivation and subsequent progesterone secretion, but rather needs the withdrawal of an inhibitory effect. In the tammar, the quiescent corpus luteum undergoes its normal growth and secretory functions after total hypophysectomy (Hearn, 1973, 1974, 1975) with a transient pulse of progesterone 7 days after the operation (Tyndale-Biscoe *et al.*, 1986; Figure 7.15).

Hearn's (1974) results did not differentiate between the anterior and posterior pituitary. Sharman (1965a) showed that oxytocin injection (and water!) could prolong quiescence, and Tyndale-Biscoe and Hawkins (1977) showed that both oxytocin and prolactin delay reactivation (see Figure 7.16).

However, after hypophysectomy only prolactin has this effect, and it is now generally accepted that during diapause prolactin is the inhibitory agent and administration of prolactin after removal of the pouch young prevents corpus luteum growth (Figure 7.16) (Tyndale-Biscoe and Hawkins, 1977; Hinds, 1989b). Confirmation of the importance of prolactin in this process is provided by the finding that the corpus luteum contains prolactin (Sernia and Tyndale-Biscoe, 1979) but not LH receptors (F.Stewart and Tyndale-Biscoe, 1982; Figure 7.17).

However, neither prolactin nor LH has any effect on steroidogenesis by luteal tissue *in vitro*, so that once the inhibition is removed the corpus luteum resumes its autonomous life (Sernia *et al.*, 1980; Hinds *et al.*, 1983; Tyndale-Biscoe, 1986). Removal or replacement of pouch young in early lactation does not cause a marked change in prolactin concentrations (Hinds and Tyndale-Biscoe, 1982b; Gordon *et al.*, 1988), and although a single injection of the dopamine agonist bromocriptine initiates blastocyst reactivation (Table 7.2) there is likewise no change in prolactin concentration measured in once-daily samples (Tyndale-Biscoe and Hinds, 1984). Although it remains possible that a prolactin pulse may have been abolished but not detected by this sampling regimen (Hinds and Tyndale-Biscoe, 1985; Tyndale-Biscoe *et al.*, 1986; Gordon *et al.*, 1988), the time from RPY to birth is the same as bromocriptine injection to birth and the time from

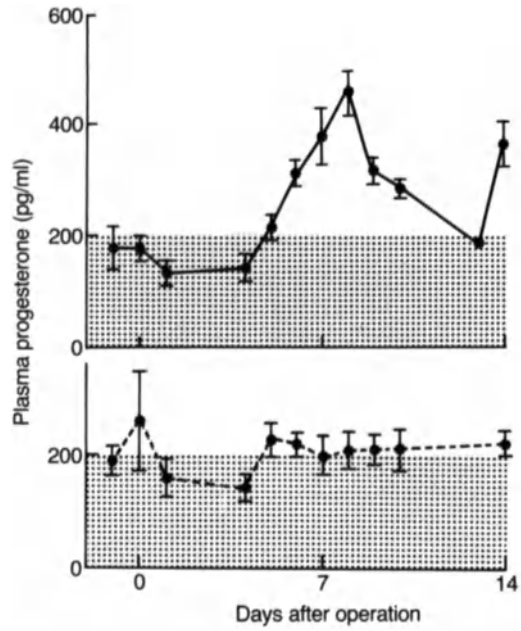

Figure 7.15 Responses in the concentrations (mean ± SEM) of progesterone in lactating tammars subjected to hypophysectomy (n = 4) (solid line) or sham hypophysectomy (n = 5) (dotted line). Removal of the pituitary released the corpora lutea from inhibition and they underwent normal development, including a change in secretion rate at day 7–8 (7.3 ± 0.2), whereas the sham operated females remained in lactational quiescence. Stippling indicates normal background plasma progesterone concentration during quiescence. (Redrawn from Tyndale-Biscoe *et al.*, 1986).

the progesterone pulse to birth is the same in both cases (Tyndale-Biscoe *et al.*, 1986). So how can this be resolved with the evidence that the sucking stimulus must be removed for 3 days? Evidence from experiments on seasonal reactivation provide clues to the mechanism. Animals induced to reactivate by experimental manipulation of photoperiod alter the time of secretion of melatonin even on the first night of the change, so that there is a synchronized melatonin release with the dark phase (McConnell *et al.*, 1986). In these animals, there is also a loss of an early-morning pulse of prolactin, and this is lost some time before day 5 after photoperiod change (McConnell *et al.*, 1986). If exogenous melatonin is administered 3 h before the dark phase in an inhibitory photoperiod of 15L:9D, thus effectively making it into a permissive period of 12L:12D, the prolactin pulse is abolished by day 3, but not by day 1, of this treatment (Tyndale-Biscoe *et al.*, 1986). The 3 day lag between removal of the sucking stimulus to irreversible reactivation must therefore be the time taken for the hypothalamic – pituitary axis to adjust to the loss of at least three consecutive dawn pulses of prolactin, presumably by withdrawal of prolactin release. However, bromocriptine does not apparently depress peripheral prolactin, although it may have abolished a dawn pulse (Tyndale-Biscoe *et al.*, 1986). Since Schallenberger *et al.* (1981) have demonstrated that a single injection of bromocriptine can suppress prolactin for 6 days in rhesus monkeys, it seems likely that it could act for at least the required 3 days in wallabies (Gordon *et al.*, 1988). This has recently been confirmed by monitoring the dawn pulse after photoperiod change and bromocriptine injection (Hinds, 1989b,c). The most critical factor for the maintenance of quiescence in the tammar is not sustained high concentrations of prolactin but the occurrence of a transient prolactin pulse. Daily injections of ovine prolactin maintained quiescence; endogenous prolactin induced by thyrotrophin-releasing hormone (TRH) also maintained quiescence, while half of the tammars treated with bromocriptine for 5 days lost their morning prolactin pulse and these reactivated. Similarly, the prolactin pulse is absent 5 days after a change to stimulatory photoperiods. Once the inhibitory effects are removed, by whatever means, the corpus luteum rapidly resumes progesterone production, which in turn induces a secretory uterus and blastocyst growth.

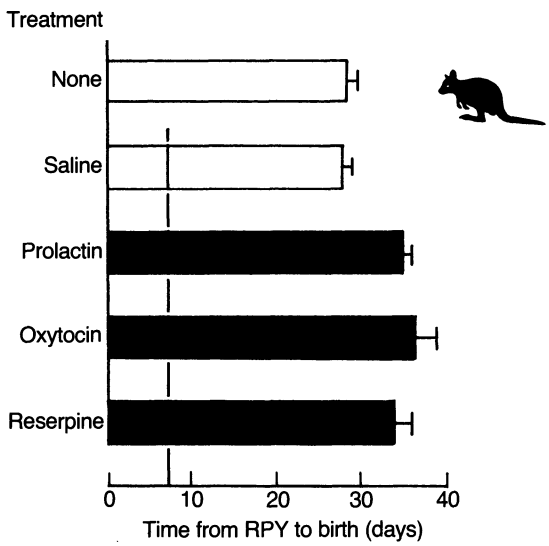

Figure 7.16 Time to birth or oestrus in *Macropus eugenii* from which the pouch young were removed (RPY) and the females variously injected three times daily for 7 days (vertical line). The apparent gestation period was extended by 7 days in the animals treated with oxytocin, prolactin and reserpine. Data from Tyndale Biscoe and Hawkins (1977). (From Tyndale-Biscoe and Renfree, 1987, with permission.)

7.6.3 REACTIVATION BEFORE THE PROGESTERONE PULSE

The first obvious change in peripheral plasma progesterone is the transient pulse on day 5 or 6, but there is evidence to suggest that both uterine and blastocyst reactivation have

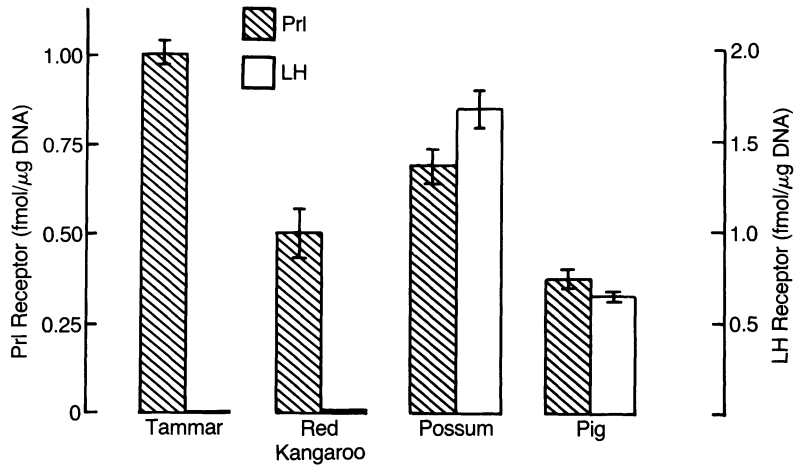

Figure 7.17 Prolactin (Prl) and luteinizing hormone (LH) receptors in luteal tissue of tammar, red kangaroo, brush-tailed possum and pig. Note that the corpora lutea of the two macropodid species contain no measurable LH receptors, but all four species have Prl receptors. Data from F. Stewart and Tyndale-Biscoe (1982).

Table 7.2 Response of tammars in lactational and seasonal quiescence to a single injection of bromocriptine (5 mg per kg body weight), at different months of the year. (From Tyndale-Biscoe *et al.*, 1986)

[a] Reactivation determined by occurrence of progesterone pulse, birth, or oestrus.
[b] Reactivation determined only by occurrence of birth; others in these groups may have undergone a non-pregnant cycle that was not recorded.

already begun by this time. As noted above, between a critical period after day 2 and before day 6 after RPY in the quokka (Tyndale-Biscoe, 1963a) in the tammar (Sharman and Berger, 1969; Tyndale-Biscoe, 1970; I.R. Young and Renfree, 1979) and in the potoroo (Bryant and Rose, 1986) ovariectomy is followed by resumption of blastocyst growth and subsequent collapse and by failure of the luteal phase to develop in the endometrium. Ovariectomy after day 6 does not prevent the appearance of a luteal uterus and fetal development to full term. In both species initiation of reactivation precedes the time when an early pulse of progesterone occurs (Hinds and Tyndale-Biscoe, 1982a), and yet it appears that the corpus luteum is necessary to influence blastocyst reactivation, either directly or indirectly through increased or specific secretion from the uterus (see later sections for fuller discussion).

No gross changes can be observed in the blastocyst before day 8 (Renfree and Tyndale-Biscoe, 1973), but a few mitoses can be observed in the blastocyst on day 4 (Berger, 1970). The first significant increase in blastocyst diameter occurs by day 8, and a threefold increase by day 10 (Renfree and Tyndale-Biscoe, 1973). Between day 5 and day 10, the volume has increased 45-fold, and by day 15 by about 10 000-fold (Tyndale-Biscoe and Renfree, 1987). Endometrial protein synthesis increases as early as day 4, with a significant increase in leucine incorporation by the endometrium (Shaw and Renfree, 1986) and some prealbumins are present in uterine exudates at day 4 which are not present at day 0 (Renfree, 1973b). Metabolic reactivation of the blastocyst has occurred by day 5, as RNA polymerase activity and uridine incorporation are significantly higher in day 5 blastocysts than at day 4 and earlier stages (Moore, 1978; Thornber *et al.*, 1981; Shaw and Renfree, 1986). Glucose incorporation has also increased by day 5 RPY but is most significant between days 5 and 10 (Pike, 1981). These data suggest that a change in uterine secretion by day 4 causes embryonic reactivation by day 5 (Figure 7.18), which is also the day of the progesterone pulse and which also coincides with a pulse of oestradiol (Shaw and Renfree, 1984, 1986).

The conclusion must be that an earlier change is responsible for triggering reactivation of the blastocyst either directly or indirectly via the uterus. Most studies conclude that the blastocyst is indirectly stimulated by the progestational stimulus on the uterine secretions (Tyndale-Biscoe, 1970; Renfree, 1972a, 1973a), a conclusion supported by the recent results of Selwood (1987), who found that addition of progesterone to the culture medium did not improve the *in vitro* culture conditions for *Sminthopsis* cleaving and expanding blastocyst stages. Exogenous oestradiol and progesterone can both cause increased uterine secretion and an increase in RNA polymerase activity in the nuclei of blastocyst cells within 48 h of injection (Moore, 1978; Shaw and Renfree, 1986). Similarly, exogenous steroids can reactivate tammar blastocysts and pregnancy proceeds to term (Berger and Sharman, 1969b; Renfree and Tyndale-Biscoe, 1973). Although both progesterone and oestradiol can initiate development, only progesterone will sustain it (Clark, 1968; Fletcher *et al.*, 1988).

An increase in uterine sensitivity to progesterone, resulting from either a change in progesterone receptor concentrations (see below) or from a change in a hormone which regulates uterine sensitivity to progesterone, could explain the apparent lack of a change in progesterone secretion rate (Shaw and Renfree, 1986). If prolactin regulates uterine sensitivity to progesterone as it does in the rabbit (Daniel, 1980; Daniel *et al.*, 1984), the removal of the inhibitory effect of sucking by day 3 RPY may allow a progestational response in the uterus before progesterone concentrations increase significantly (Shaw and Renfree, 1986).

The conclusion from the preceding section is that the first 6 days of blastocyst reacti-

vation is under maternal control (Figure 7.19).

The sucking stimulus must be withdrawn for 3 days (Gordon *et al.*, 1988), acting perhaps by failure of a single dawn pulse of prolactin on three successive occasions. The ovary (? corpus luteum only) must be present for more than 2 days but less than 4 (? 3) for reactivation to occur (Sharman and Berger, 1969; Berger, 1970). However, for maintenance of pregnancy ovarian input is required to day 6, to allow for the effects of the transient progesterone pulse on days 5–6 from a corpus luteum in which cell divisions are first seen at day 4 (Sharman and Berger, 1969). Changes in uterine secretion and uterine metabolism also occur by day 4 (Renfree, 1973b; Shaw and Renfree, 1986), and blastocyst metabolism has increased by day 5 (Moore, 1978; Thornber *et al.*, 1981; Shaw and

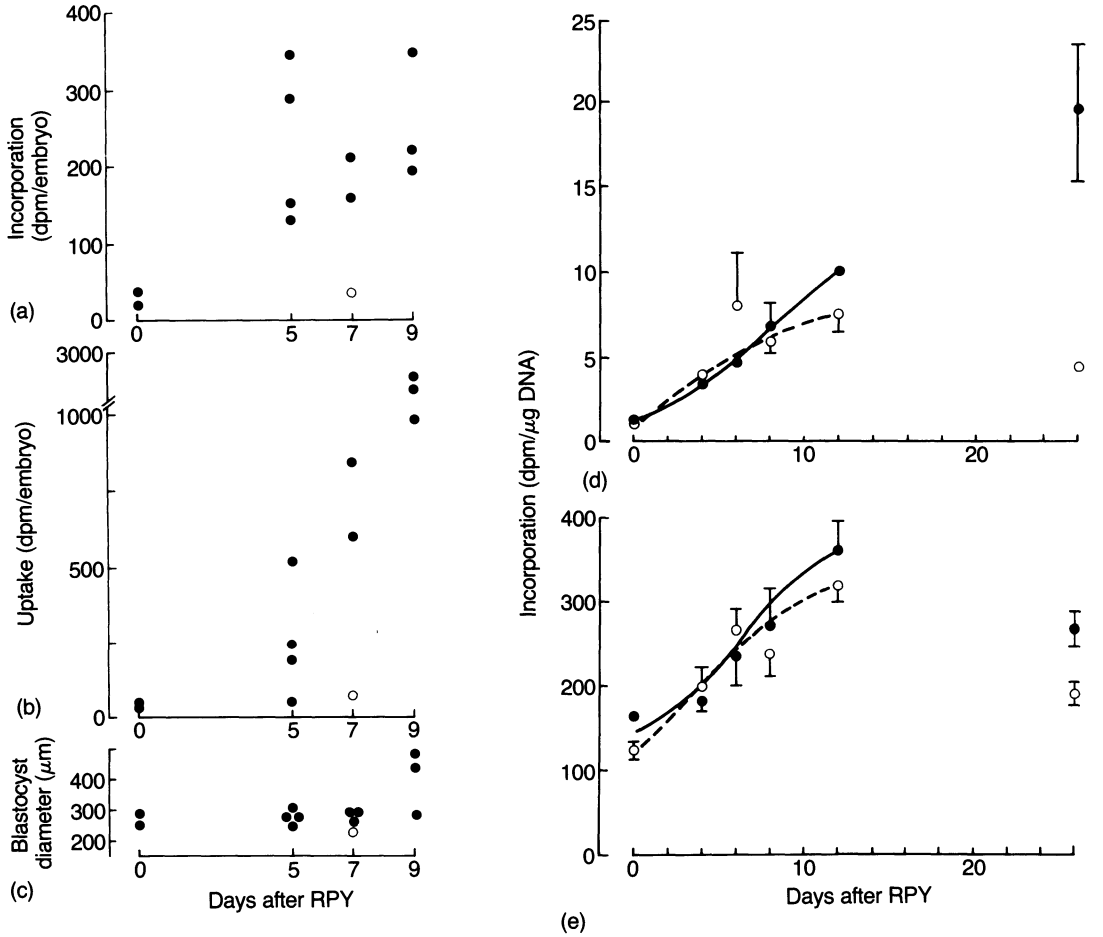

Figure 7.18 Uridine (a) incorporation and (b) uptake by individual blastocysts (d.p.m. per embryo) of the tammar during the early stage of reactivation. (○) Blastocyst with collapsed trophoblast. Blastocysts diameters are shown in (c). (d and e) Leucine incorporation by gravid (● — ●) and non-gravid (○ - - - ○) endometrium during pregnancy (d.p.m/μg of tissue DNA). Incorporation into (d) secreted protein and (e) tissue protein increased between day 0 and day 12. At day 26 gravid uteri were more secretory than non-gravid uteri. Tissue incorporation decreased between day 12 and day 26 in both uteri. Data derived from Shaw and Renfree (1986). (Redrawn from Shaw, 1983b.)

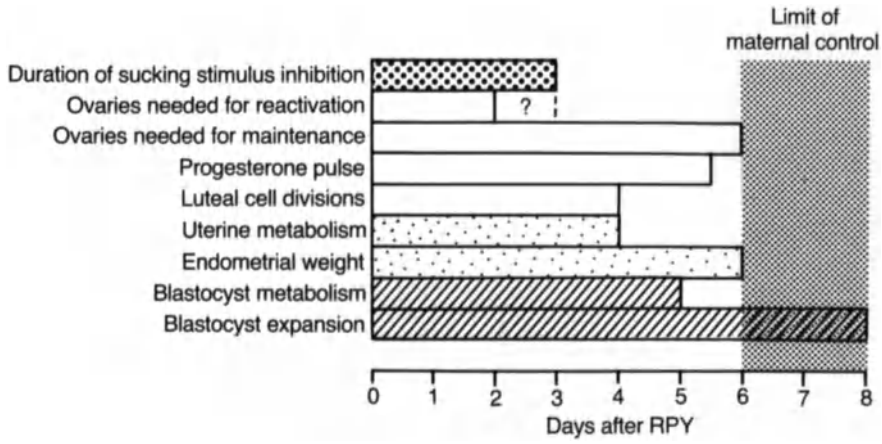

Figure 7.19 Diagrammatic representation of the timing of various maternal and embryo responses initiated by removal of the pouch young at day 0. The sucking stimulus must be withdrawn for 72 h to allow reactivation, and it appears that the ovaries must be present for all of this time. If they are removed at day 2, and probably day 3, reactivation is prevented, but at day 4 and day 6 reactivation occurs but pregnancy fails. The progesterone (and oestradiol) pulse occurs at days 5–6, after endometrial metabolism (day 4) and blastocyst metabolism (day 5) have already increased. The ovaries are necessary for a successful pregnancy only to day 8, as after removal between days 6 and 8 pregnancy can go to term in the absence of the ovary or the pituitary. Endometrial weight has significantly increased by day 6, and blastocyst diameter by day 8. Thus, the limit (earliest day 6; latest day 8) of the maternal influence on early pregnancy (stippling) is very brief, and the ovary and pituitary only become necessary again for the closing stages of pregnancy and parturition. Sucking pouch young effects ⊠; ovarian influence □; uterine responses ▩; embryo responses ▨. Based on data from various authors and see text for full references.

Renfree, 1986). The first gross morphological change, blastocyst expansion, is not seen until day 8 (Renfree and Tyndale-Biscoe, 1973) which is the limit of the maternal control as pregnancy can proceed to full term in the absence of ovaries, functional corpora lutea or pituitary after this time (Tyndale-Biscoe and Renfree, 1987; Tyndale-Biscoe and Hinds, 1989).

7.6.4 SEASONAL REACTIVATION

A great deal is now known of the endocrine control of seasonal reactivation in the tammar and in the Bennett's wallaby (Tyndale-Biscoe and Renfree, 1987). These two species are effectively pregnant for 364 of the 365 days of the year, the single non-pregnant day being the day it gives birth. In the normal course of events, tammar blastocysts reactivate shortly (about 20 days) after the summer solstice on December 22 (Figure 7.20), and it is now known that photoperiodic cues mediated via the pineal and its hormone melatonin are responsible for this (Renfree *et al.*, 1981; McConnell, 1984; McConnell *et al.*, 1986; Tyndale-Biscoe *et al.*, 1986), as it is in the Bennett's wallaby (Loudon *et al.*, 1985; Curlewis and Loudon, 1988, 1989; Loudon and Curlewis, 1989).

Since this has been reviewed extensively recently, and only indirectly relates to pregnancy (Tyndale-Biscoe *et al.*, 1986; Tyndale-Biscoe and Renfree, 1987), only a brief summary will be given here.

Manipulation of photoperiod has shown that seasonal quiescence is superimposed on the lactational inhibition of reproduction and

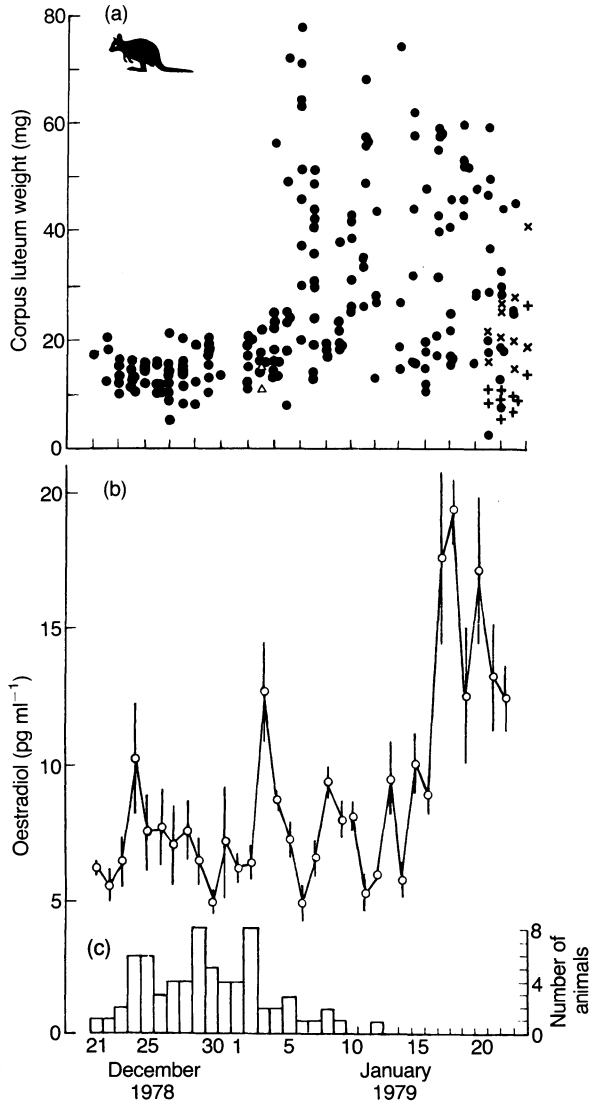

Figure 7.20 Changes at reactivation in 201 female *Macropus eugenii* shot between 20 December 1978 and 23 January 1979. (a) Weight of the corpus luteum of each animal, showing the onset of growth in early January, coincident with the expansion of the reactivated blastocyst. One animal killed on 2 January carried two blastocysts and two corpora lutea (Δ). In animals carrying newborn pouch young on or after 20 January, the corpora lutea of pregnancy are indicated by x and those resulting from the post-partum ovulation are shown by +. (b) Concentrations (mean ± SEM) of oestradiol-17–β in cardiac plasma from 143 pregnant and post-partum animals. Note the peak on 3 January and the longer period of elevated concentrations at the time of parturition and post-partum oestrus. Six of the animals sampled on 21 and 22 January carried newborn pouch young. (c) Date of reactivation calculated for 69 of these animals from the diameter of reactivated vesicles flushed from uteri between 1 and 20 January and crown–rump lengths of fetuses obtained between 14 and 22 January, using the growth curve (see Figure 7.13) derived from embryos reactivated after removing pouch young. Data from Flint and Renfree (1982). (From Tyndale-Biscoe and Renfree, 1987, with permission.)

that tammars experiencing increasing day length or long days have an inhibition of the corpus luteum (Sadleir and Tyndale-Biscoe, 1977; Hinds and den Ottolander, 1983; McConnell and Tyndale-Biscoe, 1985; McConnell *et al.*, 1986, Tyndale-Biscoe *et al.*, 1986). The evidence is that the pineal is transducing this photoperiodic information and the control of seasonal breeding through its secretion of melatonin, and the marked circadian fluctuations observed are abolished by denervation of the pineal, by pinealectomy, or by implants or injections of melatonin (Renfree *et al.*, 1981; McConnell, 1984; Renfree and Short, 1984; Loudon *et al.*, 1985; McConnell and Hinds, 1985; McConnell and Tyndale-Biscoe, 1985; Gemmell, 1987). As noted earlier, it appears that melatonin abolishes a marked pulse of prolactin of less than 2 h duration which coincides with the time of lights on (McConnell *et al.*, 1986), and that it does so within 3 days (Tyndale-Biscoe *et al.*, 1986). The abolition is permanent once the melatonin signal has been read, supporting the idea that melatonin does not affect the pituitary directly but operates through a neural mechanism in the hypothalamus (Renfree and Short, 1984; Tyndale-Biscoe *et al.*, 1986).

The time taken from a photoperiod change to birth or oestrus is longer than RPY to birth or oestrus, and yet with melatonin injections the prolactin pulse is abolished by the third day (Tyndale-Biscoe *et al.*, 1986), as in removal of the sucking inhibition (Gordon *et al.*, 1988), and if melatonin implants are given the shortest time to birth is identical to that of RPY to birth (Renfree and Short, 1984). Since the time from the progesterone pulse to birth is similar (melatonin treatment 21.6 days; photoperiod change 23.5 days; natural photoperiod change after summer solstice 22.0 days), the additional days before reaction must reflect the time taken for the message to be acted upon, and relate to how quickly and by how much the melatonin concentrations change (Tyndale-Biscoe *et al.*, 1986). Clearly these data provide new and exciting information on how seasonal breeding is controlled in mammals.

7.6.5 CONTROL OF DIAPAUSE IN MACROPODIDS

The control of diapause in macropodid marsupials is a complex interaction between the sucking stimulus, the hypothalamus, the pituitary, the corpus luteum and the uterus, resulting, in the case of the tammar, in an 11-month cessation of growth of the 100-cell blastocyst. Photoperiodic signals are superimposed on this system in the second half of the year when days are lengthening. Most of the steps on the hypothetical pathways have now been filled in (Figure 7.21), but the precise sequence of events between day 3 and day 6 after RPY needs further study.

It remains possible that the blastocyst can respond directly to pituitary or ovarian hormones, but Tyndale-Biscoe's (1970) elegant experiments transferring quiescent blastocysts to uteri of reactivated, ovariectomized recipients strongly suggest that the quiescent blastocyst does not require direct ovarian stimulation but simply awaits a changed uterine milieu. This is also further discussed below under 'The uterine endometrium' (section 7.7.3).

7.7 MAINTENANCE OF PREGNANCY

7.7.1 PITUITARY–OVARIAN INTERACTIONS

Pituitary – ovarian interactions are known for only one species, *M. eugenii* with additional unpublished results on the brush-tailed possum (see Hinds, 1983, 1988; Tyndale-Biscoe *et al.*, 1986; Tyndale-Biscoe and Renfree, 1987; Tyndale-Biscoe and Hinds, 1989). The marsupial corpus luteum does not appear to depend on a luteotrophic stimulus for progesterone secretion, nor is its activity determined by luteolysins. In *M. eugenii* the previously formed corpus luteum undergoes

its normal growth and secretory functions after total hypophysectomy (Hearn, 1974; Tyndale-Biscoe and Hawkins, 1977; Hinds, 1983).

Pregnancies also go to term in hypophysectomized tammars but the fetuses die in the uterus (Hearn, 1973, 1974). A similar independence of the corpus luteum from the pituitary is observed in brush-tailed possums after hypophysectomy, so it seems that the

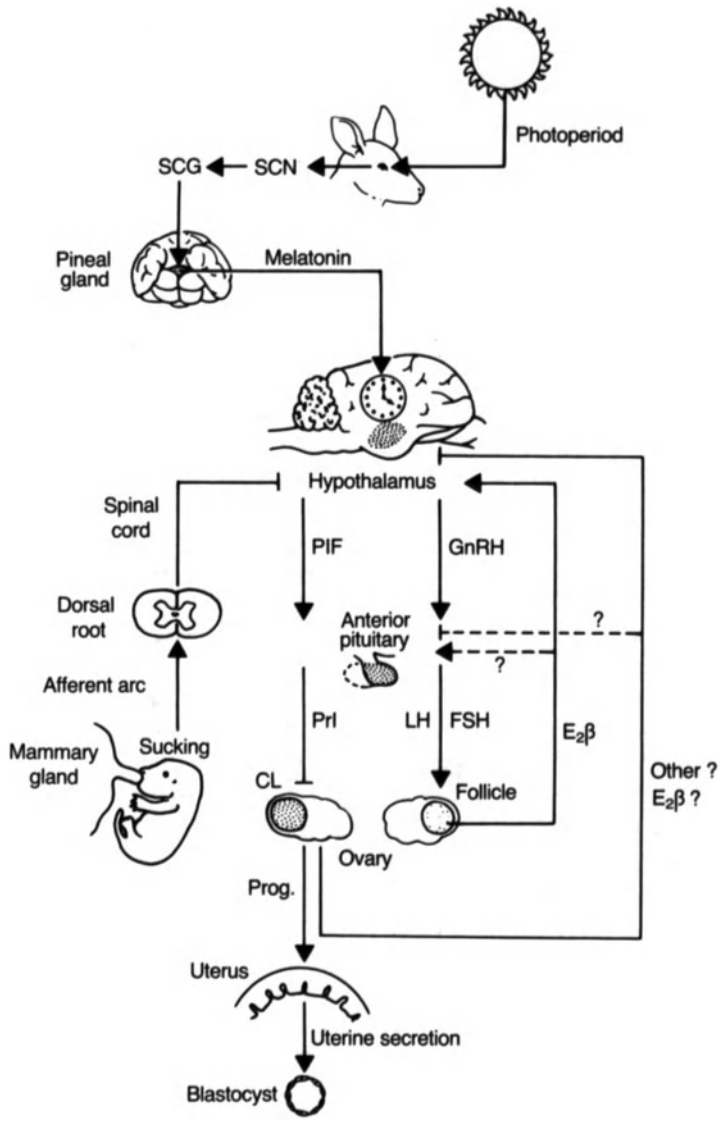

Figure 7.21 Hypothetical scheme showing the known and suggested pathways for the control of quiescence of *Macropus eugenii*. CL, corpus luteum; GnRH, gonadotrophin releasing hormone; LH, luteinizing hormone; $E_2\beta$, oestradiol-17β; FSH, follicle-stimulating hormone; Prog, progesterone; PIF, prolactin inhibiting factor; Prl, prolactin; SCG, superior cervical ganglion; SCN, suprachiasmatic nucleus. ↓ Stimulation; ⊥ inhibition. (Redrawn from Renfree, 1981b.)

autonomy of the corpus luteum may be a common feature of marsupials (Tyndale-Biscoe *et al.*, 1986). However, functional corpora lutea and successful births do occur in tammars passively immunized to GnRH (Short *et al.*, 1985), confirming that FSH and LH are not required for luteal reactivation, pregnancy, parturition or lactogenesis in the tammar, but that follicular growth and postpartum oestrous behaviour are inhibited in the absence of gonadotrophins. Hypophysectomy performed at any stage of the oestrous cycle or pregnancy prevents growth of follicles (Hearn, 1974; Panyaniti *et al.*, 1985). Using heterologous radioimmunoassays, two gonadotrophic fractions which resemble FSH and LH of eutherian mammals have been described (Gallo *et al.*, 1978), and LH remains low (0.2–1.9 ng/ml) at all times during the oestrous cycle or pregnancy except for the pre-ovulatory surge of 10–50 ng/ml, which lasts for about 12 h (Sutherland *et al.*, 1980; Tyndale-Biscoe *et al.*, 1983). In intact females FSH is not detectable (Evans *et al.*, 1980), although it is detectable in intact males (Catling and Sutherland, 1980), but it reaches very high concentrations in castrated males (Catling and Sutherland, 1980) and ovariectomized females 3–8 days after ovariectomy (100–600 ng/ml) (Evans *et al.*, 1980; Horn *et al.*, 1985). As in eutherian mammals, gonadotrophins are controlled by oestradiol concentrations, with low doses exerting a negative feedback, but high doses, similar to the levels which occur at oestrus, exerting a positive feedback on the hypothalamus to induce a transient pulse of LH (Horn *et al.*, 1985). The corpus luteum also provides a negative feedback on the pituitary (Tyndale-Biscoe and Hawkins, 1977; Evans *et al.*, 1980; Tyndale-Biscoe and Hearn, 1981; Renfree *et al.*, 1982) to suppress ovulation, apparently by the secretion or release of oestradiol (see Figure 7.21) and, although as yet no evidence can be found for oestradiol-17β secretion by the tammar corpus luteum *in vitro* (Renfree *et al.*, 1984b), there is now evidence of oestradol secretion by the corpus luteum of the quokka *Setonix brachyurus* (Bradshaw and Bradshaw, 1992).

By contrast, ovarian cortical tissue does secrete oestradiol (Renfree *et al.*, 1984b) and has a negative-feedback effect on the pituitary (Tyndale-Biscoe and Hearn, 1981).

7.7.2 THE CORPUS LUTEUM

Development of the embryo past the unilaminar blastocyst stage begins with expansion of the yolk sac to form first a bilaminar and then a trilaminar vesicle. In all the species of which we have some knowledge of the hormonal profile, progesterone increases in concentration and the endometrium proliferates. Although the importance of luteal secretion is unequivocal, the need for it is relatively brief, and it is during the first week of pregnancy that it is most important. Ovariectomy or lutectomy of the tammar, brush-tailed possum, potoroo, quokka and opossum demonstrates that fetal development can proceed to full term in the absence of the corpus luteum after 8–10 days (Hartman, 1925; Tyndale-Biscoe, 1963a, 1970; Sharman, 1965b; Sharman and Berger, 1969; Shorey and Hughes, 1973a,b, 1975; Renfree, 1975; I.R. Young and Renfree, 1979; Bryant and Rose, 1986).

The endocrine role of the corpus luteum during pregnancy and the cycle has been best defined in macropodids, and in the tammar wallaby in particular (Tyndale-Biscoe, 1984; Tyndale-Biscoe and Renfree, 1987). Progesterone has been identified as the main steroid in corpora lutea of the tammar (Renfree *et al.*, 1979; Renfree *et al.*, 1984b), reaching maximum concentrations of 32 ng/mg at day 22 of the 27-day gestation when the corpus luteum weighs around 60 mg (Figure 7.22).

The pattern of circulating plasma progesterone is similar in the macropodid species so far studied. During lactational or seasonal quiescence, peripheral plasma concentrations are low, around 100–200 pg/ml,

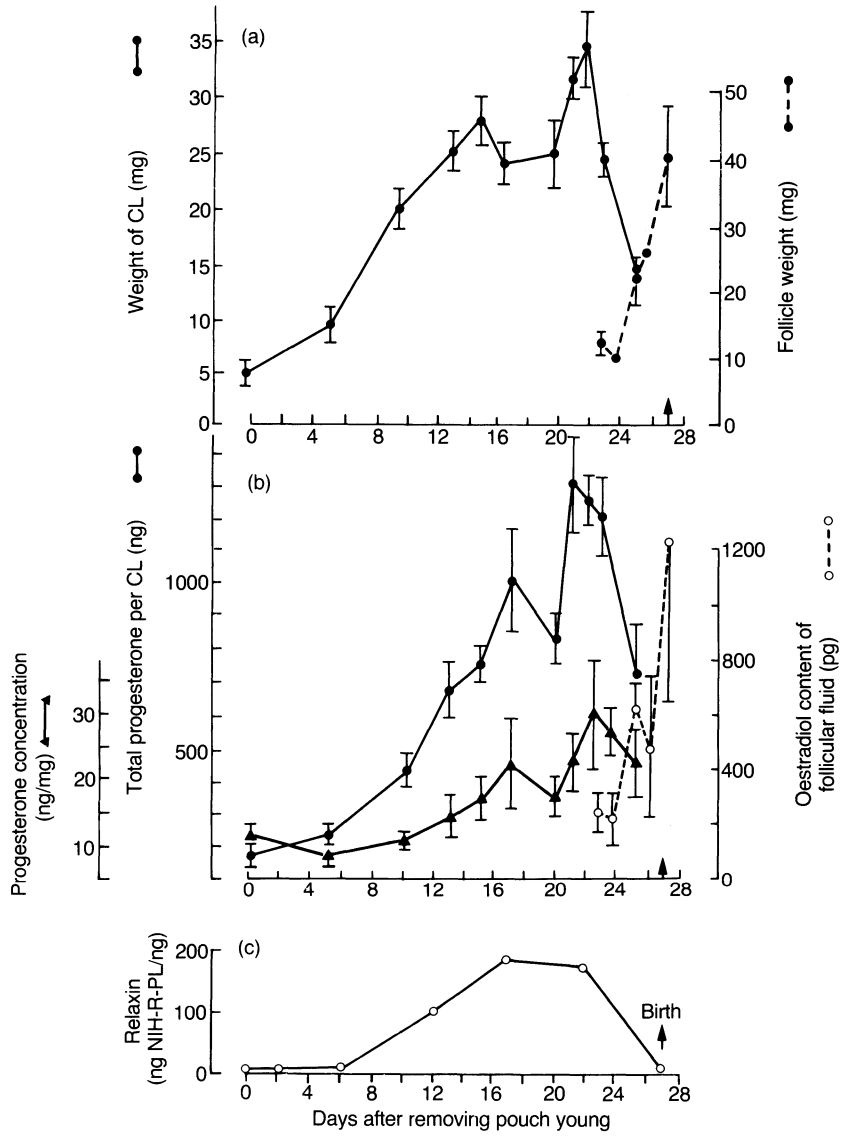

Figure 7.22 Hormonal content of the corpus luteum and follicle in the tammar during pregnancy and immediately post partum. (a) Wet weight (mg) ± SEM of the corpus luteum and follicle. (b) Progesterone concentration (△) and content (•) of the corpus luteum and oestradiol content (○) of the follicle. (c) Relaxin concentration of the corpus luteum. Progesterone and corpus luteum weight data from Renfree *et al.* (1979); oestradiol and follicle weight data from Harder *et al.* (1985); relaxin data from Tyndale-Biscoe (1981). Steroids were measured by radioimmunoassay; relaxin by the mouse pubic symphysis bioassay agonist ng NIH-R-PL/mg relaxin standard.

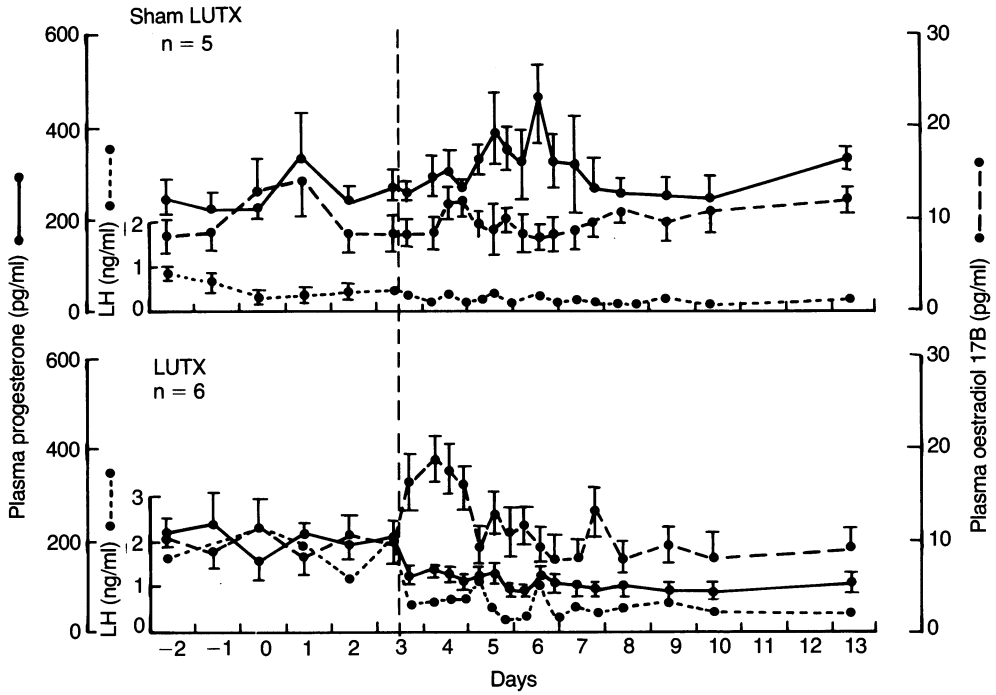

Figure 7.23 Plasma concentrations of progesterone (● — ●), oestradiol-17β (● - - - ●) and LH (NIH-oLH-23) (● . . . ●) in tammars before and after excision of the corpus luteum (n=6) and sham excision (n=5) of the corpus luteum reactivated by removal of the pouch young (RPY) on day 0. The time of operation is indicated by the vertical line. Values are mean ± SEM; error bars are not shown when less than the size of the symbol. Data from Fletcher and Renfree (1988).

rising to a transient early pulse which occurs at day 3–4 in the quokka and day 4, 5 or 6 in the tammar and Bennett's wallaby (Lemon, 1972; Renfree and Heap, 1977; Cake *et al.*, 1980; Hinds and Tyndale-Biscoe, 1982a; Walker and Gemmell, 1983a) after reactivation of the diapausing blastocyst. Peak concentrations are reached in late pregnancy followed by a precipitous fall at the time of parturition (Figures 7.22 and 7.27).

Follicular size begins to increase by about day 23 RPY, reaching the maximum at around the time of birth (Figure 7.22). Oestradiol content of the follicular fluid also increases to reach a peak post-partum (Harder *et al.*, 1985) and peripheral plasma levels remain relatively constant throughout most of pregnancy (Harder *et al.*, 1984; Shaw and Renfree, 1984). However, there is also a brief pulse of oestradiol around day 5, coincident with the progesterone pulse (Shaw and Renfree, 1984; Figure 7.5). Like the progesterone pulse, it comes too late to be involved in the resumption of development after diapause, but may be important for providing some stimulus to the endometrium.

The synthesis of progesterone by the corpus luteum increases at day 5 *in vitro* (Hinds *et al.*, 1983), and *in vivo* lutectomy experiments have shown that the pulse is of luteal origin (Fletcher and Renfree, 1988). Although the corpus luteum does contain oestrogens (Renfree *et al.*, 1984b), the oestradiol pulse occurs even after lutectomy (Figure 7.23).

The origin and function of this transient rise in oestrogen remain to be determined. It is interesting to note, however, that a transient early rise in oestradiol is also seen in wild tammars at the time of natural reactivation after the summer solstice (Flint and Renfree, 1982; Figure 7.20).

The corpus luteum is also a source of relaxin. Tyndale-Biscoe (1966, 1969, 1981) has measured relaxin using the mouse pubic symphysis bioassay in the brush possum and in the tammar. In the tammar the maximal response in corpora lutea occurs between days 16 and 23 RPY, with a marked fall postpartum (Figure 7.22). The possible significance of this will be discussed further in the section on parturition (section 7.9).

Following the early transient pulse in progesterone in macropodids there is a steady rise in progesterone, reaching a peak by mid-pregnancy at around the time the shell membrane attenuates and dissolves (Renfree, 1977; Denker and Tyndale-Biscoe, 1986) which allows the expanded yolk sac trophoblast to make its first direct contact with the uterine endometrium. The corpus luteum is the source of this mid-pregnancy progesterone, for lutectomy at day 18 RPY (Findlay *et al.*, 1983) or day 23 RPY (Harder *et al.*, 1984) causes an immediate drop in plasma levels to those seen during quiescence (Figure 7.24).

Concentrations of progesterone remain high until they fall dramatically at parturition (Figure 7.22). In most non-macropodid species, a similar pattern of luteal growth and progesterone secretion is seen, but without the early pulse (Figures 7.25 and 7.28) but in the bandicoots parturition occurs during the peak of the luteal phase and corpora lutea remain large and secrete progesterone for most of lactation (Figure 7.26).

Thus from structural and endocrine studies three broad patterns of corpus luteum growth and decline have been recognized (Table 7.3) by Tyndale-Biscoe and Renfree (1987); and the following account is derived from their classification.

These types correlate with the reproductive strategies (groups 1–4) outlined earlier (see section 7.2).

Type 1: short gestation, short luteal phase;
Type 2: short gestation, prolonged luteal phase; and
Type 3: long gestation, long luteal phase.

No data are available for group 4 animals, which include the small possum families. In the type 1 pattern, which probably holds for the majority of marsupials, the luteal phase occupies less than 60% of the oestrous cycle and is followed by a follicular phase leading

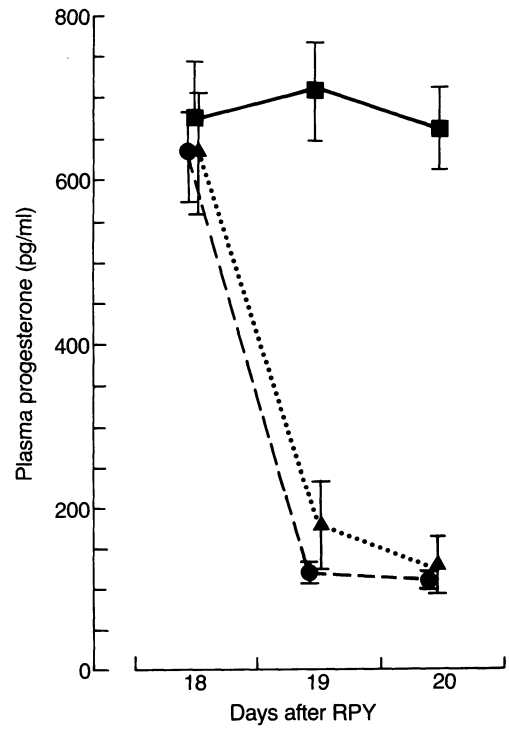

Figure 7.24 Plasma progesterone before and 24 and 48 h after surgery to excise the corpus luteum on day 18 after removal of pouch young (RPY). Values are means ± SEM of pregnant lutectomized tammars (n=6) (●), pregnant sham-operated animals (n=5) (■), and non-pregnant lutectomized animals (n=4 at day 18 and 19, n=3 at day 20 after RPY (▲). (Redrawn from Findlay *et al.*, 1983.)

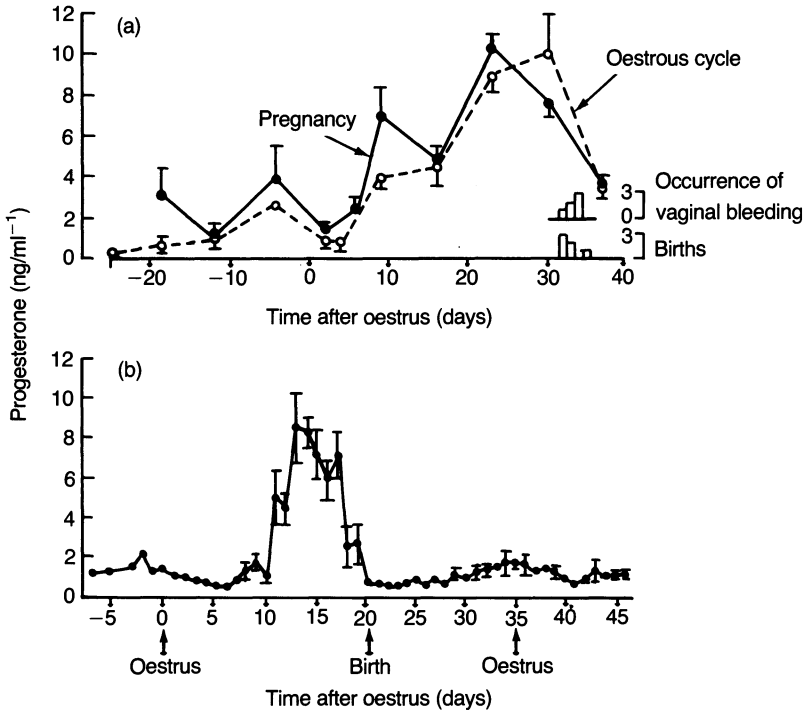

Figure 7.25 Plasma progesterone concentrations in two dasyurids during an oestrous cycle. (a) Summary of changes in a group of six *Dasyuroides byrnei* which underwent an oestrous cycle (broken line) followed by a pregnancy (solid line). Concentration (mean ± SEM) of plasma progesterone to show sharp drop before birth, or vaginal bleeding in non-pregnant cycle. All values were synchronized to day 2 and correlated with the uterine cell cycle, mating and birth. Data from Fletcher (1983, 1989b). (b) Concentration (mean ± SEM) of plasma progesterone in *Dasyurus viverrinus* through the oestrous cycle. The time that birth would occur in a pregnant animal is shown. Data from Hinds (1983, 1989a). (a and b from Tyndale-Biscoe and Renfree, 1987, with permission).

to the next oestrus and ovulation. The duration of pregnancy is shorter than the luteal phase (see Figure 7.2), and parturition coincides with corpus luteum regression. If lactation follows, the subsequent follicular phase is suppressed and the corpus luteum of pregnancy slowly disappears or remains as a corpus albicans. In the type 2 pattern, as exemplified by the bandicoots, gestation is equally short but parturition occurs during the peak of the luteal phase. If lactation follows, the corpora lutea remain large and the follicular phase is suppressed for most of lactation. In the type 3 pattern, which occurs in most of the Macropodidae, the luteal phase lasts for more than 90% of the cycle and the follicular phase is not inhibited (see Figure 7.2). Gestation occupies all of the extended luteal phase and is followed by post-partum oestrus and ovulation. If lactation follows, the corpus albicans associated with pregnancy declines further, as in the non-pregnant female, but the new corpus luteum formed at post-partum ovulation is held in a state of quiescence whilst the young is sucking, and in the tammar and Bennett wallabies for some months afterward. In all types, the rise in peripheral progesterone appears to be important for the full development of the secretory endometrium, which in

turn supports the rapid expansion of the embryo vesicle.

7.7.3 THE UTERINE ENDOMETRIUM

During pregnancy the endometrium proliferates and becomes secretory. In the monovular grey kangaroo, *M. giganteus*, R. Owen (1834) was the first to note that there were differences between the endometrium of the gravid and that of the contralateral non-gravid, uterus, a finding with which Flynn (1930) concurred in his study of the Tasmanian bettong, *Bettongia gaimardi*. Because of the similarity of the changes in the uterus during pregnancy and the oestrous cycle, these observations were largely overlooked until it was found that the wet weight of the gravid endometrium of the tammar was consistently and significantly greater than that of the adjacent, non-gravid, one (Renfree, 1972a; Renfree and Tyndale-Biscoe, 1973). The composition of the uterine secretions also differed, not only throughout pregnancy but between the two sides (Renfree, 1973b). The rate of protein synthesis is greater in the gravid uterus (Shaw and Renfree, 1986).

These observations of a unilateral effect suggested that the presence of the fetus or placenta may be responsible, and this has been confirmed in three ways. First, the

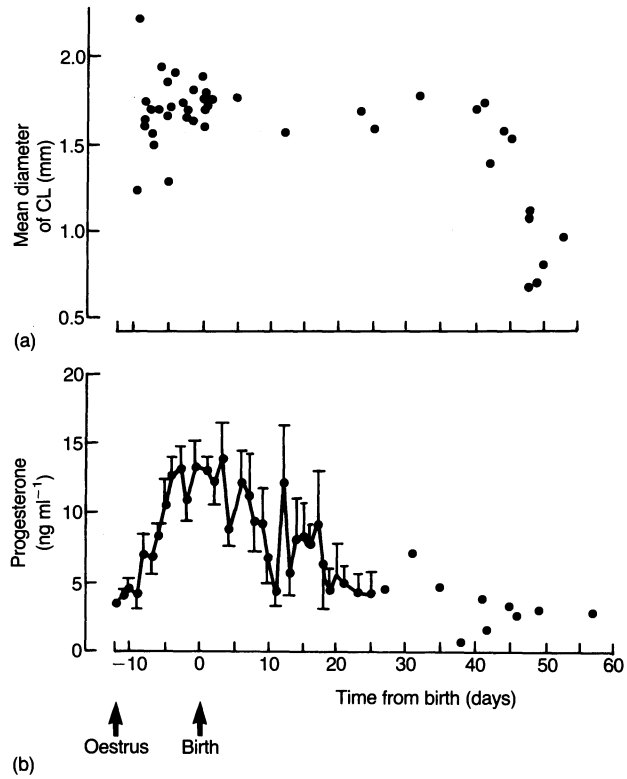

Figure 7.26 (a) Diameter of the corpus luteum (CL) in the bandicoot *Isoodon macrourus* during pregnancy (between arrows) and the subsequent lactation. During the 45–53 days of lactation, ovulation may recur. Data from Lyne and Hollis (1979). (b) Concentrations (mean ± SEM) of plasma progesterone in *Isoodon macrourus* during pregnancy and lactation. Individual samples after day 25 are shown. Data from Gemmell (1981). (From Tyndale-Biscoe and Renfree, 1987, with permission).

Table 7.3 Marsupial species for which plasma or luteal hormonal measurements are available during **pregnancy**, arranged using the classification of reproductive patterns of Tyndale-Biscoe and Renfree (1987). Nothing is known of the hormones in species with group 4 pattern (Families Tarsipedidae, Burramyidae, Acrobatidae)

transfer of a blastocyst to a cyclic, non-pregnant animal, or to the side contralateral to the corpus luteum in a pregnant one, initiated similar endometrial proliferation in each uterus in which a fetus developed and did not relate to the position of the corpus luteum, so the greater weight was not due to the proximity of the corpus luteum of pregnancy (Renfree, 1972a; Renfree and Tyndale-Biscoe, 1973). In animals in which blastocyst reactivation was initiated during seasonal quiescence with exogenous progesterone, endometrial growth was induced in both uteri for the duration of treatment. However, after the injections ceased, only the uterus containing the developing embryo continued

to enlarge while the non-gravid uterus declined to a size usually observed in the non-pregnant cycle (Renfree and Tyndale-Biscoe, 1973). Since, in this experiment, the corpus luteum was by-passed and remained inactive, the continuation of endometrial stimulation in the gravid uterus after progesterone withdrawal again must have been due to the presence of the fetus or its placenta. The third observation suggests that the placenta is the main site of the influence. In some females which were treated with progesterone during seasonal quiescence to induce blastocyst reactivation, a vesicle grew but no embryo or vascular mesoderm developed (Renfree and Tyndale-Biscoe, 1973; Fletcher *et al.*, 1988), but these vesicles, consisting only of the non-vascular yolk sac membrane, stimulated the endometrium and the uterine secretions as in a normal pregnancy.

The fact that the endometrium of the non-gravid uterus declines in weight and secretory activity during the second half of pregnancy or the cycle, even though peripheral progesterone concentrations are at their highest (Figure 7.27) suggests that there is a declining sensitivity to progesterone.

It is possible that the local stimulation of the gravid uterus may reverse this by stimulating increased progesterone receptor synthesis but there is no evidence for this (D. Blanden and M.B. Renfree, unpublished) (section 7.7.4). F.J. Owen *et al.* (1982) have observed a difference in progesterone receptor concentration between the two uteri of the quokka *S. brachyurus*, an observation also made in the tammar (D. Blanden and M.B. Renfree, unpublished). A similar unilateral response of the endometrium to pregnancy has been observed in the quokka (Wallace, 1981) and also in the potoroo *Potorous tridactylus* by Shaw and Rose (1979). So far these effects are only known in macropodids; in non-macropodids, such as the monovular brush-tailed possum *Trichosurus vulpecula* and the polyovular opossum *Didelphis virginiana*, this fetal stimulation of the endometrium is not seen (Figure 7.28).

In opossums, uteri endometrium from equivalent days of the oestrous cycle and gestation are virtually identical in size, appearance and biochemical composition (Hartman, 1923; Renfree, 1975; Fleming and Harder, 1981a,b). Likewise, in the monovular brush-tailed possums, adjacent gravid and non-gravid uteri are identical except for the better development of the subepithelial capillary bed in the gravid uterus (Pilton and Sharman, 1962) and have similar endometrial weights (N.J. Cantrill and C.H. Tyndale-Biscoe, personal communication).

In both these species, maintenance of gestation depends on a continued uterine secretory phase. Ovariectomy of opossums between days 6 and 8 of the 12½-day gestation allows development of normal-term fetuses, but parturition is inhibited (Hartman, 1925; Renfree, 1974). In possums the uterine luteal phase develops by day 7 of the 17-day gestation (Pilton and Sharman, 1962; Shorey and Hughes, 1973a,b, 1975). After ovariectomy on day 7 the uterine secretory phase continues for the normal duration, but the volume of secretion is reduced (Shorey and Hughes, 1975). Ovariectomy on day 7 or 10 does not interfere with development to term of intrauterine embryos, but the animals do not give birth, while lutectomy on day 11 or injections of progesterone for 2 or 3 days after ovariectomy on day 7 results in some live births (Smith and Sharman, unpublished, in Sharman 1965b; and in Tyndale-Biscoe, 1966). Possums and opossums differ from eutherian mammals in which embryonic development can continue for several days after ovariectomy in that, because of their short gestation, even a brief survival after the operation allows them to develop to full term. Tammars and quokkas, despite their longer gestation, are able to extend the uterine secretory phase, so that they can develop to term after ovariectomy as early as day 8 or 7 respectively. Although the fetus or

its membranes appear to be involved, how they achieve this is still unclear, but both uterine steroid receptors and endocrine activity by the placenta are likely candidates.

7.7.4 PROGESTERONE AND OESTROGEN RECEPTORS IN THE FEMALE GENITAL TRACT

Very few attempts have been made, as yet, to measure ovarian steroid hormone receptors in target cells of marsupial genital tract tissue. So far, steroid receptors have been measured in only three species: the quokka (F.J. Owen *et al.*, 1982), the brush-tailed possum (C.E. Young and McDonald, 1982; Curlewis and Stone, 1986) and the tammar (D. Blanden and M.B. Renfree, unpublished). Evidence for the binding of progesterone is also found in the quoll, *Dasyurus viverrinus*, in addition to these three marsupials (T.P. Fletcher and

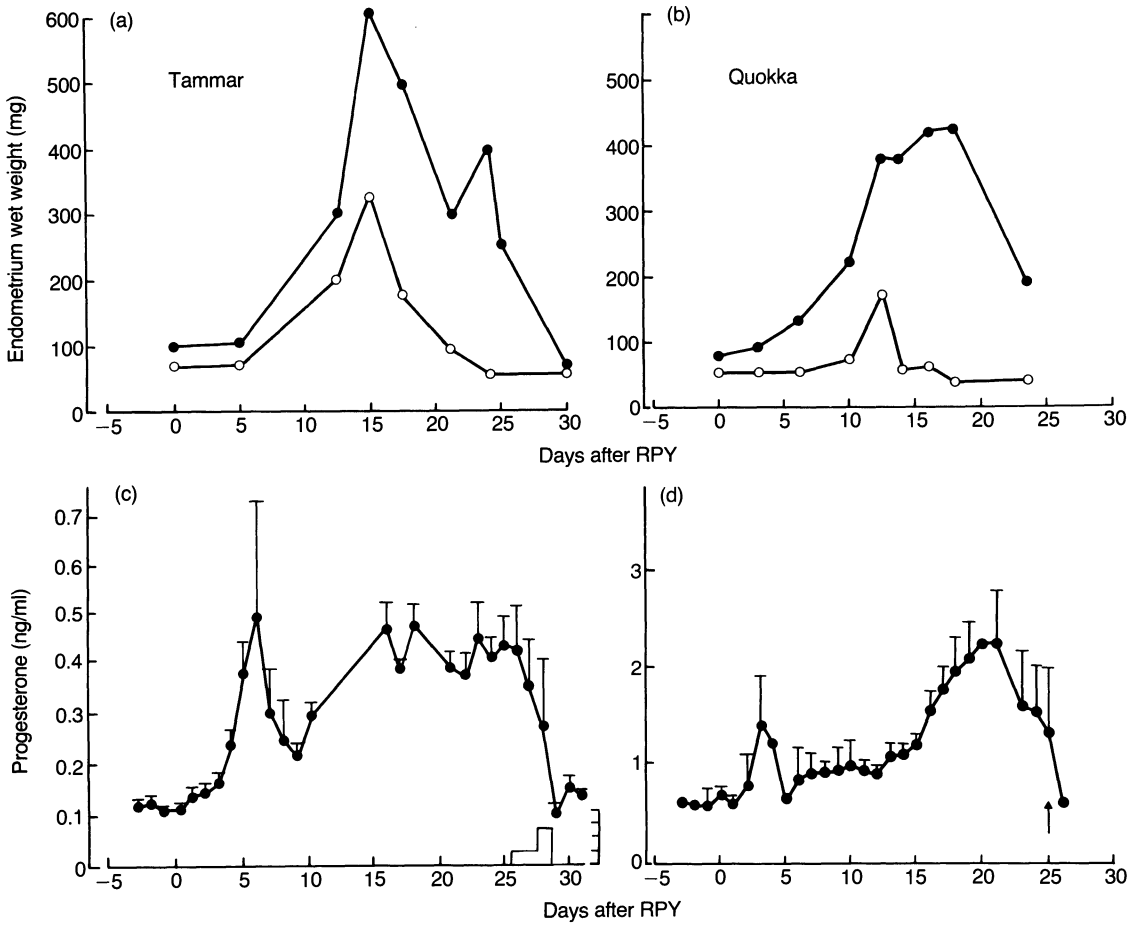

Figure 7.27 Endometrial wet weights (a and b) and plasma progesterone (c and d) in two macropodids, the tammar, *Macropus eugenii* (a and c), and quokka, *Setonix brachyurus* (b and d), during pregnancy. Gravid uteri (•) show a greater and more sustained response than contralateral, non-gravid uteri (○). Plasma progesterone measured by radioimmunoassay after removal of pouch young. Note both species show a marked pulse of progesterone 3–6 days after removal of their pouch young, and a sharp fall in progesterone at the time of parturition. [Redrawn from (a) Renfree and Tyndale-Biscoe (1973); (b) G.I. Wallace, unpublished observations, and Renfree (1980c); (c) Cake *et al.* (1980) and (d) Hinds and Tyndale-Biscoe (1982a).]

D.R. Blanden, personal communication). The properties of the possum cytosol oestrogen receptors in the endometrium and vaginal endothelium are similar to those described for eutherians, but differ in their relative binding affinities (C.E. Young and McDonald, 1982). Two distinct classes of high binding affinity for oestrogens were detected, with high (8S) and low (4S) molecular weight, the proportions of which varied with reproductive state or hormone treatment. Animals treated with oestrogen, or those in the follicular phase of the cycle had a significant increase in the concentration of macromolecular high-affinity oestrogen binding sites in the endometrium (predominantly 8S) and even more so in the vaginal endothelium (mainly 4S during pregnancy and the luteal phase) (C.E. Young and McDonald, 1982). During the non-pregnant cycle, cytosol oestradiol receptor concentrations rose between days 0 and 5, after which they declined

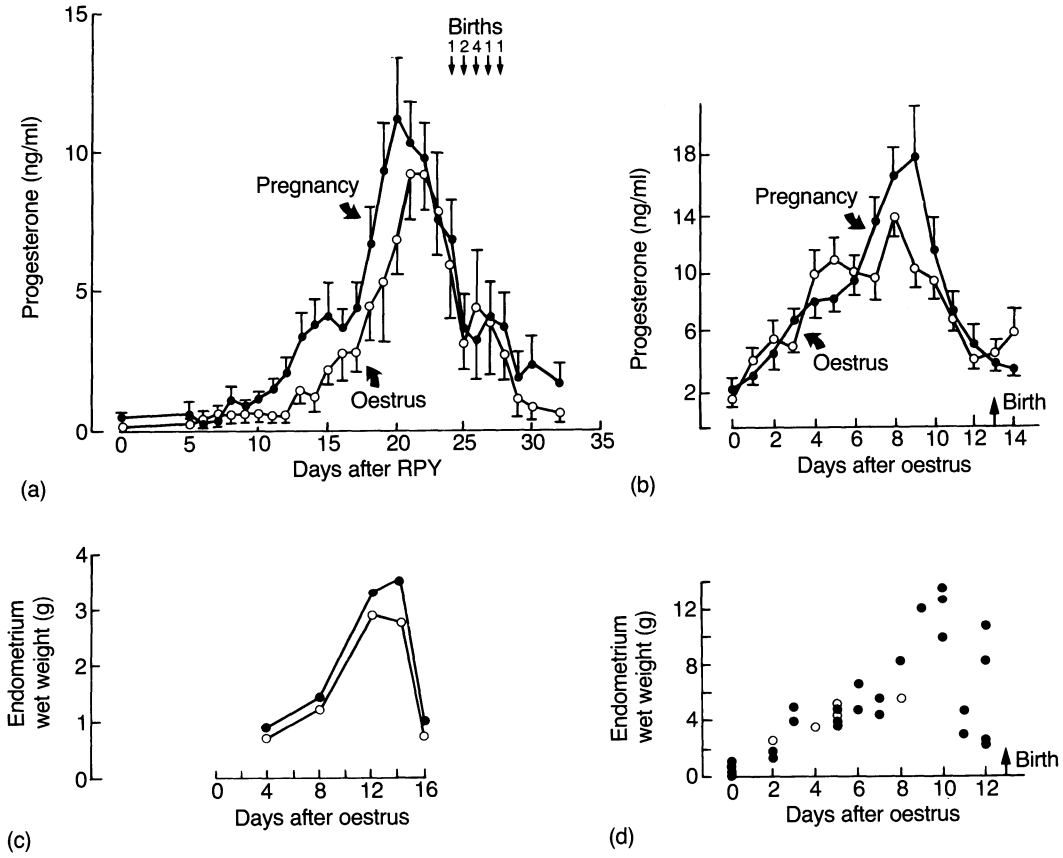

Figure 7.28 Plasma progesterone (a and b) concentrations during pregnancy (•) and the oestrous cycle (○) in brush-tailed possum, *Trichosurus vulpecula* (a), and the opossum, *Didelphis virginiana* (b). Endometrial wet weights in gravid (•) or non-gravid (○) uteri of both possums (c) and opossums (d) reflect the increasing progesterone concentrations. In the monovular brushtail possum there are no unilateral effects of pregnancy. In the polyovular opossum both uteri are normally gravid; non-gravid uteri (○) are from cycling animals at differing days after oestrus. [Redrawn from (a) Gemmell *et al.* (1987); (b) Harder and Fleming (1981); (c) N.J. Cantrill and C.H. Tyndale-Biscoe, unpublished results and (d) Renfree (1975).]

(Curlewis and Stone, 1986). In ovariectomized animals oestradiol increased the uterine weight, RNA–DNA and protein–DNA ratios and the concentration of cytosol receptors for oestradiol and progesterone (Curlewis and Stone, 1986). Thus, both studies show that oestradiol cytosol receptor levels in the uterus of the brush-tailed possum are high at oestrus and low during the luteal phase.

Progesterone receptors have been detected in uterine tissue of the quokka, and exogenous oestradiol leads to an augmentation of the uterine receptor concentration, with a six-fold increase after 5 days of treatment (F.J. Owen *et al.*, 1982). It appears that the level of oestrogen in the circulation influences the responsiveness of the uterus to progesterone, and within an hour of oestrogen priming there is a depletion of cytosolic progesterone binding and increased nuclear localization (F.J. Owen *et al.*, 1982). In the brush-tailed possum, progesterone receptor levels are highest at day 0 of the cycle, after which they decline to day 13 (Curlewis and Stone, 1986) (Figure 7.29).

Progesterone receptors in this species are low after ovariectomy, but, as in the quokka, increase in concentration after oestradiol treatment (Curlewis and Stone, 1986). The decline in progesterone cytosol receptor levels after oestrus is similar to that seen in many eutherian species during the phase of progesterone dominance (Curlewis and Stone, 1986).

A much more extensive series of measurements has been made on the steroid receptors throughout pregnancy in the tammar, and an interesting pattern is emerging (D. Blanden and M.B. Renfree, unpublished). As we found for endometrial wet weight, there is a unilateral effect throughout pregnancy for the concentration of both progesterone and oestradiol receptors, with greater concentrations in the gravid uterus, and there is also a peak concentration of both receptor concentrations at day 5 of pregnancy after RPY, coinciding with the peripheral plasma

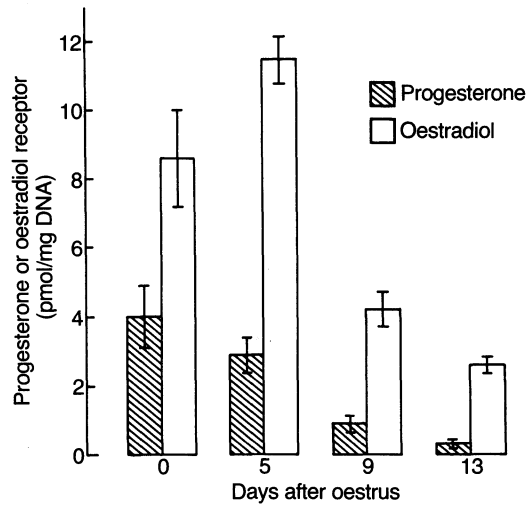

Figure 7.29 Concentrations of progesterone and oestradiol receptor during the oestrous cycle in the brush-tailed possum. It is interesting that there is a marked peak in oestradiol receptor concentrations 5 days post oestrus, while that of progesterone declines steadily throughout the cycle. Data from Curlewis *et al.* (1985).

peaks of oestrogen (Shaw and Renfree, 1984) and progesterone (Hinds and Tyndale-Biscoe, 1982a). Myometrial receptor concentrations mirror those of the endometrium although they are generally lower. Concentrations of progesterone receptor in the lateral vaginae are almost unmeasurable, while the oestrogen cytosol receptor concentrations are lower than those of the myometrium.

7.7.5 ENDOCRINE FUNCTIONS OF THE PLACENTA

The morphogenetic changes just described appear to be associated with the presence of the placenta, and it could provide a local endocrine stimulation to the adjacent uterus without any hormone being detected in the peripheral circulation. This could explain why pregnancy continues to full term after ablation of the corpus luteum or ovariectomy

in several marsupials and there is now evidence that the placenta is far from inactive. The yolk sac placenta is only three cell layers thick in the vascular region, and is bilaminar for over half of its surface (Figure 7.30).

Incubations of the meagre amount of placental tissue available (< 100 mg) from the quokka *S. brachyurus* and the tammar *M. eugenii* have shown that they have incipient endocrine activity by converting pregnenolone to progesterone (Bradshaw *et al.*, 1975; Renfree and Heap, 1977; Renfree, 1977). A more detailed study of the yolk sac membrane of *M. eugenii* showed that it can convert a range of steroid precursors into a variety of products (Figure 7.30), although levels of conversion were generally low (Heap *et al.*, 1980). Small amounts of prenenolone were converted to progesterone and pregnanediol; androstenedione was metabolized to 5α-androstane-3,17-dione and androsterone, but was not incorporated into oestrogens, providing no evidence for the enzymes arylsulphatase or sulphotransferase in the pla-

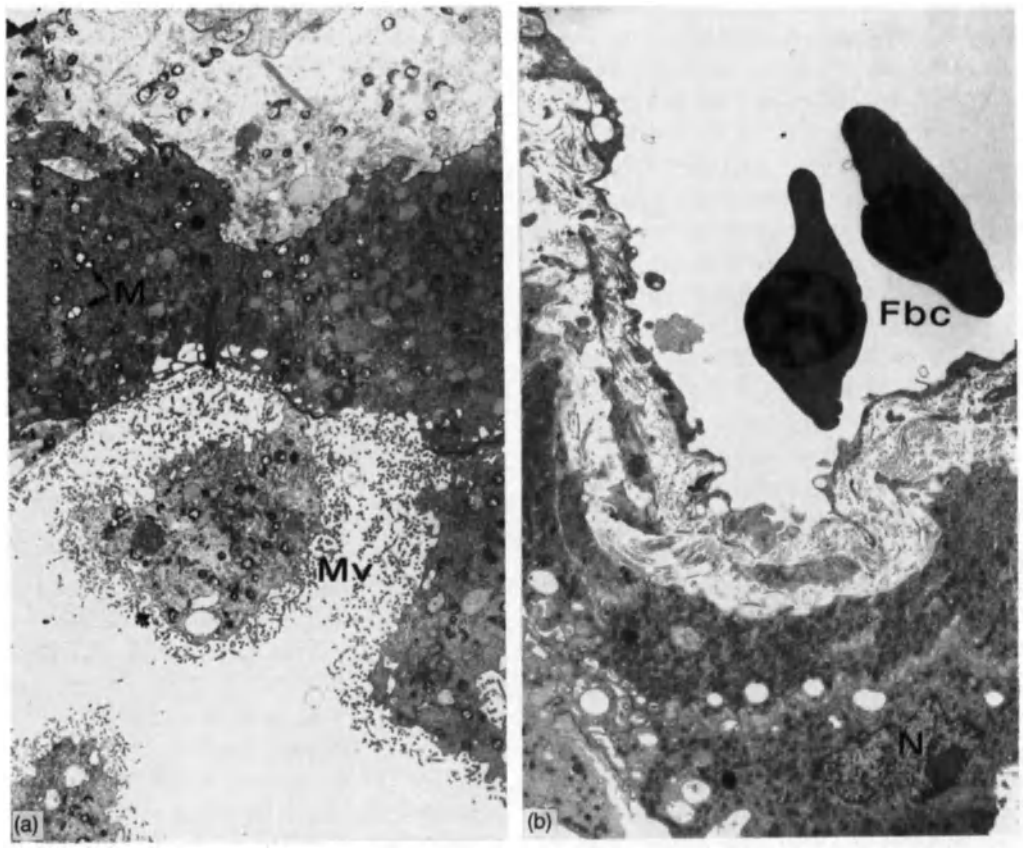

Figure 7.30 Ultrastructure of the full-term placenta of the tammar, *Macropus eugenii*, pulled free from the uterine epithelium. (a) Avascular, bilaminar yolk sac membrane, with numerous microvilli (Mv) on the ectodermal layer which would appose to the uterine epithelium. There are numerous mitochondria (M). Magnification ×1700. (b) Vascular, trilaminar yolk sac membrane in the region of the sinus terminalus shown with two fetal red blood cells (Fbc). Ectodermal cells have numerous enclosed granules and vesicles. Magnification ×2700.

centa. It thus appears that the yolk sac membrane, while capable of limited progesterone synthesis, has enzymes associated predominantly with steroid catabolism (Heap *et al.*, 1980). Although some parallels can be seen between steroid metabolism in the yolk sac placenta of *M. eugenii* and those of some eutherian mammals with superficial implantation, an important difference is that aromatase activity, which is pronounced in the placentae of pig and horse (see Gadsby *et al.*, 1980), is undetectable in *M. eugenii* (Heap *et al.*, 1980; Renfree *et al.*, 1984b), although it is detectable in the endometrium, brain, ovaries and adrenal tissues (Heap *et al.*, 1980; Callard *et al.*, 1982; Renfree *et al.*, 1984b) (Figure 7.31).

Two other observations indicate that the fetoplacental unit of macropodid marsupials may influence the maternal hormones systemically (Tyndale-Biscoe and Renfree, 1987). First, the lengths of gestation in two species of kangaroo, *Macropus giganteus* and *M. fuliginosus*, are 36 and 31 days but the gestation period of *M. giganteus* females mated to *M. fuliginosus* males is intermediate at 34 days (Kirsch and Poole, 1972; Poole, 1975), reflecting the hybrid genotype of the fetuses. The female progeny themselves had oestrous cycles intermediate in length between the parent species and, when backcrossed to *M. fuliginosus* males, had even shorter gestations (32 days, n = 12) (Poole, 1975). Second, Merchant's (1979) demonstration that gestation advances the time of oestrus by up to 3 days in *M. eugenii* and other species and that associated changes in progesterone, prolactin and luteinizing hormone are also advanced (Tyndale-Biscoe *et al.*, 1983) is strong evidence for a fetoplacental influence operating in the first instance on the corpus luteum and indirectly on the pituitary thereafter. A summary of the ways the placenta may interact with the endometrium and ovary is shown in Figure 7.32.

All these effects may be said to be a maternal recognition of pregnancy, and some or all may be due to endocrine signals from the placenta, although direct evidence for this has not yet been obtained. The vascular anatomy of the reproductive tract, which favours local circulation, would enable some of these to be unilateral effects (Towers *et al.*, 1986), so that high concentrations may not be necessary. It is of interest that laparotomy alone at the time of attachment of the yolk sac placenta (days 18 and 19) interferes with subsequent parturition in *Setonix brachyurus* and *M. eugenii*, which may further implicate the placenta as an important component in normal gestation (I.R. Young and Renfree, 1979). This form of maternal recognition of pregnancy is probably restricted to the Macropodidae, as recent studies on *D. virginiana* (Harder and Fleming, 1981) and *Dasyuroides byrnei* (Fletcher, 1983) disclosed no evidence for an endocrine recognition of pregnancy in either species.

7.8 ACQUISITION OF ENDOCRINE ORGANS DURING DEVELOPMENT

7.8.1 EMBRYONIC AND FETAL GROWTH

Up to the unilaminar blastocyst stage there is no increase in diameter of the embryo, but thereafter there is rapid expansion of the blastocyst through absorption of fluid into the blastocoele across the trophoblast. A feature of marsupial embryogenesis is the relatively slow rate of embryonic development, which only increases during the later stages of pregnancy (Tyndale-Biscoe and Renfree, 1987) (Figure 7.33).

There are few complete, timed studies of embryonic development in marsupials, and the first, of the opossum *Didelphis virginiana*, remains the most detailed today (McCrady, 1938), and provides a useful guide to the significant developmental features of marsupial embryos (Table 7.4; Figure 7.34).

There has been a burgeoning of studies over the last two decades on particular stages of embryonic development, particularly the pre-implantation stages (see Selwood, 1992)

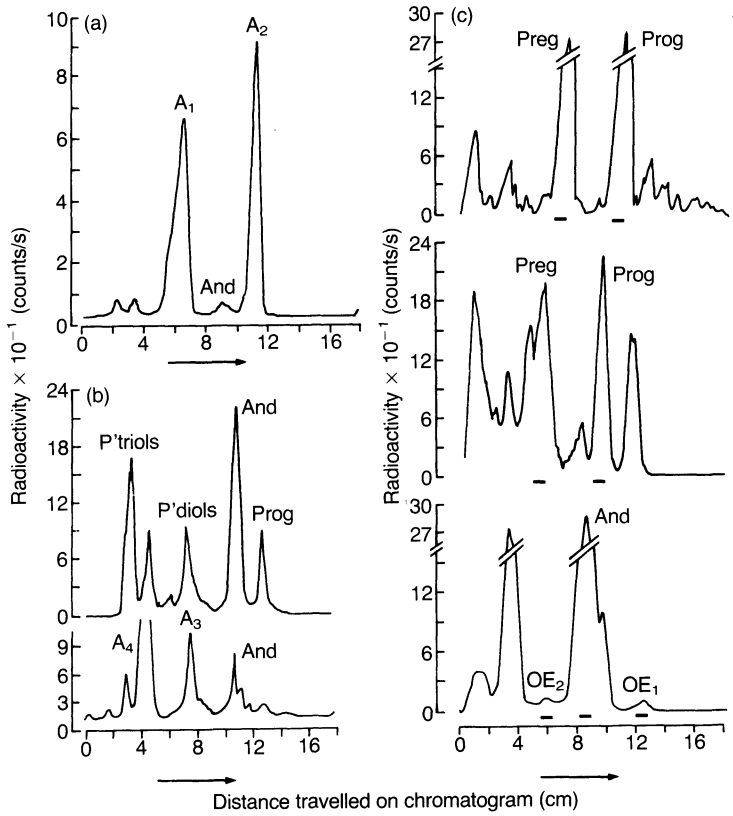

Figure 7.31 Steroid metabolism in fetal and maternal tissues of the tammar wallaby. (a) Yolk sac metabolism of [^{3}H]androstenedione *in vitro*. Tissue was obtained at day 20 after removal of pouch young and incubated for 3 h at 37°C with labelled androstenedione. After incubation, tissue and medium were extracted and the neutral steroid fraction was applied to a thin-layer chromatogram, which was developed in the solvent system, methylene dichloride–methanol (5:30, v/v). The diagram shows a radiochromatogram scan of radioactivity. A_1, 3β-hydroxyandrostan-17-one (androsterone); And, androstenedione (not metabolized); A_2, 5α-androstane-3,17-dione. (b) Endometrial metabolism of (a) [^{3}H]progesterone and (b) [^{3}H]androstenedione *in vitro* in the tammar wallaby. Tissue was obtained at day 15 and day 11, respectively, after removal of pouch young. Diagram shows radiochromatogram scan of radioactivity in the neutral steroid fraction after application to a thin-layer chromatogram plate which was developed in the solvent system, methylene dichloride–methanol (75:30, v/v). Prog, progesterone; And, androstenedione; P'diols, pregnanediols; A_3 and A_4, unknowns (see Table 7.4). (c) Radiochromatogram scans showing separation of [^{3}H]-labelled substrates and products by thin-layer chromatography. Top: Metabolism of [^{3}H]pregnenolone (Preg.) to progesterone (Prog.) by corpus luteum obtained on day 20 of pregnancy after removal of pouch young (RPY). Middle: Metabolism of [^{3}H]pregnenolone by remaining ovary (interstitial tissue + cortex) on day 15 of pregnancy after RPY; Bottom: Metabolism of [^{3}H]androstenedione (And.) by remaining ovary (interstitial tissue + cortex) on day 25 of pregnancy after RPY. OE_2, oestradiol-17β; OE_1, oestrone. Bars indicate chromatographic behaviour of corresponding authentic standards. [Redrawn from (a and b) Heap *et al.* (1980); (c) Renfree *et al.* (1984b).]

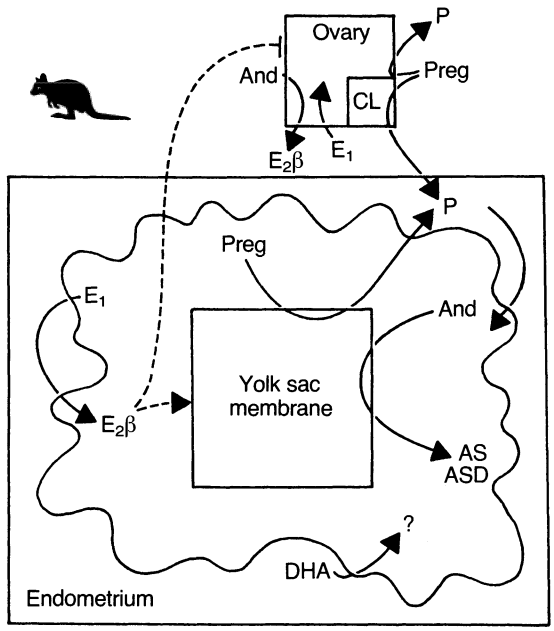

Figure 7.32 Suggested interactions of steroid hormones in the tammar *Macropus eugenii* during pregnancy after removal of pouch young, based on incubation *in vitro* with labelled steroids (see Figure 7.31). After incubation, although the placenta, weighing 100 mg, has only low levels of steroid synthetic activity, this may be sufficient to provide local stimulation of the endometrium. And, androstenedione; AS, androsterone; ASD, androstanedione; CL, corpus luteum; DHA, dehydroepiandrosterone; E_1, oestrone; $E_2\beta$, oestradiol-17β; Preg, pregnenolone; P, progesterone. Based on data in Heap *et al.* (1980) and Renfree *et al.* (1984b). [From Renfree (1980c), redrawn by Tyndale-Biscoe and Renfree (1987).]

and the fetal stages (Renfree, 1972a,b; Bancroft, 1973; Renfree and Tyndale-Biscoe, 1973, 1978; Shaw and Rose, 1979; Tyndale-Biscoe, 1979; Krause *et al.*, 1979a,b; Selwood, 1980; Walker and Rose, 1981; Hughes and Hall, 1984, 1988; Hall and Hughes, 1987; Krause and Cutts, 1983, 1984, 1985; Krause and Leeson, 1973; Hall, 1988), and most of these have been reviewed in detail by Tyndale-Biscoe and Renfree (1987); newer work on the development of the endocrine organs is given in the following section, so the following description is brief to provide the necessary framework for discussion.

After the formation of the primitive streak the embryo acquires a bilateral symmetry, with Hensen's node at the anterior end (Figure 7.35).

The first somites are seen in vesicles are between 4 and 8 mm in diameter. Amniogenesis occurs relatively late in marsupials, soon after the appearance of somites (Tyndale-Biscoe and Renfree, 1987). Cervical flexure occurs when the embryo has about 18–20 somites and the neural tube is closed along most of the length of the embryo (Figure 7.36).

It is about this time that the shell membrane (see Krause and Cutts, 1983), which has become more and more attenuated, ruptures, and a close and direct apposition of the trophoblast to the uterine epithelium becomes possible. At this time in the tammar there is a specific proteinase in the trophoblast endoderm complex for 1 day (day 18–19) exclusively in the bilaminar yolk sac (Denker and Tyndale-Biscoe, 1986). This proteinase activity is correlated with the dissolution of the shell membrane and the subsequent attachment of the trophoblast to the uterine epithelium in the bilaminar, but not trilaminar, region. Whereas all development up to this stage has been relatively slow and occupied two-thirds of the active gestation period, organogenesis is relatively rapid, and the time it takes is only a two-fold or so difference in very divergent species which may also have very different body sizes (Figure 7.33).

The placental membranes apposed to the uterine wall consist of vascular and non-vascular portions of the yolk sac in most marsupials (Sharman, 1961; Hughes, 1974, 1984) (Figure 7.30). Only a small area of true chorion remains and the allantois is enclosed in the fold of the yolk sac membrane, except in the Peramelidae, in which it forms an intimate attachment (Flynn, 1923; Padykula and Taylor, 1976, 1977, 1982). In the tammar, the

allantois never reaches the chorion, and as gestation proceeds it accumulates urea in the allantoic fluid, presumably via the patent Wolffian ducts draining the mesonephros (Renfree, 1973a). A similar arrangement of fetal membranes has been described for a variety of macropodids and phalangers (Tyndale-Biscoe and Renfree, 1987). As noted above, some marsupials have an allantoic placenta in addition to a yolk sac placenta, and the most elaborate form of allantoic placentation is found in the bandicoots – *Perameles nasuta*, *P. gunnii* and *Isoodon obesulus* – where a true chorioallantoic placenta is present in addition to the yolk sac placenta (Padykula and Taylor, 1977).

At birth, the tiny young is able to climb to the pouch unassisted by the mother (Cannon *et al.*, 1976), using its well-developed forelimbs (Hughes *et al.*, 1989; Renfree *et al.*, 1989). Its lungs are functional, the nostrils open and the olfactory centre of its brain is well developed (Gemmell and Rose, 1989a,b). The mouth, tongue and digestive system, including liver and pancreas, are sufficiently developed to cope with the change

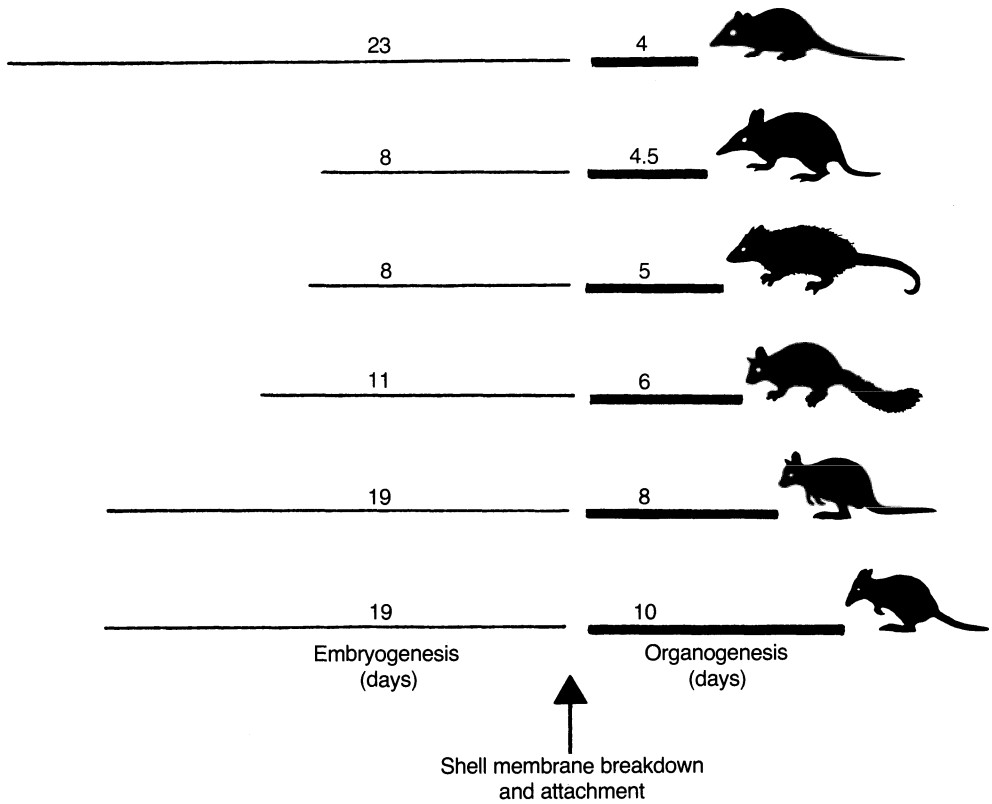

Figure 7.33 Relative duration (days) of the preattachment phases in six different marsupials. Species from top to bottom are *Antechinus stuartii*, *Perameles nasuta*, *Didelphis virginiana*, *Trichosurus vulpecula*, *Macropus eugenii* and *Potorous tridactylus*. Numbers given are days of gestation. The period of organogenesis is relatively constant (thick line) amongst these divergent species, which range in size from less than 50 g to over 6 kg. The preattachment phase when embryogenesis occurs is however very variable, and may be extended even further by embryonic diapause. (From Tyndale-Biscoe and Renfree, 1987, with permission.)

to a milk diet (Janssens and Ternouth, 1987). By contrast, features such as the eyes, the hind limbs and the gonads remain undifferentiated (Hughes and Hall, 1988; O *et al.*, 1988); the scrotum is visible in embryos from day 22 RPY, but the pouch can be clearly seen only after about 8 days after birth (Renfree and Short, 1988); the metanephros is differentiated but not functional immediately (Wilkes and Janssens, 1988). Nevertheless, the entire period of differentiation is accomplished in a short time, which prepares the neonate for birth and for its more lengthy stay in the pouch whilst the rest of its growth

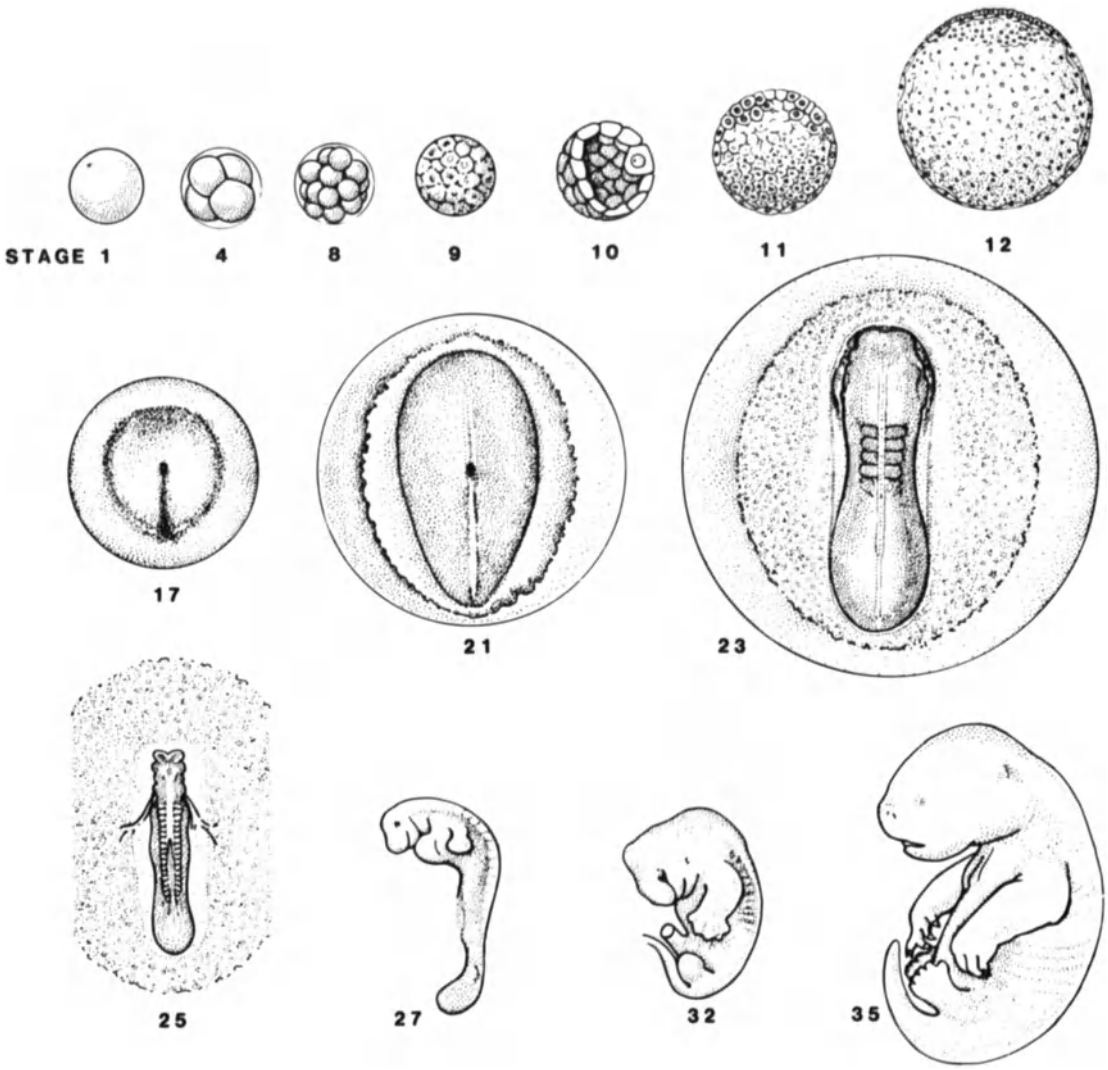

Figure 7.34 Representative stages of development of the American opossum, *Didelphis virginiana*, redrawn from McCrady (1938). Each horizontal row is drawn to the same scale. Thus stages 1–12, 17–23, and 25–35, are to the same scale. The diameter of the oocyte (stage 1) is about 0.11 mm and the diameter of the vesicle (stage 12) is 0.34 mm. No representation of the mucin layer or shell membrane is shown in this series. Detailed descriptions of the key developmental events are given in the accompanying table (Table 7.4).

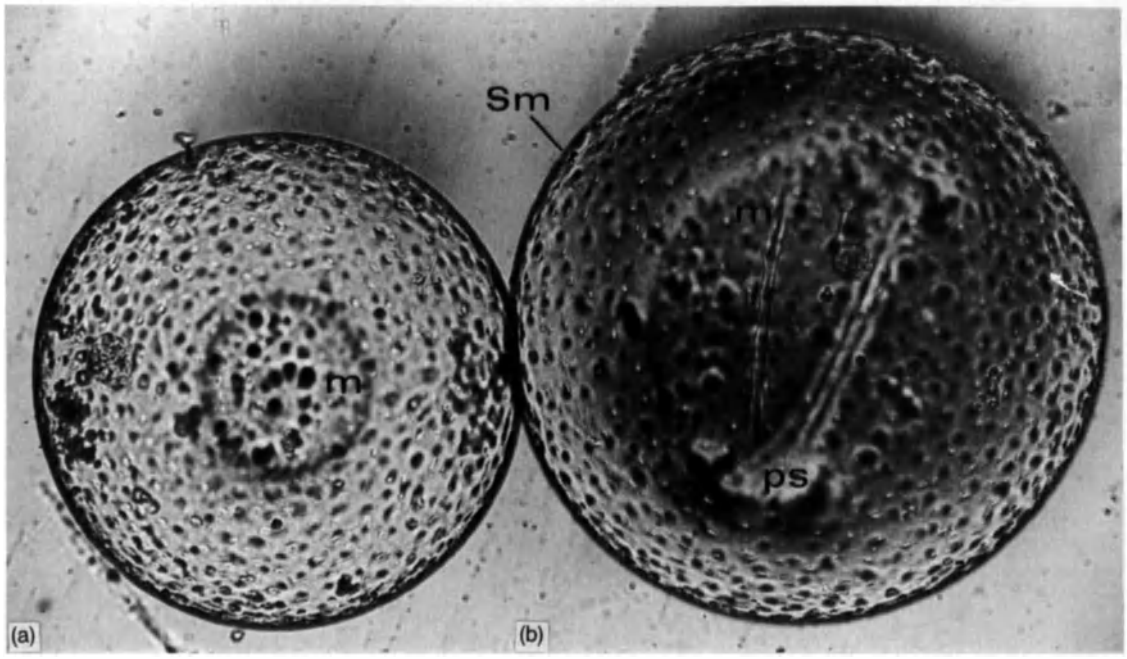

Figure 7.35 Developing embryos from one uterus of the quoll, *Dasyurus viverrinus*, 15 days post coitum. Vesicle (a) is 2.5 mm diameter, and shows the beginnings of the medullary plate (m), equivalent to McCrady stage 12 (see Figure 7.34). The trophoblastic nuclei are prominent and appear in dots. Vesicle (b) is 3.5 mm diameter, and is at the primitive streak (ps) stage, equivalent to McCrady stage 19 (see Figure 7.34 and Table 7.4). (Photograph kindly provided by Dr T.P. Fletcher.)

and development is completed (Sharman, 1973).

7.8.2 ENDOCRINOLOGY OF THE FETUS AND NEONATE

The fetal stages of all marsupials are of a very short duration, and given the range of adult body sizes, the duration of organogenesis is remarkably similar between species (Figure 7.33) whereas the period from fertilization to the end of embryogenesis is a very variable period ranging from a few days up to 11 months in those species which have embryonic diapause. By contrast, the period from birth to weaning is very long in marsupials, and maturation of many of the organ systems occurs during early pouch life.

Studies of the endocrinology of the fetus are virtually non-existent, but nevertheless data are accumulating on the morphology of the endocrine glands and the first appearance of hormones in late fetal and early pouch life. As will be seen in the following section, observations on endocrine responses in the mother which are dependent on the presence of a fetus are more numerous and support the idea that the fetus can certainly redirect maternal physiology by the influence of fetal hormones. This section will therefore concentrate on the few reports on the endocrine competence of the fetus and neonate.

The sequence of events during sexual differentiation in marsupials has recently been reviewed (Renfree *et al.*, 1987; Tyndale-Biscoe and Renfree, 1987; Renfree and Short, 1988; Short *et al.*, 1988; Sharman *et al.*, 1990; Shaw *et al.*, 1990; Renfree, 1992) so only the briefest summary will be given here. In the tammar wallaby, *Macropus eugenii*, the gonad is essen-

tially indifferent on the day of birth, and there are no morphological differences between males and females in their Wolffian and Mullerian duct systems, suggesting that the male gonad has not initiated the secretion of Mullerian inhibiting substance (MIS) from the future Sertoli cells, or androgens from the future Leydig cells (O *et al.*, 1988).

Hormonal secretion by the testis does, however, commence soon after birth. By the second day of pouch life the testes of tammars have developed seminiferous tubules and are secreting MIS (Hutson *et al.*, 1988). Testosterone production also appears to be initiated early in pouch life (Renfree *et al.*, 1992). In the tammar wallaby sufficient androgen is secreted in males before day 25 to prevent the regression of the Wolffian ducts that occurs in females (Shaw *et al.*, 1988). In another marsupial, the Virginia opossum, *Didelphis virginiana*, testes, but not ovaries, can convert pregnenolone to testosterone by day 19, and probably much earlier (George *et al.*, 1985). Likewise, the genital ducts, the urogenital sinus and the genital tubercle, which are known androgen-responsive tissues, contain the enzymes to convert testosterone to its active metabolite 5α-dihydrotestosterone.

In male marsupials the Mullerian ducts begin to regress by about day 10, apparently under the influence of MIS secreted by the testis (Renfree *et al.*, 1987; Hutson *et al.*, 1988; Short *et al.*, 1988; Shaw *et al.*, 1990). Treatment of neonatal marsupials with oestrogens prevents Mullerian duct regression, presumably by inhibiting MIS production or action (Burns, 1961; Shaw *et al.*, 1988). Wolffian duct development is controlled by androgens. Treatment of newborn female pouch young with testosterone prevents regression of the Wolffian duct, which normally disappears within a few weeks of birth (Burns, 1961; Shaw *et al.*, 1988).

By contrast, androgen is incapable of producing scrotal, processus vaginalis or gubernacular growth or suppressing mammary development in female neonatal tammars, and oestrogen is incapable of suppressing scrotal, processus vaginalis or gubernacular growth or stimulating mammary development in neonatal males (Shaw *et al.*, 1988). Likewise, Virginia opossums and neonatal grey opossums, *Monodelphis domestica*, treated with oestrogen retained their scrota (Burns, 1961; Fadem and Tesoriero, 1986). The scrotum has very low 5α-reductase activity, which is consistent with the idea that its differentiation is androgen independent (George *et al.*, 1985; Renfree *et al.*, 1992). Whilst the scrotum is present in male tammar fetuses from day 22 RPY, the pouch first becomes evident in genetic females on the eighth day after birth (Renfree and Short, 1988). A similar early scrotal differentiation occurs in *Trichosurus vulpecula* (Ullmann, 1993). The pouch does not seem to be under normal hormonal control, since androgen administration to female neonates will not inhibit pouch development, and oestrogen administration to male neonates will not induce pouch development in the tammar (Shaw *et al.*, 1988) or the grey opossum (Fadem and Tesoriero, 1986) or Virginia opossum (Burns, 1961).

Whilst the initial differentiation of the scrotum and mammary glands appears to be under direct genetic control (O *et al.*, 1988; Renfree and Short, 1988), and no adult male marsupial has mammary glands, there does seem to be a dichotomy between the Australian and American marsupials (Renfree, 1992). In the tammar, neither embryonic nor neonatal males ever have any sign of mammary primordia (Renfree and Short, 1988; Shaw *et al.*, 1990), but the didelphid opossum *Didelphis* and *Monodelphis* neonatal males have a reduced number of mammary anlage (Renfree *et al.*, 1990), which disappear after about 8 weeks of pouch life (Robinson *et al.*, 1991).

The pituitary is at an early stage of morphological development at birth in most marsupials. Presumptive somatotrophs,

(c)
5 mm
(e)

mammotrophs, thyrotrophs, gonadotrophs and corticotrophs have been identified in the pouch young of 1- to 50-day-old tammars by immunohistochemistry and electron microscopy (Leatherland and Renfree, 1982, 1983). The somatotrophs, together with non-granulated cells, make up 70% of the pars distalis. The mammotrophs, thyrotrophs and gonadotrophs increase in number and activity between 1 and 50 days post-partum, while the presumptive corticotroph cells are relatively most numerous in 25- to 30-day-old young, correlating well with the rapid increase in adrenal weight between days 20 and 40, the increase in cortical secretion (days 20–30) and the appearance of the adrenal medulla and adrenocortical zonatia (after day 20) (Catling and Vinson, 1976; Call *et al.*, 1980).

The structure of the red-necked wallaby (*M. rufogriseus*) pituitary at birth suggests that it, too, is functional, being well vascularized and many cells containing variable numbers of electron-dense membrane-bound granules (Walker and Gemmell, 1983b). The pituitary structure was similar in near-term fetuses and neonatal young (Walker and Rose, 1981; Walker and Gemmell, 1983b). However, no attempt was made to identify the cell types in this species.

There is some disagreement as to the cytological development of the pituitary in other species. In ultrastructural studies of the bandicoot *Isoodon macrourus*, Hall and Hughes (1985) could identify no obvious secretory granules in the homogeneous pituitary cells thought to be thyrotrophs before birth. Two days after birth presumptive somatotrophs were present, and 7 days after birth there were at least three cell types – presumptive thyrotrophs, presumptive gonadotrophs and presumptive somatotrophs. This pattern of differentiation is later than that reported for the tammar *M. eugenii* (Leatherland and Renfree, 1983), and Hall and Hughes (1987) concluded that the bandicoot pituitary may have little if any influence on the timing parturition after the brief 12½ days of pregnancy. In another non-macropodid, ultrastructural study on the brush-tailed possum *Trichosurus vulpecula*, the pituitary also appeared undifferentiated at birth and no secretory granules were present (Shorey, 1968). The first recognizable secretory cells were corticotrophs, which appeared at 16 days of pouch life, and acidophils (?somatotrophs) at 18 days (Shorey, 1968). These two studies differ from those of the recent study of Gemmell and Nelson (1988a) and Gemmell and Selwood (1993). These authors compared the ultrastructure of pouch young of the native cat, *Dasyurus hallucatus*, with that of *Trichosurus vulpecula* and *Isoodon macrourus* pouch young, and of the striped-faced dunnart, and found that there were three types of cells in the anterior pituitary containing different numbers of electron-dense, membrane-bound granules, and they identified them by comparison with the immunoreactive cell types described for the tammar by Leatherland and Renfree (1982, 1983). These were:

1. presumptive somatotrophs, mammatrophs and gonadotrophs;
2. presumptive corticotrophs; and
3. presumptive thyrotrophs.

Gemmell and Nelson (1988a) concluded that there are no differences in morphological differentiation between the pituitary cells of

Figure 7.36 Embryos of the tammar wallaby at (a and b) day 1 (diameter of vesicle 15 mm); (c) day 20; (d) day 21 (crown–rump length 8 mm) and (e) day 25½ (crown–rump length 16 mm) after reactivation of the diapause blastocyst. The yolk sac trophoblast forms the functional placenta, unlike the allantois, which never makes contact with the chorion. Birth occurs on day 26.4 after RPY. (From Renfree, 1982, with permission.)

newborn dasyurid, phalangerid and peramelids that they describe and those of the macropodids *M. eugenii* (Leatherland and Renfree, 1983), *M. rufogriseus* (Walker and Gemmell, 1983b), and *B. gaimardii* and *P. tridactylus* (Gemmell and Rose, 1989b) and that the pituitary of all species so far studied is functional at birth. Clearly, more studies need to be made using immunohistochemical techniques to identify the cell types and to resolve the differences in these observations.

Only one attempt has been made to measure pituitary hormones around the time of birth in marsupials, because of the generally small size of the late-term fetus and neonate. Wilkes (1984) reports that vasopressin is detectable in the pituitaries of 7-day-old tammar pouch young. The pituitaries contain about 10 ng of vasopressin (Wilkes and Janssens, 1986a,b), and are capable of releasing vasopressin from the pituitary in response to appropriate stimuli.

Adrenal function in the fetus and neonate is better described than that of the pituitary, especially in the macropodids *M. eugenii* and *M. rufogriseus*. In the tammar, the adrenal first appears at day 21 after RPY as a nodule of tissue lying close to the anterior pole of the mesonephric kidney, and has adrenocortical tissue from about day 22, with active 3βol-steroid dehydrogenase activity (Renfree, 1972b; Call *et al.*, 1980). Significant concentrations of cortisol (9–15 ng/ml) are present in fetal plasma from full-term fetuses at day 25 RPY, and the neonatal tammar adrenal can synthesize cortisol (Catling and Vinson, 1976). Similarly, the red-necked wallaby had 0.58 ng per adrenal in 12 adrenals from five neonates (day 27 RPY) and one fetus (day 26 RPY) (Walker and Gemmell, 1983b). In the bandicoot *I. macrourus* the cortisol concentration is 0.1 ng per adrenal ($n=9$) in the neonate (Gemmell *et al.*, 1982), but since the birth weight is less than that of macropodids (200–300 mg) the quantity is roughly proportional for the litter. Ultrastructurally the adrenal glands of newborn marsupials lack specific zones but consist of two distinct populations of cells (Gemmell and Nelson, 1988a). Dark staining granules are normally observed in catecholamine-secreting cells, and cells with large amounts of smooth endoplasmic reticulum and mitochondria are assumed to be the steroid-secreting cells and the source of the measured cortisol. The adrenal glands of the native cat and brush-tailed possum are similar in morphology to those of the bandicoot (Gemmell and Nelson, 1988a) red-necked wallaby (Walker and Gemmell, 1983b) stripe-faced dunnart (Gemmell and Selwood, 1993) and also of the tammar (Renfree, 1972b; Figure 7.37). Presumably all are capable of producing cortisol at birth.

The lung of the neonate also provides indirect evidence of adrenal function. The lung at birth is structurally immature but functional. Corticosteroids influence the development of the eutherian fetal lung by accelerating pulmonary maturation and increasing synthesis of surfactant. A similar maturation is observed in marsupials, and type II pneumocytes with their osmiophilic lamellar inclusions of surfactant appear at birth in *I. macrourus* (Gemmell and Little, 1982; Gemmell, 1986), *M. rufogriseus* (Walker and Gemmell, 1983b) *S. harrisii* (Hughes and Hall, 1988), *M. eugenii* (Randall *et al.*, 1984; Baudinette *et al.*, 1988; Hughes *et al.*, 1989; M.B. Renfree, unpublished observations), *D. hallacatus* and *T. vulpecula* (Gemmell and Nelson, 1988b) and *D. virginiana* (Krause and Leeson, 1973; Krause *et al.*, 1976). Thus, the evidence suggests that surfactant is produced in the structurally very immature lung of marsupials and that maturation of the surfactant system is a necessary prerequisite for breathing (Baudinette *et al.*, 1988). However, although a direct relationship between cortisol production and surfactant secretion remains to be shown, the general consensus of all these studies is that the fetal pituitary – adrenal axis of marsupials develops relatively early during the brief gestation to induce maturation of key organ systems (Table 7.5),

and is functional at birth, and, as in eutherians, is capable of influencing the length of gestation by initiating parturition.

7.9 CONTROL OF PARTURITION

The present evidence suggests that the control of parturition and the initiation of lactation are similar in marsupials and eutherians. Parturition requires the corpus luteum and both anterior and posterior pituitary, but, as in many eutherian mammals, in the macropodids the fetus and or placenta may also determine the time of birth. In marsupials the corpus luteum has an essential role for normal parturition at least up to the last few days of gestation (I.R. Young and Renfree, 1979; Bryant and Rose, 1986). Parturition occurs via the median vagina, and relaxin of luteal origin may be necessary for loosening the connective tissue of the vagina and urogenital sinus.

7.9.1 MYOMETRIAL ACTIVITY

Myometrial activity is quiescent during pregnancy, and as the gravid myometrium grows the concentration of collagen declines and the gravid myometrium, unlike the non-gravid myometrium becomes increasingly sensitive to oxytocin and prostaglandin (Shaw,

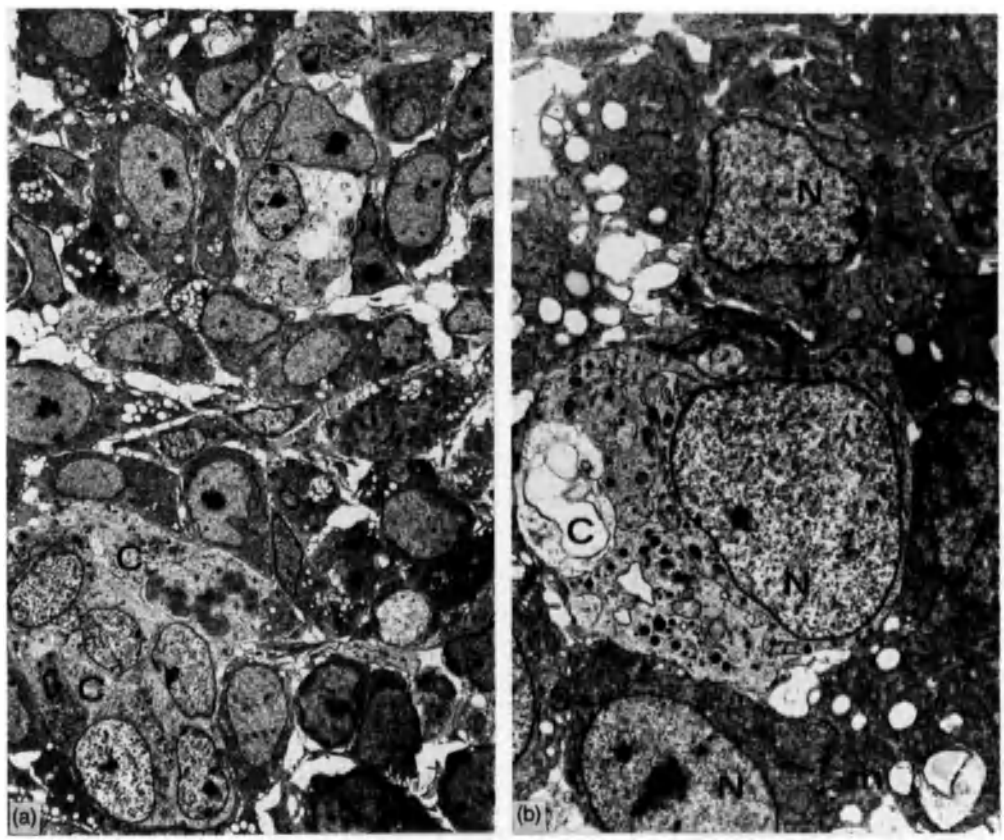

Figure 7.37 Transmission electron micrograph of the adrenal of a day 25 RPY tammar wallaby fetus. Two types of hormone-producing cells are seen: catecholamine-secreting cells (C) with distinct dark staining granules, and steroid (?cortisol)-secreting cells (S) with abundant endoplasmic reticulum and distinctive mitochondria (m). N, Nuclei. (a) Magnification ×1220. (b) Magnification ×3660.

1983a,b). Heller (1973) was the first to study contractility of the myometrium *in vitro*. In the quokka he found that isotonic contractile activity changed through the oestrous cycle, and that pregnancy influences uterine contractility. Early in the cycle (day 7 – day 18 RPY) uteri were more responsive to oxytocin than arginine vasopression, while late in the cycle (day 19 RPY to 2 days post-partum) the reverse occurred.

Myometrial activity *in vivo* has been recorded in the tammar by electromyography (I.R. Young, 1978; Renfree and Young, 1979). Spontaneous activity during seasonal or lactational quiescence is minimal. In non-pregnant females myometrial activity increases after about day 10 RPY, but activity remains low and cyclic in pregnant uteri at all stages of gestation. The gravid uterus has small responses to oxytocin at day 20 RPY, with increasing contractility and sensitivity in late pregnancy, but by day 1 post-partum both uteri are inactive and refractory (Shaw, 1983b; Figure 7.38).

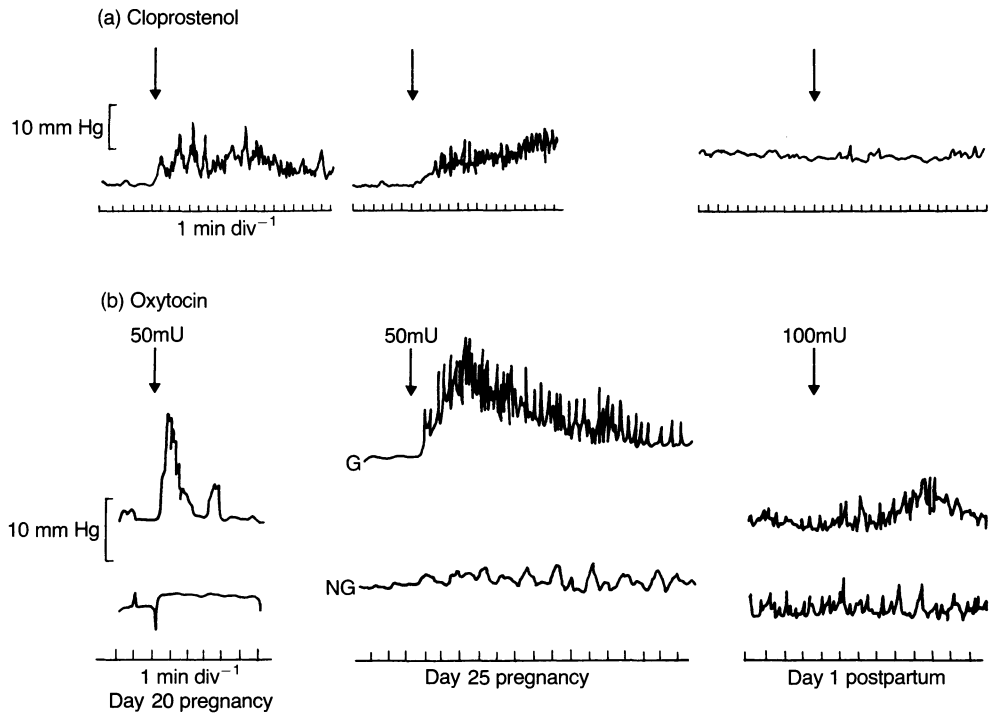

Figure 7.38 Myometrial activity in *Macropus eugenii*. (a) Effects of cloprostenol on intrauterine pressure during late pregnancy (day 20 and day 25) and 1 day post partum. Recordings were made from the gravid uterus or the recently evacuated uterus. Cloprostenol (0.5 μg) was injected into the lateral tail vein (arrow). The vertical scale is the same for all traces but the baseline differs. Data from Shaw (1983a). (b) Response of the myometrium of gravid (G) and non-gravid (NG) uteri to 50 mU or 100 mU oxytocin injection. At day 20, neither uterus showed much spontaneous activity, but the gravid uterus responded strongly to oxytocin both *in vivo* (shown here) and *in vitro*. At day 25, spontaneous activity in both uteri is slight. Oxytocin injections into the tail vein induced strong contractions in the gravid uterus but the non-gravid uterus responded weakly. In a female with a 1-day-old pouch young, spontaneous myometrial activity was slight. Oxytocin (100 mU) produced an increase in tonus of the post-partum uterus, but the stimulation was less pronounced than seen in prepartum uteri. Data from Shaw (1983b). (From Tyndale-Biscoe and Renfree, 1987, with permission.)

Since these effects differ between gravid and adjacent non-gravid uteri, they reflect a local rather than systemic influence. Myometrial responsiveness to the $PGF_{2\alpha}$ analogue cloprostenol increases markedly towards the end of gestation, but the myometrium is also refactory post-partum (Figure 7.38). Prostaglandin $F_{2\alpha}$ rises sharply at parturition (Lewis *et al.*, 1986; Fletcher *et al.*, 1990), and if administered near term will induce abortion (Renfree and Young, 1979; Shaw, 1983b). In a small number of tammars examined there is an increase in uterine $PGF_{2\alpha}$, PGE_2 and 6-keto-$PGF_{1\alpha}$ concentrations between day 25 and day 27, then a fall by 1 day post-partum (Shaw, 1983a). The extremely high concentrations measured in separated endometria and myometria at day 26, especially of PGE_2, show that at this stage the tissue can rapidly produce large amounts. The uterus is thus presumed to be the source of the circulating prostaglandins in the tammar.

The factors maintaining myometrial inactivity in gestation are not clear. In rabbits and sheep progesterone is an important inhibitor, but the success of pregnancy after lutectomy suggests that ovarian hormones are less important in this function in tammars and other marsupials. Placental progesterone production may maintain myometrial inactivity after lutectomy or ovariectomy, but the evidence is that placental progesterone production in tammars is very low. The inactivity of uteri during seasonal quiescence when peripheral progesterone concentrations are at their lowest also indicates that the myometrium does not need active inhibition by progesterone. Parturition is not invariably preceded by a fall in progesterone (Hinds and Tyndale-Biscoe, 1982a), and when progesterone levels are artifically elevated by injections or implants, parturition still occurs at the normal time (K.L. Ward and Renfree, 1984).

7.9.2 SOFTENING OF THE PSEUDOVAGINAL OR BIRTH CANAL

In marsupials the two separate uteri open into an anterior vaginal expansion from which the two lateral vaginae lead to the urogenital sinus. However, parturition occurs via the median vagina, which in all marsupials except the Macropodidae or in the honey possum, *Tarsipes*, is a short band of connective tissue that joins the anterior vaginal expansion with the urogenital sinus (Tyndale-Biscoe, 1966). After the first birth in macropodids and *Tarsipes* this birth canal becomes lined with squamous epithelium and remains patent, but in other marsupials the birth canal is rapidly repaired so that a few days after birth no evidence of the passage remains (Tyndale-Biscoe, 1966; Tyndale-Biscoe and Renfree, 1987).

A conspicuous feature of the fine structure of luteal cells of the four species of marsupial so far studied are small membrane-bound, electron-dense bodies of around 200 nm diameter (four-eyed opossum *Philander opossum*, Enders, 1973; brush-tailed possum *Trichosurus vulpecula*, Shorey and Hughes, 1973a,b; bandicoot *Isoodon macrourus*, Gemmell, 1979; tammar *Macropus eugenii* Tyndale-Biscoe, 1981). In the tammar and brush-tailed possum the maximum concentration coincides with the peak concentrations of bioassayable relaxin and progesterone, and they disappear rapidly after birth (Tyndale-Biscoe, 1966, 1981). Tyndale-Biscoe (1981) concludes that these granules may contain both relaxin and progesterone.

Although corpora lutea of tammars and brush-tailed possums contain high concentrations of bioassayable relaxin (Tyndale-Biscoe, 1966, 1981), no convincing effect of relaxin on softening the cervix and vaginal canal has been demonstrated in either species (Tyndale-Biscoe, 1966; Renfree and Young, 1979). In quokkas Lutrexin administration did ameliorate the effects of ovariectomy

(Tyndale-Biscoe, 1963a). However, the time of the ovariectomy (day 18–20) was late enough that some births would be expected at this time, as occurs in tammars and potoroos (I.R. Young and Renfree, 1979; Bryant and Rose, 1986). Progesterone treatment can also cause substantial loosening of the connective tissue of the urogenital strand in ovariectomized opossums (Risman, 1947), in the brush possum (Sharman, 1965a; Tyndale-Biscoe, 1966) and in the tammar (I.R. Young, 1978). It appears that both these hormones may be necessary for preparation of the birth canal.

Pregnancy goes to term but parturition fails in five species of marsupials so far studied without corpora lutea (after ovariectomy or lutectomy), as it does in tammars reactivated by exogenous progesterone for 10 days which have corpora lutea that remain inactive (Renfree and Tyndale-Biscoe, 1973). As in ovariectomized quokkas (Tyndale-Biscoe, 1963a) the fetuses were recovered dead in the vaginal cul de sac (Renfree and Tyndale-Biscoe, 1973), reinforcing the idea that the corpus luteum is essential for preparation of the genital tract, and the median vaginal canal in particular, for birth. However, these studies do not distinguish between the roles of the two main luteal hormones, progesterone and relaxin.

7.9.3 ENDOCRINE PROFILE AT PARTURITION

Progesterone is high prior to birth in all species so far studied, and is the major steroid hormone of the tammar (Renfree *et al.*, 1979; Hinds and Tyndale-Biscoe, 1982a; Shaw and Renfree, 1984; Lewis *et al.*, 1986; Fletcher *et al.*, 1990) and Bennett's wallaby (Walker and Gemmell, 1983a). Presumably, the need for the corpus luteum at parturition reflects a requirement for progesterone, yet progesterone withdrawal is not essential for parturition to occur (K.L. Ward and Renfree, 1984). Oestrogens are also elevated after parturition before the post-partum oestrus (Flint and Renfree, 1982; Shaw and Renfree, 1984; Harder *et al.*, 1984; Fletcher *et al.*, 1990), but oestrogen is clearly not essential in macropods for parturition, because oestrus does not invariably follow parturition, and in some species, such as the eastern grey kangaroo, *Macropus giganteus*, is not common, or does not occur post-partum at all, as in the western grey *M. fuliginosus*. In the swamp wallaby, *Wallabia bicolor*, oestrus is several days pre-partum (Tyndale-Biscoe, 1984). The Graafian follicle is the main source of oestradiol in the peripheral circulation in the tammar (Harder *et al.*, 1984, 1985) and presumably in the other species as well. Gonadotrophins are also not essential for parturition because animals immunized against GnRH give birth, although folliculogenesis is inhibited and there are no Graafian follicles (Short *et al.*, 1985).

The sequence of hormonal changes at parturition of the tammar is now clearly defined from recent detailed studies (Flint and Renfree, 1982; Shaw, 1983a; Tyndale-Biscoe *et al.*, 1983; Shaw and Renfree, 1984; K.L. Ward and Renfree, 1984; Harder *et al.*, 1984, 1985; Lewis *et al.*, 1986; Tyndale-Biscoe *et al.*, 1988; Fletcher *et al.*, 1990). Progesterone declines precipitously coincident with or occasionally within 6 h of birth. A sharp rise in oestradiol occurs 8 h after the progesterone drop, and oestrus 10 h later. The LH surge is dependent on the oestradiol rise and follows it by 7 h. Ovulation follows the LH surge by 24 h. Oestradiol levels are basal 24 h after the progesterone fall, and there is a transient small pulse of progesterone 16 h after oestrus and about 8 h after, which may reflect a switch from oestradiol secretion to progesterone by the granulosa cells (Figure 7.39).

In tammars sampled very frequently there is a marked peak of 800–1200 pg/ml of prostaglandin metabolite if collected within 10 min of birth, with values declining to less than 200 pg/ml within 45 min, and are nondetectable by 2 h post-partum (Lewis *et al.*, 1986; Fletcher *et al.*, 1990). Clearly, prosta-

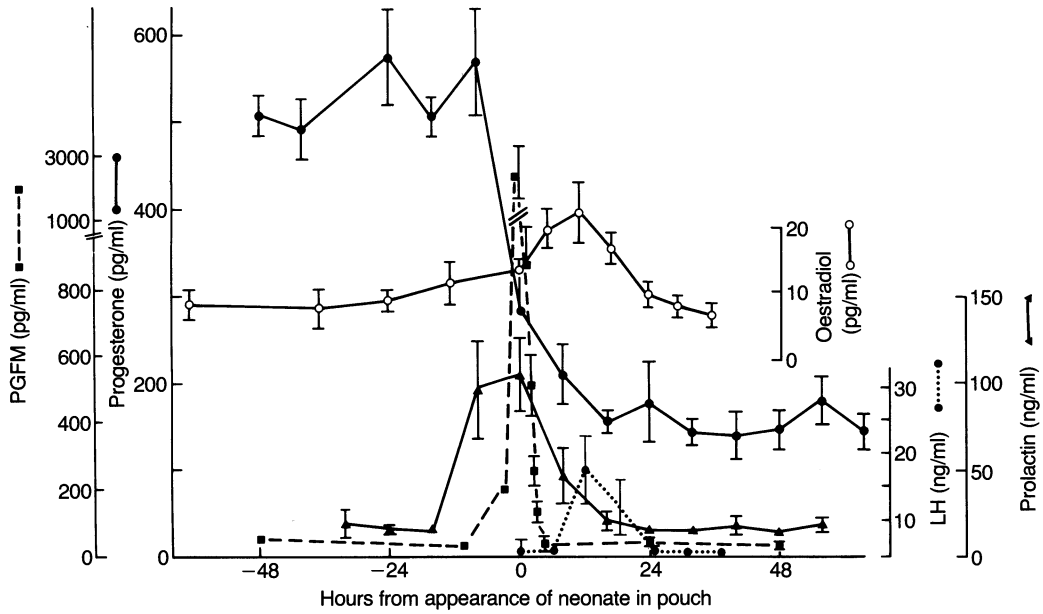

Figure 7.39 Concentrations of oestradiol-17β, progesterone, LH, prostaglandin $F_{2\alpha}$ metabolite (PGFM) and prolactin in peripheral plasma of tammars through the period of birth and post-partum oestrus. Data from Hinds and Tyndale-Biscoe (1982a,b); Tyndale-Biscoe *et al.* (1983); Shaw (1983a); Shaw and Renfree (1984); Harder *et al.* (1984, 1985); Lewis *et al.* (1986); Fletcher *et al.* (1990).

glandin is elevated during parturition, but the peak is very short-lived (Figure 7.39). In bandicoots, prostaglandin is elevated for longer periods (Gemmell *et al.*, 1980). In the red-necked wallaby, Walker and Gemmell (1983a) could not detect a marked rise, but if the pattern of prostaglandin release is like that of the tammar, a more frequent blood sampling regimen would be required to detect it.

In pregnant females there is a peak of prolactin at parturition which is not observed in non-pregnant females (Tyndale-Biscoe *et al.*, 1983), and it is now known that this pulse can, directly or indirectly, cause luteolysis (Tyndale-Biscoe *et al.*, 1988; Fletcher *et al.*, 1990; Hinds *et al.*, 1990b). This will be discussed in detail below.

7.9.4 FETAL ROLE IN PARTURITION

In all mammals maturation of the fetus is an important prerequisite for successful parturition, and in many eutherian species it is known that the fetus signals its readiness by influencing the maternal system. However, because of the similarity between the length of gestation and the oestrous cycle in marsupials, it was assumed that there was no fetal role in the timing and onset of parturition (Sharman, 1970). Since that time, a variety of studies indicate that macropodid marsupials do not differ from eutherians in this regard, and even the similarity of gestation length to oestrous cycle length has been brought into question by the finding of consistent differences which also depend on the presence of the fetus (Merchant, 1979; Merchant and Calaby, 1981). However, there is no evidence at present of any fetal influence on pregnancy in the opossum (Harder

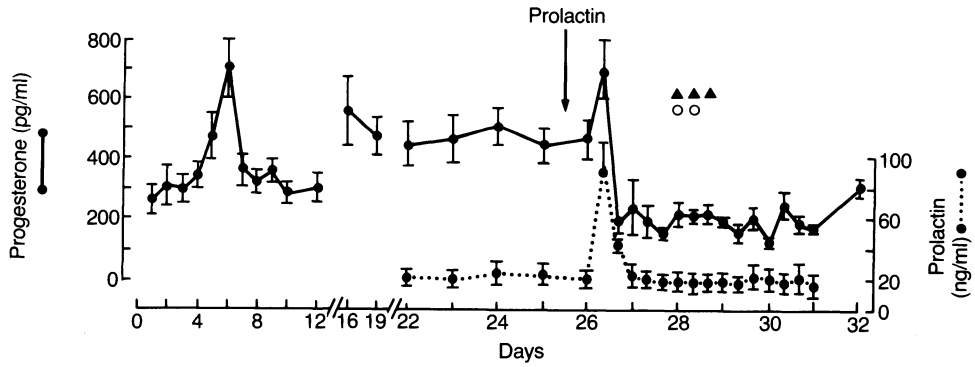

Figure 7.40 Effect of an exogenous pulse of prolactin on concentration (mean ± SEM) of progesterone (—) and prolactin (- - -), and on the time of oestrus (○) and the LH pulse (▲) in five non-pregnant tammars which were injected with 200 μg of prolactin on day 26. Values for progesterone to day 12 have been synchronized to the modal day of the early pulse of progesterone. (Redrawn from Tyndale-Biscoe *et al.*, 1988.)

and Fleming, 1981; Fleming and Harder, 1981b), or in any other non-macropodid so far studied (F. Stewart and Tyndale-Biscoe, 1983).

In the tammar the interval from oestrus to post-partum oestrus is shorter than the interval from oestrus to the next oestrus in non-pregnant tammars, an effect ascribed to the presence of the fetus. In pregnancy, the pulse in prolactin which is coincident with a sharp fall in progesterone around the time of parturition is associated with the presence of the fetus and not the stage of the ovarian cycle (Tyndale-Biscoe *et al.*, 1983; Hinds and Tyndale-Biscoe, 1982b, 1985), and it also is responsible for inducing luteolysis (Figure 7.40; Tyndale-Biscoe *et al.*, 1988; Hinds, 1990).

The short-lived rise in prostaglandin coincident with parturition (Lewis *et al.*, 1986) is now known to cause the release of prolactin, which in turn depresses the progesterone concentration (Hinds *et al.*, 1990b). However, if the prolactin pulse is blocked by the dopamine agonist bromocriptine, luteolysis still occurs after the prostaglandin pulse and parturition (Fletcher *et al.*, 1990). It therefore appears that either prolactin or prostaglandin will induce luteolysis after parturition. If the prostaglandin pulse is blocked by the prostaglandin synthetase inhibitor indomethacin, parturition fails though the prolactin pulse occurs (M.B. Renfree, G. Shaw and T.P. Fletcher, unpublished observation). There is also a short-lived pulse of prolactin just prior to birth and luteolysis in the Bennett's wallaby (Loudon *et al.*, 1990), but prostaglandin profiles at parturition have not yet been made after intensive blood sampling in this species.

Prostaglandin also has another unusual function in that it induces the adoption of the birth position by the female (Hinds *et al.*, 1990b; Shaw, 1990), an important component of birth behaviour in macropodids (see Renfree *et al.*, 1989). Even pre-pubertal females and males will adopt the birth position within 5 min of prostaglandin $F_{2\alpha}$ injection (Shaw, 1990), but the precise mechanisms involved are not yet defined. Prostaglandin also induces birth behaviour in five other marsupials so far tested: *Bettongia gaimardi, Isoodon obesulus, Petaurus breviceps, Trichosurus vulpecula* and *Thylogale billiardiei* (R. Rose, A.S. Macfayden and G. Shaw, personal communication). The question which now must be raised is how the fetus might induce the prostaglandin release.

Production of steroids by the fetal adrenal

is a common step in the early stages of initiation of parturition in many eutherian species, and typically begins several days before birth. In the sheep fetal cortisol induces an increase in synthesis of placental oestrogen, which in turn induces uterine prostaglandin release and uterine contractions (Liggins, 1982). What is the evidence for a similar cascade of events in marsupials?

In the tammar, presumptive adrenal tissue is evident by day 21 and the cortex is differentiated by day 22 RPY (Renfree, 1972b; Call *et al.*, 1980), and corticosteroids can be identified in the plasma of day 24 fetus (Catling and Vinson, 1976) (see above for more details). In a small group of tammars injected at day 20 or 22 with the 11 β-steroid dehydrogenase inhibitor metapyrone, three out of five delayed parturition (Renfree and Young, 1979), a result consistent with the idea that fetal cortisol might play an important role in the timing of parturition. We have recently shown that administration of dexamethasone at day 25 RPY results in parturition within 12 h, a day earlier than in control animals (Shaw *et al.*, 1992), providing the first direct evidence for a role of cortisol. However, whether there is any causal relationship between the fetal capacity to produce cortisol and the release of maternal prostaglandins remains to be determined. Since cortisol is also known to have many functions in the maturation of the eutherian fetus (e.g. lung maturation, surfactant release, lung liquid resorption, glucose storage, lactogenesis and closure of the ductus arteriosus) as well as parturition (Liggins, 1982), it is hardly surprising to find that the adrenal is functional by the time of birth in marsupials, too.

7.9.5 PROPOSED CONTROL MECHANISMS

Although any scheme for the control of parturition in marsupials, and in the tammar in particular, must still be regarded as hypothetical, it is now possible to update the model proposed by Renfree and Young (1979) for the tammar.

For normal parturition to occur, the corpus luteum needs to be present at least to day 23 (I.R. Young and Renfree, 1979). At this time, progesterone is high, and lutectomy at day 18 or day 23 causes an immediate fall in progesterone (Findlay *et al.*, 1983; Harder *et al.*, 1985) but not premature parturition. Relaxin is high at day 22, but has decreased to background levels by the day of birth. If relaxin and progesterone are necessary for softening the connective tissue of the cervix and the median vaginal canal, they have had sufficient effect by day 23 to allow birth. There is no evidence for oxytocin production from the corpus luteum (Curlewis *et al.*, 1988), so the maternal pituitary is the presumed source of any oxytocin. The pituitary gland is essential for parturition (Hearn, 1974) as evidenced by hypophysectomy, but gonadotrophins are not (Short *et al.*, 1985). Likewise, oestradiol from the developing Graafian follicle is also unimportant because those animals treated with anti-gonadotrophin releasing hormone had no follicular development but had normal corpora lutea and gave birth (Short *et al.*, 1985). This points to the need for a hormone(s) from the remainder of the anterior or posterior pituitary being essential for birth, and the two most likely candidates are prolactin from the anterior lobe and oxytocin from the posterior.

Prolactin, as described above, is released shortly before parturition in response to prostaglandin. Prolactin is luteolytic (Hinds *et al.*, 1990b), but since prolactin is not essential for luteolysis (Fletcher *et al.*, 1990) nor luteolysis for parturition (K.L. Ward and Renfree, 1984) and injections of prolactin at day 23 of gestation do not induce premature birth (Tyndale-Biscoe *et al.*, 1988), the peri-partum release of prolactin may be incidental to the process of parturition.

Oxytocin, like prostaglandin, can promote delivery of the young, via its action on smooth muscle contraction, but in most

species (except the rabbit) it has only a minor role and this is limited to the expulsive phase of parturition. In the rabbit it may act both directly on the uterus and to stimulate the release of $PGF_{2\alpha}$ from the endometrium. The role of oxytocin from the maternal pituitary in marsupial parturition has not been extensively tested as yet, but myometrial activity *in vivo* and *in vitro* can be stimulated by oxytocin, and the gravid uterus responds strongly (Shaw, 1983b; Tyndale-Biscoe and Renfree, 1987). Injections of oxytocin or prostaglandin cause massive contractions and expulsion of the fetus with considerable damage to it. It may be that oxytocin is necessary for evacuation from the uterus because in animals with a partial hypophysectomy in which the neurohypophysis was left intact the fetuses passed through the cervix but remained trapped in the vaginal canals (Hearn, 1973, 1974). We have recently delayed parturition using an oxytocin-inhibitor (M.B. Renfree, L.J. Parry and G. Shaw, unpublished results). It would be interesting if the oxytocin release induced the prolactin pulse, as has been recently shown in the rat (Mori *et al.*, 1990).

Prostaglandin has been measured in the uterus (Shaw, 1983b), but it is not yet established what causes the parturient prostaglandin release. Myometrial activity is increased after injection of prostaglandin (cloprostenol) during later pregnancy, but is refractory to it after parturition (Renfree and Young, 1979; Shaw, 1983a). It seems unlikely that a change in placental oestrogen induces prostaglandin release, because placental steroidogenesis occurs at a very low level (Heap *et al.*, 1980) and the placenta itself consists of only two or three cell layers (wet weight 100 mg at term). However, since there are large quantities of PGE_2 in the endometrium and myometrium (Shaw, 1983b), it is possible that this might induce the fetal adrenal to synthesize and release cortisol as it does in the sheep (Liggins, 1982; Thorburn *et al.*, 1988). It is also possible, though less likely, that fetal cortisol induces some change in the progesterone–oestradiol ratio, perhaps within the endometrium itself, since this tissue can convert oestrone to oestradiol (Heap *et al.*, 1980), but a direct effect on uterine prostaglandins cannot be dismissed at this stage. Tammar placentae also have 'gonadotrophic activity' but this needs to be further characterized (B. Hobson, L. Wide and M.B. Renfree, unpublished results).

In summary, it appears that the control of parturition has some features in common with the mechanisms of control of eutherians, but in the one species about which sufficient is known, the tammar, there is still a need for much more information. A hypothetical scheme (Figure 7.41) consistent with the present evidence summarizes the information presented above.

7.10 LACTATION: LACTOGENESIS AND GALACTOPOIESIS

7.10.1 INTRODUCTION

Lactation in marsupials lasts for relatively longer than in most eutherian species, to support the young, which are more immature at birth (Tyndale-Biscoe *et al.*, 1984; Findlay and Renfree, 1984). Although the cellular processes of embryological and prepubertal development, and the proliferation and differentiation of the mammary glands during pregnancy, are similar in all mammals, the temporal course of these events is different in marsupials (F.Stewart and Tyndale-Biscoe, 1983). The newborn marsupial climbs, unaided by the mother, into the pouch (Figure 7.42), where it spends a considerable period sustained by the specialized milk which changes in composition as the young grows (B. Green, 1984).

Pouch young remain permanently attached for about the first half of the period spent in the pouch, and are totally dependent on milk until weaning. At birth, young macropodids weigh only 0.5–1 g and are naked and blind,

depending on species, whereas at weaning they weigh up to several kilograms, are fully furred and fully mobile (Tyndale-Biscoe and Renfree, 1987). Again, most detailed information is at hand for the tammar (Tyndale-Biscoe and Janssens, 1988), and the maturation of the organs of the pouch young is completed by weaning, except in males whose testes mature at about 20 months when puberty occurs (Williamson *et al.* 1990) (Table 7.6).

The first appearance of fur is at about 150 days, when the young has some thermoregulatory ability, but homeothermy and full pelage are not established until days 180 and 200 days respectively. First excursions from

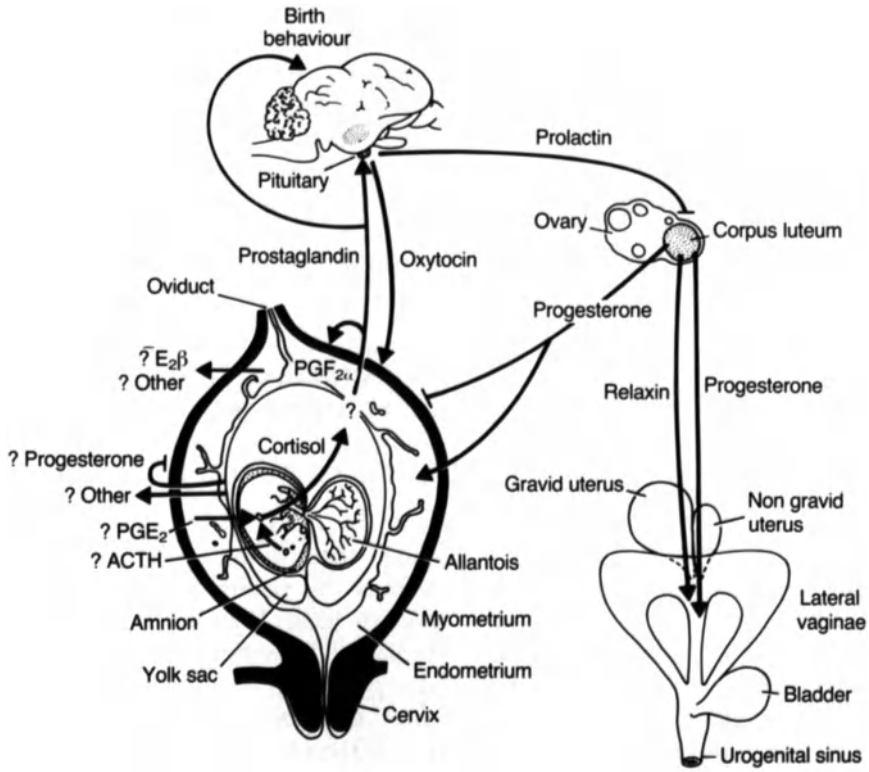

Figure 7.41 An hypothetical scheme consistent with present evidence to describe the possible control of parturition in the tammar wallaby. During pregnancy progesterone stimulates uterine secretory activity, and maintains myometrial quiescence. Fetal cortisol or endometrial oestrogen may stimulate prostaglandin synthesis in the endometrium. Fetal cortisol in turn could be stimulated by PGE_2, known to be present in endometrial tissue at this time, or by ACTH from the maturing fetal pituitary. Prostaglandin causes myometrial contraction in an oestrogen-sensitized uterus, but progesterone inhibits this effect. Prostaglandin also controls maternal behaviour and induces the adoption of the 'birth position'. Placental progesterone production may contribute to the observed unilateral effects of pregnancy. Progesterone and relaxin appear to be necessary for the softening of the cervix and the median vaginal canal to allow passage of the fetus to the outside. Prolactin during quiescence inhibits the corpus luteum, but at parturition it is released by prostaglandin to cause luteolysis. Oxytocin released from the maternal pituitary could stimulate myometrial contraction in concert with prostaglandin to evacuate the fetus through the cervix and then the long median vagina. (See text for further details and references.) ACTH, adrenocorticotrophic hormone; $E_2\beta$, oestrogens; $PGF_{2\alpha}$ and PGE_2, prostaglandins $F_{2\alpha}$ and E_2. Arrows show proposed stimulatory actions; T shows proposed inhibitory actions.

the pouch take place at 190 days, but the young is not out of the pouch permanently until over 250 days of age. Suckling may continue until the young is 340 days post-partum.

The number of teats generally limits the number of young that can survive in poly-ovular species like the family Dasyuridae, but many species have 'surplus' nipples. In all Macropodidae and Phalangeridae there are four teats available for the single-pouch young to choose for attachment. Extensive reviews on marsupial milk composition, mammary gland structure and the physiology of lactation are provided by B. Green (1984), Tyndale-Biscoe *et al.* (1984), Findlay and Renfree (1984), Tyndale-Biscoe and Renfree (1987), B. Green and Merchant (1988), Hinds (1988) and Nicholas (1988a), and on mother – young behavioural interactions by Russell (1982a,b, 1989).

7.10.2 MAMMOGENESIS AND LACTOGENESIS

Three broad stages can be recognized in marsupial lactation: the first (phase 1) of preparation of the mammary gland during pregnancy, (equivalent to lactogenesis stage I of eutherians; Fleet *et al.*, 1975; Cowie *et al.*, 1980), the second (phase 2) of initiation and maintenance of lactation during the first dependent period of pouch life, and the third (phase 3) when maintenance of an increased

Figure 7.42 Neonatal tammar wallaby (24 h old) firmly attached to one of the four available teats (right posterior) (T_4) within the pouch (P). The right anterior teat (T_2) with dark tip supported the young of the previous lactation, while the left posterior teat (T_3) has never been sucked. The pouch is normally tightly closed by the pouch sphincter, but has been opened for photography. (Photo courtesy David Parer, PO Box 337, Mt. Eliza, Victoria, 3930, Australia.)

Table 7.6 Post-natal maturation of the tammar wallaby, *Macropus eugenii*. Data compiled from various authors[a]

Days from birth	*Developmental events*
0	Birth weight around 400 mg
	Scrotum visible externally
	Adrenocortical function
	Mesonephros functional kidney
	Neocortex of brain equivalent to 25-day sheep fetus or 12-day rat fetus
2	Seminiferous tubules in testis
4	First axons from retinal ganglion cell layer cross to opposite side of brain via optic chiasm
5–6	Initial appearance of cortical plate
10	Pouch young capable of gluconeogenesis
	Pouch externally visible in females
	Pituitary capable of synthesizing sufficient vasopressin for urine concentration
10–15	Cortical plate complete throughout the telencephalon
20	Carbonic anhydrase activity of red blood cells rises to adult levels
25	Metanephros completely replaces mesonephros
30	Thyroxine (T_4) is at adult concentrations, while triiodothyronine (T_3) is much lower
70	Mature pattern of eye innervation appears
	Completion of six layers of adult cerebral cortex
100	Voluntarily releases teat
120	Four- to fivefold increase in T_4 concentration
126	Milk only in forestomach
140	Eyes open, underfur starts to appear
150	T_3 levels increase
160	Head first out of pouch, able to stand
168	Milk only in forestomach
170	Starts to nibble grass
180	Homeothermy, thyroid function complete; T_4 levels decline to adult
190	First out of pouch
192	Able to hop
196	Milk and fragments of herbage in forestomach
196–245	Change in gluconeogenic regulation
196–252	Weaning. Doubling in pituitary vasopressin content
200	Full pelage
210	Milk and some herbage in forestomach
224	Herbage and some milk in forestomach
238	Ammonia content of urine falls to adult levels of about 18 mM, concentration of urea in urine approaches adult level of 550 mM. Herbage and a little milk in forestomach
250	Out of pouch permanently
252	pH of urine rises and approaches adult levels of pH 8
315–350	Fully independent: weight 1.6–2.5 kg.

[a] These data are derived from the chapters in *The Developing Marsupial*, edited by Tyndale-Biscoe and Janssens (1988b).

milk production occurs during the later, rapid growth stages before weaning. Phase 3 is equivalent to lactogenesis stage II of eutherians (Tyndale-Biscoe *et al.*, 1984; Findlay and Renfree, 1984; Tyndale-Biscoe and Renfree, 1987). The second stage of lactation in marsupials (phase 2) has no equivalent in eutherian lactation, and is characterized by low milk production and slow growth of the young whilst it remains permanently attached to the teat (B. Green, 1984; Tyndale-Biscoe *et al.*, 1984; Findlay and Renfree, 1984).

In eutherian mammals, significant changes in the mammary glands occur during pregnancy, but in marsupials the changes are subtler, and there is no difference in the changes between the oestrous cycle and pregnancy. O'Donoghue (1911) was the first to show the relation between enlargement and regression of the mammary glands of the quoll (*D. viverrinus*) with the development and regression of the corpus luteum. In this and in other marsupials, the glands reached their maximum size and degree of lobuloalveolar growth at the stage of the oestrous cycle at which parturition occurs in pregnant animals, and a small volume of clear colostrum can be expressed from each teat (Tyndale-Biscoe and Renfree, 1987). Pregnancy is not even necessary for successful lactation in marsupials, as has been amply confirmed by fostering neonates to mammary glands of virgin females at the equivalent stage of oestrous cycle to the peri-partum (Sharman, 1962; Sharman and Calaby, 1964; Merchant and Sharman, 1966; Clark, 1968; Findlay, 1982a,b; Tyndale-Biscoe *et al.*, 1984; Findlay and Renfree, 1984). After parturition or after transfer, only those glands to which the young became attached enlarge and lactate, while the other glands regress to the anoestrous size (Tyndale-Biscoe and Renfree, 1987).

Lutectomy, which reduces progesterone concentrations immediately (Findlay *et al.*, 1983; Harder *et al.*, 1984; Fletcher and Renfree, 1988; Figure 7.24), affects the ability of the mammary gland to secrete milk, depending on the stage of pregnancy when the corpus luteum is removed. In *M. eugenii* if the corpus luteum is removed at day 17 or day 21 RPY, the neonates fail to survive, but at day 23 or day 25 lactation is successfully established (I.R. Young and Renfree, 1979). Lutectomy at day 17 significantly reduces the mammary gland weights at parturition, but not if the operation is performed later at day 23 (Tyndale-Biscoe *et al.*, 1984; Hinds, 1988). As well as being necessary for lobuloalveolar growth of the mammary gland the corpus luteum, but not pregnancy, stimulates prolactin-specific receptors in mammary tissue of the tammar (F. Stewart, 1984). There is also a four- to five-fold increase in the size and weight of the mammary gland during pregnancy or the cycle (Findlay, 1982a; F.Stewart, 1984) (Figure 7.43), and this parallels the increase in plasma progesterone in the second half of the oestrous cycle (Hinds and Tyndale-Biscoe, 1982a).

A similar requirement for luteal secretions to prepare the mammary gland has been recorded in the opossum (Hartman, 1923), brush-tailed possum (Sharman, 1962) and the red kangaroo (Sharman and Calaby, 1964).

Although the corpus luteum is necessary for mammary gland growth and prolactin receptor synthesis, neither gonadotrophins nor oestradiol of follicular origin are necessary throughout pregnancy for lactogenesis (Short *et al.*, 1985). Mammary gland growth will occur during pregnancy even after hypophysectomy (Hinds, 1988), although the pituitary is essential to maintain lactation (Hearn, 1973, 1974).

In several eutherian mammals, progesterone withdrawal at parturition is a lactogenic trigger, but this is not the case in marsupials. Maintenance of high concentrations of progesterone through the peripartum period does not prevent the normal rise in lactose in mammary tissue which occurs after parturition, nor does lutectomy induce an early rise in lactose (Findlay *et al.*, 1983). Similarly, the

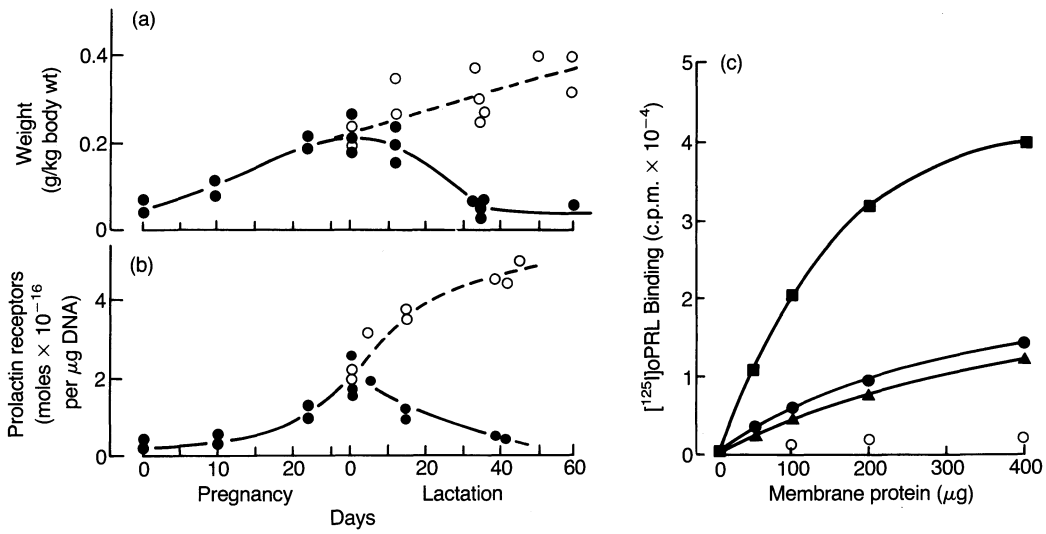

Figure 7.43 Changes in hormone levels and mammary glands throughout pregnancy and early lactation in the tammar *M. eugenii*. (a) Weight of the mammary glands and (b) prolactin receptor concentrations during the first 60 days of lactation in (○) sucked and (●) non-sucked glands. [Redrawn from Tyndale-Biscoe *et al.* (1984) and F. Stewart (1984).] (c) Prolactin binding to mammary gland membrane receptor protein, showing the effect of receptor protein concentration on specific prolactin binding to membranes from phase 3 (■, days 275–300), phase 2 (●, days 6–33) and phase 1 (▲) prepared and incubated with 105 000 c.p.m. of [^{125}I]oPRL in the presence or absence of 1 μg/ml unlabelled oPRL. (Redrawn from Nicholas, 1988a.)

synthesis of α-lactalbumin by mammary tissue *in vitro* is not inhibited by progesterone (Nicholas and Tyndale-Biscoe, 1985). These last authors also showed that the only hormone required for the synthesis of α-lactalbumin is prolactin at concentrations equal to the basal levels in the pregnant female (Nicholas and Tyndale-Biscoe, 1985). Prolactin injected intraductally into individual galactophores at day 15 RPY prematurely stimulated local secretion (Findlay and Renfree, 1984).

7.10.3 MAINTENANCE OF LACTATION

Prolactin in the tammar is relatively low during pregnancy except for a transient peak of 100–150 ng/ml around the time of birth and in early lactation remains at around 20–40 ng/ml at this time (Hinds and Tyndale-Biscoe, 1982b, 1985), which is the same as in non-lactating females until about 140 days of lactation. Likewise, plasma concentrations of prolactin remain relatively low in early (phase 2) lactation in all the other species in which prolactin has been measured (Figure 7.44).

However, during the second half of lactation (phase 3) the concentration rises markedly, and in the tammar remains at more than 100 ng/ml until about 280 days of lactation. The sucking stimulus is necessary to maintain this high concentration in late lactation but does not appear to be involved in early lactation (Hinds and Tyndale-Biscoe, 1985; Gordon *et al.*, 1988). Prolactin receptors increase in concentration to reach a peak at 30–34 weeks as evidenced by a significant progressive increase in the binding of prolactin ([^{125}I]-oPRL) to mammary gland membranes from quiescent, phase 1, phase 2 and phase 3 mammary glands (Figure 7.43; F.

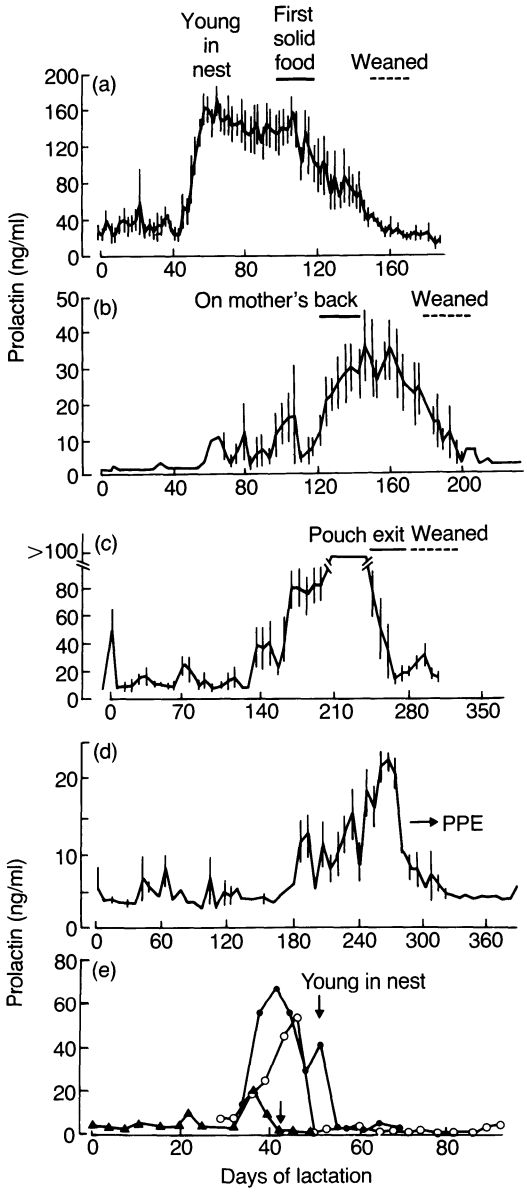

Figure 7.44 Plasma prolactin concentrations (mean ± SEM) throughout lactation in five diverse marsupials: (a) *Dasyurus viverrinus*; (b) *Trichosurus vulpecula*; (c) *Macropus rufogriseus* and (d) *Macropus eugenii*. PPE, permanent pouch exit. Data from Hinds and Tyndale-Biscoe (1985); Hinds and Merchant (1986); Hinds and Janssens (1986) and Curlewis *et al.* (1986). (e) Plasma prolactin concentrations from three individuals of *Isoodon macrourus* during lactation. ↓, pouch young lost. (a–e redrawn from Hinds, 1988.)

Stewart, 1984; Nicholas, 1988a, b). Similar prolactin profiles to the tammar have been described in the brush-tailed possum (Hinds and Janssens, 1986), the quoll (Hinds and Merchant, 1986), Bennett's wallaby (Curlewis *et al.*, 1986) and the bandicoot *I. macrourus* (Hinds, 1988). In all these species the time at which prolactin becomes elevated coincides with the increase in mammary gland size, the onset of changes in milk composition and accelerated growth of the young.

7.11 CONTROL OF MILK SECRETION AND CONCURRENT, ASYNCHRONOUS LACTATION

7.11.1 MILK COMPOSITION

One of the unusual features of lactation in marsupials is the constantly altering composition of the milk. As in all mammals, the first milk is a colostrum-type secretion, a clear, low-fat fluid with free-floating cells (Griffiths *et al.*, 1972) and with immunoglobulin G- and A-like proteins (Hindes and Mizell, 1976; Deane *et al.*, 1990). The data available from the seven or eight species studied suggest that all marsupials have a similar pattern of milk composition. The relatively dilute milk (10% solids) produced to supply the new pouch young becomes more concentrated (25–50% milk solids) as pouch life progresses (B. Green, 1984; B. Green *et al.*, 1987; B. Green and Merchant, 1988) so that the growth rates of the young are regulated by rates of milk production and its changing composition. The main constituents of marsupial milk are similar to those of eutherian mammals, but there are marked changes throughout lactation (Figure 7.45) just as the sucking regimen of the pouch young must change between the time when it is continuously attached to the teat to that when it frequently is observed off the teat (Griffiths *et al.*, 1972; B. Green *et al.*, 1980; B. Green, 1984; B. Green and Merchant, 1988).

Total solids are higher than in cow or hu-

man milk; proteins, carbohydrates and fats increase quantitatively and change qualitatively during lactation (Messer and Green, 1979). Caseins are found in marsupial milk, as well as whey proteins, but it is the whey proteins which have been best studied and show the greatest variation (Lemon and Bailey, 1966; Lemon and Barker, 1967; Lemon and Poole, 1969; S.W. Green and Renfree, 1982; Nicholas, 1988a,b). Amino acid composition also varies through lactation, and there is a correlation between sharp increases in the amount of sulphur-containing amino acids in the milk at the time of hair follicle and nail growth (Renfree *et al.*, 1981). Immunoglobulins form an important component of later marsupial milks, and the pouch young passively acquire antibodies from the milk by uptake through the gut (Yadav, 1971; Bell *et al.*, 1974; Deane and Cooper, 1988).

Concurrent, asynchronous lactation occurs

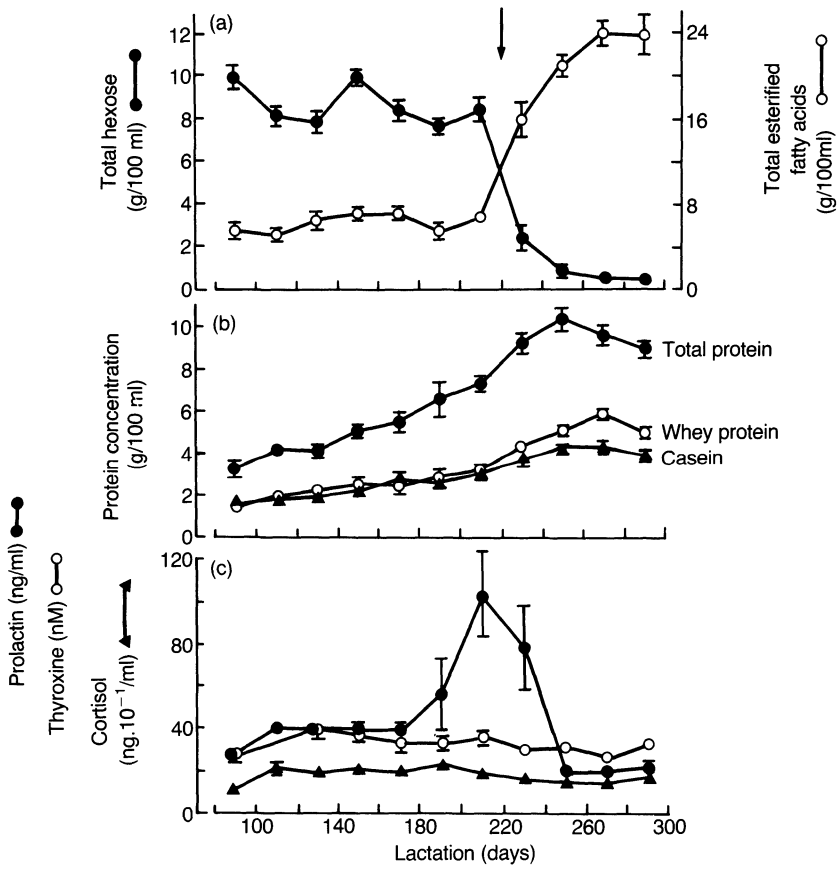

Figure 7.45 Progressive changes in milk composition and endocrine status during lactation of the tammar. (a) Total esterified fatty acid (triglyceride) and carbohydrate (total hexose) from 100 to 300 days post partum. The timing of the transition from phase 2 to phase 3 of lactation is indicated by the arrow. (b) Casein, whey, and total protein concentrations. (c) The concentration of prolactin (Hinds and Tyndale-Biscoe, 1982b), cortisol (Janssens amd Hinds, 1981) and thyroxine (Amersham radioimmunoassay kit) was measured in plasma from the same animals used for the milk analyses. (Redrawn from Nicholas, 1988a,b.)

in continuously breeding macropodids, such as the red kangaroo *M. rufus* or the agile wallaby, *M. agilis*, or even the tammar under experimental conditions. The female gives birth immediately after the pouch has been vacated by the older young, but which continues to suckle. Thus, two of the four mammary glands simultaneously secrete milk of entirely different composition. Of the two remaining glands, one may be still regressing from the previous, weaned young and the fourth regressing from the pre-partum condition. The mechanisms which control changing milk composition in marsupials and which allow the four mammary glands to differentiate and regress independently are unclear, but local factors such as sucking and milk removal are obviously important, as would be differing hormone receptor concentrations.

As mentioned earlier in this section, the induction of specific protein synthesis in phase 1 and 2 is prolactin dependent (Nicholas, 1988a,b). The response is not changed by the addition of any combination of insulin, cortisol, oestradiol-17β or thyroid hormone. In phase 3 of lactation, specific whey proteins appear in the milk, but only one, late lactation protein (LLP), has been purified (Nicholas *et al.*, 1987), and so provides a useful marker. It appears that LLP is not induced solely by the rise in prolactin soon after day 200 (Figure 7.45) because phase 2 mammary explants do not begin producing LLP when exposed to elevated prolactin (Nicholas, 1988a,b). Clearly, the mammary glands have different controls during each phase of lactation, a point reinforced by the different milk ejection responses (section 7.11.3).

Although there is as yet little information on crude growth efficiency in marsupials, their energy and growth conversions are intermediate compared to eutherian mammals (B. Green, 1984; B. Green and Merchant, 1988; B. Green *et al.*, 1988; Cork and Dove, 1989; Dove and Cork, 1989; Rose, 1987), so that the relatively long lactation and comparatively slow growth of the young is not due to inefficient conversion of milk, and must therefore be regulated/limited by the mother (B. Green and Merchant, 1988). This idea is supported by several observations. Transfer of young to pouches of larger species or mothers with larger young results in accelerated growth rates and vice versa (Merchant and Sharman, 1966; Findlay, 1982b; Findlay and Renfree, 1984; B. Green and Merchant, 1988). Only transitory effects on milk composition were produced by such transfers, but these effects were not maintained against the overriding inherent control of the cellular biochemical processes (Findlay, 1982b). It appears that changes in the composition of the milk are an intrinsic characteristic of the mammary epithelial cells and occur as the cells age (Findlay and Renfree, 1984). Such a system allows parallel but asynchronous lactations to exist independently in two adjacent glands, which can then supply different milks to physiologically different young.

7.11.2 MILK REMOVAL

The idea that contraction of the striated ilio-marsupialis muscle forcibly ejects milk from the mammary glands into the pouch young, which are considered unable to suck in the normal manner (Seiler, 1828; Morgan, 1829; Owen, 1834), continues to be expressed in the literature (Barnes, 1977) despite the fact that Enders (1966) demonstrated that milk was not expressed in the opossum following electrical stimulation of the motor nerves and associated muscles supplying the muscles of the pouch. In any event, striated muscle is apparently unnecessary for milk ejection; the glands of *Caenolestes obscurus*, the South American rat opossum, have no striated muscle at all (Griffiths and Slater, 1988).

Musculus ilio-marsupialis is a flat triangular sheet of muscle originating from the pelvis and attaching to the mammary glands; its homologue in humans is the cremaster

muscle (Tyndale-Biscoe and Renfree, 1987; Griffiths and Slater, 1988). This attachment is variable amongst species – in many, the external muscle sends branches into the secretory parenchyma of the gland. These branches diffusely invade the gland in the pouched species examined. However, in some pouchless species, such as the brown antechinus (*Antechinus stuartii*) and the dusky antechinus (*A. swainsonii*), discrete branches of the muscle attach at the base of the teats, and these may function to elevate the unprotected young from the ground when the mother is moving around (Griffiths and Slater, 1988), much as m. cremaster retracts the testis into the scrotum (Tyndale-Biscoe and Renfree, 1987). The degree to which m. iliomarsupialis penetrates the gland varies between pouched and pouchless species; in *T. vulpecula* (Bolliger and Gross, 1960; Barbour, 1963) and in the red kangaroo, *M. rufus* (Griffiths *et al.*, 1972), branches of the muscle diffusely invade the gland, and in *Tarsipes rostratus* reach each of the four teats (Griffiths and Slater, 1988). In all the pouchless species examined by Griffiths discrete branches of the muscle attach at the base of the teats. These species are *Antechinus stuartii* and *A. swainsoni*, *Dasyuroides byrnei* and *Dasysurus viverrinus* as well as the South American species *Caenolestes obscurus*. Barnes (1977) described the same arrangement in *Marmosa robinsoni*. When *A. stuartii* and *D. viverrinus* were anaesthetized the attached young hung from flaccid teats, but as the mothers regained consciousness the teats retracted and the young were again held close to the body (Griffiths and Slater, 1988).

The conclusion from these studies is that m. iliomarsupialis does not have the special function in marsupials of expressing milk and that the removal of milk in these mammals is under the same control as in eutherians, although Griffiths and Slater (1988) suggest that it is possible that striated muscle and oxytocin act synergistically in promoting contraction of the myoepithelium.

McCrady (1938), Hartman (1952) and Enders (1966) observed that neonatal opossums *D. virginiana* and *Marmosa* can suck actively, and Jurgelski (1971) using opossums and subsequently Shaw *et al.* (1988), using tammars have capitalized on this ability of neonates to suck to administer fluids containing drugs from non-distortable plastic catheter tubes. Likewise, Griffiths and Slater (1988) demonstrated that tammars, a rock wallaby, *Petrogale xanthopus*, and red kangaroo young could imbibe water or milk from rigid, non-distortable tubes. This differs from the main method of imbibition of milk in eutherians by expressing it from nipple or teat as described by Cowie (1972).

7.11.3 MILK EJECTION RESPONSE AND CONCURRENT, ASYNCHRONOUS LACTATION

It is generally agreed that milk removal is facilitated by the milk ejection reflex (Cross, 1977). The contraction of the myoepithelium investing the alveoli is effected by the humoral influence of oxytocin released from the neurohypophysis during suckling. This contraction raises intra-alveolar pressure, leading to expulsion of the milk into the ducts, and this milk can then be removed from the glands by the sucking of the young. Although, ultrastructurally, the myoepithelial network investing the mammary alveoli is similar in monotremes, marsupials and eutherians (Griffiths *et al.*, 1973), in marsupials, as noted in earlier sections, there are differing responses of the myoepithelium to exogenous hormones at the three phases of lactation as well as the structural and compositional changes. In all mammals the myoepithelial cells of the mammary gland are sensitive to oxytocin, and exogenous oxytocin causes milk ejection in marsupials as it does in eutherians. As noted above, kangaroos and wallabies are able to produce milk of two different kinds from adjacent mammary glands (Griffiths *et al.*, 1972; B. Green, 1984),

and studies of the milk ejection response also give some clues as to the manner in which this is achieved. The neurohypophysis of three American marsupials contains oxytocin, lysine vasopressin and phenypressin (Chauvet *et al.*, 1984, 1985), but in the six Australian species studied the oxytocin differs by a single amino acid – leucine is replaced by isoleucine at position 8, thus making it mesotocin (Ile^8-oxytocin) (Chauvet *et al.*, 1981). This amino acid alteration seems to have no functional significance, for heterologous (eutherian) oxytocin injected or homologous (marsupial) oxytocin released after stimulation of the presumptive oxytocinergic neurones both stimulate a milk ejection response (Lincoln and Renfree, 1981a,b).

In macropodids with concurrent asynchronous lactation, which support two young of differing ages concurrently (Figure 7.46), the question of how the milk ejection response controls the release of very different volumes of milk in the two sized glands has been addressed in the agile wallaby *M. agilis*.

Lincoln and Renfree (1981a,b) measured the intraductal pressure within the mammary gland that occurred in response to injections of oxytocin or electrical stimulation of the presumptive oxytocin neurones in the brain (Figure 7.47) and found that the basic dose – response curve is very similar to that of eutherian mammals but, early in lactation, the threshold doses of oxytocin are lower and the peak intraductal pressures obtained much higher than in late lactation (Lincoln and Renfree, 1981b).

This was clearly seen when recordings were made simultaneously in females suckling two young of different ages (Figure 7.47). In addition, there were differences in the response to electrical stimulation of the presumptive oxytocinergic neurones in the basal hypothalamus (Lincoln and Renfree, 1981a), and milk ejection also occurred when the neurones were stimulated at lower frequencies. The decline in responsiveness of the gland to oxytocin during lactation, requiring more stimulation, would thus allow the milk ejection caused by small releases of the hormone to be confined to the gland supporting the small young, while milk ejection would occur in both glands in response to the larger hormonal releases presumably triggered by the more vigorous sucking of the young-at-foot (Lincoln and Renfree, 1981a,b). This declining responsiveness as lactation

Figure 7.46 Representative stages of the pouch young and mammary gland of the agile wallaby *Macropus agilis*, during concurrent asynchronous lactation. (a) A 60-day pouch young. The enlarged nipple and gland adjacent to the attached young (arrow) is supporting a 260-day young-at-foot; (b) 210-day-old young, just about the time it makes the first excursions from the pouch. (From Findlay and Renfree, 1984, with permission.)

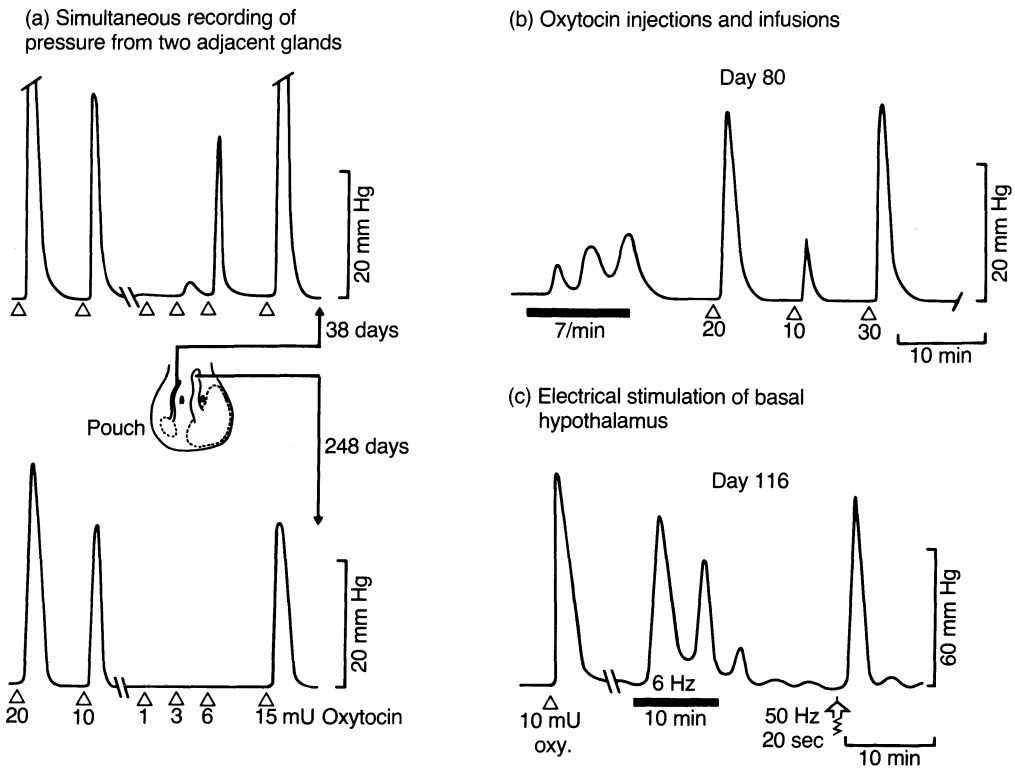

Figure 7.47 Intraductal pressure recordings taken from galactophores at different stages of lactation in agile wallabies. (a) Simultaneous recordings of intramammary pressure at 38 days and 248 days of lactation after injection (Δ) of the doses of oxytocin (mU) as shown. The 'younger' gland generated higher peak pressures and responded to lower doses of oxytocin. (b) Recording from a single galactophore at day 80 of lactation showing the response to intravenous injections (Δ) and infusions (bar) of oxytocin in the doses indicated. (c) Intramammary pressure recording at day 116 of lactation after prolonged low-frequency stimulation at 6 Hz (solid bar) compared with a short burst of high-frequency stimulation (50 Hz×20 sec. ↑) and injection of 10 mU of oxytocin (Δ). (Redrawn from Lincoln and Renfree, 1981a,b.)

progresses could be related to less effective connections between the cells of the myoepithelial network in 'older' (and larger) glands, or possibly to differences in oxytocin receptor concentrations in the cells, as has been shown for mammary gland prolactin receptors (Sernia and Tyndale-Biscoe, 1979; Tyndale-Biscoe *et al.*, 1984; Figure 7.43). Thus, milk ejection can occur semi-independently in adjacent glands during concurrent, asynchronous lactation.

7.11.4 CONTROL OF MILK SECRETION

Local intrinsic control and developmentally regulated mechanisms of the mammary epithelium appear to be responsible for the complex biochemical and physiological changes which occur in marsupial mammary glands through lactation (Findlay and Renfree, 1984; Nicholas, 1988a). Intraductal injection of prolactin causes a local secretory response in phase 1 of lactation (Findlay, 1982b; Findlay and Renfree, 1984), but specific proteins such as LLP are only induced by prolactin in phase 3 and not phase 2 of lactation (Nicholas,

1988a,b). Similarly, during phase 2 of lactation the sucking stimulus does not apparently cause a prolactin release, because neither removal of pouch young nor injection of bromocriptine depresses the low (< 40 ng/ml) concentrations of plasma prolactin (Hinds and Tyndale-Biscoe, 1982b, 1985; Tyndale-Biscoe and Hinds, 1984; Curlewis *et al.*, 1986; Gordon *et al.*, 1988), nor does denervation of the teat stop milk production (Renfree, 1979). Developmental age of the mammary gland overrides the effects of an experimentally altered sucking interval (rate) and volume of milk withdrawal so that the milk composition shows only transitory changes (Findlay, 1982b, Findlay and Renfree, 1984). These changes may be mediated by alterations in hormone receptor concentrations, such as are suggested to explain the decline in responsiveness of the mammary myoepithelium to mesotocin as lactation proceeds (Lincoln and Renfree, 1981a,b), as has been shown for mammary prolactin receptors (Tyndale-Biscoe *et al.*, 1984). This declining responsiveness in the milk ejection response could also be related to less effective connections between the cells of the myoepithelial network and older and larger glands (Lincoln and Paisley, 1982; Findlay and Renfree, 1984).

Support for the idea that the changes which occur during lactation in marsupials are internally controlled within the individual mammary glands comes from the interesting recent studies by Peaker, Wilde and colleagues on lactating goats. They have found evidence that milk secretion is modulated by local chemical feedback inhibition (autocrine control) by an inhibitor (a protein of 10–30 kDa) present in the whey protein fraction (Henderson and Peaker, 1984; Peaker and Wilde, 1987; Wilde *et al.*, 1987, 1988; G.M. Stewart *et al.*, 1988). In other words, the secretory cells of the mammary gland produce an inhibitor (or proinhibitor) of their own activity, such that more frequent removal of the protein during an increase in milking frequency enhances milk secretion. The gland does not become refractory to these autocrine stimuli, and the enhanced secretory rate is maintained for as long as the stimulus of frequent milking is applied (Peaker and Wilde, 1987). In ruminants, local production of prostaglandins can also inhibit the induction of milk synthesis (Maule Walker, 1984). Mechanisms like these may well operate in marsupial mammary glands, but although the data on autocrine control of milk secretion provide an explanation for the production of differing volumes of milk in adjacent glands, which is clearly controlled by the sucking activity of the young, the question of the control of milk compositional changes in adjacent mammary glands remains more open. These latter changes appear to be controlled by the secretory 'age' of the mammary gland and may therefore be regulated by the mother.

7.12 ADAPTIVE SIGNIFICANCE OF THE MARSUPIAL MODE OF PREGNANCY AND LACTATION

Marsupials have a different mode of reproduction from eutherian mammals, in that they give birth to small altricial young after a relatively short gestation. However, with the growing body of knowledge on marsupial reproduction it is clear that marsupials share with eutherians the same physiological complexities that control reproduction (Tyndale-Biscoe and Renfree, 1987). Progesterone is the essential hormone of pregnancy, oestradiol of ovulation and oestrus, and parturition is associated with a rise in prostaglandins and prolactin. Seasonal factors, notably photoperiod, influence the annual cycle of reproduction mediated by the pineal hormone melatonin (Tyndale-Biscoe *et al.*, 1986). Their lactational physiology is the most sophisticated of any mammal, and it is here that the greatest differences are apparent between the marsupial and eutherian mode of reproduction (Renfree, 1983). The teat is the umbi-

lical cord of the marsupial, and they have elaborated lactation instead of extending the period of intrauterine development with all its attendant hazards.

There has been a great deal of speculation as to which method is evolutionally superior; in general, perhaps because of a lack of knowledge, the marsupial mode has been assumed to be the 'primitive' and, by inference, inferior pattern. However, when the reproductive processes of the three groups of mammals – monotremes, marsupials and eutherians – are compared, many features are synapomorphic (derived) characters held in common by all three (Tyndale-Biscoe and Renfree, 1987). These are Graafian follicles, functional corpora lutea, bilaminar blastocysts, uterine secretion, yolk sac placentae, mammary glands and lactation. While monotremes retain some plesiomorphic (primitive) characters, such as egg laying, which show an early divergence from the stock leading to marsupials and eutherians, comparisons between marsupials and eutherians suggest a dichotomy in development from a common ancestral group of therian mammals, not a derivation of one from the other (Tyndale-Biscoe and Renfree, 1987). Most of the apomorphic characters of marsupial reproduction are associated with the greater emphasis on lactation than gestation.

Few attempts have been made to measure the cost of lactation (Rose, 1987; B. Green and Merchant, 1988; B. Green *et al.*, 1988). One way is to compare the maternal investment and the energy required to rear a young to weaning, and this has recently been done (Cork and Dove, 1989; Dove and Cork, 1989). Using the tammar and the sheep as models, it appears that the pattern of milk intake is similar in both types of mammals if eutherian lactation is compared only with the post-pouch exit life of marsupials. During pouch life, the marsupial pattern of milk energy intake is similar to that of the energy deposition in the eutherian fetus during pregnancy (Cork and Dove, 1989; Dove and Cork, 1989). These authors conclude that the energy cost of lactation in the tammar can thus be regarded as equivalent to the sum of the energy costs of pregnancy and lactation in the sheep. Furthermore, there are not large differences between these two herbivores in terms of weight-related allocation of energy to reproduction (Cork and Dove, 1989). Thus the marsupial strategy of spreading the offspring's intake of energy over a long lactation appears to be an important adaptation for a **small** grazing mammal living in a relatively aseasonal environment which is not faced with brief periods of seasonal food abundance. Thus, it can afford to have an extensive as opposed to an intensive grazing time, so giving it a relative ecological advantage. These important analyses of Cork and Dove show that the energy requirements for reproduction and development in their model marsupial, the tammar, fall within the range of comparable eutherians. Furthermore, they confirm that the transfer of energy in the form of milk is limited by the mother (Dove and Cork, 1989), just as the mother limits the period of pouch occupation in the Tasmanian rat kangaroos by dramatically constricting her pouch (Rose, 1986, 1987). These data are not consistent with the suggestion of Lillegraven *et al.* (1987) that energy transfer between mother and young during reproduction is less efficient in marsupials than in eutherian mammals, but show that these are highly derived patterns, and support the contention of Tyndale-Biscoe and Renfree (1987) that the major differences seen in the mode of reproduction in living mammals today evolved in response to the metabolic requirements of increasing body size and the ecological constraints imposed during the great adaptive radiations of mammals during the Tertiary epoch into new niches and ways of life.

ACKNOWLEDGEMENTS

I thank Professor R.V. Short and Drs G. Shaw, T.P. Fletcher and C.H. Tyndale-Biscoe for helpful discussions during the preparation of this chapter and Dr C.H. Tyndale-Biscoe for helpful criticisms of the manuscript. I am very grateful for the original photographs provided by Dr Lynne Selwood, Geoff Shaw, and David Parer, to Sharon Averill for assistance with electron microscopy, to Sue Simpson for the excellent artwork and especially to Sally Williams and Lynne Hepburn for their skill and patience in the mammoth task of typing the manuscript. A number of diagrams have been redrawn from *Reproductive Physiology of Marsupials*, C.H. Tyndale-Biscoe and M.B. Renfree, Cambridge University Press, 1987.

8.1 INTRODUCTION

This chapter is concerned with the physiology of the developing mammal from the time the major organs have developed to birth. Fetal physiology is of interest not only because during fetal life the foundations for future growth and performance are established, but also because the physiology of one animal growing within another is of interest for its own sake. As the fetus grows in size and the various body systems develop, so the 'physiology' of the fetus changes. Much of what we know has been based on studies in the last third of gestation when the fetus is relatively large. Special interest has also been directed to the fetus immediately before birth for, by understanding the behaviour of the fetus before birth, it is hoped to limit the damage caused by the delivery and to optimize the care of the newborn afterwards. Less is known about the physiology of the fetus in mid-gestation, although the development of several clinical techniques (ultrasonography, amniocentesis and fetal blood sampling) over the last decade has increased our knowledge of the biology of the human mid-trimester fetus (Pesonen *et al.*, 1983; Nicolaides *et al.*, 1985; Forestier, 1987; Forestier *et al.*, 1987; Peters and Nicolaides, 1990; Fisk and Rodeck, 1992; Stephenson, 1993).

We begin with a brief description of the intrauterine environment, followed by an outline of intrauterine growth and development, and the nature of the major hurdle the developing mammal has to jump at the time of birth. Section 8.2 gives an outline of the functions of the placenta related to the fetus, section 8.3 describes the working of the major systems before birth and section 8.4 highlights the adjustments made in those systems after birth. The endocrinology of pregnancy is considered elsewhere. Whilst the purpose of most functions is to support or protect the brain, the growth and function of the developing mammalian brain are not considered.

8.1.1 THE INTRAUTERINE ENVIRONMENT

The mammalian fetus has been likened to a fish swimming in its own private pool. Fellows of the Royal Society, soon after its formation, studied the survival of fish out of water in an attempt to understand how the fetus lived in the womb and adjusted after birth (Birch, 1956–57). It was a phenomenon which puzzled W. Harvey (1651). Barcroft (1946), a pioneer of fetal physiology, drew an analogy with a climber up a mountain; others prefer the idea of an astronaut floating in space with a supply cord. Helpful though these analogies are to illustrate some of the unusual aspects of the fetal environment, they can be misleading with respect to the whole.

The uterus protects the new mammal during a critical stage in its development. The membranous sac in which the fetus floats contains water with traces of salts and some protein debris of clinical interest and little else. In man, in the first half of pregnancy amniotic fluid volume related to fetal mass (Lind, 1978) is around 1.8 l per kg fetal body weight, and is probably a dialysate of fetal plasma. In mid-gestation, the skin lays down keratin and other chemicals which make the skin watertight, then the fetal fluid compartments cease to exchange through the skin with the surrounding amniotic fluid. In the second half of human pregnancy, fetal urine is the main contribution to amniotic fluid, the osmolality and sodium and chloride contents fall slightly, and the volume relates more closely to placental mass and is around 0.27 l/kg at term (Lind, 1981). There are more extensive studies on the characteristics and turnover of the fluids that surround other fetal mammals, particularly the sheep (Mellor, 1980).

The temperature of the fluid is determined by the mother's body temperature and, because the fetal metabolic rate is higher than that of the mother, the amniotic fluid tem-

Table 8.1 Gestation, birth weight and placental weight in various mammals.

	Gestation (days)	*Newborn body weight (g)*	*Placenta weight (g)*	*Placenta as a percentage of body weight*
Sheep	147	4500	350	8
Man	**280**	**3500**	**500**	**14**
Pig	120	1300	200	15
Monkey	168	500	100	20
Cat	63	100	15	15
Guinea pig	67	85	5	6
Rabbit	31	50	4	8
Rat	22	5	0.5	11
Mouse	19	2	0.01	9

perature is a fraction of a degree higher than the mother's deep body temperature. When the mother has a fever then the temperature of amniotic fluid rises, as does the fetal body temperature (Abrams, 1978).

The uterus protects the fetus from infection. The surrounding fluid is sterile. The placenta also protects the fetus, to some extent, from infectious organisms that enter the maternal bloodstream, depending on the gestation and the organism. Most common bacteria do not cross the placenta, but in man syphilis and listeria can both affect the fetus. Viraemia leads to fetal infection more commonly than bacteraemia. It has been known for some time that rubella (German measles) virus, varicella zoster virus (chicken pox) (G. Gilbert, 1993; McIntosh and Isaacs, 1993) and cytomegalovirus can all cross the placenta of the human fetus and cause miscarriage or fetal abnormalities. In the case of rubella, about 40% of women with a primary infection in pregnancy will pass the virus on to the fetus (Stagno, 1990), but it is not clear why transplacental infection does not occur in the other 60%. Human immunodeficiency virus and human parvovirus are more recently characterized viruses that can penetrate the defences of the human placenta to infect the fetus. The placenta can also be breached by parasites, such as those which cause toxoplasmosis (Peckham and Logan, 1993) and malaria. The rate of transmission of *Toxoplasma* from mother to fetus increases with increasing gestational age at the time of maternal infection (Holliman, 1992). Toxoplasmosis is one example of cross-species transmission of a zoonosis affecting both mother and fetus (Holliman, 1992).

The intrauterine environment is dark (there is no light to stimulate the eyes) and many mammals are born with fused eyelids. It is not silent: the sound of the heart beats and the bowel borborygmi reach the fetal ears but obviously have no meaning for the fetus. The fetus can contract its muscles and fetal movements do occur and are important for development (Prechtl, 1988), but the fetus is limited by the space available, and the movements become more restricted as the fetus grows. Fetal restraint can distort fetal growth causing postural deformities. In the more severe cases, often associated with profound oligohydramnios (sections 8.3.3b and 8.3.4), permanent abnormalities such as clubfoot and joint contractures may occur (Hensinger and Jones, 1992).

8.1.2 THE LENGTH OF GESTATION AND MATURITY AT BIRTH

Table 8.1 gives the length of gestation of some mammals commonly used for physiological studies and compares them with man.

Table 8.2 Fetal weight as a percentage of maternal body weight.

	Maternal body weight (kg)	*Newborn birth weight (g)*	*Average litter size*	*Fetal weight as a percentage of maternal weight*
Pig	130	1200	8	6.8
Sheep	70	4000	2	11.4
Man	**56**	**3500**	**1**	**5.6**
Monkey (rhesus)	8	500	1	6.3
Rabbit	2.5	50	6	14.0
Guinea pig	0.7	85	3	36.3
Rat	0.15	5	7	23.4
Mouse	0.03	1.5	8	37.3

In general, the larger the mother the longer the gestation. The mouse makes a new being capable of independent existence in 19 days; man takes 9 months. The newborn lamb weighs a little more, on average, than the human newborn but is made in half the time and is able to run and skip soon after birth. Thus, whilst the intrauterine environment is remarkably similar between species, the rate of growth and maturation of the fetus differs as widely as the appearance and performance of the adults. Clearly, inferences about one species based on data obtained from the study of another need to be drawn with care.

Table 8.2 also gives the litter size and an estimate of the total fetal weight as a percentage of maternal body weight.

Again there are wide variations; in the larger mammals the fetal weight forms a lower fraction. In the smaller mammals the fetuses alone (without the uterus, the fetal membranes and fluids) must make considerable demands not only on the mother's physical strength but also on the supplies of oxygen and nutrients. These demands are of a different order, relatively speaking, to the burden that the pregnancy at term places on the larger species.

Comparative physiology is fascinating in this area as in many others. The newborn polar bear weighs about 0.5 kg, which is only 0.3% of the weight of the mother; conversely, a single newborn bat can weigh as much as 30% of the adult weight. Analysis of the relationship between fetal and maternal weight has been the subject of a number of articles (Leitch *et al.*, 1959; Widdowson, 1970; Sacher and Staffeldt, 1974; Hofman, 1983). It has been proposed that the length of gestation is determined, at least in part, by the demands of brain growth and development.

The object of reproduction is to produce offspring capable of independent survival in the environment of their parents. In general, the young fall into two categories: those born into a protected environment, such as a nest or within the fur or arms of the parent, and those who run free soon after the moment of birth. The motor skills of the former are limited and the development of their motor cortex is at an early stage but they are very aware; their sensory cortex is well advanced. By contrast, in those that run free at birth both motor and sensory neural maturation are fairly advanced at birth.

The terms maturity and maturation, whilst clearly relevant to the subject, can be used in a confusing way. If adult size and performance are the gold standards, then all the fetal organs are immature. Obstetricians speak of a mature fetus in comparison with the term infant. However, in terms of biological function, the healthy fetus has physiological responses that meet its requirements at all times and thus to speak of immaturity of function of, for example, the fetal kidney and

Table 8.3 Growth rates before and after birth. (From Widdowson, 1970.)

	Length of gestation (days)	*Fetal growth rate (g/day)*	*Birth weight (kg)*	*Suckling growth rate (g/day)*

Mouse	21	0.09	0.002	0.47

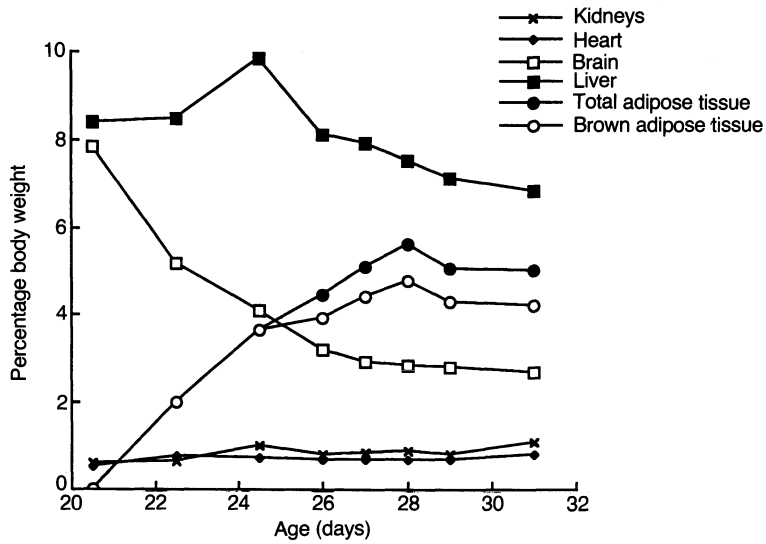

Figure 8.1 Organ weight as a percentage of body weight in the last third of gestation in rabbits.

imply therefore that it is in some way inadequate would be misleading.

8.1.3 THE RATE OF INTRAUTERINE GROWTH

Table 8.3 gives the length of gestation, birth weight and mean rate of growth of a range of mammals (Widdowson, 1970).

Whilst the larger mammals, weight for weight, do not achieve fetal development at the rate of the smaller mammals, their growth rates, in terms of weight gain per day, are remarkable. The fetal calf grows at 10 times the rate of the human fetus. Also shown in Table 8.3 are the rates of growth after birth whilst the young mammal is suckling. Again, the relatively slow-growing human young stands out as the exception.

Figures 8.1 and 8.2 give the organ weights in the last third of gestation in rabbits and man.

Table 8.4 gives the organ sizes of the mammalian fetus at birth.

Similar data are available for carcass and organ compositions. The human newborn, with its relatively large brain and high lipid content (Widdowson, 1950), is the exception, but then the human adult has a relatively large brain as well (Cross, 1979). The need to supply the requirements of the growing fetal brain has implications for transplacental transfer.

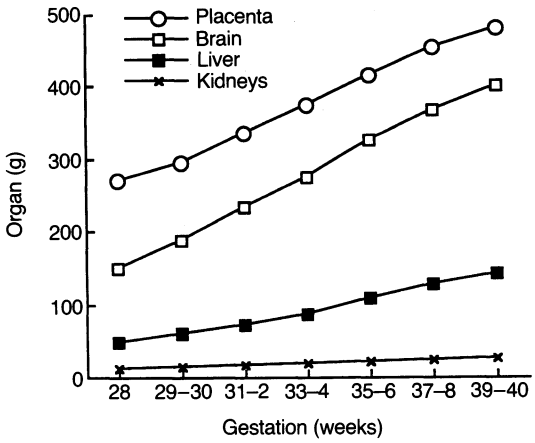

Figure 8.2 Fetal organ weight in man in the last third of gestation.

There are wide variations with respect to the amount of stored energy at birth. Most fetal mammals contain generous stores of glycogen in the liver and in muscle, but the amount of energy stored as fat varies widely (Shelley, 1961). By making assumptions about the metabolic rate, crude calculations can be made of starvation survival times after birth. Here again the human infant, with its relatively large store of triacylglycerol in white adipose tissue, is the exception (D. Hull, 1976) (Table 8.5).

Most other mammals are very dependent on the early establishment of oral feeding with the ready absorption of nutrients from the bowel.

This type of information is essential to the understanding of fetal growth and to any attempts to improve fetal development by modification of the maternal diet. These examples illustrate the wide variations between species and underline the differences in placental performance. They also illustrate why certain organs and systems are more vulnerable at various stages in development. The timing of these 'critical periods' differs between species with respect to phase in gestation and whether or not they occur before or after birth (Barker *et al.*, 1990; Lucas, 1991; Prentice, 1991; Atkinson, 1992; Steer *et al.*, 1992). The organ of major concern in this regard is the brain (Figure 8.3) (Dobbing and Sands, 1979).

The weight of the fetus at term, like the weight of the mother, is subject to biological variation (Figure 8.4).

In mammals, which usually produce a number of young, the fetal weight is increased if the litter size is very small and it may be reduced if it is very large. The values for rabbits are shown in Figure 8.5.

This reinforces the view that the environment provided by the mother determines fetal growth, and interest has been directed to, amongst other things, maternal nutrition (De Prins *et al.*, 1988; Prentice, 1991; Stephenson *et al.*, 1993a), uterine blood flow (F.C. Battaglia and Meschia, 1986), placental size (Mellor, 1984), placental position (Stevens, 1975), placental perfusion and umbilical blood flow (Stephenson *et al.*, 1990a). The studies are extensive, and there is no doubt that the severe manipulation of any of these factors will limit fetal growth. Which factors actually operate in small or large litters, or contribute to the production of a runt, or to intrauterine growth retardation in the human infant, are still not resolved. Nor can it be doubted that there are many factors within the fetus which determine and control its growth rate both in normal and disordered states (Van Assche and Robertson, 1982; Gluckman and Liggins, 1984).

8.1.4 THE CHALLENGE OF BIRTH

To complete this introduction to fetal physiology, it has to be recognized that the fetus not only establishes a pattern of growth to enable it to achieve adult size and performance, and maintains and controls its bodily systems within the intrauterine environment, but it also prepares itself for the challenge of the birth experience and the adjustment and acceleration of some functions after birth. Thus, an individual organ or structure in-

Table 8.4 Organ weights in newborn animals as a percentage of birth weight.

Rabbit	58	5	220	60	4
Rat	11	8	25	50	0.8

creases in size, develops, changes and modifies its functions and prepares itself for a major change in environment. Enzyme systems are induced in anticipation of birth; if they are not induced the system they support may fail. A prematurely delivered mammal may die not because a system, say the lung, is not anatomically developed, but because critical enzyme systems have not been induced, for example to enable the secretion of surfactant (Avery and Mead, 1959). For information on this and other aspects of the biochemical development of the fetus, the reader is referred to C.T. Jones (1982).

8.1.5 METHODOLOGIES

Our knowledge of fetal physiology is derived from a variety of sources and in this subject, perhaps more than in others, the original observations do not always justify the constructions that are put upon them. The problem is that the fetus is difficult to reach without interfering with it in some way. Much valuable information has been obtained by structural analysis of fetuses delivered normally or by Caesarean section of mothers kept under different conditions. Many observations have been made after experimental manipulation of the placenta in some way, for example tying a uterine artery in rats (Wigglesworth, 1964), or removing cotyledons in sheep (Mellor, 1984); and after experimental procedures on the fetus, for example removing the thyroid or occluding the trachea and allowing the pregnancy to continue (Jost, 1954). However, these studies of classical physiological mechanisms were made on the exteriorized fetus from an anaesthetized mother and most often the sheep has been the species employed (Dawes, 1968). The placental performance under such conditions was unlikely to be ideal, which led to the development of techniques to study the unanaesthetized fetus in the unanaesthetized mother by inserting catheters into various fetal channels, particularly the umbilical vessels, and allowing both mother and fetus

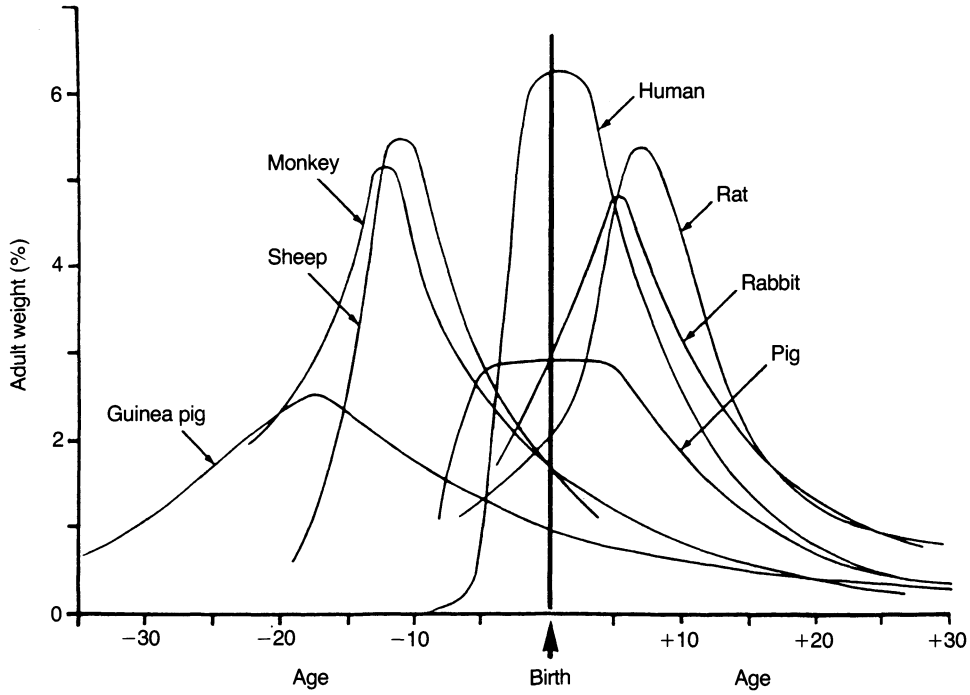

Figure 8.3 The brain growth spurts of seven mammalian species expressed as first-order velocity curves of the increase in weight with age. Rates are expressed as weight gain as a percentage of adult weight for each unit of time. The units of time for each species are as follows: guinea pig, days; rhesus monkeys, 4 days; sheep, 5 days; pig, weeks; man, months; rabbit, 2 days; rat, days.

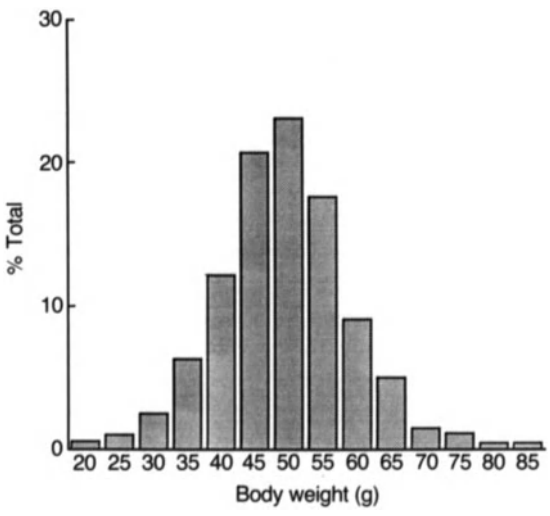

Figure 8.4 Distribution of birth weights of newborn rabbits.

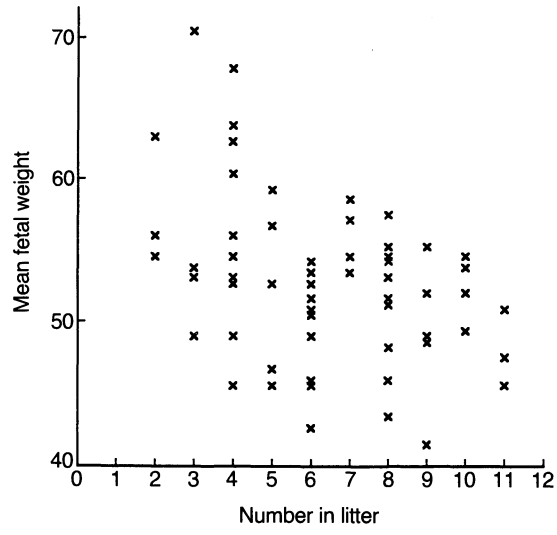

Figure 8.5 Mean fetal weight of rabbits in litters of different sizes.

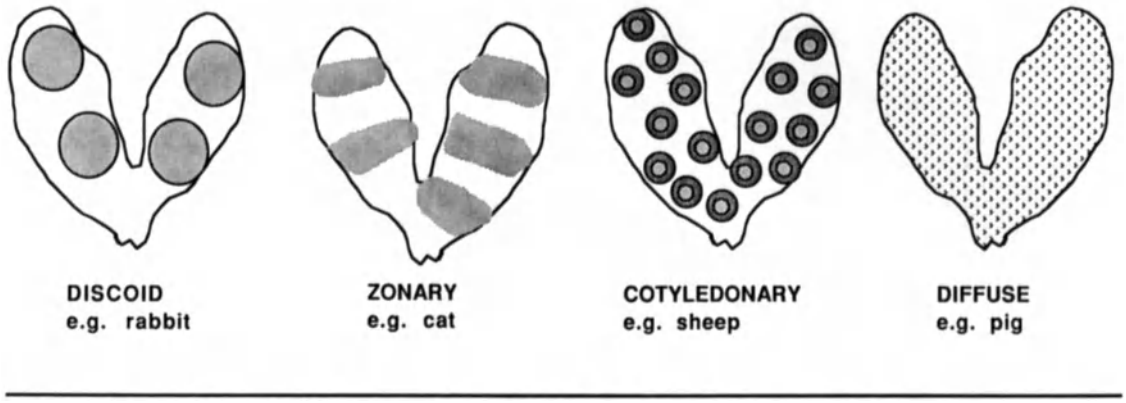

Figure 8.6 The different macroscopic structures of the mammalian placentae.

to recover (Rudolph and Heymann, 1980). This technique has been most successful in the fetal sheep, and much of our precise understanding of fetal physiology relates to that of the lamb (F.C. Battaglia and Meschia, 1986). A great deal of the work relating to placental transfer has been undertaken in the sheep, a mammal which is attractive experimentally because its large size allows repeated blood sampling and because the relatively unresponsive ovine uterus is invaluable in establishing chronically catheterized preparations. It must be remembered that the lamb (and in addition the sheep epitheliochorial placenta) has its own characteristics and, despite being of similar size to the human fetus, differs in a number of important ways.

Interpretations have also been made on spot samples taken from the fetus, for example during clinical procedures, and from studies on cord blood samples collected at birth. These have to be interpreted with caution but are sometimes all that is available. Measurements using isotopes in animals have given valuable information, but because of the many fluxes and spaces involved, calculations are not easy (Nathanielsz, 1980). The pre-term infant is mentioned briefly in section 8.4.5. However, whilst the prematurely born infant, after a brief period of adjustment, follows a similar growth curve as the fetus, its physiology is very different and provides very little information to help us understand intrauterine life.

8.2 THE PLACENTA

8.2.1 STRUCTURE

The **naked eye** appearance of mammalian placentae differs strikingly (Figure 8.6) (Stevens, 1975).

Organs such as the kidneys, liver, lung and brain are readily recognized, irrespective of the species; not so for placentae. The human placenta is shaped as a single thick dish (the word placenta means plate) which attaches itself to part of the uterine wall. Usually, the position is favourable, but occasionally it is not. It may settle over the cervical os and therefore bleed as labour commences and obstruct the outlet. Some monkeys have two such discs, whereas the sheep has many suction pads attached to predetermined sites (caruncles) whose supply and draining vessels join to form the umbilical vein and arteries. The dog and cat have placentae shaped like a collar which ring each fetus as it lies in

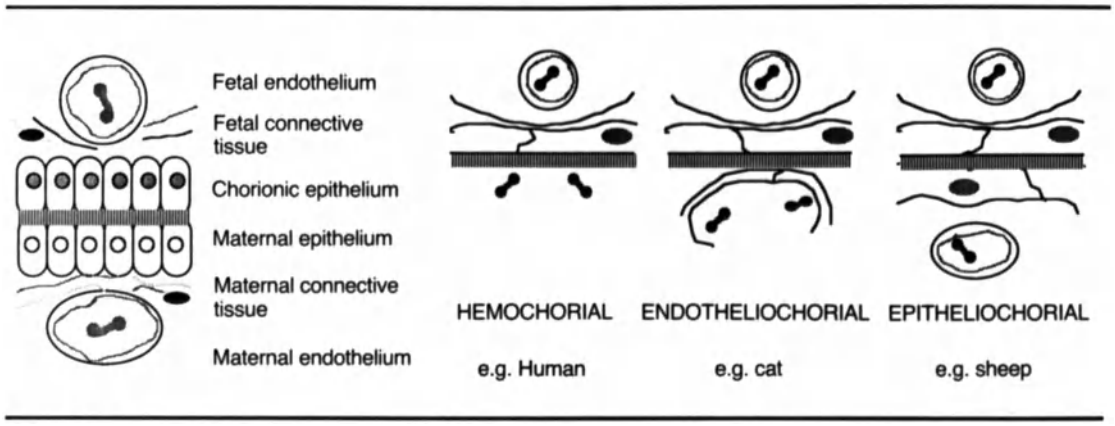

Figure 8.7 The microscopic structure of mammalian placentae.

the uterus, whereas the pig and the horse have a diffuse placenta that spreads all over the inner surface of the uterus. The significance or consequences of these anatomical variations is not known. For more on the subject of placentation see Chapter 4 of this volume.

There are equally striking differences in the **microscopic structure** (Figure 8.7).

The basic arrangement consists of a maternal blood vessel, connective tissue and epithelium, next to fetal epithelium, connective tissue and blood vessel. In some placentae all three are preserved, in others various maternal layers disappear; in man and rabbit, for example, no maternal layer of cells separates the maternal blood from fetal tissue so in that situation the whole of the placenta is a fetal organ under the direction of fetal genes. The placental barrier, that is the interface that chemicals have to cross to reach or leave the fetus, may therefore be anything from three to six cells thick. There does not seem to be any detectable difference in the transfer rates of oxygen or nutrients that obviously relate to structure; electrolytes and fatty acids may be different (Stephenson *et al.*, 1990b). The fetal–maternal interface is not of uniform thickness. Water and water-soluble substances cross the placental cells with more difficulty than fat and fat-soluble substances (Sibley and Boyd, 1988). Water is filtered through the cells, and between cells; the relative amounts of the two routes vary with the species (Stulc, 1988).

The capacity of the placenta as an organ of exchange is clearly going to be dependent on the **blood supply** to the two sides and their interface with each other. Here again there appear to be differences between species. Many have attempted, by anatomical studies, to disentangle the vascular arrangements to determine whether the direction of maternal and fetal blood flows run together, i.e. concurrent flow, or against each other, countercurrent. For an explanation of the implications of these arrangements and how the countercurrent arrangement works to maternal or fetal advantage depending on the relative blood flows the reader is referred to F.C. Battaglia and Meschia (1986).

The maternal blood supply transverses the myometrium in spiral arteries. As the human placenta implants these vessels are converted by intravascular cytotrophoblastic cells into wider uteroplacental vessels, which gently squirt maternal blood into the intervillus space. The vascular villus tissue begins to form by 3 weeks post conception. It then undergoes growth and arborization until it reaches its definitive shape by 16 weeks' gestation, after which time it grows in size and

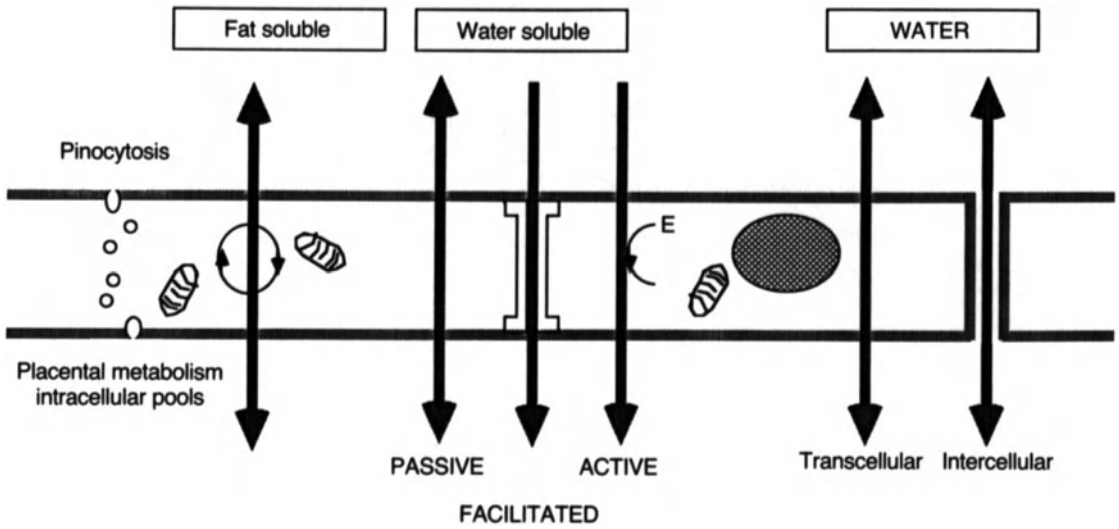

Figure 8.8 Modes of placental transfer.

complexity until term. One imagines the villus fronds washing about in maternal blood like seaweed in a troubled sea. This arrangement is closest to concurrent flow (Faber and Thornburg, 1983) or 'venous equilibration', and in that it resembles the sheep, which by contrast has a maternal epithelial layer. The horse has a placental countercurrent arrangement that works to 'fetal advantage', and the guinea pig one that works to 'maternal advantage'.

8.2.2 TRANSFER

The transfer of a substance from mother to fetus or vice versa may depend on, amongst other things:

1. The concentration of the substance in the delivery component of the maternal circulation; for glucose it is the level in the serum, for oxygen the partial pressure (Faber and Hart, 1966), and for fatty acids it is probably the concentration in the free fatty acid compartment.
2. The mechanism of transfer across the placental cell membranes, for example receptor sites (Sibley and Boyd, 1988).
3. The concentration in placental intracellular pool or pools.
4. The availability of appropriate carrier proteins if required (Stephenson *et al.*, 1993a).
5. The placental consumption of the substance.
6. The concentration in the blood feeding the fetal side of the placenta (Stephenson *et al.*, 1990b).

Substances cross by different routes; the transfer may be passive, facilitated or energy dependent or occur by pinocytosis (Figure 8.8).

(a) Water

Water diffuses across the placenta, either traversing the cells (transcellular) or running between the cells (paracellular). Some indication of the size of the paracellular route can be gauged by the diffusion coefficients of marker molecules. This has led to the view that the pores must be larger in the human haemochorial placenta than in the sheep epitheliochorial placenta (Boyd *et al.*, 1976; Faber and Thornburg, 1983; Stulc, 1988). Electrolytes in high concentrations in serum

such as sodium and chloride, will pass easily down the paracellular channels and equilibrate between the two sides.

Using labelling techniques, Hutchinson *et al.* (1959) calculated that 3.6 l/h was the transfer rate in the term human fetus weighing around 3.2 kg, and that 150 ml/h was transferred between the fetus and the amniotic cavity. The term fetus contains around 2.5 l, and accumulates water at a rate of 20 ml/day. Thus, the net transfer to the fetus is a very small fraction of the diffusional exchange (Hytten and Leitch, 1971; Hytten, 1979).

In the unstressed state, the total osmotic pressure in the fetal blood is below that in the mother, and it is not clear what counterbalances this. The pressure within the perfusing vessels may be a factor, as may the flow characteristics across the pores (see F.C. Battaglia and Meschia, 1986). If maternal osmotic pressure is lowered by infusion of hypotonic solutions, the fetus gains water (Tarnow-Mordi *et al.*, 1981); if hypertonic solutions are infused, then the fetus shrivels a little.

(b) Electrolytes and minerals

With the haemochorial placenta, the main extracellular electrolytes sodium and chloride cross to the fetus easily (Canning and Boyd, 1984). As with water, the bidirectional fluxes are much greater than the net flux; the main exchange is probably via the paracellular route, by which route water and electrolytes presumably move together as they do in serum. Water filtering across the cells is thought to be solute free, and sodium and chloride pass through in relatively small amounts. In the epitheliochorial placenta of sheep, the diffusion permeability is very low and may be controlled and in turn determine fetal growth (Faber and Thornburg, 1983). In the epitheliochorial placenta of the pig, sodium flux is thought to be unidirectional and energy dependent (Sibley *et al.*, 1986). Potassium transport in guinea pigs appears to be energy dependent (D.J. Bailey *et al.*, 1979).

(c) Calcium and phosphate

The growing fetus needs calcium to form bone. In the fetal sheep, the accretion rate has been calculated to be around 200 mg of calcium per kg per day. It also seems that in the fetal sheep there is mainly a one-way flow of calcium to the fetus, but in the monkey only around 20% of the calcium which enters the fetus is retained. Despite this net flux to the fetus in all mammals studied, the maternal concentrations of total plasma calcium and ionized calcium have been **below** fetal levels. Therefore, calcium does not flow down a pressure gradient to be taken up by fetal bone as required. Both calcium and phosphate are transported by carrier-mediated energy-dependent mechanisms (Care and Ross, 1984; Lajeunesse and Brunette, 1988; Stulc, 1988). There is some evidence that this active process is under the control of the vitamin 1,25-dehydroxycholecalciferol. This seems to be made in the maternal kidney and to be transferred across the placenta (Clements, 1988), and both the placenta and the fetal kidney have the capacity to convert it into its active form. By contrast, calcitonin and parathyroid hormone do not cross the placenta. As with many fetal systems they develop along with the structures they control. The parathyroid gland becomes active in early fetal life and is presumably involved in bone resorption and calcium homeostasis from an early stage (Brunette, 1989).

(d) Iron

Maternal serum transferrin, the carrier protein for iron, is the main source of fetal iron. The transferrin probably enters the placental cells by endocytosis, which is receptor mediated. The iron presumably enters an intra-

Table 8.6 Partial pressures, saturation and content of oxygen in the blood taken from the maternal uterine artery and vein and fetal umbilical artery and vein.

	PO_2 *(mmHg)*	*Oxygen saturation (%)*	*Oxygen content (vol. %)*
Maternal uterine artery	90	95	14.5
Maternal uterine vein	35	70	10.5
Fetal umbilical vein	28	65	13.0
Fetal umbilical artery	15	25	5.0

cellular pool before being released into the fetal circulation (Van Dijk, 1988).

(e) Blood gases

Table 8.6 shows the pressure gradient of oxygen as it travels from mother's blood to fetal blood.

The partial pressure of oxygen in fetal blood leaving the placenta (oxygenated but travelling in a vein) is relatively low compared with that leaving the lungs of a newborn infant (Comline and Silver, 1975). Nevertheless, because of the characteristics of the fetal haemoglobin–oxygen dissociation curve (section 8.3.2) and the relative polycythaemia of the fetus, the oxygen content is still high. Table 8.6 also gives the values for oxygen saturation and content of blood in the maternal and fetal circulations. The difference in oxygen dissociation combined with the difference in haemoglobin concentrations (the fetal haemoglobin concentration being higher than the mother's) results in the oxygen content in maternal uterine vein blood being lower than that in umbilical vein blood.

The rabbit placenta has a countercurrent system and is the most effective so far studied with respect to gas exchange (Faber and Hart, 1966). The primate placenta probably has a countercurrent system also, as have the guinea pig and the mare. The fact that umbilical venous oxygen tension can exceed that in the uterine vein is evidence in favour of this. Although the sheep cotyledon was originally thought to conform to the countercurrent pattern, more recent evidence has suggested that it may function as a double-pool venous equilibrator, a cross-current arrangement, or a mixture of concurrent and countercurrent exchanger types (Metcalfe *et al.*, 1965; Faber and Thornburg, 1983; F.C. Battaglia and Meschia, 1986). It also seems unlikely that the cow, another ruminant, possesses the countercurrent exchanger.

Maternal arterial blood gases do not vary greatly between species, but the blood gas tensions in the fetus do vary. The different uterine vein–umbilical vein PO_2 gradients in different species may reflect the range of exchanger types in the mammalian kingdom (Meschia *et al.*, 1967; Metcalfe *et al.*, 1967). This is an easier subject to speculate on theoretically than to elucidate experimentally, and much work remains to be done. Nevertheless, it now seems clear that the countercurrent arrangements found in man and rabbit can be exploited preferentially by either mother or fetus. This was predicted mathematically, and it has been demonstrated that the guinea pig countercurrent placenta works to 'maternal advantage' (a lower maternal placental blood flow for a given rate of placenta transfer compared with a concurrent arrangement), whereas the countercurrent placenta of the mare operates to confer 'fetal advantage' (a higher fetal substrate concentration for a given flow rate).

The fetus does not store oxygen. Therefore, it is dependent on a continuous supply and it must have a robust and efficient delivery system to survive. Considering its complexity, it is remarkably efficient. There is, however, an element of arteriovenous shunting in both maternal and fetal circulations, analogous perhaps in physiological terms to

Table 8.7 Oxygen consumption of the placenta and of the fetus in sheep. (From Battaglia and Meschia, 1986.)

	Oxygen content (μmol/ml)		
Maternal uterine artery	6.00		
	−	Uterine flow	1.35 × 1600
Maternal uterine vein	4.65	(1600 ml/min) =	2160 μmol/ml (maternal to placenta)
Fetal umbilical vein	5.45		
	−	Umbilical flow	1.47 × 800
Fetal umbilical artery	3.98	(800 ml/min) =	1176 μmol/ml (placenta to fetus)

the ventilation–perfusion mismatch which occurs in the lungs. The placenta itself has a high demand for energy; the figures calculated by F.C. Battaglia and Meschia (1986) for the sheep placenta are shown in Table 8.7.

This appears to be what economists call 'top slicing', but it is not clear that the placenta inevitably has priority.

The transfer of oxygen does not appear to be limited by the diffusion characteristics of the barrier. Rather, the restraints rest with supply and uptake. The supply taps directly into the maternal arterial supply, but it can be reduced by factors which interfere with uterine perfusion, and these include any stimulus which provokes sympathetic nervous activity or the release of catecholamines. Apparently uterine blood flow is optimal in the resting state.

The umbilical circulation is unique in that it appears to have no innervation and the umbilical artery shows little or no response to changes in partial pressures of oxygen, carbon dioxide, pH or catecholamines. Hormones such as angiotensin II, vasopressin or prostaglandins may play a physiological role in placental fetal vascular resistance (e.g. Tuvemo, 1980). However, anyone who has attempted to catheterize the umbilical artery will have no doubts about its ability to contract. Notwithstanding this, the current position appears to be that the resistance in the major vascular bed of the fetal circulation, namely that through the placenta, is determined primarily by its anatomy.

Thus, given a fixed umbilical flow, a flow-limited transfer across the placental membranes and a supply pool formed from maternal arterial blood, the oxygen content of the umbilical vein will remain fairly constant, and the oxygen content in the umbilical artery will directly and immediately reflect fetal oxygen consumption. The way the fetus appears to exert control over its oxygen supply is by changes in the umbilical arterial partial pressure.

The robustness of the system is reflected by its reserve capacity. This is illustrated by the clinical condition of rhesus incompatibility, in which maternal antibodies cross the placenta and destroy fetal red cells, causing the fetus to become anaemic. The fetal haemoglobin can fall to one-third of normal and the fetus still survives.

Carbon dioxide also diffuses readily across the placental membranes, and the diffusion capacity is some 20 times that of oxygen. The umbilical artery/maternal artery difference is around 5 mmHg. In women, this pressure difference is in part due to the lowering of the

Table 8.8 Glucose concentration in maternal and fetal blood. (From Shelley, 1979.)

	Blood glucose (mg/dl)			
	Maternal	*Fetal*	*Ratio*	*Source of fetal blood*
Sheep	60	15	4.0	Umbilical catheter
Cow	70	23	3.0	Umbilical catheter
Horse	80	40	2.0	Umbilical catheter
Rabbit	58	40	1.5	Neck vessels
Man	**71**	**63**	**1.3**	**Scalp stab**

maternal PCO_2 due to increased pulmonary ventilation, which gradually increases towards term.

(f) Glucose

Glucose is subject to fairly strict homeostatic control in the maternal circulation and thus it is always present on the maternal supply side. Glucose is as constantly and readily available as oxygen. On average, the fetal serum concentration of glucose is lower than that in the maternal circulation but the average concentration gradient varies widely between species (see Table 8.8; Shelley, 1979).

Glucose passes through the placenta as it does into red cells, that is at a faster rate than might be expected on the basis of simple diffusion alone and certainly faster than many chemicals of similar structure and size. There are 'doors' that open only to glucose because there is a carrier system which binds glucose molecules selectively. The evidence that glucose crosses the placenta by facilitated transfer is compelling (Shelley, 1979). It is the nature of facilitated transfer that it has a limit, that it can be saturated and that it can also be reduced by competition with like chemicals. Given those characteristics, transfer will be determined by the maternal–fetal gradient, the blood flow on both sides and by the morphology of the placenta. But is it subject to further control? Fetal pancreatectomy led to intrauterine growth retardation (Fowden *et al.*, 1984; Fowden, 1989), although there was relative sparing of brain growth, and decreased fetal uptake of the glucose from the placenta. However, it was unclear whether this decreased uptake was simply due to a decreased gradient across the placenta, because of the fetal hyperglycaemia following pancreatectomy, or was mediated via decreased stimulation of the insulin receptors on the placenta (Posner, 1974; Witsett *et al.*, 1979; Potau *et al.*, 1981). It is not known whether these insulin receptors are on the fetal or maternal surface of the placenta. In the experiments by Fowden and co-workers (Fowden, 1989), fetal glucose utilization fell by half, presumably because of the impaired entry of glucose into cells in the absence of insulin. However, approximately half of fetal glucose metabolism appeared not to be insulin dependent, although this proportion might have been raised artefactually by the fetal hyperglycaemia (see above) and hence an increased gradient for transfer of glucose into cells.

In contrast, when fetal insulin concentrations were increased (Kervan and Girard, 1974), umbilical glucose uptake was enhanced (F. Battaglia and Hay, 1984). This occurred whether or not the fetal hyperinsulinaemia was created by an exogenous fetal insulin infusion (Bassett and Madill, 1974; Simmons *et al.*, 1978) or by the stimulation of endogenous fetal secretion (R.D.G. Milner and Hales, 1965; Kervan and Girard, 1974; Phillips *et al.*, 1981). The placenta possesses both insulin (Posner, 1974) and somatomedin receptors, which may promote placental growth (Demers *et al.*, 1972) or the transfer of

nutrients across the placenta (Gluckman and Liggins, 1984). Whilst many other hormones have been shown to exert an effect on fetal metabolism and substrate utilization (Fowden, 1980; Fowden *et al.*, 1990), few studies have investigated their effects on placental transfer.

As with oxygen, the placenta takes what glucose it needs before passing on the remainder (F.C. Battaglia and Meschia, 1988). In the lamb, the placenta consumes glucose at twice the rate of the fetal body and double-labelling experiments suggest that much of the glucose (and some of the amino acids) for placental metabolism is taken up from the fetal circulation and not directly from the maternal circulation (F.C. Battaglia and Meschia, 1986). The lamb placenta makes lactate and releases it into both the maternal and the fetal circulation, which makes a significant contribution to the energy supply to the fetus, around 25%. Lactate may be an important source of energy in other mammals and its presence in the fetal circulation does not necessarily indicate anaerobic metabolism.

(g) Fructose

Fructose, unlike glucose, does not cross the placenta, which emphasizes that the facilitated transport of glucose is specific and the carrier will not bind any hexose molecule. Some fetal animals make fructose but do not readily use it as an energy source, so-called 'fructogenic species' (e.g. the lamb). Fructose is found in the fetal circulation of those species which have placentae which are relatively impermeable to sodium, potassium and chloride (e.g. the sheep and goat). The supplies of these electrolytes are only ensured by steep concentration gradients across the placenta. Fructose increases the osmotic pressure in the fetal circulation, and it is postulated that this may act to offset the osmotic pressure generated by the higher electrolyte concentrations on the maternal side of the placenta (Faber and Thornburg, 1983; Canning and Boyd, 1984). Fructose is not present in significant amounts in the fetal plasma of species with a haemochorial placenta in which electrolyte diffusion permeabilities are much higher, and in 'fructogenic species' plasma fructose concentration falls rapidly after birth (F. Battaglia and Hay, 1984). Both of these observations are consistent with the proposed role of fructose in transplacental osmotic balance. The only other suggestion for a potential role for fructose has come from studies showing that fetal fructose concentrations fall as maternal fasting progresses in pregnant sheep. Perhaps fructose represents a slowly mobilized substrate for gluconeogenesis by the fetus (Hay, 1979).

(h) Amino acids

This mixed group of organic compounds, characterized by the presence of nitrogen, are the building blocks of protein; the fetal proteins are formed from amino acids which cross the placenta. Amino acids travel free in the circulation. The concentrations in the maternal circulation are lower than those in the fetal blood, but both are lower than the placental intracellular concentrations, which inter-relate with protein turnover in trophoblast cells. Table 8.9 gives the main amino acids and indicates the mechanisms of placental transfer, which differ depending upon the form of the amino acid, some of which are actively transferred.

Placental and fetal tissue metabolize and change amino acids depending in part on protein turnover. Protein turnover in the placenta and fetal tissues occurs at 10–20 times the rate in maternal tissues.

The net flux of most, but not all, amino acids is from the placenta into the fetal circulation. The data for sheep reported by Lemons *et al.* (1976) show that the net flux does not mirror the fetal requirement for structure. For example, glutamine passes from the fetal circulation **into** the placenta.

Table 8.9 Transport of amino acids across the placenta.

	Metabolism	*Examples*	*Transport*
Acidic	Purine and pyrimidine synthesis	Aspartate Glutamate	Little transported
Neutral	Glucogenic	Glycine Alanine	Active Energy dependent
	Ketogenic	Valine Leucine	? Passive
Basic	Protein structure	Lysine Histidine	Active Energy dependent

Table 8.10 Maternal and fetal plasma fatty acids (mmol/l).

	Maternal plasma	*Fetal/Newborn plasma*		*V–A difference*
		Umbilical vein	*Umbilical artery*	
Pig	0.217	0.037	0.024	±
Cat	0.320	0.190	0.180	±
Sheep	0.578	0.097	0.124	±
Man	**1.010**	**0.242**	**0.206**	+
Rabbit	1.09	1.10	0.70	+

The acidic amino acids do not appear to cross the placenta in significant amounts, and aspartate and glutamate are presumably made from asparagine and glutamine. The basic amino acids appear to be transferred in amounts just sufficient for structure. The neutral amino acids, in particular, are transferred into the fetal circulation in excess of fetal requirement and are thought to be an energy source (M. Young, 1979; F.C. Battaglia and Meschia, 1986).

(i) Fatty acids

Glucose is the main source for fetal cellular energy in man, and a major source in lambs, and amino acids are essential for the construction of protein, so it is not unexpected that both have been shown to cross the placenta in substantial amounts in all species studied, and it would be most unlikely that the same is not true for all mammals. The position with respect to fatty acids is different. In some species, the placenta is relatively permeable to fatty acids, in others it is not.

Table 8.10 gives the free fatty acid concentrations in maternal and fetal circulations of a number of species.

It does appear that those placentae with maternal layers, e.g. lamb, pig and cat (Elphick *et al.*, 1979, 1980; Elphick and Hull, 1984), are not permeable but that those without are permeable. However, the horse, with a six-layer placenta, is an exception to this generalization (Stammers *et al.*, 1987). In those species which let fatty acids through, the transfer appears to be related to maternal free fatty acid concentrations, and if the maternal level goes up, as it does with stress, starvation and labour, then more fatty acid

flows to the fetus (Hershfield and Nemeth, 1968; Elphick *et al.*, 1978a,b; Haugel *et al.*, 1988; Stephenson *et al.*, 1990b). Some mammals voluntarily starve themselves prior to delivery, the rabbit being an example; the effect is to fatten the fetus and thus increase the energy stores of the newborn at birth (Edson *et al.*, 1975). Fatty acids in exogenous and endogenous triacylglycerol fractions may also be available to the placenta and so to the fetus (Stephenson *et al.*, 1993b). Certainly the maternal free fatty acid fraction does not appear to be the sole source in rabbits (Stephenson *et al.*, 1990b).

In the main, fatty acids in the free fatty and triacylglycerol serum fractions reflect dietary lipids, which are of variable chain length, mainly between 14 and 20 carbon atoms, with either zero, one, two or three unsaturated bonds. Linoleic acid ($C_{18:2}$) and linolenic acid ($C_{18:3}$) are essential fatty acids and important for the structure of membranes in all tissues, including the brain (Anderson *et al.*, 1974; Brenner, 1984; Carlson *et al.*, 1986; Brody *et al.*, 1987; Koletzko *et al.*, 1989; Uauy *et al.*, 1990). In general, the differing fatty acids cross the placenta in proportion to their concentrations in the maternal free fatty acid compartment, but there are exceptions, and the flux may depend on competition for carrier proteins (Brandes *et al.*, 1987; Stephenson *et al.*, 1993a). Arachidonic acid ($C_{20:4}$), the precursor of prostaglandins, may be made by desaturation of linoleic acids in the placenta or by selective uptake of arachidonic acid from maternal phospholipids, as arachidonic acid enters the fetal circulation in excess of that which might be expected from maternal concentrations. The problem remains as to how the essential fatty acids reach the fetal sheep or fetal pig, for significant arteriovenous differences in free fatty acids have not been detected.

With the exception of arachidonic acid and, in one uncorroborated study, oleic acid (Hendrickse *et al.*, 1985), the evidence points to non-selective transfer of free fatty acids across the human and rabbit placenta. Non-selective uptake by the placenta from the maternal circulation does not easily explain the high percentage of arachidonic acid found in the free fatty acid fraction of the placenta itself (Robertson and Sprecher, 1968). The free fatty acid composition of the placenta is sufficiently different from that of the maternal plasma to suggest that at least some components of the placental free fatty acid pool are derived from other sources. It seems more likely therefore that the placenta alters the pattern of free fatty acids presented to it before they enter the fetal circulation rather than there being a selective mechanism favouring transplacental transfer of particular longer chain fatty acids. The human placenta has the capacity to elongate and desaturate $C_{18:2n6}$ (linoleic acid) to $C_{20:4n6}$ (arachidonic acid) *in vitro* (Zimmerman *et al.*, 1979). Alternatively, maternal phospholipids are rich in 20:4n6 and human and rat placentae have been shown to contain the phospholipases necessary for release of polyunsaturated fatty acids from phospholipids (Robertson and Sprecher, 1967; East *et al.*, 1975). In infants with severe intrauterine growth retardation, or those born to women with pre-eclampsia, Mead acid has been consistently found in the fetal plasma. This is considered to be a marker for severe malnutrition in adults (Rivers and Frankel, 1981; Orchard *et al.*, 1983).

Very different results were obtained in the sheep (Leat, 1966). The profile of fetal plasma lipids suggested synthesis from non-lipid precursors and the degree of unsaturation of free fatty acids was consistent with a relative paucity of essential fatty acid transfer across the placenta from the ewe. Although the sheep placenta has a very low permeability for fatty acids, there is a suggestion that even in this species essential fatty acids are handled differently from non-essential fatty acids. In experiments on chronically catheterized fetuses in which [^{14}C] linoleic acid and [^{3}H] palmitic acid were infused intravenously

into three ewes, only traces of label crossed the placenta, but these traces were almost entirely confined to ^{14}C (Elphick *et al.*, 1979). Although the data suggested that the ^{14}C label had crossed the placenta as [^{14}C] formate and [^{14}C] acetate (i.e. short-chain metabolic breakdown products of linoleic acid rather than intact linoleic acid), virtually no ^{3}H-labelled products derived from the non-essential palmitate appeared in the fetus. The linoleic acid content of fetal lamb adipose tissue, liver, lung and cerebellum was very low (Elphick *et al.*, 1979), and these authors estimated that, although only a maximum of 4 mg/day of linoleic acid could be transferred across the sheep placenta, this might be sufficient to account for the 500 mg of linoleic acid in a term lamb.

Amounts of other longer chain free fatty acids ($C_{22:5n3}$ and $C_{22:6n3}$ in addition to $C_{20:4n6}$) over and above the amount predicted from non-selective transfer have been found in the pig (Elphick *et al.*, 1980), a species in which transfer of free fatty acids is generally very low. Examination of the published data from the sheep (Elphick *et al.*, 1979) shows that, although there was no evidence of net transfer of free fatty acids into the umbilical circulation, $C_{20:4n6}$ accounted for a greater proportion of the free fatty acid fraction in fetal blood than maternal blood. It could be argued that in these species with multi-layered placentae relatively impermeable to lipids, there would have been a strong evolutionary advantage if essential fatty acids were handled more favourably. Presumably, this is because the fetus still requires essential fatty acids and these must be donated by the placenta even if the placental characteristics are otherwise hostile to lipid transfer.

In conclusion, the fetus draws from the placenta a variable mixture of glucose and amino acids for energy (with lactate in sheep) and amino acids and fatty acids for structure. We are only just beginning to understand the mechanisms involved and know little of the controlling factors. This section, at best, is a brief overview of a fascinating and complex biological system.

8.3 FETAL PHYSIOLOGY

8.3.1 HEART AND CIRCULATION

A circulation is essential for any complex organism; the developing fetus needs to draw nourishment either from the yolk sac or later from the maternal bloodstream via the placenta. In man, the heart tube begins to contract by the end of the third week of gestation and to achieve unidirectional flow by the end of the fourth. The beating heart can be recognized with ultrasonography by the seventh post-menstrual week of human pregnancy. Whilst it is pumping, the internal septa develop and the tube gently contorts to the shape found in the second half of gestation and in adult life.

Despite its form, the fetal heart acts more like a single pump. Both ventricles discharge the majority of their output into the systemic circulation, and ventricular function is often considered in terms of the combined ventricular output. The combined ventricular output is approximately 400 ml/min/kg in the near term fetal sheep (Teitel, 1992), which is approximately the same as the output of each ventricle when they are pumping in series after birth. There is, therefore, a dramatic increase in ventricular output after birth. The right ventricle ejects about two-thirds of the combined ventricular output in the fetal lamb, but in the human fetus this fraction is somewhat less because of the greater brain blood flow, which is supplied by the left ventricle. However, Doppler ultrasound studies in the human fetus have confirmed that the right ventricle is still predominant, and this is consistent with the 'right dominant' voltages seen in the chest leads of the neonatal electrocardiogram (O'Callaghan and Stephenson, 1992). Although the ventricles function in parallel in prenatal life, the chambers perform similar functions to post-natal life. The

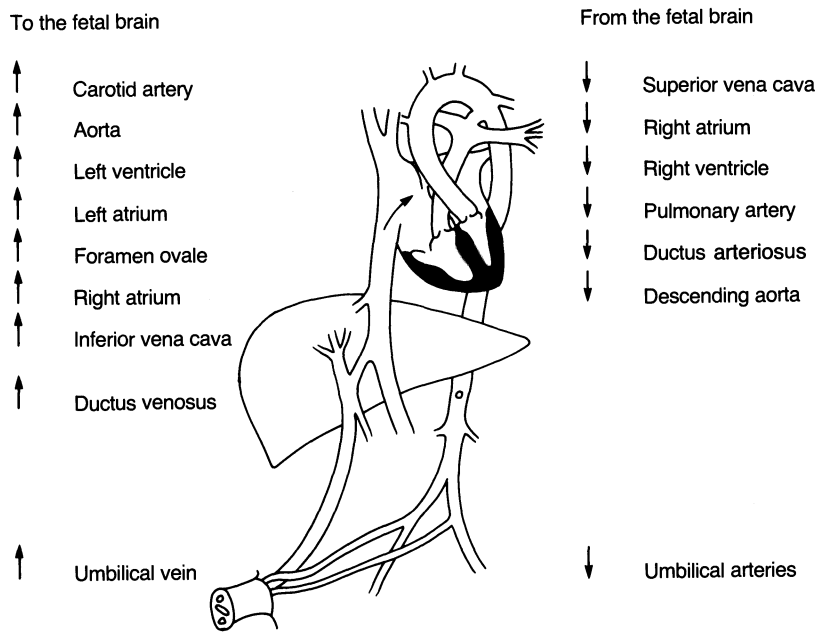

Figure 8.9 The fetal circulation.

fetal right ventricle primarily delivers blood for oxygen uptake (because post-ductal blood perfuses the placenta), just as in post-natal life the right ventricle pumps blood to the lungs; and the fetal left ventricle principally ejects blood for oxygen delivery (well-oxygenated blood, via the foramen ovale, for the coronary arteries and brain), just as the left ventricle supplies the systemic circulation after birth.

If one ventricle fails to form *in utero*, e.g. hypoplastic left heart, then the fetus experiences no difficulty but the condition is quickly fatal after birth. Very rarely in twins, the heart of one twin supports both of them so that one twin has no heart at all (acardia).

(a) Distribution

It is not so much the structure of the heart and vessels as the route of oxygen supply which is so different in the fetus (Figure 8.9).

Oxygenated blood passes up the umbilical vein or veins from the placenta to join the portal vessels and ductus venosus in the liver. The ductus venosus provides a short-cut between the umbilical vein and the inferior vena cava. Not all fetal mammals have one, for example foals do not. The oxygenated blood passes via the ductus venosus to the vena cava, from where it is preferentially streamed through the foramen ovale in the atrial septum to the left atrium, so to the left ventricle and from there to the coronary and cartoid arteries. This wonderful adaptive mechanism can be demonstrated beautifully with modern 'colour flow' Doppler ultrasound equipment. Deoxygenated blood returning from the upper (superior vena cava) or lower (inferior vena cava) parts of the body flows into the right atrium, on to the right ventricle and into the pulmonary arterial trunk. However, little of this pulmonary arterial blood flows into the high-resistance vascular bed of the lungs; rather, the majority of the right ventricular output passes through the ductus arteriosus and down the aorta to the iliac vessels, from which arise the two

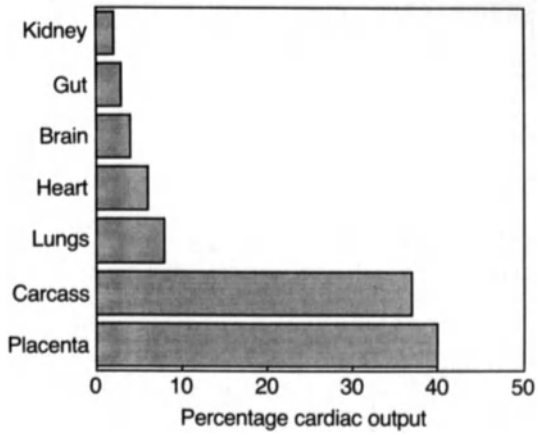

Figure 8.10 Percentage distribution of the fetal cardiac output.

large umbilical arteries which take the blood back to the placental bed. In the fetal lamb, approximately half of the combined ventricular output enters the umbilical arteries.

As a result of this anatomical arrangement, between 75 and 80% of the blood supply to the liver is from the umbilical vein, and this will be oxygenated blood rich in nutrients. Most of the remainder of the supply comes from the portal vein; in the fetal lamb, most of the portal blood goes to the right lobe of the liver; thus the liver will have a low risk for damage due to fetal hypoxia. The brain and heart receive a preferential delivery of oxygenated blood. In lambs, these organs take around 4 and 3% of the combined output respectively (Figure 8.10).

In man, the fetal brain receives 15% of the cardiac output. The lungs, on the other hand, are perfused with blood with relatively low oxygen content and partial pressure. So too are the kidneys and bowel.

(b) Hypoxia – a challenge

The mature adult heart responds to acute hypoxia by an increase in rate and cardiac output and with a redistribution of the circulation. The fetus may experience hypoxia following an interruption in oxygen supply anywhere from the mother's nose to the umbilical vein. Depending on which, the effects may be different. Experimental studies which induced hypoxia by lowering fetal arterial oxygen content, limiting umbilical blood flow or clamping the umbilical vein all caused fetal bradycardia and a reduction in combined ventricular output to some degree. Teleologically, this paradoxical response may be appropriate in so far as myocardial oxygen consumption will be reduced with the fall in heart rate and is directly comparable with the diving reflex in marine mammals. With maternal hypoxaemia or fetal anaemia, which have relatively less effect on cardiac output, the circulation to fetal heart and brain were enhanced, whilst those to gut, kidney and lung were reduced. These are the organs which are damaged, sometimes irreparably, by intrauterine hypoxia (Peeters *et al.*, 1979; Fumia *et al.*, 1984). It is noteworthy that, in the majority of fetal tissues, oxygen delivery is maximal at the relatively high haematocrits of the normal fetus (Fumia *et al.*, 1984). Cord clamping, as might be anticipated, invariably reduces cardiac output; the circulation to the brain and heart, whilst not enhanced, is maintained, but all other organs suffer.

Most of these classical experiments were performed with acute challenges. Of equal importance are the effects of chronic hypoxia, which have been studied in much less detail. However, recent experiments in the chronically catheterized sheep exposed for up to 4 days of hypoxia have again demonstrated the remarkable 'oxygen margin of safety' of the fetus compared with the mature animal (Rurak *et al.*, 1990). Initially, an imposed 40% reduction in oxygen delivery to the fetoplacental unit was compensated for by a 30% increase in umbilical blood flow. By 8h, there was a progressive metabolic acidaemia and a 70% reduction in oxygen delivery, but myocardial oxygen delivery was maintained.

The fetus has, in addition to these primary cardiovascular reflexes of bradycardia and

blood flow redistribution, many other adaptive mechanisms which help protect it against hypoxia. The higher oxygen-carrying capacity of the blood is described below. Fetal tissue oxygen extraction can increase and metabolic activity can be reduced, aided by behavioural state changes and reduced fetal movements. The human fetal liver is much larger, as a fraction of total body weight, than the adult organ, and this is partly due to extensive liver glycogen stores. Aerobic glucose metabolism is the optimum energy source for the normoxic fetus as this provides the maximum amount of ATP per unit of oxygen. During hypoxia, hepatic glycogenolysis releases large amounts of glucose to fuel the less efficient production of ATP from anaerobic metabolism (utilization of fetal myocardial glycogen is also an important factor in the fetal resistance to hypoxia). Hence, the growth-retarded fetus is much more vulnerable to asphyxia because the reserves of liver glycogen, and peripheral stored fat, have already been depleted.

There are also hormonal adaptations to fetal hypoxia (Court *et al.*, 1984; Martin *et al.*, 1987; Cheung and Brace, 1988). Infusion of adrenaline or noradrenaline into the sheep fetus results in a lowering of fetal insulin concentrations and an elevation of fetal cortisol and lactate concentrations and femoral artery PaO_2 (Hooper and Harding, 1990). Catecholamine concentrations rise in the fetus in response to both acute and chronic hypoxia, and one interpretation of these infusion experiments is that this humoral response may protect the hypoxic fetus by inhibiting insulin secretion, reducing entry of glucose into peripheral tissues, thereby sparing tissue oxygen consumption and allowing oxygen and glucose delivery to the brain to be maintained.

There are a few clinical footnotes which are relevant to this discussion of acute and chronic fetal hypoxia. Traditionally, the Apgar score, based on heart rate, respiration, muscle tone, reflex response and colour (Apgar, 1953), has been used to assess the degree of asphyxia of the human infant at birth. In theory, the more asphyxiated the infant, the worse the Apgar score, although the soundness of this correlation has often been questioned (Marlow, 1992). Umbilical arterial or venous pH has been suggested to be a more accurate marker of intrapartum hypoxia than the subjective Apgar score, but there is little evidence from longitudinal studies that cord acid–base status is a reliable predictor of brain damage (Dennis *et al.*, 1989). It seems that chronically hypoxic infants with a metabolic acidosis, who do not respond to further acute hypoxia with increasing acidosis, may be at greatest risk of subsequent handicap (Dennis *et al.*, 1989). The implication is that, in the human infant, the ability to respond to intrapartum hypoxia with acidosis, suggesting a switch to anaerobic metabolism, is protective, and this is consistent with the animal data described above. Unfortunately, however, prospective studies have not shown cord lactate concentrations to be of predictive value (Marlow, 1992). Abnormalities of the fetal heart rate pattern or morphology (loss of variability, decelerations or ischaemic changes), measured through the mother's abdomen by ultrasound or from a fetal scalp electrode, have been described as indicators of fetal hypoxia. However, monitoring the fetus during labour may not improve the outcome (D. MacDonald *et al.*, 1985). The presence of meconium in the amniotic fluid, assumed to reflect a stress response by the fetus, is an unreliable indicator of intrapartum asphyxia. In terms of active therapeutic interventions to help the fetus, as opposed to simply monitoring fetal well-being, one study has shown that in the human maternal hyperoxygenation may improve fetal outcome (F.C. Battaglia *et al.*, 1992).

(c) Control

The control of the fetal circulation by baro- and chemoreceptors, central and peripheral, and other higher nervous mechanisms has received much attention over the last three decades (Biscoe *et al.*, 1969; Purves, 1981; Hanson, 1993). The hypoxia-induced bradycardia in the late-gestation fetal sheep appears to be primarily mediated via peripheral chemoreceptors and the vagus (Walker, 1984). A qualitatively similar response to fetal hypoxia is seen in the llama but at an earlier fractional gestation, and this may represent an evolutionary adaptation in an animal which may climb to 15 000 feet altitude during the pregnancy (Benavides *et al.*, 1989).

Baroreceptors are located at the bifurcation of the carotid arteries (carotid sinus) and in the aortic arch, and vagal discharge synchronous with the fetal arterial pulse has been recorded in fetal lambs (Ponte and Purves, 1973). The maturation of the function of the baroreceptors during fetal life has been studied in the sheep fetus but, although baroreceptor sensitivity appears well developed in the newborn human infant (Long and Henry, 1992), baroreceptor reflexes exhibit a depressed sensitivity at birth and a progressive post-natal maturation to adult levels (Walker, 1984). Induced decreases in heart rate using an aortic balloon in fetal lambs were abolished by denervating the carotid sinus and stripping the aorta, suggesting a functional role. Atrial stretch receptors also appear to be competent in fetal life (Stephenson and Broughton-Pipkin, 1990) and may contribute to the regulation of blood pressure via their influences on circulating volume (Cheung and Brace, 1989). As gestation proceeds, baroreceptor sensitivity remains unchanged but baroreflex sensitivity to an increased blood pressure decreases and sympathetic tone increases, both of which may contribute to the increase in blood pressure which is seen with increasing gestation (Stephenson *et al.*, 1991). Baroreceptors also discharge in response to hypoxia (Eckberg and Sleight, 1992). The role of central neuroregulatory mechanisms in controlling blood pressure in the fetus, and their interaction with intravascular volume, remains unclear. A number of new transmitters which may be involved in this process have been investigated recently, but a full discussion is outside the scope of this review and the reader is referred elsewhere (Long and Henry, 1992). The renin–angiotensin system is active in fetal life (Stephenson *et al.*, 1991) and may contribute to control of blood pressure (Iwamoto and Rudolph, 1981).

The fetal heart responds weakly, if at all, to increased peripheral resistance, and a rise in peripheral resistance results in a fall in cardiac output. The cardiac output varies primarily with heart rate, there being much less variability in stroke volume in the fetus. Fetal tachycardia means increased output, bradycardia a decrease and a marked bradycardia causes a marked decrease in cardiac output.

8.3.2 BLOOD AND OXYGEN TRANSPORT

(a) Red blood cells

The need for an efficient oxygen transport system is paramount for the growth and development of the conceptus. The evolution of the respiratory proteins, from a relatively simple form like myoglobin to the more complex haemoglobins, allowed an increase of some hundredfold in the oxygen-carrying capacity of extracellular fluids. Initially, most mammalian species produce an embryonic and/or fetal form of haemoglobin with a higher affinity for oxygen than the adult form. This is not, however, universal, and neither cats nor pigs appear to make a 'fetal' haemoglobin (Hb_F; Delivoria-Papadopoulos *et al.*, 1974).

In the very early stages of development, precursor cells (haemangioblasts) arise from the mesenchyme and are the originators of

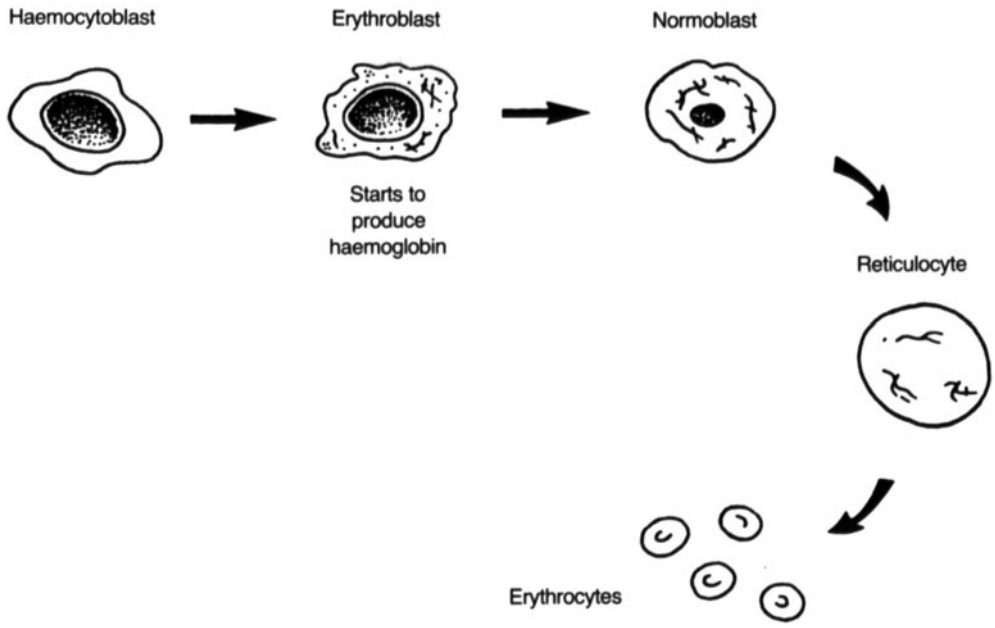

Figure 8.11 The chain of cell transformation which results in erythrocyte production. Erythropoietin acts on the haemocytoblasts to increase their rate of division and initiate the synthesis of haemoglobin in the erythroblasts so formed.

both the capillary endothelial cells and the haemoblasts (Figure 8.11).

These cells are large, basophilic and migratory. The blood islands of the yolk sac are the first fixed site of haemopoiesis and their successful development requires an interaction between the extraembryonic endoderm and the mesoderm. The blood islands themselves consist of sinusoids, full of erythroid cells, which are nucleated red cells containing embryonic haemoglobin (Hb_E). The capacity to synthesize Hb_E is evident by about 3 weeks of gestation in man, 8 days of gestation in the mouse and 13 days in the gerbil. This Hb_E has two forms in man, known as Gower 1 and Gower 2. The Gower 1 form is the most primitive, and consists of four epsilon-chains. There is rapid development of Gower 2, with two alpha- and two epsilon-chains ($\alpha_2\epsilon_2$). The structure of both alpha and epsilon chains closely resembles myoglobin, which itself has a fetal as well as an adult form (Kagen, 1973). Production of this primitive haemoglobin in the yolk sac appears not to be controlled by erythropoietin (E_p), unlike that from other sites later in development (R.J.Cole and Paul, 1966). The earliest haemopoiesis results in nucleated red cells with a relatively short lifespan, while definitive erythropoiesis requires expulsion of the nucleus.

When yolk sac erythropoiesis is at its height, the liver begins to act as a site of erythropoiesis and continues as such until after delivery. It seems likely that both yolk sac and liver are 'seeded' by migratory haemoblasts, probably with a common precursor. The erythrocytes produced are non-nucleated, and slightly bigger than adult erythrocytes (8 μm compared with 6 μm), although smaller than the yolk sac cells. It is around this time that an increasing proportion of cells are found to contain $Hb_F(\alpha_2\gamma_2$, and it seems possible that the type

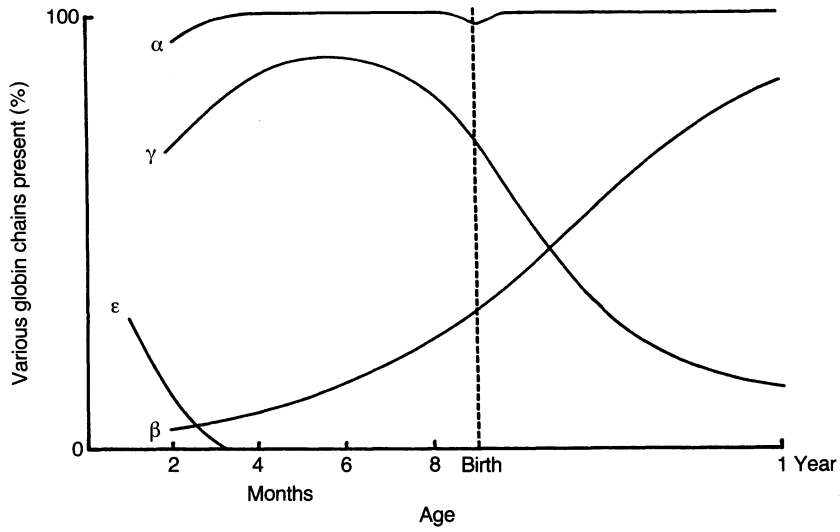

Figure 8.12 Summary to show the proportion of the various globin chains present during human fetal and neonatal life. The alpha and epsilon chains are structurally very similar to myoglobin. (Redrawn from Pearson, 1966.)

of haemoglobin produced depends on the site of production. The fetal liver can also synthesize adult-type haemoglobin (Hb_A). Although erythrocytes are the primary blood cell produced by the liver, megakaryocytes and granulocytes can also be identified in the circulation from this time and are thought to be hepatic in origin.

The spleen plays a more minor role in fetal erythropoiesis and appears to be seeded via the liver. Splenic red cell production antedates that of the bone marrow in mice and gerbils but is initiated later in man. Although hepatic and splenic erythropoiesis declines after birth, severe anaemia can stimulate both tissues again, even in adulthood (C.H. Smith, 1972).

The bone marrow, the adult site of erythropoiesis, develops late in rodents (R.A. Smith and Glomski, 1977) but is capable of some haemopoiesis from approximately halfway through gestation in man. The functional capacity of bone marrow also shows species differences, both granulopoiesis and erythropoiesis being present antenatally in man and gerbils but only granulopoiesis in the mouse.

(b) Haemoglobin

The dominant adult-type haemoglobin, Hb_A, is present in low concentration from fairly early in gestation in man but not until late gestation in other species such as the sheep (Bard *et al.*, 1978; Horvath *et al.*, 1988). Hb_A consists of two alpha- and two beta-chains ($\alpha_2\beta_2$). The beta- and gamma-chains resemble each other more closely than they do the alpha- and epsilon-chains (Pearson, 1966). It seems likely that these various globin chains have arisen by gene duplication from an epsilon or myoglobin-type ancestor. The genetics of the switching from one type of haemoglobin to another has been discussed in some detail by Stamatoyannopoulos and Nienhuis (1981). There are considerable implications for the treatment of the haemoglobiopathies if this developmental switch could be prevented (Weatherall, 1982). The proportions of the various type of globin chain produced during human gestation are summarized in Figure 8.12.

Some 15% of the haemoglobin in man is still of the fetal type by the age of 1 year, but

in other species Hb_A may be the only form present by late gestation (e.g. rats: Stein *et al.*, 1971).

Fetal muscle is deficient in myoglobin, the content in man being only approximately 1% at 5–7 months' gestation, by comparison with adult values, and 6% at birth (Kagen, 1973); other species (horse, dog, cow, pig) show similarly low values. The synthesis and function of myoglobin *in utero* do not appear to have been extensively studied.

The two major factors affecting the oxygen affinity of haemoglobin *in utero* are the Hb_F concentration and the content of the inorganic phosphate 2,3-diphosphoglycerate (2,3-DPG) in the red cells. The total inorganic phosphate content is 65% greater in fetal lambs than in adult sheep and this difference lies largely in the ATP and DPG contents (F.C. Battaglia *et al.*, 1970). Hb_F has a much lower affinity for 2,3-DPG than Hb_A, and the synthesis of 2,3-DPG is also lower *in utero* than in the perinatal period. This has the effect, summarized in Figure 8.13, of shifting the fetal oxyhaemoglobin dissociation curve to the left.

Since the maternal red cell has a somewhat greater affinity for 2, 3-DPG during pregnancy, the curves are still further separated. Thus, at blood gas tensions of 25–60 mmHg the fetal blood absorbs oxygen, and gives up carbon dioxide, more efficiently, although at the cost of somewhat lower efficiency in releasing oxygen to the tissues.

From around 0.85 of gestation the P_{50} (the partial pressure of oxygen at which 50% of the haemoglobin is saturated) rises steadily in the fetal lamb, synchronously with the appearance of increasing proportions of Hb_A in the circulation (Figure 8.14) (sheep, Bard *et al.*, 1978; man, Linderkamp *et al.*, 1984a,b).

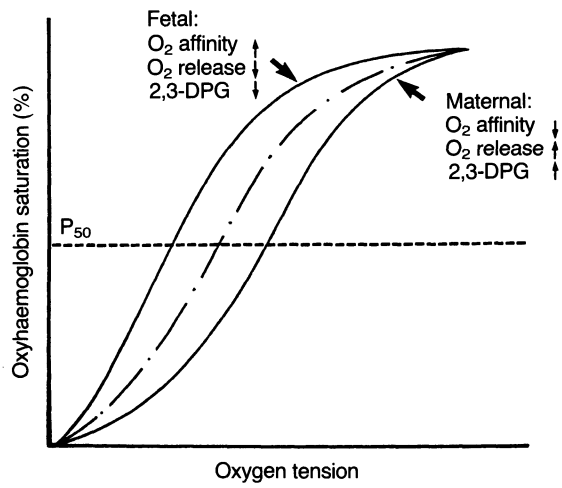

Figure 8.13 The lower affinity of fetal haemoglobin for 2,3-DPG leads to a leftward shift from the normal adult oxyhaemoglobin dissociation curve (–·–·–). The opposite is true of maternal haemoglobin during pregnancy. Oxygen and carbon dioxide are thus more easily transferred across the placenta. P_{50} = oxygen tension at 50% oxygen saturation of haemoglobin.

(c) Erythropoietin

Just as the site of erythrocyte production changes during gestation, so does the site of erythropoietin (Ep) production change (Anonymous, 1987; Hambley and Mufti, 1990). The liver is the predominant site of Ep production during intrauterine life and, even in adulthood, can be stimulated by severe hypoxia to produce 10–20% of the total circulating Ep (Zanjani *et al.*, 1977). The kidneys appear functionless in this respect until about 0.82 gestation in the lamb, after which time they synthesize an increasing proportion of Ep until some six weeks postnatal age when, under normal conditions, they become the sole site of synthesis (Zanjani *et al.*, 1981). However, in the rat, renal synthesis of Ep does not appear to be initiated until around the time of weaning (day 20) and is not of primary importance until about day 40 (Lucarelli *et al.*, 1964). This is the time when the last primitive progenitor cells disappear from the circulation and the two events may be linked. The initiation of renal Ep synthesis is coincident with the appearance of Hb_A in

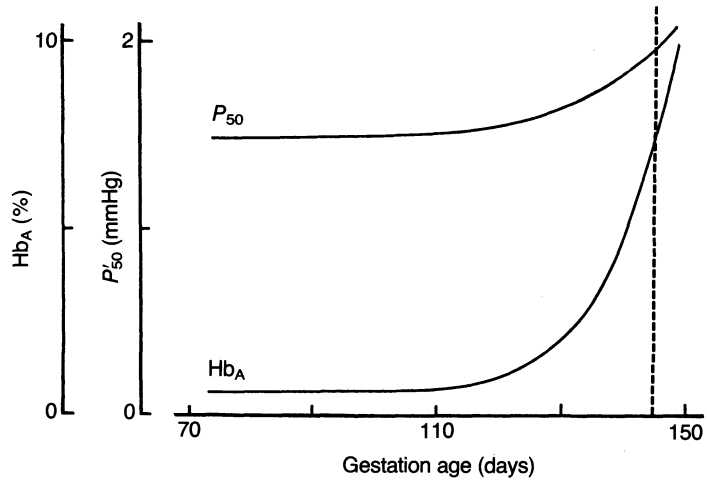

Figure 8.14 There is a temporal coincidence between the rise in P_{50} and that in the proportion of Hb_A in the circulation of the fetal lamb in the last weeks of gestation. The intracellular concentration of 2,3-DPG is unchanged over this period. (Redrawn from Bard *et al.*, 1978.)

the circulation of the fetal lamb but it is not known whether the coincidence is more than temporal.

Yolk sac erythropoiesis appears not to be stimulated by Ep (Cole and Paul, 1966), but hepatic erythropoiesis is, from early gestation in the lamb (Zanjani *et al.*, 1977) and mid-gestation in the rat (Cole and Paul, 1966). The sensitivity of the haemopoietic tissues to Ep increases to a maximum by mid-gestation. Ep acts early in the production of the red cells, acting on the haemocytoblasts to promote cell division, and commit them to haemoglobin synthesis. Once the cells are committed, they cease being sensitive to Ep. Ep appears not to cross the placenta, and fetal synthesis appears to be under local control. For example, if pregnant rats are made polycythaemic by transfusion, although maternal erythropoiesis is suppressed to zero, fetal erythropoiesis is not (Jacobson *et al.*, 1959). If, on the other hand, the mother is made hypoxic, then fetal erythropoiesis increases before maternal erythropoiesis, and to a greater extent (rats, Matoth and Zaizov, 1971; lambs, Zanjani *et al.*, 1974). This is presumably because the fetus is in a chronically mildly hypoxic state, and can respond instantly to an exacerbation of the stimulus. In the human, the infant who has experienced intrauterine growth restraint is more likely to be born with a higher haemoglobin concentration (Jones and Roberton, 1986), presumably because of the confounding variable of chronic hypoxia in association with placental nutritional failure. Macrosomic infants born to a diabetic mother also tend to have higher packed cell volumes (Lemons *et al.*, 1981), suggesting that fetal hyperglycaemia or hyperinsulinism, or other tissue growth factors, can stimulate either Ep production or the bone marrow cells directly.

Plasma Ep concentrations rise rapidly at birth, presumably under the stimulus of birth hypoxia, and may be several-fold that of the mother (Tchernia *et al.*, 1981). In the rat, even 2 h after birth, plasma concentrations of an Ep-like substance have risen significantly by comparison with those measured at delivery (Nagel and Nagel, 1984). In species immature at birth Ep concentrations remain high during suckling (e.g. mice, Meberg *et al.*, 1980;

rabbits, Holter *et al.*, 1987), whereas in those more mature Ep concentrations fall sharply after birth (lambs, Zanjani *et al.*, 1977).

(d) White blood cells

A few granulocytes and megakaryocytes are produced in the yolk sac blood islands and there is a progressive rise in both cell types from the time at which the liver takes over haemopoiesis (C.H. Smith, 1972), increasing further in mid-gestation as medullary haemopoiesis begins.

Lymphocytes are first demonstrable in the embryonic thymus (Ackerman, 1967), but these thymic colonies can rapidly disseminate during embryonic life and lymphocytes are found in blood, spleen, lymph nodes and the gastrointestinal tract during the first quarter of gestation. The thymic cells are epithelial in origin, and follow two lines of differentiation: a limited period of lymphoblast proliferation and the formation of reticuloepithelial cells. The lymphocyte content of bone marrow rises significantly between 25 and 30 weeks' gestation in man to some 25% of the total marrow cells (Yoffey and Thomas, 1964; Kalpaktsogrou and Emery, 1965). Changes in lymphocyte proportion are the only major changes in the human fetal differential cell count in the third trimester rising from 2 to 8% between 26 and 30 weeks' gestation (Kalpaktsogrou and Emery, 1965; Forestier *et al.*, 1986).

Studies of lymphocyte type and function in neonatal human blood revealed a lower proportion of both mature T cells and helper cells, together with uncommitted cells (Solinger, 1985), the proportion of which fell sharply from 32% at 24 weeks' gestation to 0% at term. It is possible that these uncommitted cells may differentiate in an extrathymic site and migrate to the spleen, bone marrow or other sites. Although there is a good mixed lymphocyte reaction at birth, cell-mediated lympholysis is poor (Solinger, 1985). Marodi *et al.* (1984) studied granulocyte and monocyte function in neonatal blood. Granulocyte function appeared mature and the oxygen consumption and hydrogen peroxide production were normal in the monocytes, indicating normal functioning of the oxygen-dependent microbicidal systems of the cells. However, there was a considerably diminished capacity to phagocytose and kill group B streptococci and *Staphylococcus aureus*. This diminished ability may partly account for the susceptibility of the newborn to infection.

(e) Platelets and clotting

Platelet counts are not markedly different in the fetus in the second half of gestation compared with adults (e.g. Forestier *et al.*, 1986). Platelet function is, however, somewhat diminished by comparison with adults, especially in relation to response to proaggregatory agents such as adrenaline (Mull and Hathaway, 1970; Ts'ao *et al.*, 1976; Andrews *et al.*, 1985). The lower response to adrenaline is associated with a lower number of adrenoceptor binding sites (C.R. Jones *et al.*, 1985) and may be a protective mechanism in the face of the extremely high plasma adrenaline concentrations found following vaginal delivery in man and other mammals.

There are also some differences in the clotting cascade, especially in relation to the vitamin K-dependent clotting factors (II, VII, IX and X), which are between 30 and 70% of adult values at full-term delivery, and even lower when studied in preterm human infants (Glader and Buchanan, 1976). The other clotting factors are either unchanged or marginally lower. Even well term infants, especially if breast fed, are at risk of cerebral bleeding or death from haemorrhagic disease of the newborn as a result of this relative immaturity of the clotting system (McNinch and Tripp, 1991). Both the partial thromboplastin time (testing the intrinsic clotting system) and the prothrombin time (testing

the extrinsic clotting cascade) are increased in the newborn, and increased further after pre-term delivery (Glader and Buchanan, 1976).

(f) Blood viscosity

The whole blood viscosity rises throughout the last third of gestation, with parallel increases in haematocrit, fibrinogen and total protein concentrations although adult viscosity has not been reached by term. When tested at low shear rates, the whole-blood viscosity of adult blood, adjusted to a 'fetal' haematocrit of 60%, was 90% greater than that of very pre-term human infants (Linderkamp *et al.*, 1984b). The difference became less at higher shear rates. The increased blood viscosity at low shear rates is a consequence of erythrocyte aggregation caused by bridging of fibrinogen molecules between cells (Linderkamp *et al.*, 1984a). Since fibrinogen concentrations are decreased before birth, the lesser aggregation would be expected. This is obviously of physiological benefit to the fetus with its low vascular resistance and perfusion pressure. But when human infants are delivered prematurely, the same poor red cell aggregation could predispose to intracranial haemorrhage.

The deformability of red blood cells is another important determinant of oxygen transport and release to the tissues in the microcirculation. Fetal and neonatal red cells do not differ from adults in their deformability on testing *in vitro* (Linderkamp *et al.*, 1986). Their filterability may, however, be less, and this may in part account for their somewhat shorter lifespan. The maternal llama has elliptical red cells, presumably an adaptation which is favourable during chronic hypoxia at high altitude. Although Sir Joseph Barcroft likened the challenges faced by the fetus to those of the mountain climber, this unusual type of corpuscle has certainly not evolved in the human fetus although spherocytes (rather than the mature biconcave form) are not uncommon (O'Callaghan and Stephenson, 1992).

8.3.3 LUNG DEVELOPMENT

(a) Anatomical development

In man, lung growth and development begins early in gestation and continues into childhood. Hence, disturbances *in utero* and in early childhood (e.g. congenital abnormalities, maternal smoking during pregnancy (Young *et al.*, 1991) may have profound effects on the subsequent lung growth and function of the child (Hodson, 1992). At about 4 weeks after conception, the lungs begin as a bud arising from the foregut; this divides and branches to form the lining of the respiratory tract. Bronchial budding continues with further subdivisions so that three-quarters of bronchial branching is achieved by the 10–14 weeks and the process virtually complete by 16 weeks (Helms, 1992). The canalicular period from 17 to 26 weeks' gestation represents the first appearance of potential gas-exchange surfaces (Boyden, 1977), during which alveoli appear and develop in both complexity and surface area. Not surprisingly, there is an exponential increase in the mortality due to pulmonary immaturity for infants born within this gestational age window. At birth, the newborn human infant possesses terminal air spaces, sufficient for initial gaseous exchange. However, only after birth do alveoli form and develop to the state found in adults. Splanchnic mesoderm envelops the dividing bud to form the supporting structures. In the upper airways these are the surrounding muscle and cartilage; in the lower they form the matrix of elastin and collagen which determine the lungs' performance characteristics. It also provides the other interface of the gaseous exchange, the pulmonary capillaries and circulation (Hislop and Reid, 1981).

(b) Lung growth

Over the second half of gestation, the fetal lung grows at a rate similar to the body as a whole, whether expressed as wet or dry weight or DNA content. Physical factors have a powerful influence on the growth of the lung whilst hormonal factors modify its rate of maturation. The major physical factors include: the space in the thorax, the volume of amniotic fluid, fetal breathing and airway distending pressure (Kitterman, 1986).

Thoracic cage volume

It has been known for many years that babies born with ill-formed diaphragms, such that the bowels in part develop in the thoracic cage (diaphragmatic hernia), have small hypoplastic lungs, and it is this consequence of the disorder which is often lethal. This effect has been mimicked experimentally in fetal animals. For example, Harrison *et al.* (1980) placed an inflatable balloon into the left thoracic cage of a fetal lamb and were able to demonstrate that when it was inflated the lung ceased to grow but when the balloon was deflated it began to grow again. So, for the lung, the size of the container determines its growth, unlike the brain in its distensible box. Under normal circumstances, the junctions of the cranial vault only seal when the brain stops growing.

Adequate amniotic fluid

The lungs of the term fetus are not collapsed. The potential airways are filled with about 30 ml/kg body weight of lung liquid, which is secreted by the pulmonary epithelium (Jobe, 1984) (for comparison, the tidal volume of air in a newborn infant is 6–10 ml/kg). The clinical correlation between chronic amniotic fluid leakage (and hence oligohydramnios and failure of lung liquid volumes to be preserved) and pulmonary hypoplasia is well recognized. Once the fetal skin becomes impermeable to water (section 8.3.8), the kidney is the main source of amniotic fluid. If the kidneys are ill formed and no urine is produced (renal agenesis), then there is very little amniotic fluid. This is usually, if not invariably, associated with hypoplasia of the lungs. In experimental studies, fetal urine release was stopped in rabbits by tying the ureters (in lambs by removing the kidneys). This produced oligohydramnios and lung hypoplasia but the results were not always clear cut. Tapping the amniotic space in early human pregnancy (amniocentesis) and drawing off fluid also leads to lung hypoplasia. The results are variable and may depend on the time of the procedure in the pregnancy and whether the membranes continue to leak. This has been mimicked experimentally in guinea pigs, and it has been shown that even a short period of oligohydramnios interferes with lung development (Moessinger *et al.*, 1986). In this species, the extent of this interference depends to a large extent on the time of onset (greater impact during canalicular stage than terminal sac stage) and to a lesser extent on the duration of oligohydramnios. Oligohydramnios in the fetal guinea pig for a period as short as 8% of gestation led not only to a significant decrease in lung volume (and the surface area available for gas exchange) but also to pulmonary structural alterations. The hypoplastic lungs contained fewer saccules (fetal 'alveoli') and the amount of elastic tissue per unit volume was reduced (Collins *et al.*, 1986). So it does seem that loss of amniotic fluid produces the lung hypoplasia. The question is how. It might be secondary to limitation in movement and compression of the thorax because of the loss of liquid (oligohydramnios) or to a fall in tracheal distending pressure, or a variable combination of these and other factors.

Fetal breathing movements

The nature of fetal 'breathing' movements will be described later (section 8.3.3d). There

is some evidence that integrity of the nervous control of the diaphragm, and therefore fetal breathing movements, is important in lung growth. In human infants, paralysis of the diaphragm at birth is rare but does occur; in fetal lambs phrenic nerves have been deliberately cut. In both situations the lungs are hypoplastic. However, it could be argued that the paralysed diaphragm ballooned upward and exerted its effect by reducing thoracic space, and it is this effect, rather than the cessation of breathing movements, which resulted in lung hypoplasia. However, cutting the cervical cord above the phrenic nuclei appears to leave the diaphragmatic tone intact but abolishes breathing movement. In this situation, lung hypoplasia occurs, indicating that it is the breathing movements which are important (Wigglesworth and Desai, 1979).

Pressure in the potential airways

If the trachea of the fetus is occluded by a ligature the lungs become distended (Jost and Policard, 1948). The lungs secrete fluid and the laryngeal sphincter influences its flow into the amniotic space. Experimental partial obstruction of the respiratory tract increases lung growth; chronic drainage of lung liquid has the opposite effect. Thus, a modest airway pressure may act as a stimulus to lung growth, and this will be determined by the rate of lung liquid secretion and laryngeal sphincter activity. For the purpose of description, the physical factors have been discussed in isolation but it is obvious that they are inter-related.

(c) Lung liquid

The lungs secrete a liquid, an activity which appears to be essential for lung growth. The volume of lung liquid at any moment is 20–30 ml/kg in the lamb in the last trimester of pregnancy (the net flow from the lungs into the amniotic cavity is around 500 ml/day) and this traffic results in an intratracheal pressure around 2 torr, a distending pressure. The flow is episodic and reflects fetal breathing movements (Adamson *et al.*, 1973). Transient negative deflections in intratracheal pressure are seen with fetal breathing movements, due to downward movement of the diaphragm, and these are associated with 'inspiration' of a small volume of fluid, but over a period of time there is a net efflux of lung liquid into the amniotic cavity. If the pressure increases, the lung grows more (Alcorn *et al.*, 1977). It also matures faster, developing more surfactant-producing cells (type II pneumocytes). The opposite is also true (Olver, 1983; Bland, 1986).

Lung liquid is derived from the pulmonary circulation. Water from the pulmonary capillary passes first to the interstitial space across the endothelial barrier and then into the respiratory tree across the pulmonary epithelium. Strang and colleagues worked out some of the rules of this transfer (Olver and Strang, 1974). Lung liquid is low in protein and bicarbonate, high in chloride, and has a relatively low pH. It is the active transfer of chloride across the pulmonary epithelium, the chloride pump, which draws the water out of the protein-rich interstitial space. Altering pulmonary perfusion, blocking respiratory breathing and various drugs and hormones have relatively small effects with the exception of beta-adrenergic agonists (see below).

At birth the lung liquid has to be cleared to make way for air. It was thought that the fluid was cleared, in part, by flowing out of the upper airway once the head emerged from the birth canal and, in part, by lung lymphatics and circulation after birth. However, there is reasonable evidence in experimental animals (Kitterman *et al.*, 1979) and in man (Strang, 1977) that:

1. The rate of lung liquid secretion falls and virtually stops by the moment of birth.
2. Some of the lung liquid has already been

cleared out of the potential air space by the pulmonary circulation, that is the process is reversed.

Cortisol may be involved in the former and beta-adrenergic agents in the latter.

An increased risk of respiratory symptoms following Caesarean section is well recognized in the human newborn (Tudehope and Smyth, 1979; Cohen and Carson, 1985). The effect of mode of delivery on lung expansion at birth has been examined, and a striking difference between vaginal delivery and delivery by elective section was that the babies in the latter group were more likely to fail to retain air in the lungs at the end of the first breath (Vyas, 1986). In contrast, babies delivered by emergency Caesarean section, following the onset of spontaneous labour, all achieved an immediate functional residual capacity. The differences between the vaginal delivery and emergency Caesarean section babies is partly due to the fact that about one-third of the fetal lung fluid is removed by the squeeze of the baby's chest during passage through the birth canal (Greenough *et al.*, 1992). The differences between the babies delivered by elective Caesarean section and emergency Caesarean section are likely to be due to a combination of the squeezing of the thorax within the uterus (especially if the membranes have ruptured) and the exposure of the fetus to an adrenaline surge.

(d) Fetal breathing movements

If one were asked, knowing nothing about the subject, whether the fetus would flex its diaphragm prior to birth, for otherwise it would have to start to contract rhythmically at the moment of birth and continue without fail until death, then it would seem obvious that it would. If one then asked the question 'how could it work, knowing that the lung was filled with fluid rather than air?', then the problem becomes more interesting. Add to that the question of whether such performance would be reflex or under higher cortical control and then place that within a developmental scale and it is not difficult to appreciate why it has fascinated some of the finest fetal physiologists (see review Dawes, 1986). Leonardo da Vinci thought that the fetus did not breathe because, if it did, it would drown. However, from the time of Vesalius, fetal breathing movements have been observed indirectly, and from the 1970s fetal breathing has been visualized directly in human pregnancy by ultrasound scanning. In lambs, fetuses also have intermittent periods of rhythmic breathing movement, and this has been observed mostly in the second half of gestation. Breathing movements are irregular in rapid eye movement (REM) sleep but become regular in deep (non-REM) sleep. Breathing movements may be important in lung growth and may well be critical for post-natal performance. In the sheep fetus, the amount of breathing decreases as birth approaches and then must change to a continuous pattern following parturition.

There is no doubt that fetal breathing movements reflect fetal well-being and are influenced by hypoxia and hypercapnia and are modulated by neurotransmitters and neuropeptides, often in ways contrary to those which occur after birth. However, fetal breathing is discontinuous and, because of this and conflicting studies in the literature (Blott *et al.*, 1987; Moessinger *et al.*, 1987), the use of fetal breathing movements as an index of fetal health in clinical practice is limited.

(e) Lung maturation

When they speak of the process of lung maturation, authorities seek to comment on function more than structure and, to a certain extent, maturation can be dissociated from growth. Thus, a lung may be small but mature. That is, it has the right balance of structural material and epithelial cells to permit lung expansion with air and the maintenance

of a functional residual capacity. One key element of this, which has received considerable attention, is the secretion of a natural detergent, surfactant, by the pneumocyte type II cell (Comroe, 1977). By contrast, some large lungs may have delayed maturation and insufficient surfactant and these present the newborn with breathing problems after birth. An example is a diabetic infant born by elective Caesarean section at term. Some of these maturation phenomena are associated with birth induction and are accelerated during the birth process.

Mechanisms involved include glucocorticoids, which have been used to induce maturation in infants who are threatening to be born prematurely (Dancis *et al.*, 1980; Crowley *et al.*, 1990; Levene, 1992). Cortisol, prolactin and triiodothyronine appear to act synergistically in accelerating lung maturation in fetal sheep (Liggins, 1990). Neither prolactin nor triiodothyronine crosses the human placenta in significant amounts, thus ruling out the option of fetal therapy via maternal administration. However, thyrotrophin-releasing hormone, a small peptide, does cross the placenta, and the results of further clinical trials are awaited (Morales *et al.*, 1989). It is the beta-receptor agonists which are released during the birth process which have the most immediate and powerful effect, stimulating surfactant release and manufacture as well as reducing the secretion rate of lung liquid (Liggins, 1990).

(f) Pulmonary circulation

Owing to the central communications between the circulations in fetal life, there are, effectively, large intracardiac (through the foramen ovale) and extracardiac (through the ductus arteriosus) right-to-left shunts. *In utero*, the two chambers of the heart work in parallel, the pulmonary bed taking less than 10% of the combined output (Teitel, 1992). This is not because the vasculature is meagre and narrow, but because the vessels are permanently and strongly constricted. This is achieved by generous muscles in the walls of the arteries and arteriole. The tone is maintained partly by the low fetal PO_2 (A.I. Hyman *et al.*, 1975; Alpan and Glyman, 1990) and fluid-filled unexpanded lungs. Expanding the lungs with nitrogen causes a fall in pulmonary vascular resistance; it falls further if they are expanded with oxygen. With the fall in resistance, there is an increase in flow and the sequence of events essential for lung gaseous exchange and oxygen supply is set in train (section 8.4.2).

8.3.4 KIDNEY DEVELOPMENT AND WATER BALANCE

The fetal kidneys in late gestation appear to be the primary source of the amniotic fluid (D.P. Alexander and Nixon, 1961; Houston and Zeis, 1976) but are not necessary for volume regulation or nitrogen excretion since the placenta is an extremely efficient dialysis unit. A fetus can survive to term without kidneys, but the deficient amniotic fluid results in pulmonary hypoplasia, and multiple skeletal and cartilaginous anomalies due to it being 'squashed' within the uterus (Potter, 1946).

The ionic and osmolal characteristics of the extracellular fluids of all the vertebrates are very similar, and suggest that our common ancestor lived in brackish water. The transition from the sea into brackish or fresh water with its much lower osmolality, and subsequently to dry land, demanded the development of regulatory mechanisms to avoid on the one hand the cell swelling with rupture and on the other desiccation. There also developed the need to protect the embryonic stages of these adventurous species from being osmotically disrupted. The parallel development of the genital and urinary tracts subserved both these functions, and this evolution is recapitulated during mammalian fetal development.

Another requirement imposed on the creatures who left the water was the need to reorganize nitrogen metabolism so that the ammonia resulting from protein metabolism could be converted into other metabolites which, unlike ammonia, are relatively nontoxic. The mechanisms for nitrogen excretion and water conservation developed together.

(a) Structure

Pronephros

The pronephros, the most primitive form of vertebrate kidney, develops from a mesh of capillaries originating from the abdominal aorta and functions at a perfusion pressure of more than half that in the aorta (see Brod, 1973). This results in a plasma ultrafiltrate which drains into open-ended primitive kidney tubules (nephridia) where reabsorption of individual electrolytes takes place. Pronephroi are developed in the mammalian fetus, but are only present transiently in very early gestation. Before the pronephroi degenerate, they have sent paired collecting ducts caudally, to empty into the cloaca. These structures are essential to the subsequent development of the meso- and metanephron (Gruenwald, 1952).

Mesonephros

Mesonephroi first appear in fishes, and in lower vertebrates they serve as the major excretory organ throughout life. The mammalian mesonephros, which is present only in fetal life, shares many features with the adult mesonephros in fish, particularly in relation to the degree of glomerular and tubular development and the sinusoidal nature of the tubular circulation (Davies, 1952). It seems primarily adapted to life in an aquatic environment, where water conservation is not a problem. This limitation may be the reason for the evolution of a third type of kidney, the metanephros, programmed for water conservation as well as the maintenance of ionic and osmolar balance and nitrogen excretion.

Table 8.11 The mesonephroi of different mammalian species appear at different periods of development and are present for differing periods of time. The proportion of total gestation at which the organs develop and regress is shown. Data from: Bremer, 1916; Kaplan and Friedman, 1942; Leeson and Baxter, 1957; de Martino and Zamboni, 1966.

Species	*Gestation length (days)*	*Mesonephroi present*
Rat	22	Vestigial
Rabbit	31	0.35–0.74
Guinea pig	68	0.36–0.41
Pigs	114	<0.25–0.71
Sheep	147	0.12–0.38
Man	**280**	**0.08–0.40**

In fetal mammals, the mesonephroi develop from thoracic and lumbar mesoderm in the nephrogenic cord as the pronephroi degenerate. The general development appears to be similar in all mammals, but the relative stage of gestation at which the mesonephros appears (Table 8.11) and its apparent functional importance vary widely.

The mesonephric tubules differentiate into proximal and distal segments. The proximal tubules have columnar epithelium, characteristic of secretory function, and show a form of brush border which stains with periodic acid–Schiff (PAS) and contains alkaline phosphatase, which is an indicator of the functional ability to transfer solutes across cell boundaries (Davies, 1952; Leeson and Baxter, 1957). The distribution of alkaline phosphatase seems linked to areas of rapid growth and differentiation. The cuboidal cells of the distal tubules have neither brush border nor alkaline phosphatase but contain glycogen like the longitudinal mesonephric duct (Wolffian duct), into which they all drain, and the ureter. No loop of Henle is present in mesonephroi (Kaplan and Friedman, 1942; de Martino and Zamboni, 1966). The longitudi-

nal mesonephric duct persists into adult life in the male, as the ductus deferens, but disappears almost completely in the female.

The medial end of the primitive mesonephric tubule develops into a flattened concave disc, which gradually deepens into the form of a cup. The outer wall becomes the parietal epithelium of Bowman's capsule, while the inner wall extends over the differentiating capillary loops and becomes the glomerular epithelium, rich in endoplasmic reticulum (see Kazimierczak, 1971). Until relatively recently, it was thought that the glomerulus developed by the action of formed capillaries invaginating Bowman's capsule, but it is now generally accepted that glomerular capillaries probably develop *in situ* from mesenchymal cells which have migrated into the cleft of the S-shaped tubules (for references see Kazimierczak, 1971). These glomerular capillaries become covered with cuboidal epithelium (see above) and progressive connection to the primitive dorsal aortae proceeds from head to tail (Davies, 1952).

Although mesonephroi are structurally similar in mammalian fetuses, their functional capacity and duration of existence (Table 8.11) are not. Davies (1952) suggested parallels between mesonephric and allantoic development, the relative rates being primarily dependent on placental permeability. Thus in pigs, with epitheliochorial placentae, which may present more of a barrier to placental transfer of all but the simplest substances, the mesonephros is large and persistent, and excretes large volumes of fluid into a large allantoic sac. Sheep, also with epitheliochorial placentae, have smaller, less persistent mesonephroi, and a smaller allantois, while man, with a very permeable haemomonochorial placenta, has a minimal allantois and a small, non-functional, short-lived mesonephros. Rats and mice, with haemoendothelial placentae, have only vestigial mesonephroi (Zamboni and Upadhyay, 1981) and allantois. There is, however, an exception to this interesting concept in the rabbit, which, with a haemodichorial placenta, has a functional mesonephros present for some 40% of gestation (Table 8.11) and a small allantois which is restricted to the placental surface area.

The sheep mesonephros is functional by day 18 of gestation, and it is at this time that the allantois, which has been present as a small, almost empty, sac begins to fill up (Davies, 1952). In the rabbit, a functional mesonephros is not present until day 13 (Leeson and Baxter, 1957). In the pig, in early fetal life, the mesonephroi form up to 20% of the total fetal weight and secrete large volumes of fluid (Stanier, 1960). The efferent arterioles of the porcine mesonephros form a network of capillaries over the mesonephric tubules, suggesting a capacity for reabsorption even though the loop of Henle is absent. However, bladder fluid in the pig is iso-osmotic with serum, although that in the allantois is hypo-osmotic (Stainer, 1960). It appears that the chorioallantois in the pig can reabsorb sodium and presumably chloride from at least 0.4 of gestation (McCance and Widdowson, 1960; Stanier, 1960). Fructose is also accumulated in increasing concentrations in allantoic fluid in the fetal lamb in early gestation, although in the amniotic fluid the concentration is only about one-tenth (Davies, 1952). The reason for this accumulation is not known.

The marsupials are in many ways anomalous, but it is interesting that the American opossum *Didelphis virginiana*, whose young are born after only 12½ days' gestation, has mesonephric kidneys at birth which persist until the 10th post-natal day and appear to provide the primary excretory capacity for the newborn during that time (Krause *et al.*, 1979).

Metanephros

Although structurally similar, the metanephroi initially develop their collecting

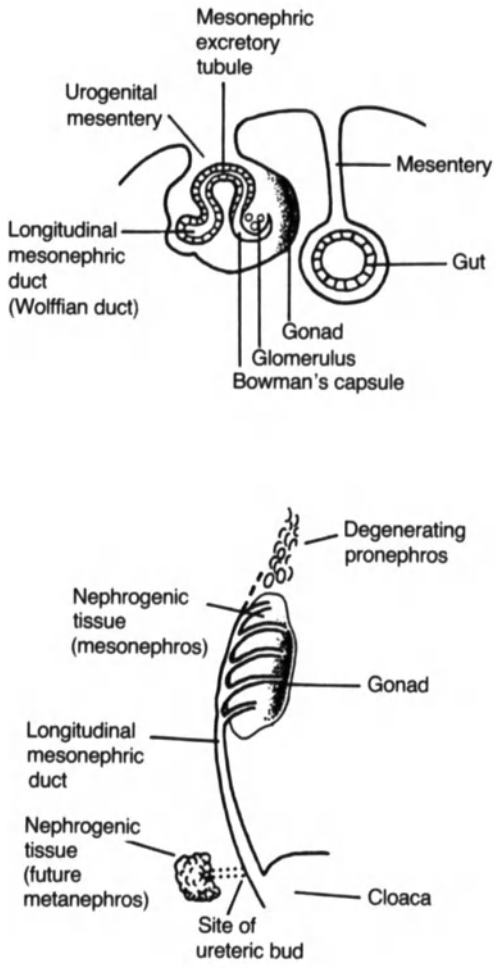

Figure 8.15 Top: Representation of a transverse section through the lower thoracic region of a 35-day human fetus, showing development of the mesonephros and its association with the future gonad. Bottom: Longitudinal section through the abdominal region of the same fetus.

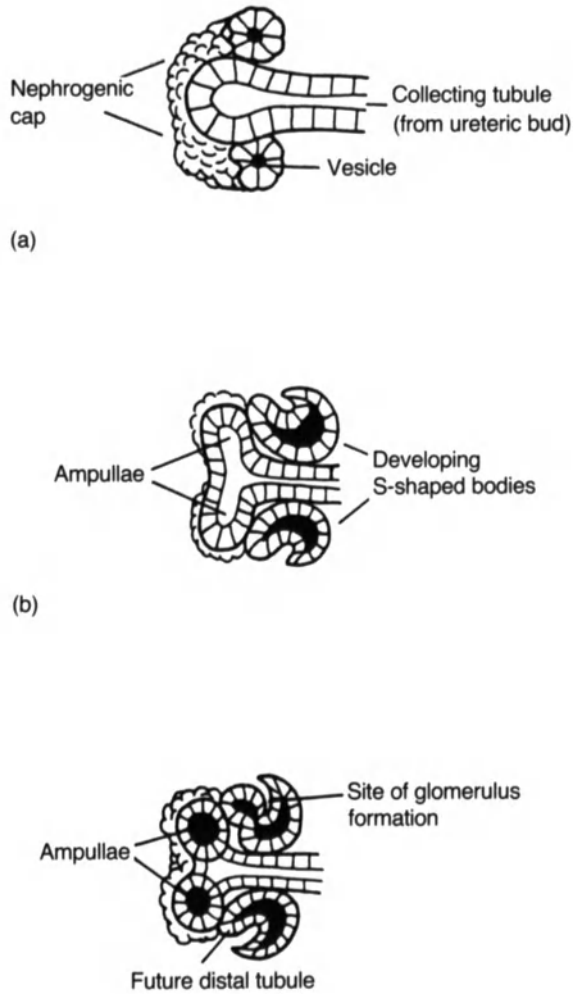

Figure 8.16 Stages in nephron development in the mammalian metanephros. The collecting tubule system arises from the ureteric bud (see Figure 8.15) and not *de novo* as in the mesonephros. (Redrawn from Kazimierczak, 1971.)

ducts in a substantially different fashion from the mesonephros.

As the mesonephros starts to regress, a ureteric bud grows out from the mesonephric duct close to its junction with the cloaca (Figure 8.15) and grows cephalad into the most caudal nephrogenic mesoderm, which forms a nephrogenic cap over the blind end (Figure 8.16).

This blind end dilates and subdivides, forming first the major and subsequently the minor calyces. The mesoderm forms condensation vesicles around these ampullae. The vesicle walls grow differentially and form the characteristic S-shaped bodies of very immature glomeruli. The 'tail' closest to the ampulla eventually fuses with it, forming the distal convoluted tubule; the middle section,

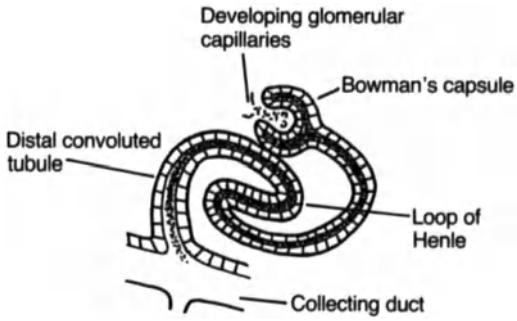

Figure 8.17 Development of the glomerulus and proximal and distal tubules of the metanephros.

as it lengthens, forms the loop of Henle and the proximal convoluted tubule, while the proximal end of the nephron forms the cup-shaped invagination (Bowman's capsule) within which the glomerular capillaries form (Figure 8.17) (Aoki, 1966).

The early calyces themselves subdivide, and this process is repeated until some 12 generations of tubules are present, with their associated nephrons. In any species, the juxtamedullary nephrons are, thus, most mature at any time during gestation, and glomerular maturation proceeds centrifugally. This pattern of development, and the state of maturity at birth, determines renal function at birth and in the neonatal period.

The renal blood supply also develops centrifugally, with the arcuate arteries forming the first major subdivision after ramification of the renal artery. Indeed, the only arteries in the developing nephrogenic cortex of pigs and rats at the time of birth are the arcuate arteries (Kazimierczak, 1971), with interlobar and interlobular branches in the more mature cortex. These latter give rise to the afferent arterioles which run along the prospective distal tubules of the more mature glomeruli. The efferent arteriole originates from the capillaries formed within the glomerulus and becomes continuous with the peritubular capillary plexus in the more mature nephrons.

One of the differences between meso- and metanephroi is that a juxtaglomerular apparatus is developed in the more cortical nephrons of metanephroi at the hilum of the glomerulus, where the early distal tubule runs in close apposition to the afferent arteriole. This is a relatively late development in glomerular differentiation, and has been described in detail by Kazimierczak (1971) in fetal pig, rat and human kidneys. It appears that the juxtaglomerular apparatus, with its intimate associations with the renin–angiotensin system, has developed to allow the fine tuning of sodium balance. Conditions which result in increased renin synthesis and release from the macula densa, with consequent afferent arteriolar vasoconstriction in the more cortical glomeruli, will increase the proportion of the intrarenal blood flow passing through the juxtamedullary nephrons, which have a higher capacity to reabsorb sodium. The development of the loop of Henle and the juxtaglomerular apparatus is thus linked to the ability to regulate salt and water balance within narrow limits, an absolute requirement for terrestrial life, whether emergence has been from brackish lagoons or from the amniotic fluid.

A pressor substance, believed to be renin, is present in pig mesonephroi (Kaplan and Friedman, 1942), but not in the mesonephroi of man (de Martino and Zamboni, 1966), cat or sheep (Tiedemann, 1976). Pig mesonephric renin is not present in specific granular cells, and this discrepancy has also been noted in the metanephroi of fetal rats near term (Tsuda *et al.*, 1971). In rats, nephrogenesis is not complete until after birth (Cain and Krause, 1971; Goncharevskaya and Dlouha, 1975; Table 8.12).

Renin has also been identified in human fetal kidneys before Bowie-positive granules are identifiable (Molteni *et al.*, 1974). Cells containing renin granules can be present before macula densa differentiation has occurred (Dhiab *et al.*, 1981); their association with the adult-type juxtaglomerular apparatus is thus a late phenomenon.

Table 8.12 Nephrogenesis is completed at widely differing rates in different mammalian species. The timing is shown as a proportion of the length of gestation, thus in those species in which nephrogenesis is incomplete at birth, a figure of more the 1.0 will be found. Data from: Potter and Thierstein, 1943; Leeson and Baxter, 1957; MacDonald *et al.*, 1959; Spitzer and Edelman, 1971; Broughton-Pipkin, 1973; Goncharevskaya and Dlouha 1975; Merlet-Benichou *et al.*, 1977; Friis, 1980.

Species	*Age at completion*	
Rat	10 days post-natal;	1.45
Rabbit	17 days post-natal;	1.55
Guinea pig	55 days gestation;	0.81
Pig	21 days post-natal;	1.19
Sheep	128 days gestation;	0.87
Man	**35 weeks' gestation;**	**0.88**

(b) Function

The study of renal function before birth is not easy. Measurements of fetal fluid volume and electrolyte composition have been made for many years in anaesthetized laboratory or freshly slaughtered domestic animals (e.g. rabbits, McCance and Stainier, 1960; guinea pigs, Boyland *et al.*, 1958; pigs, McCance and Stanier, 1960; McCance and Widdowson, 1960; sheep, D.P. Alexander *et al.*, 1958; rhesus monkeys, Chez *et al.*, 1964) but these were, at best, static measurements. The realization that electrolyte and water absorption could take place across bladder and amniotic membranes, thus modifying the composition of contained fluids, was rapidly followed by techniques for measuring function *in utero*, initially in acute experiments and more recently in chronic preparations. Indeed, the work of Mellor and Slater (1971) showed, beyond doubt, the very marked effect of anaesthesia and surgery in the fetal lamb on amniotic and allantoic fluid composition, and in an increased variability in maternal and fetal plasma electrolyte concentration. Thus, many of the data obtained under anaesthesia must be viewed with caution. Longer term experiments are, at present, technically impossible for the smaller species, and the fetal lamb has come to be used very widely in studies of fetal renal function, as indeed it has for the development of other organ systems. This is, in some respects, unfortunate since there appears to be considerable species variations in maturation of intrauterine renal function. However, in the discussion which follows, data will primarily relate to the fetal lamb, with mention made of other species as available. Some information gained in the immediate neonatal period in premature human infants will be mentioned, but should not be considered representative of normal maturation for the reasons outlined in the Introduction.

Glomerular filtration

The first stage in urine production requires ultrafiltration of plasma. The glomerular filtration rate (GFR) is substantially lower in the fetus than in the newborn, both in absolute terms and when expressed relative to body weight, body surface area, extracellular fluid volume or kidney weight (e.g. Boyland *et al.*, 1958; D.P. Alexander and Nixon, 1962; Robillard *et al.*, 1977; Alt *et al.*, 1984). There are both anatomical and functional reasons why this should be so: total glomerular surface area is less since individual glomeruli are smaller (Fetterman *et al.*, 1965; Merlet-Benichou *et al.*, 1981) and their absolute number per gram of kidney tissue is less, with nephrogenesis continuing in some species for days, or even weeks, after birth (Table 8.12); the glomerular capillaries are still morphologically immature, with a small pore size and relatively low water permeability (Vernier and Birch-Andersen, 1962); renal perfusion pressure is lower as a consequence of the low fetal arterial blood pressure (see Dawes, 1968; Gomez *et al.*, 1984) and the fetal haematocrit is usually higher than the adult (see Dawes, 1968), although this may not be so in the pig (A.A.

MacDonald, 1983). Other features influencing GFR are the colloid osmotic pressure, which is lower in fetus than newborn (Baum *et al.*, 1971), and a considerable degree of intrarenal vasoconstriction. This latter may well be hormonally mediated, possible through local generation of angiotensin II, since it decreases too rapidly after birth (Guignard, 1982) to be accounted for in anatomical terms. The renin–angiotensin system appears to be hyperactive in the newborn of all species so far studied (see Broughton-Pipkin and Symonds, 1984), and the early development of renin-containing granules in cells in apposition to the developing renal arterioles (see above) suggests a role in the regulation of intrarenal blood flow.

The renal plasma flow (RPF) is difficult to measure *in utero* since *p*-aminohippurate, the most commonly used marker molecule, is less well filtered and secreted by the immature kidney (Calcagno and Rubin, 1963; B.R. Cole *et al.*, 1972; Friis, 1979). However, measurements made in the young of various species post-natally (Calcagno and Rubin, 1963; Gruskin *et al.*, 1970; Horster and Lewy, 1970; Kleinman and Lubbe, 1972) suggest strongly that RPF in *utero* will be low, whether measured in relation to body or kidney weight.

The maturation of GFR, and the rate at which it changes after birth, varies between species. In species such as the guinea pig and human, where nephrogenesis is complete by late gestation (Table 8.12), the post-natal rise in GFR is rapid, and will primarily be due to the rise in systemic arterial pressure and the subsequent perfusion of previously poorly perfused, though apparently structurally mature, nephrons (Merlet-Benichou *et al.*, 1981; Chevalier 1982) and the fall in renal vascular resistance. However, in species such as the rat and rabbit, in which nephrogenesis is not complete at birth, the rate of rise will be slower, since it will include an actual anatomical component in addition to the features mentioned above.

The plasma ultrafiltrate leaves the glomerulus and passes into the proximal convoluted tubule, where, in the adult, approximately 70% of its sodium ions and all of its potassium ions are reabsorbed; there is active reabsorption of glucose and passive reabsorption of non-ionized organic acids and bases and there is secretion by active transport of some organic acids and bases. However, the fetal glomeruli develop before the tubular system and the elongation of the loop of Henle is the last major structural development. Thus, there is a degree of glomerulo tubular imbalance during fetal development (Fetterman *et al.*, 1965), which may persist after birth.

Glucose

The fetal need to conserve its primary energy substrate glucose (Girard *et al.*, 1979) is such that no glucose is present in the urine of either fetal pigs or lambs from at least as early as 0.4 gestation (Parry and Stanier, 1962; D.P. Alexander and Nixon, 1963). This evidence of early active reabsorption is consistent with the presence of alkaline phosphatase in the proximal tubules by the end of the first third of gestation. However, fetal plasma glucose concentrations are low and increasing them by infusion, even to concentrations as relatively low as some 6.5 mmol/l1 results in urinary glucose loss in the fetal lamb (D.P. Alexander and Nixon, 1963). Fetal piglets, near term, conserve glucose very efficiently with a fractional excretion of glucose of only 0.4% (Alt *et al.*, 1984). Adult guinea pigs usually have a fractional excretion of glucose of approximately 1.2% (Merlet-Benichou *et al.*, 1981), but at about 0.71 of the gestational duration the fractional excretion is about 8%, rising to 12% at 0.81 gestation, the period of maximal glomerulo tubular imbalance in this species, and falling thereafter to 2.5% at term (Merlet-Benichou *et al.*, 1981). The immature human kidney appears to have a low transport maximum (T_M) for glucose, even when expressed in terms of body weight or body

surface area (Tudvad and Vesterdal, 1953). These low T_Ms may reflect partly the low GFR and partly the tubular functional immaturity. The low T_M of PAH at this time has already been mentioned above in relation to measurement of renal plasma flow. Fructose is less well reabsorbed than glucose and is present in high concentrations in sheep allantoic fluid from as early as 0.12 gestation, when the mesonephros begins to function (Davies, 1951). This has led to speculation that the secretion of fluid into the largely impermeable allantois helps to keep the uterine cavity expanded (D.P. Alexander *et al.*, 1958) and the membrane layers apposed.

Sodium

Sodium accumulation is a primary requirement for fetal growth. The ion freely crosses the placenta, and the kidney does not therefore 'need' to conserve sodium until term. However, immediately after birth that need becomes paramount, especially since milk has a low sodium concentration and the ability to conserve sodium is in fact well developed in species mature at birth (Spitzer, 1982). It differs from adult salt conservation in that the distal tubule probably plays a more important role *in utero* and in the immediate perinatal period in species which are mature at birth.

Fractional sodium excretion (FE_{Na}) falls progressively during fetal life. In the sheep, it is 40% halfway through gestation, falling to 10% at close to term (D.P. Alexander and Nixon, 1961), paralleled by a marked fall in urinary sodium concentration (D.P. Alexander and Nixon, 1961; Lingwood *et al.*, 1978a). This increase in sodium reabsorption is less than the rise in GFR until late gestation, but exceeds it thereafter (Robillard *et al.*, 1977). Acute experiments in guinea pigs undergoing a saline diuresis showed FE_{Na} to be 27% at 0.7 gestation, and actually rising to 45% at 0.78 gestation (Merlet-Benichou *et al.*, 1981). By term, FE_{Na} was still 20% but by days 2–5 post partum it had fallen to 1%. Human babies delivered early in the third trimester have FE_{Na} of some 5–6% (Siegel, 1982) and can rapidly develop hyponatraemia if not given sodium supplements (Al-Dahhan *et al.*, 1983a). Fetal pigs near term have FE_{Na} of some 2%, falling rapidly to 0.07% by the end of the first week of post-natal life (Alt *et al.*, 1984).

It appears that the progressive rise in GFR with fetal age is accompanied by a parallel rise in sodium and fluid reabsorption across the proximal tubule, as is seen post-natally (Horster and Valtin, 1971; Spitzer and Brandis, 1974). The balance between hydrostatic and colloid osmotic pressures across the peritubular capillaries will change in late gestation, as the colloid osmotic pressure rises (Baum *et al.*, 1971), favouring fluid reabsorption. The main difference in sodium reabsorption in the fetal kidney is that the very short loops of Henle in the fetal kidney do not permit adult-type sodium reabsorption, so that a much greater filtered sodium load is presented to the distal tubule (Aperia and Elinder, 1981). However, considerably more sodium is reabsorbed in this segment than in the adult kidney, partly compensating for the inadequate loops of Henle. It seems highly probable that the raised plasma aldosterone concentrations, characteristic of the neonate (Beitins *et al.*, 1972; Katz *et al.*, 1974; Siegel and Fisher, 1980), may be reflecting increased secretion before birth. The demonstration of inverse associations between urinary sodium–potassium ratio and either plasma concentrations or urinary excretion of aldosterone in the human newborn (Raux-Eurin *et al.*, 1977; Sulyok *et al.*, 1979) and the fetal lamb (Lingwood *et al.*, 1978a; Robillard *et al.*, 1980) strongly suggests a functional interaction between the two parameters in the perinatal period. There is also greater binding of radiolabelled aldosterone in fetal than adult guinea pig kidney (Pasqualini *et al.*, 1972).

Sodium–potassium ATPase (Na^+,K^+-

ATPase) is a well-defined enzyme which drives the sodium pump. Its activity is less in kidney tissue from immature than adult rabbits (Schmidt and Horster, 1977) and rats (Dobrovic-Jenik *et al.*, 1984). The administration of aldosterone to immature but not adult rats was associated with a marked increase in tubular cellular content of Na^+,K^+-ATPase (Aperia *et al.*, 1981), again suggesting aldosterone responsiveness at this age.

Data from human infants delivered early in the third trimester suggest that, although their marked sodium wasting can stimulate activity of the renin–angiotensin system (Stephenson *et al.*, 1991), their adrenal cortices may be unable to synthesize sufficient aldosterone to counter the salt loss at this stage (Sulyok *et al.*, 1979). Similar data are available for fetal lambs, in which a progressively greater aldosterone response to evoked rises in plasma renin activity (PRA) was seen during the last third of gestation. Younger fetal lambs showed no increase in PRA, and hence aldosterone concentration, in response to frusemide-induced sodium loss (Siegel and Fisher, 1980). The prematurely delivered foal continues to lose sodium on challenge with frusemide, despite very large increases in plasma renin and aldosterone concentrations, which may suggest actual unresponsiveness of the tubular cells (Broughton Pipkin *et al.*, 1984).

Potassium

The fractional excretion of potassium is approximately 20% in the middle third of gestation in the lamb, rising to 45% in the last third and 92% by term, falling rapidly thereafter (D.P. Alexander and Nixon, 1961; Robillard *et al.*, 1980). The concentration of potassium in fetal urine, allantoic and amniotic fluid rises steadily towards term in the fetal lamb (D.P. Alexander and Nixon, 1961; Mellor and Slater, 1971; Lingwood *et al.*, 1978b; Robillard *et al.*, 1980) and there is evidence for the tubular secretion of potassium near term in both sheep (Robillard *et al.*, 1980) and guinea pig (Merlet-Benichou and de Rouffignac, 1977). The increased kaliuresis in late gestation could be a function of the increasing GFR, but is more likely to relate to the effects of the increasing plasma concentrations of steroids, especially aldosterone (Robillard *et al.*, 1980), as gestation proceeds.

Water excretion

McCance and Young (1941) observed that the urine of newborn infants was invariably hypotonic to plasma, sometimes very much so. This observation has been made repeatedly, in all animal species studied (e.g. rabbit, McCance and Stanier, 1960; pig, McCance and Stanier, 1960; sheep, D.P. Alexander and Nixon, 1961; Matson *et al.*, 1981; guinea pig, Boyland *et al.*, 1958; Chez *et al.*, 1964). Indeed, the osmolality of fetal pig urine collected from the bladder was only 13% of plasma osmolality in mid-gestation, reflecting the extremely low urinary urea at this time (McCance and Stanier, 1960).

Since transplacental water flux is substantially higher than that needed for normal fetal growth (Flexner and Gellhorn, 1942), the production of a hypotonic urine is not surprising. The greater part of the glomerular filtrate is reabsorbed in the proximal tubule, where fluid transport is isosmotic. The passive reabsorption of water following active sodium transport is determined by the water permeability of the proximal tubule, which is increased in the immature kidney (Horster and Larsson, 1976), and the oncotic and hydrostatic pressure gradients in the lumen, interstitium and peritubular capillaries (see above). The remaining water reabsorption occurs mainly in the countercurrent multiplication system of the loop of Henle (anatomically immature *in utero*; see above) and the concentrating tubules.

The two main factors militating against efficient concentration, once fluid has left the proximal tubule, are the very low medullary

sodium and urea concentration and a relative insensitivity of the duct to vasopressin, possibly mediated by the low cortisol concentrations *in utero* (Towstoless *et al.*, 1989). Stanier (1972) studied the development of intrarenal solute gradients and described marked interspecies variability. For example, the sodium concentration gradient between cortex and papilla in the fetal pig kidney is very small indeed up to term, and only steepens post-natally, while in fetal lambs, by late gestation, the sodium concentration gradient is steep. The urea gradient is also very small in fetal pigs, and because of their extremely fast rate of post-natal growth only builds up relatively slowly thereafter. McCance and Widdowson (1957) suggested that this was likely to be a characteristic of species which grow very rapidly **post partum**, but the pig is also anomalous in having a water requirement for urea excretion.

Common to all mammalian fetuses, is the fact of earlier development of inner cortical nephrons. These take the largest proportion of the renal blood flow and, since their efferent arterioles supply the medullary vasa recta, there will also be a 'washout' effect, impeding the build-up of a solute gradient.

Although the urine is characteristically hypotonic at birth, the term fetus can concentrate it to approximately 150–200% plasma osmolality (Robillard and Weitzman, 1980), although this is markedly less than the adult's concentrating ability. The chronically catheterized fetal lamb appears to have functional volume and osmoreceptor controls for arginine vasopressin (AVP) secretion (Ross, 1988) and atrial natriuretic peptide secretion (Ross *et al.*, 1987), and shows a gradual increase in free water reabsorption in late gestation (Robillard *et al.*, 1979). The fetus can respond to increases in maternal plasma osmolality by increasing its urinary osmolality (Lumbers and Stevens, 1983) and markedly decreasing the urinary flow rate. The fetus will also respond appropriately to the infusion of exogenous AVP in the last quarter of gestation, by decreasing free water clearance and increasing urinary osmolality (Lingwood *et al.*, 1978b; Robillard and Weitzman, 1980). It seems likely, however, that the fetal kidney is less sensitive to AVP than is the adult, and Joppich *et al.* (1981) suggested that this might be due to inhibitory effects of the high intrarenal concentrations of prostaglandin E_2 at this time. It might also be related to a lesser response of adenyl cyclase to AVP (Schlondorff *et al.*, 1978).

Protein

The urine from the human fetus in the middle trimester contained no or trace amounts of protein when tested with trichloroacetic acid (Vernier and Birch-Andersen, 1962) but more sophisticated detection techniques have shown that urinary proteins of various kinds are present in human urine from at least mid-gestation (Kronquist *et al.*, 1984). These included albumin, α–fetoprotein, transferrin and Tamm–Horsfall protein. However, in the last quarter of gestation the relative abundance of serum-type proteins in the urine was much less and resembled the adult pattern. Whereas urine from mid-gestation contained a complex assortment of polypeptides of molecular weight 12 000–40 000 daltons, the mechanisms increasing the reabsorption of small proteins appeared to have matured. The greater permeability of younger fetal glomerular capillaries (Vernier and Birch-Anderson, 1962) presumably accounts for the relatively large early concentrations of urinary protein. The appearance of Tamm–Horsfall protein in the urine of the fetal rat parallels functional development of the thick ascending limb of the loop of Henle, and may be related to the development of impermeability to water in this segment.

The anatomical and functional development of the fetal kidneys, in which ontogeny so well recapitulates phylogeny, is among the most complex aspects of fetal physiology. The marked effects of anaesthesia and sur-

gery on renal function also hinder its study, and areas such as the renal effects on acid–base balance *in utero* remain poorly understood.

8.3.5 THE REPRODUCTIVE SYSTEM

Like the developing kidney, with which it is closely associated, the fetal reproductive system needs to grow and develop, but will not have functional demands made on it until after birth.

(a) Structure

The primitive gonads develop from the genital ridges which form on the mesonephroi. They consist of coelomic epithelium, an underlying mesenchyme of mesonephric origin, and the germ cells. The germ cells arise in the yolk sac very early in gestation and migrate to the germinal ridges by amoeboid movement, multiplying as they go. The germ cells and coelomic epithelium together form the cortical germinal epithelium (Figure 8.18), while the inner mesenchyme and the mesonephric tubules form the medulla.

Differentiation in the chromosomal male fetus precedes that in the female, as the primary cords grow, branch and attract germ cells, becoming the medullary spermatogonia. The cortex thins and the tunica albuginea forms (Figure 8.18). In the chromosomal female fetus, the cortex continues to grow, with the germ cells embedded in it developing as oocytes.

There is sexual differentiation in the timing of the onset of meiosis in germ cells, which occurs substantially earlier in the female than in the male fetus. Meiosis of oogonia in the human female fetus begins at around 8 weeks' gestation, resulting in haploid primary oocytes, arrested in prophase and remaining like this until individual oocytes start to mature further at puberty. There is no further mitotic division, and the number of primary oocytes thus falls thereafter. In the male, however, mitotic division of the spermatogonia continues, and meiosis is only initiated at puberty, continuing throughout life. It is interesting to note that the mesonephros may secrete a 'meiosis-inhibiting hormone'. In those species, such as the pig and rabbit, in which mesonephric function continues until relatively late in gestation

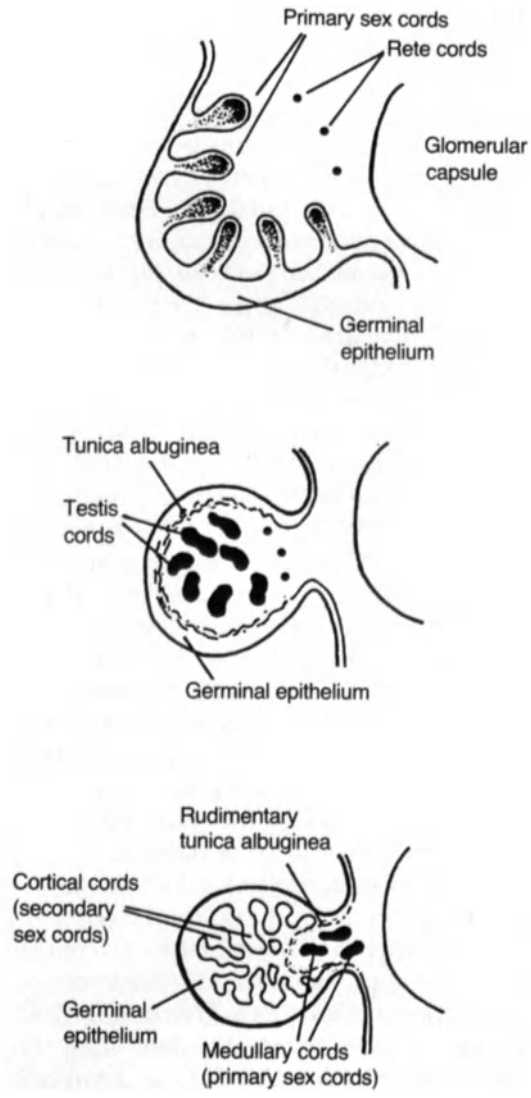

Figure 8.18 General gonadal development in the mammalian fetus.

Table 8.13 The proportion of gestation at which gonadal differentiation in the chromosomal male fetus develops varies widely between species. Data from: Attal, 1969; Black *et al.*, 1969; Catt *et al.*, 1975; Tanner, 1978; MacDonald, 1979; Pointis and Latreille, 1986.

Species	*Proportion of gestation*
Man	**0.23**
Sheep	0.24
Pig	0.25
Guinea pig	0.35
Rabbit	0.55
Rat	0.82

(Table 8.13), the onset of meiosis in the oogonia occurs after sexual differentiation, whereas in those species having small and minimally functional mesonephroi, such as the rat and human, the onset of meiosis and sexual differentiation is approximately synchronous (Grinsted and Aagesen, 1984).

Gonadal differentiation is the first sexual differentiation to occur and is initiated through the presence of a Y chromosome. The testis determining factor (TDF), a 120 kilobase segment of the short arm of the Y chromosome, induces testicular differentiation by the fifth or sixth week of pregnancy in the human fetus (N. Barnes, 1992). The presence of testes thus indicates the presence of a Y chromosome (unless there is a translocation of the TDF onto the paternal X chromosome, in which case an XX male or XX true hermaphrodite can develop). Male sex is also associated with the male histocompatibility antigen, the H-Y antigen, a cell-surface protein which is found in the males of all mammalian species. The function of this protein, and the nature of its relationship to TDF, is not clear. Subsequent male differentiation requires testicular hormone production from the Leydig cells and Mullerian inhibitory factor (MIF) from the Sertoli cells. Testosterone stimulates the Wolffian ducts to become the epididymis, vasa deferentia and seminal vesicles. MIF causes local regression of the Mullerian ducts. Androgenic stimulation is also necessary for differentiation of the external genitalia which, without such stimulation, are female in character regardless of chromosomal and gonadal sex.

The Mullerian ducts are retained in the female fetus, and form the Fallopian tubes, uterus and upper vagina; it is the Wolffian ducts which regress in this sex, although contributing to the ureter and the trigone of the bladder. In both sexes the external genitalia develop from the urogenital sinus and tubercle, and are the last part of the reproductive tract to differentiate (see this series, Volume 2, Chapter 4).

Male development is, therefore, an active embryological process which is complete by 13 weeks of the human pregnancy. In contrast, female development may be described as the 'default option', a passive process which proceeds even in a castrated fetus irrespective of the genetic sex (Jost, 1953).

The importance of hormonal change in governing development and function of the reproductive system cannot be overstated, and is the subject of the rest of this section.

(b) Hormonal effects

Testosterone

The onset of testosterone secretion by the fetal testis appears to be governed by placentally produced gonadotrophin (Huhtaniemi *et al.*, 1977). It is this locally produced testosterone which is responsible for the male development of the testis. The fetus is provided with a rich source of steroid precursors such as progesterone and pregnenolone from the placenta, and does not, therefore, need the capacity to take acetate or cholesterol through the biosynthetic chain to testosterone. However, there are species differences in substrate preference, in that both newborn mouse and fetal human testes can utilize either progesterone or pregnenolone equally *in vitro*, while fetal rabbit testis preferentially

utilizes pregnenolone in the synthesis of testosterone (Siiteri and Wilson, 1974). Probably very little maternal testosterone crosses the placenta (Rigaudière and Després, 1986).

The development of a synthetic capacity for testosterone either precedes (rabbit and rat, Black and Christensen, 1969; sheep, Attal, 1969) or appears to be simultaneous with (guinea pig, Black and Christensen, 1969; human, Siiteri and Wilson, 1974) the time of testicular cytodifferentiation and enlargement of the interstitial cells. These interstitial cells contain substantial quantities of tubular smooth endoplasmic reticulum and are the primary source of testicular androgens (Black and Christensen, 1969; Veyssiere *et al.*, 1977).

The concentration of testosterone in the testis reaches a peak during the differentiation of the internal genital tract, and falls thereafter (rabbits, 0.63 gestation, Catt *et al.*, 1975; Veyssiere *et al.*, 1976; man, 0.36 gestation, Siiteri and Wilson, 1974; pig, 0.31 gestation, A.A. MacDonald, 1979). The decrease in testosterone formation coincides in man with a regression in both the size and number of the interstitial cells during the second half of gestation (Siiteri and Wilson, 1974) and is associated with an accumulation of 17α-hydroxypregnenolone, implying a change in enzyme activity. Circulating testosterone concentrations are also high during internal genital differentiation in fetal pigs, cattle and humans, falling thereafter (Veyssiere *et al.*, 1976). However, although circulating testosterone concentrations rise sharply after birth in some species (e.g. rabbit, Veyssiere *et al.*, 1976; pig, Ponzilius *et al.*, 1986), in others plasma testosterone continues to fall for some time post-natally, with only a delayed and transient rise (e.g. human, Tanner, 1978; rat, Huhtaniemi *et al.*, 1982).

The fetal ovary appears to have little capacity to synthesize testosterone, but such as there is peaks at much the same time as the testicular synthetic capacity. In the rabbit, fetal ovarian testosterone concentrations are only 2% of testicular values at the peak (0.65 gestation, Veyssiere *et al.*, 1976). Plasma testosterone concentrations in newborn female rabbits, pigs and rhesus monkeys are also lower than in males at birth (Veyssiere *et al.*, 1976; Huhtaniemi, 1977; A.A. MacDonald, 1979), and in this they differ from such species as cattle, sheep and man, in which there are no sex-linked differences in plasma testosterone at birth.

While locally-synthesized testosterone is the active inducer of testicular and Wolffian duct differentiation, the embryonic anlagen of the external genitalia and the prostate primarily synthesize dihydrotestosterone (2-OH-testosterone). In man, the 2-OH-testosterone production per milligram of tissue in the urogenital sinus is already high by 0.2–0.25 of gestation, considerably before differentiation of this region. The Mullerian and Wolffian ducts show no *in vitro* capacity to synthesize 2-OH-testosterone before the end of the first trimester, while none is evident in the epididymis until about halfway through gestation (Siiteri and Wilson, 1974).

Testosterone plays another important role in the development of the reproductive system. The testis must remain as a non-cyclical organ, while the ovary becomes cyclically active. Determination of cyclicity is made through the action of testosterone on the hypothalamus, and once exposure to testosterone has occurred the change is irreversible and 'maleness' is dominant. This 'sensitive period' appears to be at the start of the second trimester in man (G.W. Harris and Levine, 1965), but in species born in a less mature state may not occur until after birth. This is so, for example, in the rat, in which the 'sensitive period' is around 5 days post-natally (G.W. Harris and Levine, 1965). Such differences may account for the sexual dimorphism of gonadotrophin release seen in the fetus of some species but not others.

Testosterone must be converted either to oestradiol or to 2-OH-testosterone in the

hypothalamus before it can exert its effect on the brain. Binding sites for both hormones are present in the guinea pig brain halfway through gestation, and, like man, this is a species in which hypothalamic dimorphism is of prenatal onset (Pasqualini *et al.*, 1977; Rigaudière and Després, 1986). Such sites are not present in the rat brain until after birth (Pasqualini *et al.*, 1977) when hypothalamic oestradiol concentrations are high in male pups (Rhoda *et al.*, 1987). Once sexual differentiation of the hypothalamus has occurred, growth rates are enhanced in the male fetus.

Oestrogens

The gonadal capacity to synthesize oestrogens lags behind that for testosterone. Rat fetal testicular cells have a very low capacity for aromatization, and undetectable oestrogen production (Tsai-Morris *et al.*, 1986). In the sheep, no gonadal oestrogens are detectable before halfway through gestation (Attal, 1969). However, measurable plasma concentrations of sulphated oestrogens are found in fetal guinea pigs (Pasqualini *et al.*, 1977), mostly unbound. This may be peculiar to the guinea pig which has either very low or absent concentrations of α-fetoprotein (AFP), which in other species binds the oestrogens. Fetal guinea pigs also have high-affinity oestradiol binding sites in both uterus and testis, from at least halfway through gestation, rising towards term (Sumida and Pasqualini, 1979), although those in the testis are only present at one-seventh the concentration of those in the uterus (Pasqualini *et al.*, 1976). Conversely, fetal rat gonads have very low concentrations of oestradiol receptors (Tsai-Morris *et al.*, 1986).

Gonadotrophins

Although it is placental, rather than pituitary, gonadotrophin which initially stimulates testosterone production by the future testis, the fetus in later gestation does acquire a functional hypothalamo-pituitary axis quite independent of the mother's. The degree to which this influences the fetal gonad depends largely on the general maturity of the fetus at birth.

Luteinizing hormone (LH) and follicle-stimulating hormone (FSH) are present in the anterior pituitary gland of pigs, cattle and man from about one third of gestation (Kiser *et al.*, 1975; J.A. Clements *et al.*, 1976; Ponzilius *et al.*, 1986). The peak pituitary concentrations occur before birth in both sexes, and appear not to differ with gender. The concentrations fall towards term. Gonadotrophin-releasing hormone (GnRH) may be present earlier in the hypothalamus (e.g. at 0.16 gestation in man) but *in vivo* appears not to interact with the pituitary until considerably later (see below).

Basal plasma concentrations of LH are measurable soon after the hormone can be detected in the pituitary gland. Release is probably pulsatile, as in the adult, but the number and amplitude of such pulses is low before birth (Ponzilius *et al.*, 1986), falling to a nadir at term. Basal concentrations have been variously reported as higher in the female than the male fetus (rhesus monkeys, Resko and Ellingwood, 1985; humans, J.A. Clements *et al.*, 1976); lower (cattle, Kiser *et al.*, 1975) or the same (pigs, A.A. MacDonald, 1979; Ponzilius *et al.*, 1986). The lack of sexual differences in plasma LH in fetal pigs has been attributed to an apparent lack of negative feedback by the moderate testosterone concentrations of the fetal male piglet (Ponzilius *et al.*, 1986).

By contrast, the basal FSH concentration is substantially higher in human female than male fetus during the second trimester (Gennser *et al.*, 1976), but even so the concentration in males exceeds that in the maternal circulation. FSH in the female fetus rises during the second trimester, falling thereafter to very low concentrations at term (Clements *et al.*, 1976); this fall is not seen in the male fetus.

Both LH and FSH plasma concentrations rise dramatically after birth in humans and pigs, LH concentrations being greater in the human male fetus (Clements *et al.*, 1976; Ponzilius *et al.*, 1986) but the concentrations then fall and remain low until beginning their prepubertal changes.

The concentration of gonadotrophin receptors appears to be determined by endogenous hormone concentrations in the fetus, unlike the adult. Where concentrations are low, as in the rat, treatment with exogenous hormone up-regulates the receptors, and allows biological responsiveness to the hormone to emerge (Huhtaniemi *et al.*, 1982; Tsai Morris *et al.*, 1986). The association constants of the LH-hCG receptors of fetal rabbit testis halfway through gestation are identical to those of adults, suggesting that biological activity of the gonadotrophins will depend more on receptor number (Catt *et al.*, 1975). Binding of labelled hCG by fetal rabbit and rhesus monkey testis rises until late mid-gestation, but is stable thereafter, while ovarian binding sites are present in much lower concentrations (Catt *et al.*, 1975; Huhtaniemi *et al.*, 1977). In a series of precisely timed observations, Catt *et al.* (1975) were unable to show a temporal dissociation between the appearance of the LH-hCG receptor at 0.60 of gestation and the ability of the fetal rabbit testis to synthesize testosterone.

The mutually inter-regulatory role of the gonadotrophins and gonadal steroid production is well documented *in utero*. The crudest demonstration of this is that, following castration of male fetuses, LH and FSH concentrations rise substantially (Resko and Ellingwood, 1985; Ponzilius *et al.*, 1986), a rise which is blocked by the administration of testosterone or 2-OH-testosterone. This rise in gonadotrophin concentration is much smaller in some species than others, presumably relating to immaturity of the pituitary–gonadal axis. In the pig, plasma LH concentrations only rise after birth following antenatal castration; in this respect, as in many others, the pig differs from other species of similar size and gestation length. Conversely, decapitation of the near-term fetal rat is associated with retardation of testicular growth and the volume and number of the Leydig cells (Eguchi and Morikawa, 1968). This is a species which does not have a placental gonadotrophin, so that pituitary–gonadal interaction must occur *in utero* for normal development.

The administration of LH or hCG in late pregnancy stimulates testicular testosterone production in all species studied. This, of course, differs from the effects of similar administration to adults, in which there is a short-lived increase in testosterone secretion, followed by receptor down-regulation and blockade of synthesis. The transition to an adult-type response is well documented in the neonatal rat (Huhtaniemi *et al.*, 1982) and is paralleled by the disappearance of AFP, which binds oestrogen, from the circulation, and the rapid development of oestradiol receptors in the testis, both allowing the onset of negative feedback by oestrogens on testosterone synthesis.

Hypothalamic effects on the gonads are the last to manifest themselves in the hormonal chain of development of the reproductive system. *In vivo*, fetal calves at 0.40 of gestation respond to GnRH by increasing plasma LH, female calves showing a substantially greater response. Serum testosterone also rises following GnRH administration in male, but not female, fetal calves (Kiser *et al.*, 1975). However, GnRH was without effect on human fetal FSH or LH/hCG during the second trimester (Gennser *et al.*, 1976), although fetal pituitaries *in vitro* released gonadotrophins in response to GnRH at this age. Experiments with fetal lambs, rabbits and monkeys *in vivo* near term showed stimulation of LH and testosterone secretion, although high doses of GnRH were needed in the lambs and monkeys (Foster *et al.*, 1972; Huhtaniemi *et al.*, 1977; Veyssiere *et al.*,

1977). This may be due to the low pituitary concentrations of gonadotrophins at this time. The response tended to fall towards term. The fall in basal testicular testosterone production towards term (see above) is, thus, likely to be related to the declining concentrations of gonadotrophins, rather than to immaturity of the hypothalamo-pituitary–gonadal axis *per se*.

Thus, by the time of birth the anatomical and hormonal differentiation necessary for reproductive function is to a considerable extent complete. The fascinating thing is that the system is then largely held in abeyance, until such time as maturation of the other body systems will allow the female to support a pregnancy. How this state of quiescence is maintained remains something of an enigma.

8.3.6 THE LIVER

(a) Structure

The liver develops as a large diverticulum of the foregut, from which endodermal cells detach themselves and surround the developing network of vitelline veins. The hepatic venous circulation is formed by the anastomosis and remodelling of the anterior vitelline and the umbilical veins, while the portal vein is derived from the caudal ends of the vitelline veins. The hepatocytes are surrounded by a network of developing bile canaliculi which appear to bud off from the hepatic plates. The bile ducts and ductules run in parallel with the branches of the developing portal venous and hepatic arterial systems (Kaufman, 1992).

In the fetal lamb, the umbilical vein enters the liver and gives rise directly to portal branches to the left lobe of the liver. The ductus venosus then arises from the umbilical vein, which continues to join the portal vein, the portal branches to the right lobe of the liver arising from near this junction. The communication between umbilical and portal veins is sometimes referred to as the portal sinus, but no true anatomical sinus exists (Rudolph and Rudolph, 1992). Hence, part of the flow from the placenta by-passes the liver via the ductus venosus which joins the inferior vena cava (IVC) in a joint connection with the left hepatic vein. The right hepatic vein joins the IVC through an adjacent, but separate, orifice. In both the sheep and the primate fetus, the proportion of umbilical venous return crossing the ductus venosus, and avoiding the hepatic microcirculation, averages slightly more than half (Edelstone and Rudolph, 1979). Within the IVC, this well-oxygenated blood from the placenta, which returns via the ductus venosus, does not completely mix with either the poorly oxygenated blood returning from the lower body or the hepatic venous blood. The stream of highly oxygenated blood preferentially crosses the foramen ovale and contributes to the cerebral arterial supply (Rudolph, 1983), this preferential streaming being most pronounced in the fetal primate.

In the horse, however, the caudal end of the ductus venosus is obliterated in early gestation (e.g. R.J. Barnes *et al.*, 1979). Thus, in this species the umbilical venous blood actually perfuses liver tissue before draining into the inferior vena cava via the hepatic veins. It used to be thought that a ductus venosus was also absent in the fetal pig, but later work (R.J. Barnes *et al.*, 1979) has confirmed the presence of a functional hepatic by-pass in late gestation, even though its anatomical origin may differ from that in other mammals.

About three-quarters of total hepatic blood flow *in utero*, in the sheep and primate, is derived from the well-oxygenated blood (saturation 80%) returning from the placenta (Rudolph and Rudolph, 1992). The remainder is supplied by poorly oxygenated portal venous blood, there being minimal supply from the hepatic artery *in utero*. The left and right sides of the liver receive different blood supplies in fetal life. The left lobe of the liver is perfused with relatively well-oxygenated

blood from branches arising directly from the umbilical vein. The blood perfusing the right side of the liver is poorly oxygenated (Dawes, 1968), with an oxygen saturation little higher than that of the portal venous blood (27%) in the newborn lamb. The higher proportion of haemopoietic foci in this area (Emery, 1956) presumably reflects this, erythropoiesis being stimulated by hypoxia (section 8.3.2, 'Blood and oxygen transport').

(b) Function

Bile production

Experimental study of fetal bile production is technically difficult because the bile canaliculus is relatively inaccessible and therefore less is known about the ontogeny of this process than many other aspects of fetal liver function. In the fetus, nutrition is via the placenta, not by the gastrointestinal tract, so that the mechanisms for the release of bile, including cholecystokinin release, are not invoked, and the need for detergent and micellar-forming properties of bile in the intestine is absent. Perhaps not surprisingly then, there is a lower rate of spontaneous bile flow in the fetal sheep near term than in the adult sheep (Hardy, 1980). Bile can also be secreted from the gall bladder from around halfway through gestation in man, and there appears to be some enterohepatic circulation (see Grand *et al.*, 1976). The fetal intestine is bacteriologically sterile, and it must therefore be assumed that free deoxycholic acid, which is formed by bacterial 7-α dehydration of cholic acid, does not occur *in utero* (Gustafsson *et al.*, 1985). However, the primary bile acids are found in meconium, which suggests that some hydroxylation of cholic acid can occur. Human fetal liver *in vitro* can also hydroxylate taurodeoxycholate at least during the second trimester, which adult liver only does minimally (Gustafsson *et al.*, 1985). This presumably provides an alternative pathway preventing the build-up of the toxic conjugated deoxycholic acid.

Bilirubin metabolism

The fetal liver plays a major role as a haemopoietic organ; indeed, in early fetal life haemopoietic cells outnumber hepatocytes and contribute to the proportionally greater size of fetal than adult liver. This aspect of fetal liver function is discussed in section 8.3.2, 'Blood and oxygen transport'. Bilirubin is one of the major endpoints of red cell breakdown. In the adult, free bilirubin is rapidly bound by plasma albumin. Almost all of the bilirubin which is absorbed into the hepatic cells is then rapidly conjugated, mostly to glucuronic acid but a little to the sulphate and other substances, before being excreted into the bile canaliculi. However, in the fetus, although red cell destruction proceeds and bilirubin is produced, plasma albumin is relatively low (e.g. Baum *et al.*, 1971; Spitzer and Edelmann, 1971; Cartlidge and Rutter, 1986) and the ability to conjugate is diminished due to the absence or very low concentrations of hepatic glucuronyl transferase. In the rat, for example, there is almost no conjugation before 0.82 gestation and the free bilirubin concentration is two to three times higher than in the adult, partly due to slower placental transport in this species than in the guinea pig or primates (Muraca *et al.*, 1986). The ability to monoconjugate precedes deconjugation, and by term only 6% of the bilirubin in fetal rat plasma is conjugated. However, there is a rapid rise in conjugating ability after birth, and within 24 h approximately 40% of plasma bilirubin is conjugated in this species (Muraca *et al.*, 1986). The process takes longer in other species, such as man and horse (e.g. Gartner, 1981; J.W. Harvey *et al.*, 1984). Hence, there is a period of neonatal hyperbilirubinaemia (neonatal jaundice) due to the breakdown of fetal red cells with increased production of bilirubin, enhanced bilirubin reabsorption from the intestine via the enter-

ohepatic circulation and a slowly improving ability to conjugate bilirubin. It should, however, be remembered that placental transfer of bilirubin, the main excretory route before birth, depends on the bilirubin remaining unconjugated, as a relatively lipid-soluble polar substance. 'Inadequate' conjugation may thus be an adaptive, rather than an immature, mechanism. Bilirubin glucuronides have been identified in the amniotic fluid of pregnancies complicated by fetal haemolysis due to blood group incompatibility (Rosenthal, 1992). This suggests that the fetal capacity to conjugate bilirubin may be stimulated by raised circulating bilirubin levels, a condition which does not normally obtain until after birth because of the efficiency of the placenta. The lower conjugating ability of the fetal liver means that the ability of the fetus and newborn to metabolize and excrete drugs is impaired by comparison with the adult.

Plasma protein production

The liver makes other contributions to the composition of the blood (Dancis *et al.*, 1957). Fetal hepatocytes synthesize α-fetoprotein. This occurs from 0.15 gestation in man, and plasma levels reach a peak halfway through gestation, by which time all hepatocytes are synthesizing the protein. Concentrations then fall as the cells are switched progressively to the production of albumin (Lindblad, 1976; Stone, 1981). Even so, plasma albumin concentrations tend to be low at birth, especially after premature delivery (Spitzer and Edelmann, 1971; Baum and Harris, 1972; Cartlidge and Rutter, 1986). The function of α-fetoprotein is unknown, but it may serve as a primitive form of albumin or have an immunoregulatory function (Ruoslahti and Hirai, 1976). Very elevated concentrations at term are seen in infants born with a teratoma. α-fetoprotein also acts as one of the 'tumour markers' if plasma concentrations increase in later life, being particularly associated with hepatomas and seminomas.

The fetal liver also synthesizes various coagulation factors, particularly prothrombin and factors VII, IX and X. This synthesis is particularly susceptible to vitamin K deficiency, which is therefore associated with haemorrhagic disease of the newborn (McNinch and Tripp, 1991). These clotting factors are present in lower concentrations in late fetal and early neonatal life than in adulthood in all species studied (Dancis *et al.*, 1957).

Glycogen storage

At the moment of birth, the fetus is removed from its continuous and regulated supply of glucose from the mother, and must rapidly switch to utilizing the high-fat relatively low-carbohydrate diet of mother's milk. There is usually an interim period before the newborn begins to suckle, and during this phase the hepatic glycogen stores play a vital role in maintaining normoglycaemia. These are built up during gestation in all species studied (Figure 8.19) at rates which are partly dependent on length of gestation, species with longer gestations starting to lay down stores relatively early, and in a more leisurely fashion, than those with shorter gestations (Shelley, 1961; Randall and L'Ecuyer, 1976).

By term, hepatic glycogen concentrations are twice those in the adult (approximately 12 mg per g wet weight compared with 6 mg per g wet weight; Lafeber, 1981). Glycogen synthesis *in utero* is under hormonal control, with the hypothalamus playing an integrative role (see Girard, 1986). As well as insulin, the insulin-like factor and cortisol, epidermal growth factor (EGF) appears to be involved in glycogen deposition in the fetal liver (Freemark, 1986). The concentration of EGF binding sites rises rapidly from 0.85 gestation to term in fetal mouse liver, in parallel with the ability to stimulate the incorporation of labelled glucose into glycogen and the rise in

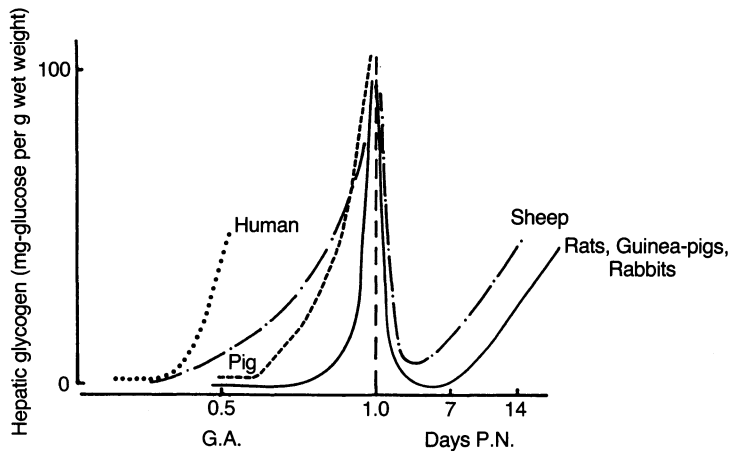

Figure 8.19 There is a marked rise in hepatic glycogen concentration towards term in all species. The transition to an extrauterine environment and activation of the digestive system is accompanied by an abrupt fall in these stores, which can then take several weeks to reach adult values. (Redrawn from Shelley, 1961, and Randall and Ecuyer, 1976). GA, gestational age; PN, post-natal.

hepatic glycogen deposition. A stimulatory effect of EGF on the size of fetal lamb liver has also been reported (Thorburn *et al.*, 1981), but this appears to be a generalized phenomenon, rather than specifically related to glycogen deposition.

It is worth remembering that, although the fetal liver markedly accumulates glycogen as term approaches, other tissues are also storing this energy substrate. Thus, in species which have very little fat at birth, such as piglets, the skeletal muscle accumulates substantial glycogen stores before birth, some 90% of its energy reserves being in this form (Randall and L'Ecuyer, 1976). Conversely, term fetal rabbits have low glycogen concentrations in their skeletal muscle (see Dawes, 1968). Instead they have considerable brown and white adipose tissue, providing fuel sources for heat production and gluconeogenesis which can be switched on after birth. For example, beta-oxidation of fatty acids by rabbit hepatocytes is eightfold greater in 24-h-old newborn rabbits than in fetal rabbits (Duee *et al.*, 1985). Hepatic fatty acid oxidation also increases in the rat during the suckling period, compared with fetal life, and falls to adult levels during the weaning period (E. Bailey and Lockwood, 1973; Zimmermann *et al.*, 1986). Such differences may also relate, in part, to the fact that the piglet is active immediately after birth, and needs a direct energy supply for running about, while the newborn rabbit lives in a nest and has minimal requirements for skeletal muscular activity.

Gluconeogenesis

The process of birth and the interruption of a continuous food supply very rapidly deplete the hepatic glycogen stores (Figure 8.19; Shelley, 1961). The enzymes necessary for gluconeogenesis are present in the fetal liver of most species except the rat, development again occurring relatively sooner in those species with longer gestation periods. However, providing that the mother is receiving an adequate nutrient intake, intrauterine gluconeogenesis does not seem to occur in species as diverse as the rat, the sheep and man. Should the mother rat, rabbit, guinea pig or sheep be fasted, hepatic enzyme induction can occur *in utero*, espe-

cially that of phosphoenolpyruvate carboxykinase (PEPCK), essential in the early steps of gluconeogenesis which can then be initiated. Birth itself is an important stimulus to cytosolic PEPCK induction. Glycerol is another substrate which can be utilized for fetal gluconeogenesis (M. Gilbert, 1977) and the enzymes concerned in its metabolism, primarily glycerol kinase and glycerol-3-phosphate (G3P) dehydrogenase, are present in fetal liver (Vernon and Walker, 1970; Sadava *et al.*, 1987). Hepatic mitochondrial G3P dehydrogenase rises sharply after birth, which may suggest the activation of a glycerol phosphate shuttle. The whole topic of perinatal gluconeogenesis has been reviewed by Girard (1986).

Amino acid breakdown

The degradation of amino acids occurs mainly in the liver, and has been studied in the fetus largely in terms of induction of the various enzyme systems. It is, however, important to remember that the fetus's primary need is to synthesize protein, rather than to break it down. The fetal lamb can oxidize amino acids (F.C. Battaglia and Meschia, 1988) and can therefore use them as an alternative energy source, as can the guinea pig (Lafeber, 1981). The rat, however, appears unable to do this (Snell and Walker, 1973). Many liver enzymes are present but with low activity, possibly explained by the low blood flow and high insulin concentrations pertaining *in utero*. The free amino acid concentration, with the exception of valine and cystine, is high in fetal liver, following placental transfer, and this might enhance the enzyme activities needed for nucleic acid synthesis. However, it has been suggested that various hepatic enzymes such as tyrosine aminotransferase are inhibited *in utero* (Raiha, 1971) and that the increase in PaO_2 or hepatic blood flow post-natally allows full activity of the enzyme. Tryptophan oxygenase also increases markedly immediately after birth (Lindblad, 1976). A summary of amino acid metabolism during fetal life is available to the interested reader (Lindblad, 1976).

Fatty acids

Fatty acids are mostly used in early gestation for membrane formation (Naughton, 1981), and as triglycerides for fat storage in later gestation. The guinea pig, relatively mature at birth, has a peaking of the enzymes concerned with fatty acid synthesis and of such synthesis at two-thirds of the way through gestation, coinciding with the development of the smooth endoplasmic reticulum and with a peak of the enzymes involved in NADPH production (Lafeber, 1981). The exception is acetyl CoA carboxylase, which is barely detectable in the guinea pig liver at term (C.T. Jones and Ashton, 1976). In species less mature at birth, such developments occur in the immediate perinatal period.

Urea synthesis

Hepatic cyclic urea synthesis is a complex process involving both mitochondrial and cytoplasmic enzymes. The need for urea synthesis *in utero* is small since protein synthesis exceeds degradation at this age. It is possible that the primary role of the urea cycle antenatally is to synthesize arginine, since relatively little crosses the placenta. Arginine synthetase is, however, still relatively low at birth (Raiha and Suihkonen, 1968a). Increasing synthetic capacity for urea can be demonstrated *in vitro* from mid-gestation in man, and in the last third of gestation in the guinea pig and rhesus monkey, in parallel with the development of ornithine transcarbamylase (Raiha and Suihkonen, 1968a; Lafeber, 1981; Holzgreve *et al.*, 1985). In species of short gestation, such as the rat, the capacity for cyclic urea synthesis *in utero* is very low, but rises rapidly in the first 24 h post-natally to

Table 8.14 Some markers of the anatomical development of the stomach in various mammalian species in relation to the proportion of gestation at which they are identified. Data from: Hill, 1956; Hayward, 1967; Helander, 1969; Arey, 1974; de Lemos, 1977; MacDonald *et al.*, 1982.

Species	*Gastric pits*	*Mucous neck cells*	*Chief cells*	*Intestinal villi*
Man	**0.15**	**0.15**	**0.30**	**0.15**
Sheep (abomasum)	0.46	?	0.58	0.27
Pig	0.63	?	?	?
Rabbit	0.77	0.97	0.77	?
Rat	0.86	0.86	1.27	?

some 25% of adult capacity (Kadowaki *et al.*, 1983). This rise in capacity parallels the development of argininosuccinate synthetase activity, which seems to be rate-limiting in this species (Raiha and Suihkonen, 1968b).

8.3.7 THE GASTROINTESTINAL TRACT

The gastrointestinal (GI) tract is one of the organ systems which contributes little to fetal well-being before birth, but which becomes immediately vital in the post-natal period. Maturity of the GI tract varies widely at birth. Thus, in the guinea pig the anatomical structure and hormone and enzyme systems of stomach and small intestine are effectively mature at birth. In the lamb, on the other hand, the anatomical and histological development of the forestomach (rumen, reticulum and omasum) lags markedly behind that of the abomasum until birth, with rapid catch-up growth thereafter (Nickel *et al.*, 1973); the abomasum is, however, sufficiently developed to allow the efficient digestion of colostrum and milk. Species born after a very short gestation, such as rats, have functionally very immature GI tracts at birth, and the direct intestinal transfer of macromolecules continues for some 3 weeks post-natally (see below). The phased development of gastric enzyme systems in man has clinical relevance in relation to the selection of appropriate feeding for the very prematurely delivered human infant, since survival from before the end of the second trimester is now possible in specialized units. This topic is not considered further in this chapter on normal fetal physiology, but is mentioned as an example of the numerous ways in which basic and applied research are directly related in this area.

(a) Structure

Although the stage of gestation at which gastric development is initiated varies between species its early stages are similar in all species, with developmental maturity progressing from the proximal to the distal end of the tract. Once the dilatation in the primitive foregut which will form the stomach has arrived at its definitive position, the columnar cells of the gastric mucosa are pushed progressively into folds with mesodermal 'cores', forming primitive villi. Gastric pits form at the base of these folds, the precursors of the gastric glands. The rate of development of these glands is proportionally slower in species with shorter gestation lengths (Table 8.14).

There are also species differences in the rate at which different regions of the stomach develop; glandular development is faster in the fundus than the antrum in man (0.15

compared with 0.25 gestation), while the converse is true in the rabbit (1.0 compared with 0.61 gestation) (Deren, 1971).

The histological demonstration of gastric enzymes in the fetal stomach is made difficult by the apparently different characteristics of some of these enzymes before birth. For example, although granulation is present in human fetal chief cells in the late first trimester, its staining characteristics differ from adult pepsinogen (Deren, 1971). The same is true for human fetal D cells (gastrin-containing cells; de Lemos, 1977). It is possible that such differences may partly account for the wide spread of gestational age across which chief cell and parietal cell secretion is stated to occur (Table 8.14). It seems likely that the neutral gastric pH until close to or even after term (see below), may explain the differing characteristics of the enzymes.

The intestinal epithelium is initially stratified, with columnar epithelium developing by the end of the first third of gestation in man (Kelley, 1973) and the sheep (Trahair and Robinson, 1986). Microvilli develop roughly in synchrony with columnar epithelium, together with mitochondria and Golgi bodies. Dense bodies and vesicles ('meconium corpuscles') which may be primitive lysosomes appear in the villous epithelial cells at much the same time (Andersen *et al.*, 1964). The rates of cell turnover and migration in the small intestine appear slower *in utero* than in adulthood in some species (rat, human, sheep) but not in others (pig, guinea pig) (see Grand *et al.*, 1976; Trahair and Robinson, 1986). The colon develops in parallel with the small intestine.

(b) Function before birth

The function of the gastrointestinal tract falls into three broad phases: intrauterine, during which minimal, if any, nutritive function is served; neonatal, during which a single, entirely specific food must be ingested and digested; and infant and adult, when weaning and maturation of function to deal with adult foodstuffs occur. Thus, the fetal gastrointestinal tract has, as it were, a breathing space after birth before the full complexities of adult feeding are thrust upon it.

Swallowing

The fetus shows episodic swallowing movements surprisingly early in gestation. The human fetus in the early second trimester can apparently swallow some 2–7 ml/day, a volume which increases with gestation age (Pritchard, 1965; Abramovich, 1970) to some 450 ml/day at term with substantial individual variation. The fetal lamb, studied directly with implanted flow probes, swallows a very similar daily volume by term (Mistretta and Bradley, 1975), although estimates made by a less accurate tracer dilution technique suggest considerably greater daily swallowed volumes (Tomoda *et al.*, 1985). It is fascinating to conjecture whether the fetus can taste what it swallows. Morphologically mature taste buds are present in man at about one-third and in the lamb from about two-thirds of gestation (Bradley and Mistretta, 1973), while in species of substantially shorter gestation, such as the rat, mature taste buds do not appear until after birth (1.52 gestation, Farbman, 1965). The application of various taste stimuli to the tongue of fetal lambs in the last third of gestation is accompanied by consistent responses in fibres of the chorda tympani, which does suggest that the fetus may be able to sense (although not necessarily perceive the 'taste' of) its surrounding liquor.

Protein digestion

Work by Gitlin *et al.* (1972) suggested that the human fetus could digest proteins present in amniotic fluid, and it was therefore suggested that the fetus might derive some of its nutritional requirements from swallowed liquor. Infants with oesophageal atresia

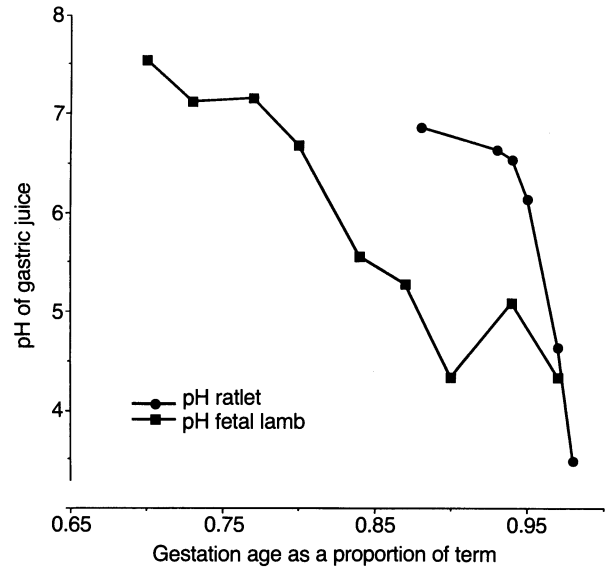

Figure 8.20 The pH of the gastric contents falls markedly in late gestation in the fetal lamb and rat, but does not reach adult values until after birth. (Data from Shulkes *et al.*, 1985, and Garzon *et al.*, 1981.)

tend to be smaller than normal infants. Oesophageal ligation in fetal rabbits resulted in reductions in both birth weight and crown–rump length (Mulvihill *et al.*, 1985), but when fluid was continuously infused into the fetal stomach after ligation no such effect was seen. These authors suggested that swallowed liquor might account for 10–14% of the fetuses' daily calorie intake, a figure similar to that suggested for the human fetus by Grand *et al.* (1976) and for the rhesus monkey fetus (Pitkin and Reynolds, 1975). In passing, it is perhaps interesting to note that the consumption of carbohydrates and amino acids across the intestinal circulation of the fetal sheep is such that it appears that nutrients derived from the amniotic fluid may in fact be being used by the intestine for its own metabolism and growth, rather than making any general contribution to the fetal nutrient pool (Charlton *et al.*, 1979a). It has also been suggested that early exposure of the gut to various proteins might be a requirement for gastric enzyme induction (e.g. Pitkin and Reynolds, 1975) and, furthermore, that the amniotic fluid contains unspecified gastrointestinal trophic factors, but this remains to be confirmed.

The fetus acquires its amino acids by placental transfer, and the need for protein denaturation *in utero* is thus minimal. Gastric acidification, which denatures proteins and stimulates pepsin activity for their digestion, is a feature only of late gestation. The functional ability for acid secretion is, however, present before it is physiologically expressed and appears to parallel parietal cell development (Wright, 1963). Figure 8.20 shows the temporal changes in the pH of the gastric contents of the fetal lamb and rat towards term, and it will be seen that, even at term, the gastric pH is substantially higher than that in the adult (Garzon *et al.*, 1981; Shulkes *et al.*, 1985).

This is a universal finding, and may partly be due to the buffering effect of ingested amniotic fluid.

Animal experiments suggest strongly that the control mechanisms for gastric acid secretion differ in fetus and adult.

Immunoreactive gastrin is present in the fetal stomach from at least halfway through gestation in man (see Grand *et al.*, 1976) and two-thirds through gestation in rabbits (Deren, 1971), but in addition to the basally low gastric acid secretion the acid secretory response to pentagastrin is both slow and small before birth (e.g. Garzon *et al.*, 1982; Shulkes *et al.*, 1985). This, in conjunction with the high plasma gastrin concentrations *in utero* (Shulkes *et al.*, 1982) and at birth (Euler *et al.*, 1977), suggests receptor immaturity, either in avidity or number, or the presence of a competitive inhibitor.

Gastrin administration to mature animals stimulates DNA and RNA synthesis and promotes the growth of the pancreas. The hypergastrinaemia of late gestation, with no negative feedback control via low gastric pH, may thus be exerting a trophic effect on the fetal digestive tract.

In the adult, the stimulatory effects of gastrin, histamine and acetylcholine on gastric secretion appear to be closely related, and it has been suggested that histamine may provide a final common pathway. This is not so in fetal rats or lambs, in which the responses to pentagastrin, carbachol and histamine, which begin to appear in late gestation, are entirely independent of each other (Garzon *et al.*, 1982; Shulkes *et al.*, 1985), as also seems to be the case in the newly born piglet (Forte *et al.*, 1975). Both histamine and vasocative intestinal peptide stimulate cAMP in gastric glands from human fetal stomach in the early second trimester (Gespach *et al.*, 1981), but pentagastrin administration was without effect in a proportion of infants born in the early third trimester (P.E. Hyman *et al.*, 1985).

Prostaglandin E_2 (PGE_2) exerts a cytoprotective effect on the mucosal cells in the adult, by its effect on sodium transport and mucus production. Little is known of its role in this respect before birth, but gastric PGE_2 concentrations were unmeasurable in infants delivered before the third trimester (Marino *et al.*, 1983). An adult-type correlation between gastric pH and PGE_2 concentration was not reached until 37 weeks' gestation.

Pepsin secretion may antedate (lamb), coincide with (rat) or follow (rabbit, pig) the onset of gastric acid secretion (Deren, 1971). Where its secretion develops post-natally, intestinal antibody transfer (see below) will be possible until such secretion develops. The optimum pH for pepsin activity is 1.8–3.5, so the high pH of the gastric contents *in utero* and in the immediate perinatal period will inhibit its activity. Pepsin secretion occurs relatively late in man (approximately 0.86 gestation), which could theoretically impair digestion in the premature newborn. However, the very process of birth, and gastric distension through feeding, have substantial effects on gastrointestinal functional development (see below).

Intrinsic factor appears to be synthesized by the parietal cells from the time of their differentiation (see Grand *et al.*, 1976). Its function *in utero* has not been studied and its secretion only increases slowly after birth (Deren, 1971).

Peristalsis in the human small intestine is demonstrable in the late first trimester, at which time beta-adrenergic receptors are already present (see Grand *et al.*, 1976). Alpha-adrenergic receptors are only demonstrable somewhat later, and appear to be anatomically differently sited. The prominent microvillus border, with marked ATPase activity, suggests the possibility of some absorption during fetal life, from at least a quarter of gestation (Lev *et al.*, 1972). The development of the brush border enzymes such as disaccharidases, peptidases and alkaline phosphatase is rapid from this time (Menard and Arsenault, 1985), with potential functional differentiation of different segments of the small intestine from 0.28 gestation. Thus, at 0.28 gestation glucose transport is similar in jejunum and ileum, but by 0.40 gestation such transport is greater in the jejunum (Koldovsky, 1970).

Macromolecules such as ferritin and horseradish peroxidase can be taken up from small intestine by the end of the first trimester in the human (Moxey and Trier, 1979) and in the rhesus monkey (Lev and Orlic, 1973). These villous absorptive cells resemble those of the adult in primates by approximately halfway through gestation, whereas a similar appearance is not found until weaning in the rat (Moxey and Trier, 1979).

Carbohydrate digestion

The intestinal digestion and absorption of carbohydrates before birth has been most widely studied in the chronically cannulated fetal lamb. Ruminant gastrointestinal physiology is obviously markedly different from that of other animals, so that even more caution than usual is required for between-species extrapolation. The response to duodenal instillation of glucose increased from late gestation to term, in terms of absolute blood glucose concentration reached, change from basal blood glucose concentration and the time to peak response and return to basal levels (Charlton *et al.*, 1979b). Lactose administration had similar age-related effects, while maltose and sucrose were without effect on blood glucose level at any gestational age. The smaller, slower effects in younger fetus probably relate to lesser absorption across the gut, either because of the smaller surface area or because of lesser activity of a glucose carrier. Maltase and sucrase are evidently absent in fetal lambs, by contrast with the human fetus, in which both are abundant in the third trimester (Lebenthal and Lee, 1980). Fructose absorption is by facilitated diffusion, rather than active transport, and is slow from the fetal lamb gut, regardless of gestational age (Charlton *et al.*, 1979b). In these experiments there was a good overall correlation between the change in blood glucose and that in lactate, the lactate presumably accumulating in the absence of other pathways for pyruvate metabolism.

Similar experiments performed acutely in the rhesus monkey in late gestation also showed a blunted response by comparison with adults, with, under these circumstances, no change in plasma insulin, growth hormone or glucagon (Chez *et al.*, 1974). Interestingly, infant monkeys delivered prematurely over the same gestation range, studied 4–5 h after birth, showed a much enhanced response in blood glucose concentration, and some increase in plasma insulin concentration.

Fat digestion

Fatty acids are transported across the placenta, and are then used as 'building blocks' for more complex lipid structures by the fetus. The functional demands for fetal intestinal lipid absorption must be small, but there is evidence for some intrauterine enterohepatic circulation for biliary lipids. Lipid can be absorbed from human fetal small intestine by 0.25 gestation, while biliary lipid secretion is present at least by halfway through gestation (see Grand *et al.*, 1976). However, the bile salt concentration is too low *in utero* to allow the solubilization of lipids, so although pancreatic lipase activity is present from approximately 0.4 gestation in rat, lamb and human fetus (Koldovsky, 1970), it may be functionally unimportant. Lingual and gastric lipase activity is discussed briefly below in relation to digestion in the newborn.

In the human embryo, by 4 weeks after conception two pancreatic buds have appeared as outgrowths of the lower end of the foregut. By 7 weeks, these buds have rotated and fused to give the appearance of the definitive gland and the pancreatic duct has formed. Although the human pancreas is anatomically and histologically mature well before birth, enzyme secretion is still immature. Differentiation of acinar cells takes place from 10 to 14 weeks and endocrine cells appear from 8 to 12 weeks. Pancreatic secretion does not begin until around the fifth

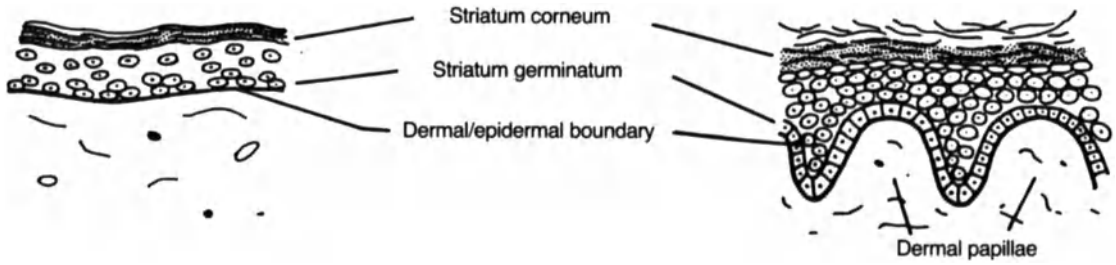

Figure 8.21 Transverse sections through the skin of human fetus of 28–30 weeks' gestation (left-hand panel) and one at term (right-hand panel). Note the development of the stratum corneum, with desquamation of the outermost epidermal layers by term, and the development of the dermal papillae.

month, and enzyme activity is detectable in human fetal pancreatic tissue from about this time. Trypsin, chymotrypsin and carboxypeptidase appear first in the human fetus, to be followed by enterokinase and pancreatic lipase (McClean and Weaver, 1993). However, even by term the levels of the last two are still less than 20% of the levels achieved in childhood. Enterokinase is necessary for the conversion of trypsinogen to trypsin, which in turn activates chymotrypsin and carboxypeptidase. Pancreatic amylase is not detectable in significant amounts until after birth, but human milk contains some amylase, which may aid digestion of starch at the time of weaning (Dewitt *et al.*, 1990).

The ontogenesis of gastrointestinal and pancreatic enzyme systems forms a substantial subject in itself, and is not further considered here. The interested reader is referred to the reviews by Grand *et al.* (1976) and Saraux and Girard-Globa (1982). Pancreatic endocrine function is considered in the review by Van Assche and Hoet (1984) and in section 8.2.2 in relation to glucose metabolism.

8.3.8 THE SKIN

The most important functions of the skin in extrauterine life are to act as a barrier to prevent the loss of water and electrolytes; to form a protective layer against the entry of such hazards as bacteria; and to provide a degree of insulation against extremes of environmental temperatures. The barrier properties of the skin lie in the stratum corneum, with its flattened, anuclear cells and high keratin content, bound together by a lipid layer with a specialized 'waterproofing' ceramide, polyoxyacyl ceramide (Nugteren *et al.*, 1985). However, the stratum corneum develops relatively late in gestation, so that the barrier properties of fetal skin are poorly developed by comparison with those of adults.

(a) Structure

The early development of the skin is very similar in all species. There is an initial single-layered ectoderm (primordial epidermis) and a single-layered mesoderm (primordial dermis). By 0.2–0.38 gestation (man, mouse) the germinative ectoderm has produced a single-layered periderm which covers the entire surface (Sengel, 1976; Holbrook and Odland, 1980). The germinative layer will also ultimately give rise to the strata spinosum, granulosum and corneum (Figure 8.21).

By the end of the first trimester in man the periderm is beginning to thicken in the plantar and palmar regions, and keratinocytes are distinguishable beneath it. These are also of ectodermal origin. Keratin proteins are found in fetal rabbit epidermis at 0.39 gestation, considerably before morphological differentiation of the epidermis has occurred, but are

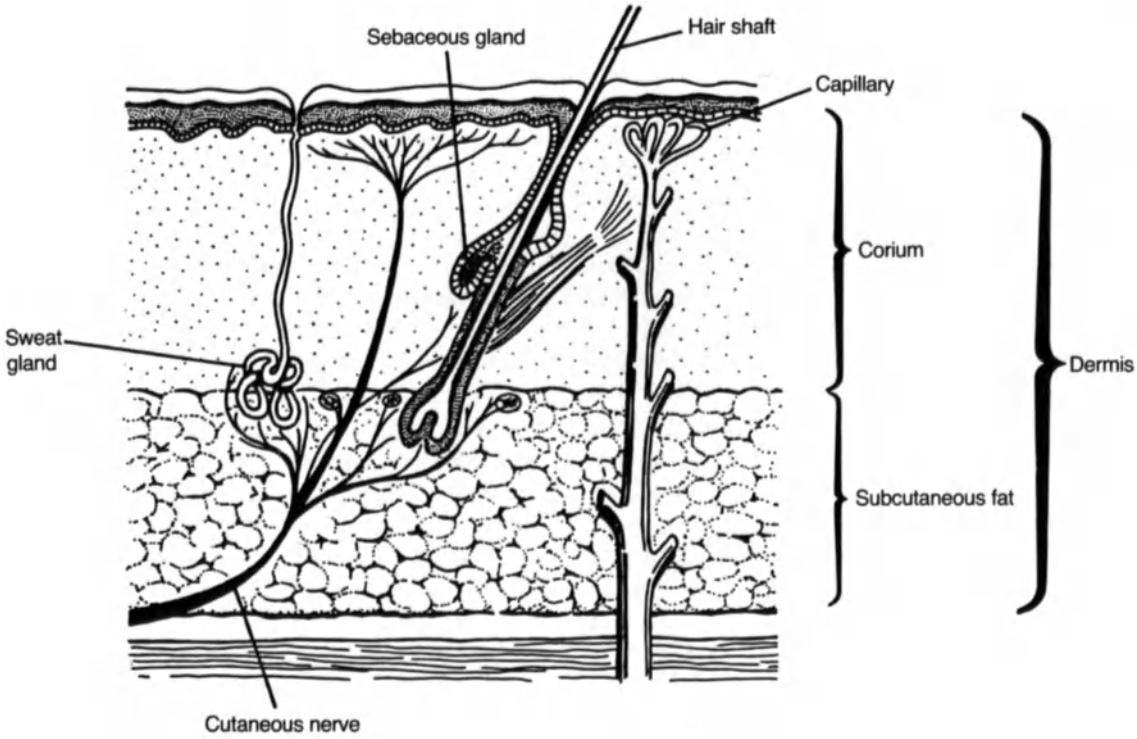

Figure 8.22 A transverse section through the skin of a term human fetus to show the epidermal appendages.

not present until much later (0.77) in the rat (Green and Couchman, 1984). There is a form of fetal keratin, of rather lower molecular weight, which disappears in late gestation in the rabbit (Banks-Schlegel, 1982). Interestingly, this is the keratin synthesized by the adult human conjunctiva. The development of a stratum corneum is dependent on synthesis of higher molecular weight, adult-type keratins (Banks-Schlegel, 1982). Full keratinization is first achieved in the nails (0.40 gestation, human) but epidermal keratinization is not complete until 0.7 gestation (Weston, 1985). As the stratum corneum forms, so the outer periderm is sloughed off, but this can occur at any stage from mid-gestation (man) to post-natally (mouse, Holbrook and Odland, 1980).

The dermis forms from mesenchyme, and is initially poorly differentiated. It is however, absolutely necessary for the normal development of the epidermis. It is identifiable from about a quarter of the way through gestation in the human and pig fetus, but not until halfway through in mice (Sengel, 1976). Differentiation into the two adult layers is fairly slow, and the subdermal fat layer develops still later.

A variety of epidermal appendages (Figure 8.22) are formed during fetal life, including the structures of the hair follicle, the sebaceous glands, the apocrine and eccrine sweat glands and the nails.

Hair follicles begin as downgrowths from the basal layer at the end of the first trimester in man and monkeys (Bressler and Munger, 1983) but much later in rats (0.73, Green and Couchman, 1984). However, while in man

subsequent development to actual hair formation takes several weeks, the same progression occurs in 4 days in fetal rats (Green and Couchman, 1984). It has been suggested that epidermal growth factor (EGF) is implicated in the development of hair follicles, since numerous receptors for EGF can be demonstrated over the outer root sheath and the epithelial cell layers at the follicle base (Green and Couchman, 1984). Actual hair formation begins on the scalp and proceeds cephalocaudally, and the hair follicles themselves are directed backwards. Animals which have whiskers (vibrissae) start to develop these in parallel with normal hair follicles. Small nerve plexuses, probably of Schwann cells, are found by halfway through gestation at the base of vibrissae follicles in mice (Bressler and Munger, 1983), and it seems probable that vibrissae only develop from such early innervated follicles. Animals with hairy skin use hairs as mechanosensitive receptors, and here again innervation develops relatively early (about 0.40 gestation in the rhesus monkey, Bressler and Munger, 1983) with circularly arranged afferent nerve terminals apparent soon after differentiation of the hair follicle.

The initial hair formed by the human fetus is the fine, silky lanugo hair, which resembles the vellus hair of post-natal life. Lanugo hair may be very prominent on the forehead and sides of the face, as well as the scalp, but by about halfway through gestation the follicles on the forehead start to involute and vellus hair formation begins, initially at the eyebrows and scalp (Holbrook and Odland, 1980). Wool-bearing animals do not develop lanugo hair (Thorburn *et al.*, 1981) and the primary wool fibres only become evident in late (> 0.8) gestation.

Sebaceous glands form from the epidermal downgrowths which result in the hair follicles and are first evident in human fetus at the end of the first trimester. They are active *in utero*, with high concentrations of hydroxysteroid dehydrogenases present by 0.4 gestation (Weston, 1985). They are particularly responsive to the high levels of androgenic steroids which are encountered in the fetal circulation and secrete lipid-filled cells in increasing numbers into the amniotic fluid as gestation progresses. This secretion is presumably an important component of the protective vernix caseosa (see below).

The eccrine sweat glands also form from downgrowths of the basal layer. The terminal coils of the sweat gland gradually increase in complexity, but the duct can be patent considerably before the adult-type structure is reached.

In man, the Pacinian (deep pressure receptor) corpuscles are fully formed at term, but Meissner's touch receptors are not (Maiback and Boisits, 1982). Interestingly, the function of the Merkel cells, which are simple touch receptors in the adult, may be different *in utero*. It has been suggested (Moll *et al.*, 1986) that they subserve a neuroendocrine function, secreting a tissue hormone(s) which promotes or induces the local formation and growth of such special structures as the hair follicles, eccrine sweat glands and/or nerves. They appear in the epidermis at the end of the first third of gestation and migrate into the dermis. However, by late gestation their distribution is again confined to the epidermis, suggesting that their dermal function is complete.

The hormonal factor(s) which regulate differentiation of the skin and its glands and appendages are not well defined. Certainly, EGF receptors are demonstrable in the last third of gestation in the areas of fetal rat skin in which rapid epidermal growth is occurring (Green and Couchman, 1984) and the number of receptors falls in parallel with the rate of mitosis. The administration of large doses of EGF to fetal lambs in the last quarter of gestation also evokes a marked hypertrophy of epidermal glandular structures, and increased skin wrinkling, but the changes in the primary wool fibres are degenerative in nature (Thorburn *et al.*, 1981). Furthermore,

the urinary excretion of EGF is low in neonates, whether lambs (Thorburn *et al.*, 1981) or humans (Evans and Rutter, 1986a).

(b) Permeability

The composition of amniotic fluid in early pregnancy closely resembles a dialysate of fetal and/or maternal serum (see above). It can be shown that the permeability of fetal skin to tritiated water before keratinization has occurred is very similar to that of chorion laeve or amnion (Parmley and Seeds, 1970). It thus seems likely that in early gestation both water and solutes can pass freely across the fetal skin. However, as gestation progresses, and the fetal kidneys begin to excrete urea into the liquor, the need to avoid osmotic dehydration becomes pressing. As soon as keratinization is initiated, the skin's permeability to water begins to drop dramatically, and with the attainment of full keratinization water diffusion detectable *in vitro* effectively ceases (Parmley and Seeds, 1970).

There has been considerable interest in transepidermal water loss after birth, since in the human newborn epidermal development is not complete until 0.85 gestation, and an increasing number of babies younger than this now survive and need nursing. Even at term, skin water losses are considerably higher than those of adults for the first few hours after birth (Rutter and Hull, 1979b). This is largely due to immaturity of the stratum corneum, but may also be influenced by the low serum albumin concentration normal at birth (Hammarlund *et al.*, 1984). Anyone who compares an infant delivered at less than 28 weeks (0.7) with a term neonatal mouse will see the similarities in skin colour and texture, with a thin, moist pink skin, with prominently visible blood vessels. The degree of keratinization is also similar, and in a dry environment skin water loss may be up to 10 times higher than that in adults (Harpin and Rutter, 1983). However, the neonatal mouse survives because of the high humidity in the nest, and humidification of the incubators used for nursing the very premature infant is a recent development, in which clinical practice has learnt from nature.

In both mouse and man, exposure to the extrauterine environment results in a very rapid development of the stratum corneum, with corresponding falls in water loss through the skin (Harpin and Rutter, 1983). This 'speeding-up' occurs even when delivery has been very premature indeed. Another consequence is that the evaporative heat loss, due to high skin water loss, is reduced. A further consequence of the high skin permeability before the stratum corneum has developed might be turned to use for the very premature human newborn. Experiments conducted 23 years ago showed that if previable human and mouse fetuses were immersed in fluid-filled incubators at 35°C with liquid oxygen tensions of 250 p.s.i., they could survive for at least 23 h (cited in Gleiss and Stuttgen, 1970). From this observation arose the concept of enhanced percutaneous respiration in the newborn, a concept recently supported by studies of human infants born between 25 and 41 weeks' gestation. In very premature infants in which the stratum corneum was poorly developed, oxygen and carbon dioxide were transferred up to 11 times faster than in term infants (Evans and Rutter, 1986b). It can be calculated that the very premature human newborn could obtain up to 20% of its total oxygen requirements transepidermally (Cartlidge and Rutter, 1987). The skin of such infants is also much more permeable to drugs and agents such as phenylephrine (Harpin and Rutter, 1983). This might provide an extra route of administration such as is being tested in adults for the continuous administration of drugs to combat angina. Experiments with fetal lambs suggest that drugs may also be absorbed from the amniotic fluid across the fetal skin (Mears and Van

Petten, 1977), but it has not been determined whether this might be of clinical benefit.

(c) Temperature regulation

The adult's skin is an important regulator of body temperature, both through variations in the blood flow to the cutaneous vasculature and by heat loss through eccrine sweating. The importance of sweating in this respect varies substantially between species, in that adult mice, rats, guinea pigs, rabbits and dogs hardly sweat at all, whereas men, cattle and horses sweat strongly (Precht *et al.*, 1973). Even at term, however, the human newborn is comparatively resistant to sweating, with a considerably higher threshold than adults. Infants of less than 32 weeks' gestation are apparently unable to sweat at all (see Maiback and Boisits, 1982). Term infants can respond by sweating to both acetyl choline and adrenaline given intradermally, but this ability develops late in gestation, and is not found at 0.9 gestation or less. As with transepidermal water loss, exposure to the extrauterine environment accelerates the development of eccrine sweating, but at a considerably slower rate.

Eccrine sweating, induced by increased ambient temperature, is under hypothalamic control. The so-called 'emotional' sweating, induced by stressful events, involves a higher centre in the premotor cortex, and its development appears to be much more tightly tied to post-conceptional age. The only species in which its development has been studied in any depth is man. It is only apparent in the human newborn after 36–37 weeks' gestation, regardless of whether the baby was delivered before this time or not (Harpin and Rutter, 1982), and by 40–41 weeks the response induced by a painful stimulus is similar to that in adults.

8.4 RESPONSE TO BIRTH

8.4.1 THE ONSET OF BREATHING

The immediate requirement of the independent newborn is to establish an alternative supply of oxygen. The first step is to open the lungs and form a functional residual capacity.

When the fetus emerges from the birth canal it has already experienced many powerful physiological stimuli, in part a consequence of the labour on the mother, but in part due to the effect of uterine contractions on the placenta and fetus itself. A noxious stimulus which might stimulate a gasp *in utero* would have little permanent consequence for only a relatively small volume of fluid would be drawn into the lung. Once the head is surrounded by gas then a stimulus that provokes a gasp usually leads to a sequence of events which is irreversible. The pulmonary adaptation to extrauterine life is completed rapidly in healthy, vaginally delivered infants but is somewhat slower if the infant is born by Caesarean section (Palme-Kilander *et al.*, 1993).

Under normal circumstances the newborn gasps within seconds of birth. Precisely what causes this response is uncertain, but it may well be the consequence of a crescendo of novel stimuli, including cold air, particularly on the face, the movement of limbs and joints into positions they have never been in before and the contact with new and different surfaces. Many mammals lick the faces of their young and in so doing remove fetal membranes, clear away debris and provoke respiratory responses. The whale, which delivers under water, immediately turns after the birth to follow the newborn as it dashes to the surface to take the first breath. Whales have been observed to toss their young repeatedly out of the water, which may well assist in the initial aeration of the lungs. In man, infants slow to take that first gasp have, over the centuries, been subjected to a range of stimuli aimed at provoking a first deep respiration,

from anal dilation to a splash of champagne on the face. Dangling them by their heels and slapping them on the back must be a particularly painful experience and is unnecessary; nothing seems to stimulate a gasp more effectively than blowing cold oxygen around the nose and mouth, and this has the advantage that when the gasp does occur an oxygen-rich mixture is drawn into the lungs.

There are a variety of reasons why newborn infants might fail to gasp at birth, from intrauterine asphyxia to congenital abnormalities, but the management of such matters is outside the subject of this chapter (Roberton, 1986). So too are the mechanisms which invoke gasping in asphyxiated newborns; it is probable that only in such situations does hypoxia or hypercapnia act as a stimulant. It is not necessary to postulate that the 'normal' infant is asphyxiated by the birth process and that asphyxia is a requirement for stimulating the initial gasp. Fetuses experimentally asphyxiated *in utero* do make gasping efforts, and babies born after intrauterine asphyxia often have vernix and meconium in their lungs, indicating that they must take deep respiratory efforts prior to birth. However, anyone who has attempted to study the exteriorized fetus close to term knows well that even minimal handling or a hint of cool air on the face provokes a gasp. Given modern anaesthetic techniques, infants born by elective Caesarean section are not hypoxic at delivery, the cord is pulsating freely and yet the majority gasp immediately with handling and clamping of the cord.

(a) The consequence of the first gasp

With the first gasp, air is drawn into the lung and the liquid–gas interface disappears down the respiratory tree. Such would be the surface forces that, despite the strength of the respiratory effort, that interface would not travel very far down the finer divisions of the airway if it were not for a natural detergent, 'surfactant'. This is a phospholipid secreted by the type II pneumocytes lining the air sacs, and it is the properties of this chemical that permit the air to be held in the terminal air sacs and alveoli to form the reservoir, the residual volume, which is essential for gaseous exchange (J.A. Clements, 1977). Natural or synthetic exogenous surfactant, used to improve lung function in immature infants who lack endogenous surfactant (OSIRIS Collaborative Group, 1992), probably helps by increasing functional residual capacity rather than increasing lung compliance (A. Milner, 1993).

With the first inspiratory effort, air usually enters the lungs and with expiration some is retained. But this is not inevitably so (A.D. Milner and Vyas, 1982). The formation of the functional residual capacity does not always follow the first inspiration. Examples of pressure–volume loops during the initial respiratory efforts of three infants are shown in Figure 8.23.

In Figure 8.23a, as the intrathoracic pressure falls, air is drawn in to a volume of 60 ml. With expiration air leaves the lungs until 20 ml is left as a first contribution, as it were, to the formation of the residual volume. With the second inspirating effort 80 ml is drawn in, and at the end 40 ml remains in the lung. The residual volume forms in steps. This is probably the usual pattern. In human infants the functional residual capacity (40 ml/kg) forms to about 80% of its final volume in the first few minutes.

However, there are wide variations in pattern and timing; this can be easily appreciated by watching the respiratory movements of newborns at birth. For example, some with their first efforts draw very little air in. This, along with studies on isolated lungs, led to the concept of an 'opening pressure'. By this is meant that a certain negative pressure had to be generated before any air entered the lung, and then air 'rushes in'. The opening pressure phenomenon is the rule when collapsed isolated lungs are inflated via the trachea. It may occur under

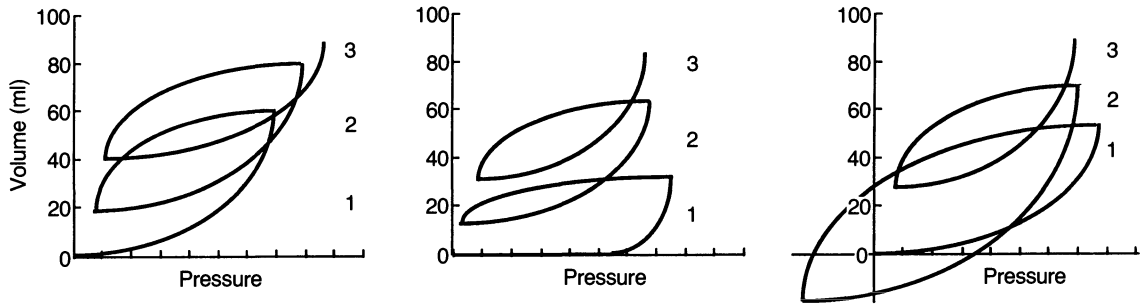

Figure 8.23 Stylized pressure–volume curves of the first three respiratory efforts. The first shows a rapid stepwise formation of a residual volume. The second illustrates an opening pressure. The third show and infant expelling gas which had entered due to recoil of the chest cage after birth.

normal circumstances, but whilst in the former it probably relates to surface characteristics in the latter 'the opening pressure' is more likely to be due to upper airway obstruction.

(b) The formation and maintenance of the functional residual capacity

A third sequence of events is shown in Figure 8.23c. Here the first gasp draws in air but it all leaves again; indeed more leaves than was inhaled! This clearly demands an explanation. Whilst surfactant permits gas to be held in the alveolar sacs with the gas–liquid interface lining the type I and II pneumocytes, it will not, of itself, retain gas in the lungs. That demands other forces, namely the shape of the chest wall and the tone of the diaphragm. For more to leave than is inhaled implies that air has entered without obvious inspiratory effort.

In section 8.3.3(c) the formation and circulation of lung liquid was reviewed. The volume of lung liquid in sheep is 40 ml/kg, which is close to the functional residual capacity after birth. It would seem that the thorax and diaphragm in its resting state *in utero* hold a volume of fluid equivalent to the volume of gas the lungs hold after birth. There is some evidence in sheep that this lung liquid begins to clear from the lungs in preparation for birth. However, at birth in man, and presumably other mammals born head first, the thorax is squeezed in the birth canal. Not infrequently, liquid can be seen pouring out of the nose and mouth. When the thorax emerges from the birth canal it may well resume its initial shape and thus air is drawn passively into the lung. Various attempts have been made to estimate this volume; in man, it can be as much as 40 ml, but it is very variable.

Other mechanisms which have been postulated have been 'frog breathing' by gulping air, and priapism of the pulmonary vasculature, thus splinting the lungs open to hold gas. At the present there is little evidence to support either idea. It seems far more likely that the formation of the functional residual volume depends primarily on the tone and position of the diaphragm, and this may well change prior to the first gasp. Similar sequences can be seen in the limb muscles as they pick up tone and begin to move after birth.

Once the first gasp has been made, then the functional residual capacity will be held in part by air trapping, but also by the tone and position of the diaphragm and chest wall. Once a functional residual capacity has formed, and only when it has formed, will tidal respirations, breathing, commence.

After birth, with the opening of the pul-

monary circulation (section 8.4.2), lung liquid is drawn from the lungs probably in the main via the capillaries and veins, and at a slower pace via the pulmonary lymphatics. This too results in a passive formation of a residual volume, but on a different time scale, and may well be responsible for the slow increase in functional residual capacity after the first few minutes and over the first few hours (for review, see Strang, 1977).

8.4.2 CIRCULATORY CHANGES AT BIRTH

Whilst the most dramatic action seen at birth is the newborn's efforts to expand its lungs, the event which has the most profound and widespread consequences is the sudden irreversible occlusion of the umbilical cord.

The cord may be occluded in the last stages of labour, it may snap at the birth, or it may pulsate for a while until some action, stretching or chewing (or, in man, clamping) causes the vessels to go into spasm. A whole variety of steps are taken by parents, usually mothers, to get rid of the 'afterbirth'. For herbivores it appears to be the only time they eat flesh – a meal rich in iron and long-chain polyunsaturated fatty acids amongst other things.

In human infants, many papers have been written on the desirability of early or late clamping of the cord (Oh *et al.*, 1966), and the position of the baby in relation to the placental bed, and the benefits or harm that may accrue from milking or massaging the cord. In animals who deliver whilst standing, the placental bed is higher than the fetus and the fetus may receive an additional flow of blood via the umbilical vein as it falls free of the birth canal before the vessels go into spasm. When a mother, lying on her back, is delivered by a Caesarean section, the infant is lifted out of the womb and blood can then flow from baby to placental bed. That obviously must be avoided. However, the advantages and disadvantages of early or late clamping appear to balance out, except perhaps in the preterm infant (Kinmond *et al.*, 1993). The newborn with extra blood has more problem with neonatal jaundice (Saigal *et al.*, 1972) but is less at risk of subsequent anaemia.

Occlusion of the cord leads to certain predictable events. The venous return via the umbilical vein ceases, thus the ductus venosus collapses, and from then on the portal vein is the sole supplier of the portal venous system. With the drop in flow through the inferior vena cava, the pressure in the right atrium falls and the foramen ovale closes, an event which is reinforced when the increasing pulmonary venous return increases the pressure in the left atrium. Also, within seconds, the chemoreceptors are perfused by blood drawn from the lungs rather than oxygenated blood from the placenta. With the clamping of the umbilical artery, a sudden increase in the peripheral resistance occurs and the blood pressure rises (Dawes, 1968).

Expansion of the lung leads to a fall in pulmonary arterial resistance and pulmonary flow increases. This happens even if the lung is filled with nitrogen. If it is expanded with air, oxygen is drawn into the body. This mechanical effect of lung inflation on pulmonary vasculature is reinforced by the effects of falling carbon dioxide, rising pH and rising PO_2, all of which favour pulmonary vasodilation, and thus lung perfusion is established, maintained and controlled. Hormonal changes may also influence pulmonary vascular resistance (Soifer and Heymann, 1984; Mott, 1985; Soifer *et al.*, 1985a,b; Kühl *et al.*, 1989; Davidson and Eldemerdash, 1990; Hargrave *et al.*, 1990) and there must also be receptors responsive to agents which do not occur naturally but have potent pulmonary vasodilator properties, such as magnesium sulphate and nitric oxide (Kinsella *et al.*, 1992). The sudden drop in pulmonary vascular resistance results in a reversal of the flow through the ductus arteriosus. Now oxygenated blood flows back to the left atrium, and is distributed by the left

ventricle, so that oxygenated blood flows back through the ductus. The ductus is a muscular vessel and its muscular wall is susceptible to PO_2 such that as the PO_2 rises the muscle contracts, a mechanism which involves prostaglandins. Drugs inhibiting the synthesis of prostaglandins cause the duct to close (Heymann *et al.*, 1976; Rennie and Cooke, 1992), whereas an infusion of prostaglandin E_1 can keep the ductus open (Hallidie-Smith, 1984). With muscle spasm, the ductus closes 'physiologically' within a matter of minutes of birth but at this time, with an episode of asphyxia, it will open again. However, over a matter of weeks the closed ductus slowly, seals up anatomically and is replaced by a fibrous cord.

With the fetal channels closed, the ventricles now contract in series with equal stroke volumes. The systemic blood pressure rises and the pulmonary blood pressure falls. The systemic arterial PaO_2 also increases and the supply and uptake of oxygen to many of the organs of the body rises. In most mammalian species the resting metabolic rate at birth is relatively low and it gradually increases over the first days of life. However, the timing and magnitude of the rise varies from species to species, and in some little or none takes place. The reasons for the increase presumably reflect increasing activity in organs such as the bowel and liver but possibly, in those animals with advanced motor development at birth, increased muscular activity to maintain posture.

8.4.3 NUTRITION

A less urgent but equally critical consequence of interruption of the placental circulation is the withdrawal of a 24 h near-constant supply of glucose, amino acids and fatty acids. The glucose, being available and controlled by maternal haemostatic mechanisms, was the main source of cellular energy, amino acids were directed for structure and fatty acids for structure and energy storage. As we have seen in section 8.3.6(b), the energy reserves of glycogen and fat vary widely with species, and hence their capacity to survive in the face of total starvation.

Independent existence demands a number of adjustments. The most immediate is the maintenance of the blood glucose level. In all species studied, the already relatively low blood sugar concentration falls after birth to slowly rise again. The fall presumably reflects an uptake in excess of supply. The immediate source of supply is liver glycogen. Although this can be rapidly consumed in the face of asphyxial episodes, in most species under usual conditions it meets the body's glucose needs for some hours. Next, the liver accelerates gluconeogenesis from amino acids, ketones and fatty acids, and from any lactate produced as a consequence of asphyxia (Girard, 1986). Ketones themselves may be a significant alternative source of energy in some species (Warshaw, 1979; Robinson and Williamson, 1980). The enzymes involved in hepatic gluconeogenesis can be induced by catecholamines, glucocorticoids and pituitary peptides. Their activity is greatest in fetuses with poor growth rates before term (intrauterine growth retardation).

Species differences are important in the metabolic adaptations to the nutritional changes following birth. These changes have been most comprehensively studied in the rat. The rat fetus is largely dependent on a carbohydrate 'diet' (principally transplacental glucose) from the mother but, following birth, rat milk contains lipid as the predominant energy source. The amount of lipid intake then falls again when the rat pup is weaned on to an adult rat diet. In an elegant series of experiments (Girard *et al.*, 1979; Girard, 1986), marked hormonal and enzyme changes have been observed during these nutritional transitions from placental supply to suckling to weaning. These are necessary because the newborn rat has a greater requirement for glucose utilization per unit body weight than the adult animal, partly

because of the relatively larger brain size, but must achieve this despite a milk which is relatively lacking in carbohydrate. The adaptations involve the switch on of gluconeogenesis from amino acid substrates, the utilization of alternative fuels such as fatty acids and ketone bodies to spare glucose, and the inhibition of storage of glucose as glycogen. These changes occur very soon after birth, and it has been shown that the concomitant changes in the necessary enzymes, such as phosphoenolpyruvate carboxykinase (section 8.3.6b), are induced partly by the substrates in the diet. At weaning, there is a second switch in gene expression to promote the synthesis of enzymes which favour storage of glycogen as a protection against fasting (starvation being more likely in the foraging adult than the pup which has a ready supply of milk). These adaptations are most obvious in the rat, compared with the sheep or the human, which have less abrupt substrate transitions, but all mammals show similar, although perhaps less pronounced, responses following birth.

In utero, adipocytes are set to store fat and indeed take up free fatty acid from the circulation. After birth, this process is reversed, presumably in response to circulating catecholamines and sympathetic nervous activity, and there is release of fatty acids into the circulation for use elsewhere. Again *in utero*, peripheral tissues probably have a low rate of fatty acid oxidation as an energy source; the enzymes for fatty acid oxidation are present, but it may take time before they become fully functional (Warshaw, 1972; Roux and Myers, 1974; Zimmermann *et al.*, 1986). Certainly triglyceride droplets appear in many cells after birth from muscle to mucosal lining suggesting fatty acid uptake in excess of cellular capacity to use them. In contrast, brown adipocytes – at least in rabbits – do not appear to have this delay (section 8.4.6).

Whilst the internal adjustments are made, the newborn animal seeks an external source of nutrient. It is the peculiarity of mammals that their mothers supply a special complete food mix to meet all the nutritional requirements of their young. The physiology of this remarkable phenomenon is reviewed in Chapter 12.

8.4.4 THE GASTROINESTINAL TRACT IMMEDIATELY AFTER BIRTH

To obtain food the young must suckle. The physiological events involved in establishing digestion and absorption and the colonization of the bowel to assist in final digestion and excretion are as dramatic, though more leisurely, as those involved in establishing gaseous exchange (Weaver, 1992).

Suckling

Although the fetus swallows amniotic fluid, this is less of a challenge than suckling, when it is vital that milk is not aspirated in to the air-filled lungs. Coordinated sucking and swallowing requires competent neurological reflexes, laryngeal function and a degree of pharyngeal muscle tone that are only achieved in the human infant by 35 weeks' gestation (Herbst, 1989). This gestational age coincides with a significant increase in circulating concentrations of intestinal regulatory polypeptides (gastrin, motilin, neurotensin) in response to milk feeds (Lucas *et al.*, 1978). Therefore, unlike other systems which mature earlier in gestation and can function adequately, although not perfectly, following extremely preterm delivery (e.g. the kidney and endocrine pancreas), the gastrointestinal system cannot support independent nutrition until well into the final trimester.

Gastric acid secretion

Gastric acid secretion increases dramatically after birth in humans (Euler *et al.*, 1979) and guinea pigs (Hill, 1956), giving the gastric contents a pH compatible with pepsin

activity within 1–2 h. This process takes some 36 h in the lamb, and 21 days in the rat (Hill, 1956). Acid output per kg body weight is low at birth in all species, but once initiated rises rapidly. In the relatively mature newborn lamb and guinea pig it occurs whether or not the neonate is fed (Hill, 1956). Pentagastrin is without stimulatory effect on acid secretion in the newborn term human infant (Euler *et al.*, 1979) and basal acid output does not correlate with plasma gastrin concentrations. This is also so in infants delivered before 37 weeks' gestation (P.E. Hyman *et al.*, 1985), but in both there is a progressive increase in response to pentagastrin with post-natal age, regardless of post-conceptional age. Plasma gastrin concentrations are high at birth in most species except rodents, and fall slowly, presumably as the negative feedback loop from gastric pH is established and gastrin receptors mature.

Effect of feeding

Natural milk contains a least one growth-promoting hormone, epidermal growth factor (Oka *et al.*, 1983; Read *et al.*, 1984), which stimulates gastric and intestinal growth to a greater extent than isocaloric formula feeding. The presence of food in the stomach itself initiates surges in a variety of gastrointestinal hormones. This has been shown in comparisons of enterally and parenterally fed premature human infants (Lucas *et al.*, 1986). Plasma concentrations of enteroglucagon, gastric inhibitory polypeptide, motilin and neurotensin were all substantially increased by comparison with levels at delivery if enteral feeding had been given, but were the same or lower following parenteral feeding. Since both gastrin and enteroglucagon appear to be trophic hormones for gastrointestinal tissue, the clinical importance of this observation is apparent. In later-maturing species, such as the rat, weaning has a similar effect. Antral gastrin concentrations increase sharply at weaning in this species with parallel increases in intestinal wet weight and development and relative nucleic acid content. Forced early weaning accelerates all these processes (Herbst and Sunshine, 1969), while prevention of weaning delays it (Lichtenberger and Johnson, 1974). The administration of pentagastrin to rat pups which have been prevented from weaning stimulates the normal developmental changes (Lichtenberger and Johnson, 1974).

Immunoglobulin transfer

One of the most interesting consequences of differing gastric acidity, both between species and with post-natal age, is the effect on immunoglobulin transfer, and hence the acquisition of passive immunity. The guinea pig, relatively most mature at birth, receives maternal antibodies by placental transfer, with no post-natal intestinal absorption in the face of rapid gastric acidification (Hill, 1956). Lambs, foals and human infants take somewhat longer to achieve low gastric pH, and absorb antibodies from colostrum in the immediate post-natal period (Hill, 1956; Jeffcott, 1975; Grand *et al.*, 1976). Newborn piglets fail to acidify their gut contents to pepsin-activating levels until about 5 days post-natally, again coinciding with the period of colostrum absorption across the small intestine (A.A. MaçDonald *et al.*, 1982). The rat is the most extreme in this context, with highly selective uptake, transport and discharge of homologous IgG immunoglobulins in the proximal small intestine until day 22 post-natally (Deren, 1971; Rodewald, 1973; Murphy and Daniels, 1979). At this time 'closure' occurs abruptly, coincident with the onset of gastric acidification and weaning (Rodewald, 1973).

Carbohydrate digestion

The ability to digest different carbohydrates develops at different times in gestation (see above) but is adequate at term for sugars

characteristic of that species' milk. Thus, in man both lactase and sucrase are present and functional at term (Lebenthal *et al.*, 1983), whereas in the sheep, sucrase is not present at birth (Charlton *et al.*, 1979b). There is rapid post-natal maturation of the response to a glucose load, which appears to be dependent on post-natal, rather than post-conceptional, age (see Van Assche and Hoet, 1984).

Protein digestion

Protein digestion in the newborn occurs mainly in the proximal small intestine and appears to be adequate, at least in dealing with milk proteins. The intestinal concentration of trypsin in the human duodenum in the neonatal period approaches that of the adult (Lebenthal *et al.*, 1983). However, such widely differing species as man and the rat show very low duodenal concentrations of chymotrypsin and trypsinogen at this time (Saraux and Girard-Globa, 1982; Lebenthal *et al.*, 1983), which increase markedly in the post-natal period. The peptides and amino acids resulting from primary protein digestion are readily absorbed in the neonatal period, cytosolic peptidases peaking early and declining towards weaning (see Lebenthal *et al.*, 1983). Even in the neonatal rat, with minimal luminal protein digestion, the small intestine has an apparently functional active transport system for both neutral and basic amino acids, the neutral forms being preferentially transported (Murphy and Daniels, 1979). The proximal colon of the newborn pig, a species idiosyncratic in many ways, can also transport amino acids from its lumen to the circulation for the first few days (Jarvis *et al.*, 1977). Whether this extra site of absorption is related to their almost total retention of ingested nitrogen in early life (section 8.4.5) is not known.

Fat digestion

Fat digestion, conversely, is not especially efficient in neonates, presumably related to their low intraluminal concentrations of lipase, colipase and bile acids (Saraux and Girard-Globa, 1982; Lebenthal *et al.*, 1983). This is faintly surprising in view of milk's high fat content (up to 53% in the fur seal; Jenness, 1974), and the presence of a potent lingual lipase in the fetus and newborn, which can catalyse gastric lipolytic activity, may be a specific adaptation in response to these deficiencies. Furthermore, grossly raised intestinal concentrations of colipase, which protects lipase from rapid degradation, have been found in the neonatal rat, which may enhance the activity of such lipase as is present (Saraux and Girard-Globa, 1982). Again, the neonatal piglet is anomalous, with a considerable colonic capacity for lipid absorption during the first few post-natal days (Jarvis *et al.*, 1977), presumably necessitated by the low (7%) fat content of pig milk (Jenness, 1974).

It seems possible that the relatively poor lipid absorption of the neonatal period may adversely influence the absorption of the fat-soluble vitamins A, D, E and K, but the neonate has been born with placentally derived stores of these vitamins, so that deficiency is not usually encountered. Absorption of the water-soluble vitamin B_{12} in the newborn rat is highest in suckling and lowest in adult rats (Said *et al.*, 1985) and involves a carrier-mediated system. Serum B_{12} concentrations in the human are high at birth, but fall to a nadir by 30–40 days, only reaching adult values by 3–4 months (Grand *et al.*, 1976). This might be related to the substantial requirements for the vitamin in the face of low concentrations of intrinsic factor.

Ion absorption

Ion absorption in the immediate neonatal period seems not to have been widely studied, although species differences would be expected in view of the differing ionic composition of the milks. Iron uptake across

the duodenum has been found to be substantially higher in the newborn guinea pig than the adult, probably because all the villus enterocytes take up iron, rather than only those at the villus tips (Debnam *et al.*, 1987). It is of some practical interest that the gastrointestinal absorption of sodium in the human newborn is directly related to conceptional age, and that premature infants are thus at risk of sodium loss in the stools as well as in the urine (Al-Dahhan *et al.*, 1983b). The increasing gastrointestinal sodium absorption is probably mediated via aldosterone, as in the kidney.

Peristalsis and defecation

The neuromuscular development of the human gut occurs principally in the first trimester. Circular and longitudinal muscle are present in both small and large bowel by 10 weeks, and the autonomic neural plexi are identifiable by 13 weeks. These structures, necessary for peristalsis, are morphologically mature long before enteral feeding is required or coordinated sucking and swallowing possible (see above). The preterm human infant passes an average of one stool per day from as early as 25 weeks' gestation, even if not enterally fed (Weaver and Lucas, 1993). This suggests that there is an intrinsic pattern of large bowel motor activity which can function in a coordinated propulsive fashion from just after mid-gestation. This does not usually lead to defecation *in utero*, though what prevents prenatal evacuation is not known, meconium-stained liquor occurring only rarely before term (Lucas *et al.*, 1979; Mathews and Warshaw, 1979). At term, this is often not a normal event but, rather, occurs as a sympathetically mediated response to fetal distress.

The newborn infant has no voluntary control over evacuation, and defecation probably occurs as a reflex response to rectal load. Milk feeds entrain the intrinsic activity of the colon and induce regular defecation at a frequency determined by the volume of the products of digestion which reach the rectum; the more feeds, the more stools (Weaver and Lucas, 1993). Although the amount of stool varies, the water content remains within a narrow range (around 70%) even in preterm infants, suggesting that the water reabsorptive functions of the colon are present before term. After the first week of life, stool volume falls although milk intake continues to increase, partly due to a further maturation of the water-conserving capacity of the gut.

Although the fetus derives its nutrients transplacentally, nevertheless gastrointestinal development at birth is such that function can be immediately 'switched on', and in a way matched to the composition of the mother's milk. The widely differing ways in which individuals of differing species ultimately reach the common stage of weaned self-sufficiency is one of the many marvels of growth and development.

8.4.5 KIDNEY FUNCTION AFTER BIRTH

At the moment of birth, the fetus is abruptly removed from its dialysis unit, and must very rapidly run its own excretory function. It is helped in this by the fact of being in an anabolic state, so that requirements for urea excretion are low, and by the fairly low sodium content of milk. However, the low urea excretion itself influences the kidney's ability to concentrate the urine, and the low sodium content of milk can put in jeopardy those species such as the horse and man which can to some extent tolerate preterm delivery, since the premature foal and human are both at risk of moving into negative sodium balance (Al-Dahhan *et al.*, 1983a; Broughton-Pipkin *et al.*, 1984). The post-natal maturation of renal function is partly dependent on anatomical changes, but the importance of these changes varies from species to species. Thus in man, and in guinea pig, nephrogenesis is complete before term (Table 8.12; M.S. MacDonald and Emery, 1959;

Spitzer and Edelmann, 1971), while in the pig and rabbit nephrogenesis continues for up to 3 weeks post-natally (Leeson and Baxter, 1957; Broughton-Pipkin 1973; Friis, 1980). However, in all species there is an initial glomerular preponderance, with short proximal tubules and loops of Henle at birth.

The distribution of the cardiac output changes dramatically after birth, particularly in the renal circulation. Thus in fetal lambs some 3–4% of the combined ventricular output perfuses the kidneys, but shortly after birth this has risen to 8–10% (Iwamoto *et al.*, 1985) and similar or greater increases are seen in other species. This must suggest a fall in renal vascular resistance and such has been shown in the immediate perinatal period (e.g. Jose *et al.*, 1971; Spitzer and Edelman, 1971; Bailie *et al.*, 1980). The plasma angiotensin II concentration falls after birth (Robillard and Nakamura, 1988; Robillard *et al.*, 1988), and may partly account for this fall in renal vascular resistance; increased production of vasodilator prostanoids may also be implicated, as may the release of atrial natriuretic peptide, which antagonizes angiotensin (P.J. Harris *et al.*, 1987; Varille *et al.*, 1989; Stephenson and Broughton-Pipkin, 1990).

Glomerular filtration

The GFR rises after birth in all species studied at a rate too fast to be the result of purely anatomical change. For example, the GFR is nearly five times higher at the end of the first post-natal week in the lamb than in late gestation (Robillard *et al.*, 1980), while it doubles over the first week in the term human infant (see Aperia and Zetterstrom, 1982; Coulthard, 1985). The rise in the guinea pig is less dramatic, more maturation having taken place *in utero* (Spitzer and Edelman, 1971; Merlet-Benichou and de Rouffignac, 1977). The rise is still slower in piglets, which only increase their GFR by a third over the first 7 days (Friis, 1979), but there is an anatomical impediment in the shape of epithelial diaphragms over the glomerular fenestrae in this species.

Most of the rise in GFR is undoubtedly due to the rise in mean arterial pressure and fall in renal vascular resistance after birth, but these are not the only explanations. The hydraulic permeability of the glomerular membrane itself and the surface filtration area also increase with post-natal age (Spitzer and Edelman, 1971). There are also changes in the forces opposing filtration, as the colloid osmotic pressure and the hydrostatic pressure in the early proximal tubule rise, but these are more than counterbalanced by the rise in systemic arterial pressure and fall in renal vascular resistance.

Sodium

The distal tubular sodium reabsorption in the term newborn is highly efficient, a necessary corollary to the otherwise high sodium loss consequent on the short proximal tubules. This appears to be due to the very high plasma aldosterone concentrations found at birth (e.g. Beitins *et al.*, 1972; Giry and Delost, 1974) and results in a fractional excretion of sodium of less than 1% shortly after birth (e.g. Merlet-Benichou and de Rouffignac, 1977; Robillard *et al.*, 1977, 1980; Alt *et al.*, 1984), allowing the accumulation of the sodium needed for growth. The darker side of this lies in the inability of the newborn to excrete a sodium load (Dean and McCance, 1949; Goldsmith *et al.*, 1979), but this is unlikely to be of practical importance to species other than man in whom iatrogenic interference or over enthusiastic formula feeding may overload the baby's kidneys.

The marked rise in sodium reabsorption after birth is paralleled by a sixfold rise in renal oxygen consumption in the lamb and rat (Iwamoto *et al.*, 1985). Fetal kidneys can store glycogen, and it appears that the necessary enzymes for gluconeogenesis are present in the kidney at birth, since higher renal venous than arterial plasma glucose

concentrations can be observed post-natally (Iwamoto *et al.*, 1985). This ability presumably provides the kidney with an energy reserve to allow for the rapid increase in function during the period after birth and before suckling and digestion are initiated when circulating plasma glucose concentrations can fall fast (section 8.4.4).

Potassium

The fractional excretion of potassium rises sharply after birth (e.g. Robillard *et al.*, 1980), and this is also presumably a function of the high plasma aldosterone concentrations. Urinary acidification is not very efficient in the first few post-natal days (see Guignard, 1982), and this may partly reflect preferential exchange of potassium for sodium at the distal tubule. The neonatal kidney reabsorbs nearly all the filtered phosphate (McCance, 1972), and this will also inhibit hydrogen ion excretion. Furthermore, the renal threshold for bicarbonate is low at birth (see Guignard, 1982) so that urinary pH is relatively high at this time.

Water excretion

In most species the urinary osmolality is low at birth, although the mature guinea pig fetus can produce a hypertonic urine, thought to be due to its high plasma AVP concentrations (Merlet-Benichou and de Rouffignac, 1977). It appears however, that in other species the effector link between AVP and cyclic AMP may be immature at birth (see Joppich *et al.*, 1981; Siegel, 1982). Free water clearance is therefore reduced and water intoxication occurs more easily than in the adult (Tarnow-Mordi *et al.*, 1981; Vanapruks and Prapaitrakul, 1989). The osmotic threshold (the plasma osmolality above which AVP secretion is stimulated) is lower in term infants than in adults (Sujov *et al.*, 1984), but there is some evidence for a suppression of AVP with fluid loading in term human babies (Aperia *et al.*, 1984). The high prostaglandin production of the medulla will also inhibit the action of AVP. Furthermore, the urea-dependent concentrating gradient is very small in the medulla of the newborn kidney because of the rapid utilization of nitrogen by the growing tissues (see Siegel, 1982). The hypertonicity of the inner medulla is still further lowered by the decreased sodium reabsorption in the shortened ascending limb of the loops of Henle. The extracellular fluid volume is considerably greater per kg body weight in the newborn than the adult (Anthony *et al.*, 1992; Stephenson and Rutter, 1992a), and the initial 'failure' of concentrating ability allows the excretion of this excess fluid in the physiological diuresis and weight loss of the first few days. This diuresis is most marked in species such as the guinea pig, which are relatively mature at birth, and least in those born at a more immature stage, such as the rat, although even in the latter the ability develops rapidly after birth (D.P. Alexander and Nixon, 1961). Conversely, the inability of the newborn to excrete a concentrated urine means that it can become dehydrated considerably more easily than the adult, so that conditions such as scouring (diarrhoea) and vomiting are of greater clinical significance at this age.

Relatively little appears to be known about the effect of parathormone (PTH) on the neonatal kidney (Senterre and Salle, 1988), but since that kidney avidly reabsorbs virtually all the filtered phosphate it must be assumed either that plasma PTH is very low at this time or that PTH receptors are absent or non-functional (McCance, 1972). Conversely however, the kidney's ability to convert vitamin D_3 to the active 1,25-dihydroxycholecalciferol appears to be present well before term in man (McCance, 1972).

The kidney of the newborn mammal differs markedly in function from that of the adult, and yet we should not be too hasty in regarding this 'immaturity' as being disadvanta-

geous. Rather, it stems from the newborn's need for different patterns of solute reabsorption to allow for rapid growth and the excretion of the 'excess' extracellular fluid volume of the fetus (Shaffer, 1987; Simpson and Stephenson, 1993). It is only when for ethical or economic reasons we attempt to salvage the prematurely born human infant (Stephenson and Rutter, 1992b) or thoroughbred foal that the lack of integration of the facets of renal function before birth can become life-threatening (Wilkins, 1992).

8.4.6 COLD

Not only does birth result in occlusion of the cord so that the lungs must begin gaseous exchange, the bowel to absorb nutrients and the kidney control water and ions, the developing mammal also loses the protection of the uterus. *In utero*, the fetus is largely inactive and warm. With birth comes the freedom to move about. For some newborn it is a necessity if they are to survive. For example, the newborn whale must swim to get oxygen, the newborn caribou born on migration must stay with the herd. Exercise will put much greater demands on the cardiorespiratory system than those necessary to meet resting requirements. The fact that the newborn survive suggests that the cardiorespiratory reserves after birth are considerable.

A major metabolic challenge that all newborn experience is cold exposure. Except under experimental procedures the fetus does not experience cold, so in its broadest sense the systems for thermoregulatory control are untested. An outline of the nature of thermoregulatory responses is given in Figure 8.24 (Mount, 1979).

The environmental temperature at which mammals feel 'comfortable', that is given the choice the one they would select, is determined, amongst other things, by size, thermal insulation (amount of fur) and resting metabolic rate. For these reasons the 'comfortable' temperature will be higher in newborn than in adults. Newborns can withstand prolonged hypothermia, just as they can survive prolonged asphyxia and trauma, much better than adults. Nevertheless, hypothermia is a common cause of death. Parents, usually mothers, often go to considerable lengths to minimize the effects of the cold environment. Thus, they provide nests in which a litter can huddle (e.g. rabbits) and they may adjust the time they spend huddled with their young in the nest according to ambient temperature (rats and mice in cold environments), they may go to great lengths to select a warm dark protected spot (cats) or hide their young deep in their fur (polar bears in ice caves) or continually cuddle their young so that they become a part, as it were, of the maternal body, thus negating the disadvantage that follows the body weight–surface area ratio. It is the behavioural characteristics of the parents which are paramount in keeping their young warm to ensure their survival.

However, the young also make behavioural responses within minutes of birth aimed at keeping themselves warm (D. Hull, 1982). The blind, comparatively hairless newborn rabbit senses the cold and drags itself, given a choice, to a warm spot which it will select to ±1°C (J. Hull and Hull, 1982). It is warmth that attracts the newborn and creates the huddle in a litter, and probably draws them to their mother when she visits the nest to feed (once or twice daily). Newborn rats clustered in a ball take turns to be on the outside or in the middle (Alberts, 1978). Similarly, piglets in a row continually move their positions so that the same piglet is not always at the end.

The behavioural responses of newborn human infants to overheating are limited to reducing insulation by kicking the covers off, putting hands or feet outside the bedclothes or adopting the 'sunbathing' posture which exposes the greatest possible surface area to the air (Rutter and Hull, 1979a). The inadequacy of these behavioural responses is suggested by the epidemiological associ-

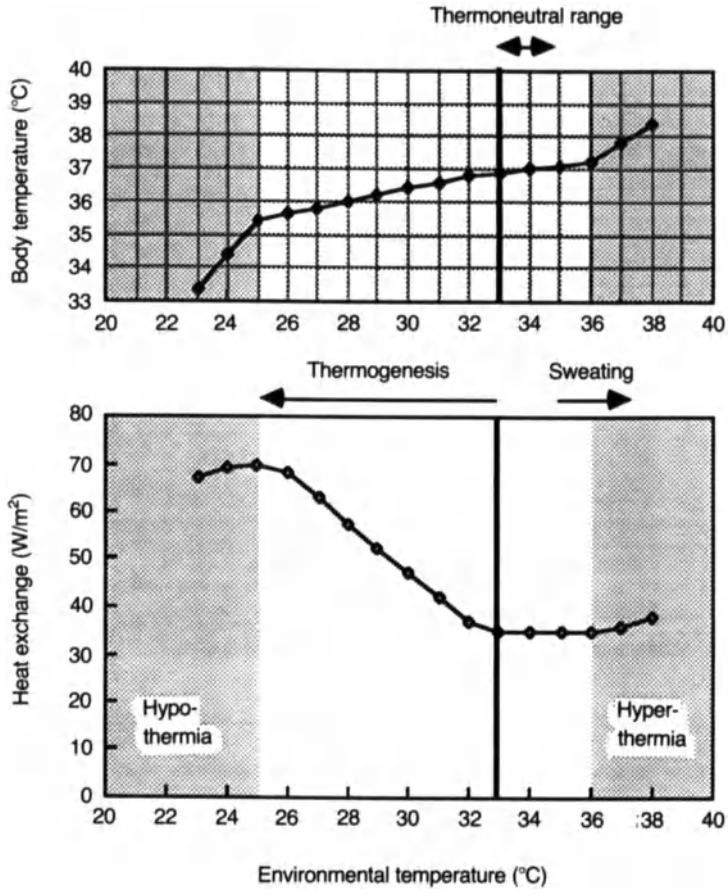

Figure 8.24 Thermoregulatory diagram. Data shown are for a naked infant at term.

ations between both sleeping prone and the amount of bedclothes and an increased risk of sudden unexpected death in infancy. The face and forehead account for up to 25% of the surface responsible for heat loss in the newborn infant, and it is thought that the prone infant cannot lose heat effectively and that overheating is a crucial step in 'cot death' (Anonymous, 1990).

It was once thought that newborn mammals were poikilothermic. Certainly some have very little capacity for thermogenesis for some days after birth (hamsters, lemmings) (Edson and Hull, 1981); others develop a considerable thermogenic capacity within the first 2 or 3 days (mice and rats) (Vinter and Hull, 1982), whilst others show a striking response within minutes of birth (guinea pigs, rabbits, pigs, lambs) (Holloway, 1984). In most newborn mammals the site of this non-shivering thermogenesis is brown adipose tissue (Nicholls, 1984; Cannon, 1985) (rabbits, guinea pigs), but in others it is a mixture of brown adipose tissue and shivering (lamb and ox), whilst the piglet appears to depend on shivering alone (G. Alexander, 1975). The human infant has a modest metabolic response to cold within hour of birth, but by 24 h cold exposure can double the metabolic rate (Ricquier, 1984). However, it is rabbits, pigs and lambs that have been shown to have impressive metabolic responses to

cold exposure. They can often treble their minimal rate within minutes of cold exposure, demonstrating in another way their considerable cardiorespiratory reserve (Hey, 1969).

Brown adipose tissue is yet another illustration of the wide variation between species (Benito, 1985). In some species it is a major organ and when fully active it can consume twice as much oxygen as the rest of the body; in others it is absent (D. Hull, 1966, 1970). But it also illustrates why the study of fetal physiology is of interest for its own sake, for the tissue in many species develops in the uterus where it has no function, to respond at birth and in the early phase of independent existence only to bow from the stage before adulthood.

8.5 CONCLUSION

This chapter is too brief to be comprehensive. Inevitably the topics which have been emphasized reflect the authors' own interest and in that sense it lacks balance. Likewise, not every assertion is supported by a reference to the relevant observations and investigations. The aim has been to provide the reader with an introduction to some of the characteristics of fetal physiology and the various ways they have been studied.

Much remains to be learnt about the fetus in mid-gestation, about the determinants of organ growth and development, on how the fetus controls its nutrient uptake and gaseous exchange and about the mechanisms and determinants of placental function.

9.1 INTRODUCTION

The discovery in 1910 (see Liggins, 1988, for historical review) of the dependence of continuing pregnancy in rodents on the corpus luteum and the subsequent isolation of progesterone seemed to provide a sound basis for the mechanism initiating parturition. The 'progesterone withdrawal' hypothesis gained widespread acceptance regardless of whether the maintenance of pregnancy was corpus luteum dependent or placenta dependent. Because the luteotrophic complex of hormones in rodents is of maternal origin, little reason existed to depart from the traditional view that the mechanism resided in the mother rather than the conceptus. However, the 1950s saw increasing awareness of the evidence that fetal genotype in farm animals and certain fetal malformations in both man and farm animals influence the duration of pregnancy. With the unequivocal demonstration in 1967 that hypophysectomy in fetal sheep abolishes the initiation of parturition, the pendulum swung decisively away from maternal control towards fetal control and the fetal endocrine system became the focus of attention of most investigators.

Their convenient size, docility and tolerance of complex surgical procedures in the fetus ensured the sheep was the favoured experimental animal, but hopes that the mechanism elucidated in sheep could be extrapolated across all species were soon dispelled. Broad fundamental differences in the comparative physiology of parturition emerged. At one end of the spectrum lies the sheep, in which the fetal endocrine system dominates all other influences; at the other end lie the primates, in which the fetus itself appears to have only a very minor role. The latter should not be misunderstood as indicating a major maternal role but rather that tissues of the conceptus other than fetus (the placenta and membranes) are important.

Two discoveries in particular have been helpful in determining where in the spectrum a particular species is likely to be. First, prostaglandins, particularly prostaglandin $F_{2\alpha}$, were found not only to activate contractility of the pregnant uterus but also to induce luteolysis. Second, activity of the placental 17α-hydroxylase enzyme, which catalyses the conversion of progesterone or pregnenolone to oestrogen, was shown to be inducible by fetal cortisol, thus providing a link between the fetal hypothalamic–pituitary–adrenal system and the relative production rates of oestrogen and progesterone in those species in which the placental enzyme is present.

Species lying at the 'non-fetal' end of the spectrum have been the most resistant to successful investigation, mainly because the system is paracrine rather than endocrine; the study of the chemical messengers by which the fetal trophoblast of the placenta and membranes communicates directly with the contiguous uterine epithelium (decidua) presents obvious difficulties.

Given a previously unstudied species, designing experiments that will place the individual appropriately in the general classification has become relatively straightforward, requiring an answer to only two questions:

1. Does luteectomy or $PGF_{2\alpha}$ -induced luteolysis lead to parturition?
2. Does the placenta contain an active 17α-hydroxylase?

If the answer to either question is affirmative, further investigations can follow the patterns established for species such as the rabbit and the sheep respectively. If the answers to both questions are negative, further investigations are ill-defined because of the lack of strong hypotheses.

Abbreviations used in chapter:

17α-OH-P_4	17α-hydroxyprogesterone
17α-P_5	17α-hydroxypregnenolone
20α-P_4	20α-hydroxypreg-4-en-3-one (20α-dihydroprogesterone)

20α-ol	5β-pregnane-3α,20α-diol
ACTH	adrenocorticotrophic hormone
BNC	binucleate cells
CG	chorionic gonadotrophin
CL	corpus luteum/corpora lutea
CRF	corticotrophin-releasing factor
DAG	diacylglycerol
DHEA	dehydroepiandrosterone
DHEAS	dehydroepiandrosterone sulphate
E/P_4	oestrogen–progesterone ratio
EIPS	endogenous inhibitor of prostaglandin synthase
EMG	electromyogram
EGF	epidermal growth factor
GH	growth hormone
GnRH	gonadotrophin-releasing hormone
hCG	human chorionic gonadotrophin
HDL	high-density lipoprotein
HETE	hydroxyeicosatetraenoic acid
HSD	hydroxysteroid dehydrogenase
IL	interleukin
IP	inositol phosphate
LDL	low-density lipoprotein
LH	luteinizing hormone
LT	leukotriene
MCR	metabolic clearance rate
MPA	medroxyprogesterone acetate
oPL	ovine placental lactogen
P_4	progesterone
P_5	pregnenolone
PAF	platelet-activating factor
PAPSI	pregnancy-associated prostaglandin synthase inhibitor
PG	prostaglandin
PGE_2	prostaglandin E_2
$PGF_{2\alpha}$	prostaglandin $F_{2\alpha}$
PGEM	prostaglandin E_2 metabolite
PGFM	prostaglandin F metabolite
PGHS	prostaglandin H synthase
PL	placental lactogen
PL	phospholipase
RIA	radioimmunoassay
RU486	mifepristone
TPA	12-*O*-tetradecanoylphorbol 13-acetate
TX	thromboxane

9.2 MAN

9.2.1 INTRODUCTION

The mechanism of initiation of parturition in man is unknown, but several hypotheses have a general acceptance. Foremost among these is the view that the release of eicosanoids underlies the major physiological changes in both the smooth muscle and connective tissue of the pregnant uterus that lead to the onset of parturition. Since neither progesterone (P_4) nor oestrogen concentrations change acutely at term as they do in many other species, other triggers to eicosanoid release are being sought; most favoured for this role is oxytocin which, although unaltered in circulating concentration, may have heightened activity at term by virtue of increased numbers of receptor sites. The eicosanoid mainly responsible for parturition (PGE_2 or $PGF_{2\alpha}$) and the major site of synthesis (amnion or decidua) are subjects of controversy.

Circumstantial evidence from experiments in nature provided by congenital defects of the pituitary or adrenals points to the human fetus having a modulating rather than a controlling role in initiating parturition. Accordingly, attention tends to be directed to the likelihood that the mechanism resides in a paracrine relationship of the fetal membranes and/or placenta and the maternal decidua. Several possible paracrine signals have been proposed but all remain speculative.

This review of human parturition assumes a central role for eicosanoids and considers the evidence supporting this assumption, the known actions of eicosanoids on the uterus, and the sites and control of eicosanoid synthesis. In addition, the possible contributions of hormones other than eicosanoids that act on the uterus independently of interactions

with eicosanoid synthesis are reviewed. It is recognized, however, that the field of smooth muscle physiology is advancing rapidly and that endothelium-derived relaxing factor (EDRF) and endothelin, which are probably important in the paracrine control of vascular smooth muscle, are unexplored as potential agonists for uterine smooth muscle. A major shift in emphasis in human parturitional physiology in the future remains a possibility.

9.2.2 ROLE OF THE FETUS

The weight of circumstantial evidence derived from various congenital malformations and disorders involving fetal endocrine organs is against an active role of the fetus in initiating parturition. A malformation that is associated consistently with early or late delivery in the absence of a mechanical factor such as polyhydramnios has yet to be identified. Lack of the pituitary in anencephaly (W.M. Hcnnebier and Swaab, 1973) or of the hypothalamus (Janigan *et al.*, 1962) is compatible with delivery at term, as is congenital absence of the fetal adrenals (Pakravan *et al.*, 1974). The administration of large doses of corticosteroids to the mother is not associated with preterm delivery, although glucocorticoid activity in fetal blood rises to concentrations at least equal to those of the term fetus (Ballard and Liggins, 1982).

Corticotrophin-releasing factor (CRF) is secreted by the cytotrophoblast and is present in fetal blood (Goland *et al.*, 1986). CRF synthesis is stimulated by glucocorticoids, and a positive-feedback loop involving fetal pituitary ACTH and adrenal cortisol secretion may lead to rising cortisol concentrations prepartum (B.G. Robinson *et al.*, 1988). Quartero and Fry (1989) proposed that CRF potentiated the inotropic effect of oxytocin on strips of human myometrium. The concentration of CRF in maternal plasma increases 50-fold during the third trimester (Sasaki *et al.*, 1984; Goland *et al.*, 1986), suggesting that CRF could contribute to the increasing sensitivity to oxytocin that develops at this time.

9.2.3 PROGESTERONE

The assumption is usually made that uterine quiescence throughout human pregnancy is dependent on a direct effect of progesterone (P_4) on smooth muscle, as it does in various experimental animals. However, the supporting evidence is not conclusive, depending mainly on observations that removal of the corpus luteum (CL) before 50 days in pregnant women is followed by abortion 3 or 4 days later when the plasma P_4 has fallen from >60 to <15 nmol/l (Csapo and Pulkinnen, 1978). Administration of P_4 prevents abortion after CL excision (luteectomy). When luteectomy is performed between 50 and 60 days, P_4 concentrations fall to 30 nmol/l but pregnancy is not interrupted. Studies with pharmacological agents that inhibit P_4 synthesis or block its actions are not entirely in keeping with observed effects of luteectomy. Epostane, which interferes with the synthesis of P_4 and oestrogen by inhibiting 3β-hydroxysteroid dehydrogenase, is ineffective in inducing abortion although a sustained fall in plasma P_4 concentrations to <20% of pretreatment values is maintained for several days (Pattison *et al.*, 1984). Mifepristone (RU486), a potent P_4 antagonist that displaces P_4 from its receptor, consistently interrupts early pregnancy (Kovacs *et al.*, 1984) but is unreliable after the first trimester unless used in conjunction with a PG (Bygdeman and Swann, 1985). This difference may reflect a more complete blockade of progestational action by mifepristone or may also be due to the concomitant inhibition of oestrogen synthesis by epostane. However, neither agent reliably interrupts midtrimester pregnancy, suggesting that a reduction in the concentration or action of P_4 is insufficient in itself to cause parturition.

Low concentrations of plasma P_4 throughout pregnancy are compatible with normal-

term pregnancy (see Parker *et al.*, 1986), but administration of P_4 or potent analogues to women at term fails to prolong pregnancy (Csapo *et al.*, 1966), an observation that is not surprising in view of the likelihood that nuclear P_4 receptor sites are likely to be saturated at term and that receptor site concentrations do not diminish before labour starts (Kreitmann and Bayard, 1979). The concentration of P_4 in the myometrium increases to term and the ratio of P_4 to oestradiol-17β remains unchanged (Batra and Bengtsson, 1978).

The weight of evidence is therefore strongly against parturition at term being the result of loss of the inhibitory effects of P_4. However, P_4 may have an important role in the maintenance of human pregnancy by contributing to the maintenance of uterine quiescence.

Spontaneous and oxytocin-induced contractility of strips of human pregnant myometrium are inhibited by P_4 (Kumar *et al.*, 1962, 1967). The inhibitory effect was attributed by Daniel and Singh (1958) to hyperpolarization of smooth muscle cell membrane, but Jung (1962) and Kao and Nishiyama (1964) reported contradictory findings and the matter remains unresolved. However, P_4 has a characteristic effect on the action potential, the amplitude of which becomes irregular, with a poor correlation of action potentials and mechanical activity. Carsten (1979) reported that P_4 inhibits ATP-dependent calcium binding in a microsomal preparation of pregnant myometrium. Garfield (1988) described a marked increase in the number of gap junctions in human myometrium during labour, which is likely to cause the myometrium to function as a syncytium with enhanced propagation of action potentials. P_4 inhibits gap junction formation in rat myometrium, but evidence of such an effect in human myometrium is lacking.

Progesterone has the potential to modulate uterine contractility by influencing the concentration of various receptors. Progesterone down-regulates activity of oxytocin receptors and oestrogen receptors in rats (Soloff *et al.*, 1983). Neither of these actions is known to occur in human pregnancy, but low concentrations of oxytocin receptors until late pregnancy (Fuchs *et al.*, 1984) and of oestrogen receptors throughout pregnancy (Batra and Bengtsson, 1978) are consistent findings.

Local changes in tissue concentration of steroid hormones may take place that are not reflected in the circulation. A direct action of P_4 on the fetal membranes is unlikely because of the absence of specific binding, although specific binding of testosterone is readily demonstrable (De Cicco *et al.*, 1984). Schwarz *et al.* (1977) described a specific P_4-binding protein in amnionchorion which could regulate local concentrations of P_4. However, the protein is transcortin-like rather than a unique P_4-binding protein, having a 10-fold greater affinity for cortisol than for P_4. Decidua, like the endometrium, has specific P_4 receptors and, in view of the responsiveness to P_4 of the non-pregnant endometrium from which the decidua is derived, it is likely to be a target tissue for P_4 action in regulating oxytocin action and PG synthesis. Local P_4 concentration could also be influenced by a change in rate of metabolism at the site of its local (non-placental) production.

Challis and Mitchell (1988) suggested that P_4 acts in an autocrine or paracrine fashion and that local changes in concentration would not be detectable in the systemic circulation. The hypothesis had two main tenets: (1) that extraplacental intrauterine tissues can synthesize and metabolize P_4 and (2) that P_4 production within the fetal membranes and decidua is sufficient to not be overwhelmed by placental production or that production occurs in a compartment that is isolated from systemic influences. Confirming the report of Gibb *et al.* (1978), Challis and Mitchell (1988) demonstrated the uptake of pregnenolone (P_5) and its conversion to P_4 by dispersed cell preparations of amnion, chorion and decidua, the activity being greatest in the chor-

ion. The activity was less in tissues obtained after the spontaneous onset of labour than in those obtained at elective Caesarean section at term (B.F. Mitchell *et al.*, 1987). Amnion contains little 3β-hydroxysteroid dehydrogenase (3β-HSD), being formed predominantly from 20α-dihydroprogesterone, and activity is greatest before the onset of labour (Challis and Vaughan, 1987). Fetal plasma concentrations of pregnenolone sulphate are high in late pregnancy, indicating that the conversion of P_5 to P_4 by chorion and decidua forms an important local source of P_4 which is 'withdrawn' at the onset of labour. Pulkkinen and Enkola (1972) reported a gradient of P_4 concentrations with increasing distance from the placenta, a finding consistent with local production, but the concentration did not differ between tissues obtained before or during labour. Further support for the concept of local production of P_4 by membranes and decidua comes from the observation that the concentration of P_4 in these tissues is considerably higher than that in the maternal circulation. The role of P_4 in regulating PG synthesis is considered below.

9.2.4 OESTROGENS

The concentrations of oestrone, oestradiol-17β and oestriol rise progressively throughout pregnancy, but there is no abrupt increase before the onset of labour (Chew and Ratnam, 1976; Boroditsky *et al.*, 1978; Hartikainen-Sorri *et al.*, 1981; B.S.B. Block *et al.*, 1984) unless the subjects are highly selected (Turnbull *et al.*, 1974). The concentration of oestradiol-17β in myometrium during pregnancy is low and does not increase at term (Haukkamaa and Lahteenmaki, 1979), but an increase in the nuclear fraction in labouring patients was described by Hilary and Cohen (1981). The human placenta lacks 17α-hydroxylase activity and consequently depends on androgen (mainly dehydroepiandrosterone sulphate, DHEAS) derived from the fetal and, to a lesser extent, maternal adrenals as the substrate for oestrogen synthesis. DHEAS is present in the fetal circulation in increasing concentrations to term (Laatikainen *et al.*, 1980; Parker *et al.*, 1982).

Attempts to alter the length of pregnancy by manipulating the concentration of circulating oestrogen, either by changing the rate of production of oestrogen by the placenta or by administering oestrogen, have not been convincing. Intravenous injections of DHEAS markedly increase circulating levels of oestradiol-17β and oestriol but do not cause uterine contractions (Korda *et al.*, 1975). Conversely, administration of corticosteroids (e.g. 20 mg of prednisone per day) depresses circulating oestrogen concentrations to about 10% of normal values by inhibiting fetal and maternal adrenal secretion of DHEAS but does not prolong pregnancy. Similarly, depressed concentrations of circulating oestrogens occur in a sex-linked genetic disorder, placental steroid sulphatase deficiency, which impairs the conversion of DHEAS to DHEA (France and Liggins, 1969) but is compatible with the spontaneous onset of labour at term, although dystocia may be associated with impaired cervical ripening in some primigravid patients. Whether the administration of large doses of oestradiol-17β to women at term stimulates labour remains uncertain. Pinto *et al.* (1967) claimed that significantly more women in a controlled trial started labour within 7 days of a single intravenous dose of 200 mg of oestradiol-17β and increased uterine activity was found in uncontrolled studies after administration of large doses of oestrogens (Jarvinen *et al.*, 1965; Larson *et al.*, 1973). Flint (1979) considered that any part played by oestrogens in the onset of labour is likely to be permissive rather than obligatory.

Nevertheless, oestrogen synthesis at a local level may have an active part in the initiation of labour. The amniotic fluid contains high levels of steroid conjugates, particularly oestrone sulphate and DHEAS, both of which increase rapidly in concentration towards

term and are accessible to the fetal membranes as substrates for metabolism to oestrogens (Turnbull *et al.*, 1977). Chorion and decidua, but not amnion, contain steroid sulphatase activity capable of hydrolysing oestrone sulphate and DHEAS and liberating free oestrone and DHEA (Romano *et al.*, 1986). The presence of 17β-HSD in the membranes and decidua was evident because of the conversion of oestrone to oestradiol-17β. The greater activities of the enzymes in labour are not reflected in the tissue concentrations of oestrone or oestradiol-17β, which are the same before and after labour, and the extent to which these findings *in vitro* can be extrapolated to the situation *in vivo* is unknown.

Oestrogen administration stimulates uterine activity, but the spontaneous and oxytocin-induced contractility of myometrial strips *in vitro* is consistently inhibited by oestrogen. The inhibitory potency of oestrogen greatly exceeds that of P_4, not only in animal tissues (Hempel and Newman, 1965) but also in human tissues (Barnafi and Larraguibel, 1974). This paradox may be resolved by the stimulatory effects of oestrogen on the release of PGs which are evident *in vivo* but may be absent in muscle strips separated from the endometrium.

Oestrogen is undoubtedly important in promoting growth of both the muscular and connective tissues of the pregnant uterus, readily demonstrated by observing the response of the non-pregnant uterus to prolonged treatment with oestrogen. The uterus, although devoid of contents other than hypertrophied endometrium, may reach a size and appearance equivalent to that of pregnancy at 3 months. There is no direct evidence that oestrogen enhances oxytocin sensitivity or promotes the formation of oxytocin receptors, P_4 receptors and gap junctions in women. The role of oestrogen in the control of PG synthesis is discussed below.

9.2.5 OXYTOCIN

The discovery of oxytocin and its subsequent clinical use in human pregnancy led to observations that fulfilled many of the requirements for an agent with a dominant place in the physiological mechanism initiating parturition. Oxytocin is measurable by highly sensitive assays in most women throughout pregnancy (Kumaresan *et al.*, 1974; Dawood *et al.*, 1979a) and there is a weak trend to rising concentrations through pregnancy (Dawood *et al.*, 1979b; Sellers *et al.*, 1981). The amniotic fluid contains oxytocin, which is apparently of maternal origin because the concentration in pregnancies with anencephalic fetuses do not differ from those in women with normal fetuses (Swaab and Oosterbaan, 1983). Oxytocin is the most potent known natural substance that stimulates uterine contractions in pregnancy. During labour, spike concentrations of oxytocin may (Gibbens *et al.*, 1972; Leake *et al.*, 1981) or may not (Sellers *et al.*, 1981) occur. Intravenous infusion of oxytocin stimulates contractions at any stage of pregnancy although very large amounts are required in early pregnancy. In late pregnancy, the sensitivity to oxytocin progressively increases to the extent that a response is elicited at term by an infusion rate (1 miu/min) equivalent to the estimated rate of endogenous production (Caldeyro-Barcia and Sereno, 1961). However, oxytocin infusions are effective in inducing labour only when the pregnancy is at term or beyond, and the response is inconsistent unless amniotomy is performed concurrently. The rapid increase in oxytocin sensitivity appears to begin around the 20th week of pregnancy (Turnbull and Anderson, 1968) for reasons that are uncertain.

Although studies of oxytocin were eclipsed when the possibilities of PGs were realized, there has been a resurgence of interest in oxytocin, particularly in relation to its receptor concentrations in the myometrium and

decidua. Oxytocin may also be a specific stimulus to PG synthesis.

Crude membrane fractions of human myometrium contain specific binding sites for oxytocin that fulfil several criteria for receptors (Soloff *et al.*, 1974; Sakamoto *et al.*, 1979), including inhibition of binding of labelled oxytocin by synthetic oxytocin analogues in the rank order of their potencies. Fuchs *et al.* (1982a) obtained samples of myometrium and decidua parietalis from women at Caesarean section or hysterotomy at or before term. Crude membrane fractions were prepared from homogenates incubated with EDTA to dissociate endogenous oxytocin from binding sites. Myometrial receptor concentrations increased eightfold from low concentrations at 13–17 weeks to term and more than doubled early in labour. In advanced labour, the concentration had fallen sharply, possibly because the samples taken from lower segment incisions were composed mainly of cervical tissue. Similar concentrations of receptor sites and changes with gestation length and labour were found in decidua. It was suggested that the increase in receptors lowers the sensitivity of the myometrium to oxytocin to the point where activation occurs and labour begins.

Incubation of decidua parietalis with a high concentration of oxytocin stimulates the release of PGE and PGF (Fuchs *et al.*, 1981; T. Wilson *et al.*, 1988), suggesting that myometrial activity is stimulated by oxytocin directly and indirectly by PG liberated from the decidua.

The increase in receptors with the onset of labour in women cannot be attributed to an increase in the oestrogen–P_4 ratio, which appears to be unchanged. In rats there is a close correlation between the concentrations of oxytocin receptors and tissue $PGF_{2\alpha}$ and a marked reduction in receptors during treatment with an inhibitor of PG synthesis (W.Y. Chan, 1987). Enhanced responsiveness to oxytocin after treatment with PGE_2 occurs in human pregnancies near term (Embrey, 1969; Brummer, 1971) and *in vitro* in excised human myometrial strips (Brummer, 1971) and is consistent with the formation of receptors in response to PGs.

An oxytocin antagonist, 1-deamino-2-D-Tyr(OE+)-4-Thr-8-Orn-oxytocin (CAP 440), inhibits oxytocin-stimulated activity of human myometrial strips (Melin *et al.*, 1986), and appeared to inhibit contractions in preterm labour in an uncontrolled pilot study (Akerlund *et al.*, 1987).

Chibbar *et al.* (1991) demonstrated the presence and expression of oxytocin mRNA in chorionic membrane and decidua and concluded that oxytocin is synthesized in fetal membranes. Whether the rate of synthesis changes at the onset of labour remains to be determined.

9.2.6 RELAXIN

Human relaxin, a protein of approximately 6 kDa molecular weight, has been sequenced (Hudson *et al.*, 1983) and recombinant material is available. It shares considerable structural homology with insulin and the insulin-like growth factors. Despite progress with genetic aspects of human relaxin, the role of relaxin on the myometrium in human pregnancy remains enigmatic (for review see Bryant-Greenwood, 1991).

Plasma concentrations of relaxin in pregnant women are low compared with sows (Eddie *et al.*, 1986) and fall progressively through pregnancy, showing no evidence of the marked prepartum rise in concentration that is characteristic of certain animal species. In early pregnancy relaxin is secreted by the CL and circulating concentrations become undetectable after luteectomy. Whether other sources, such as the decidua, contribute to plasma levels in late pregnancy is unknown.

Immunofluorescence studies using antibodies raised against the connecting peptide of human relaxin (Sakbun *et al.*, 1987) have demonstrated the presence of relaxin in the decidua at term, and it is likely that

the tissues synthesize rather than sequester the hormone because it persists after luteectomy (Yki-Jarvinen and Wahlstrom, 1984). Although the concentration of relaxin in decidua is very low, Bryant-Greenwood and Greenwood (1988) postulated that the hormone diffuses from the site of production to adjacent smooth muscle and connective tissues to exert a variety of biological actions.

Porcine relaxin applied to the cervix of women at term causes it to ripen rapidly in a manner similar to that occurring normally before labour or after treatment with PGs (MacLennan *et al.*, 1980), but whether endogenous relaxin promotes collagenolysis in the cervix and fetal membranes under physiological conditions remains to be determined. The effect of relaxin is uncertain (Beck *et al.*, 1982; MacLennan *et al.*, 1986). Indeed, a report that relaxin inhibits the production of PGE by amnion when the membrane is taken at elective Caesarean section, but stimulated production in membranes taken after spontaneous labour (Lopez-Bernal *et al.*, 1987a), suggests that inhibition or stimulation of uterine activity might occur, depending on the circumstances.

9.2.7 PROLACTIN

Prolactin, produced by the decidua, accumulates in high concentrations in amniotic fluid, reaching maximal values at 14–18 weeks. Although placental prolactin is immunologically indistinguishable from pituitary prolactin and is biologically active, control of its secretion appears to be independent of the dopamine system (Golander *et al.*, 1979) but dependent on a product of arachidonic acid metabolism, its secretion being inhibited by arachidonic acid (Handwerger *et al.*, 1981). Decidual prolactin is probably involved in the regulation of water exchange across the fetal membranes and the control of amniotic fluid volume (see McCoshen, 1988 for review) but the relevance of decidual prolactin to parturition is unclear. Krug *et al.* (1983) reported that the production rate by decidua obtained after spontaneous labour was greater than that obtained at elective Caesarean section, which is inconsistent with the observation that prolactin inhibits the production of PGE in incubates of combined amnion–chorion–decidua (Tyson *et al.*, 1985). Furthermore, the finding that steroid sulphatase activity in decidual cells harvested at delivery is higher than in those harvested at elective Caesarean section (Braverman and Gurpide, 1986) is inconsistent with the observation that prolactin stimulates the hydrolysis of oestrone sulphate (sulphatase activity) in prelabour cells, whereas hydrolysis in cells obtained after delivery is inhibited (Krug *et al.*, 1983). Further investigations are required to elucidate the interrelationships of decidual prolactin, hydrolysis of oestrogen sulphates and synthesis of PGs.

9.2.8 EICOSANOIDS

The evidence that eicosanoids dominate the mechanism initiating human labour is strong but not conclusive. A crucial piece of evidence (the release of eicosanoids immediately preceding the start of labour) is missing, which is not unexpected when the difficulties of predicting labour and of obtaining samples from suitable sites are considered. The hypothesis that favours involvement of eicosanoids is supported by a number of clinical observations.

1. Administration of prostaglandin (PG)$F_{2\alpha}$, E_2 or various active analogues causes abortion or labour at any stage of pregnancy from soon after implantation to term. The clinical features of abortion or labour mimic those of the spontaneous event and include not only myometrial contractions but also increased distensibility and effacement of the cervix. Eicosanoids differ in this respect from other oxytocic agents such as oxytocin, which cause strong contractions but not cervical effacement or

progressive labour unless the pregnancy is near term.
2. PG antagonists such as indomethacin or fenamic acid derivatives inhibit labour even when the cervix is partly dilated. Labour resumes when the antagonist is withdrawn.
3. The concentrations of $PGF_{2\alpha}$, PGE_2 and their metabolites in amniotic fluid and plasma increase progressively after the onset of labour.
4. Successful, but not unsuccessful, induction of labour at term with oxytocin is associated with a sustained increase in the concentration of prostaglandin F metabolite (PGFM) in maternal plasma.
5. Infection (amnionitis) and trauma (amniotomy), which cause release of eicosanoids, are often followed by labour.
6. Intra-amniotic injection of arachidonic acid causes abortion.
7. No agents are known to induce abortion or labour without having at least the potential for stimulating release of eicosanoids.

Measurements of primary eicosanoids in tissues and fluids that accurately reflect concentrations *in vivo* are difficult to obtain for a number of reasons. In tissues, they are rapidly released rather than stored and so the concentrations are very low. Trauma stimulates the rapid synthesis of arachidonic acid metabolites, which then accumulate during the short time between excising and processing tissues. The primary PGs, particularly PGE_2, are unstable and tend to decompose during extraction. Furthermore, PGE_2 and thromboxane (TX) A_2 are released by platelets trapped in tissues and present in blood samples. These problems have been overcome to a large extent by the addition of enzyme inhibitors such as aspirin to collected samples and by assays of stable metabolites such as PGFM, bicyclo-PGE, TXB_2 and 6-keto-PGF_1. Stabilizing primary PGs by methoximating them in the sample and assaying the conjugate with a specific antibody is an alternative approach that is proving successful.

(a) Concentrations in plasma and amniotic fluids

Reports of plasma concentrations of $PGF_{2\alpha}$ in pregnancy are notable mainly for lack of agreement on absolute values or patterns. In reviewing these reports, Keirse (1979) concluded that the concentrations of PGF in the peripheral circulation cannot be interpreted as a measure of uterine PG production. Assays of PGFM, however, have resulted in more consistent results showing low and unchanging values throughout pregnancy with a marked rise in established labour and a progressive increase as the cervix dilates (Green *et al.*, 1974; Fuchs *et al.*, 1983a; Nagata *et al.*, 1987). Close sequential sampling immediately before and after labour has not been reported, and whether PGFM values rise before labour is unknown. Rasmussen *et al.* (1985) found up to a 25-fold increase in concentrations of PGFM in peripheral plasma in women infused at term with $PGF_{2\alpha}$ at a rate sufficient to induce labour, a finding they interpreted as indicating that if $PGF_{2\alpha}$ is causally related to the onset of spontaneous labour generation must take place locally in tissues in, or close to, the site of action. The concentrations of PGF and PGFM in amniotic fluid follow a pattern similar to that of PGFM in plasma, showing no changes before the onset of labour but a progressive increase during labour (Keirse, 1979). Amniotomy is associated with a rapid rise in concentration of PGFM and TXB_2 but not of 6-keto-$PGF_{1\alpha}$ in amniotic fluid (M.D. Mitchell *et al.*, 1978a, 1979a). Makarainen and Ylikorkala (1984) confirmed the increase in TXB_2 but found that levels of 6-keto-PGF_1 also increased. The observation that the concentrations of PGFM in plasma and amniotic fluid rise early during spontaneous labour but not until late in oxytocin-induced labour (Keirse *et al.*, 1974;

Fuchs *et al.*, 1983a) is consistent with the idea that the release of $PGF_{2\alpha}$ is causally related to the onset of labour rather than being a consequence of uterine contractions.

The concentration of PGE_2 in amniotic fluid is similar to that of PGF_2 and rises in parallel (Keirse and Turnbull, 1972), but there is disagreement about plasma values. M.D. Mitchell *et al.* (1978b), who assayed PGE, found no significant change in PGE, whereas Husslein (1984) found an approximate doubling of PGE metabolite (PGEM) values in labour. Assays of bicyclo-PGEM (a very stable substance) showed little (M.D. Mitchell *et al.*, 1982a) or no (Brennecke *et al.*, 1985) increase in plasma concentration in labour.

Products of the lipoxygenase pathway are present in amniotic fluid and the concentrations are higher in labour. Concentrations of 12-HETE (hydroxyeicosatetranoic acid) are similar to those of PGE_2 and $PGF_{2\alpha}$, whereas those of 15-HETE and leukotriene $(LT)B_4$ are much lower (Romero *et al.*, 1987a).

Measurements of eicosanoids in tissue are unlikely to indicate concentrations *in vivo*, but probably indicate the capacity of the tissue for synthesis which, assuming massive release of arachidonic acid in response to trauma, is likely to be rate-limited by PGH synthase. With these qualifications, the data of Willman and Collins (1976) indicate that the amnion and decidua have the highest concentrations after labour, which is consistent with observations of production rates of incubated or perfused tissues.

(b) Production of eicosanoids by intrauterine tissues

Eicosanoids modulate cell activities throughout the body, but the tissues of the uterus and fetoplacental membranes show considerable variation in the quantity of eicosanoids released and in the spectrum of products. Production rates have been studied in several ways, including measurement of radioactive products formed from labelled arachidonic acid and measurement of unlabelled materials using static incubations of homogenates, organ cultures or superfusion systems. Organ culture or superfused dispersed cells are the preferred systems. In general, results with different systems are similar. The amnion is the most active tissue and generates predominantly PGE_2 and lesser amounts of $PGF_{2\alpha}$ (M.D. Mitchell *et al.*, 1978c; Okazaki *et al.*, 1981a; Olson *et al.*, 1983; Manzai and Liggins, 1984; K.A. Skinner and Challis, 1985). Myatt *et al.* (1985) found that radiolabelled confluent cultures of amnion cells release mainly HETEs when the cells are obtained before labour and mainly PGE_2 when the cells are obtained during labour.

Decidual tissue releases more $PGF_{2\alpha}$ than PGE_2 or PGI_2 (Olson *et al.*, 1983, Manzai and Liggins, 1984), whereas release of PGI_2 predominates in cultures of myometrium (Omini *et al.*, 1979). The source of PGI_2 in myometrium is likely to be vascular endothelium, but smooth muscle cells also produce PGI_2 (Keirse *et al.*, 1984). The chorion cells release $PGF_{2\alpha}$, PGE_2 and 6-keto-$PGF_{1\alpha}$ but are most active in the metabolism of prostanoids by 15-dehydrogenase and reductase enzymes (Okazaki *et al.*, 1981b), which is reflected in a greater output of PGFM than from other tissues (K.A. Skinner and Challis, 1985). Comparison of the rates of production of prostanoids by decidua and fetal membranes obtained before or after the onset of labour consistently shows greater activity of the in-labour tissues (Olson *et al.*, 1983), but the cause is uncertain (see below). The specific activity of phospholipase (PL) C and PLA_2 measured in the various tissues is unchanged with the onset of labour (Okazaki *et al.*, 1981a), but this may reflect the difficulty of assessing the activity *in vitro* of an enzyme such as PLA_2 that is present *in vivo* mainly in an inactive form but readily activated by extraction procedures.

Other sources that may contribute to the pool of prostanoids in amniotic fluid include

the umbilical cord (cultures of which release PGI_2 from the blood vessels), the amniotic epithelium, predominantly PGE_2 (M.D. Mitchell *et al.*, 1980a), and fetal urine, which contains PGE_2 and $PGF_{2\alpha}$ in appreciable concentrations (Casey *et al.*, 1983a).

The hypothesis that PGE_2 arising from the amnion initiates labour has been suggested because the major prostanoid formed by fetal membranes *in vitro* is PGE_2, the concentration of PGE_2 in amniotic fluid rises in labour, the rate of production of PGE_2 increases in labour and PGE_2 is more potent than $PGF_{2\alpha}$ in inducing parturition. However, more reliable assays of PGE_2 metabolites reveal no increase in circulating concentrations during labour (Brennecke *et al.*, 1985). Moreover, doubt has arisen as to the amount of unmetabolized PGE_2 that is able to pass through the membranes to reach the decidua and myometrium. McCoshen *et al.* (1987) studied membranes mounted in a dual-chamber perfusion apparatus which allowed the passage of labelled PGE_2 in either direction: about 50% of PGE_2 placed on the fetal side of the amnion alone crossed the membrane within 4 h and less than 5% traversed the combined amnion and chorion. To the contrary however, Nakla *et al.* (1986) reported that unmetabolized PGE_2 traversed full-thickness membranes in either direction and the rate of passage was greater after labour. The reason for these disparate results is not clear. Furthermore, pregnancies in which the amnion is detached from the chorion deliver normally at term unless the membranes rupture prematurely.

Casey and MacDonald (1988) reject amnion as the primary source of PGs, preferring the decidua as the source and $PGF_{2\alpha}$ rather than PGE_2 as the active PG for a number of reasons. They argue that through most of pregnancy the rate of production of $PGF_{2\alpha}$ by the decidua is rate limited by inhibition imposed by the fetal decidual paracrine system and that it is withdrawal of this inhibition that leads to labour. The amnion acquires arachidonic acid only from the amniotic fluid and, although arachidonic acid is lost from the membranes in early labour, the content is restored in late labour at a time when the concentration of arachidonic acid in amniotic fluid is rising rapidly (Keirse *et al.*, 1977; Okita *et al.*, 1983). This suggests the decidua as a source of arachidonic acid entering the membranes and amniotic fluid.

Casey and MacDonald (1988) calculated that the rates of production of $PGF_{2\alpha}$ and PGE_2 are low, even in labour, and that because of the very high rate of clearance in the lungs the concentrations in maternal peripheral blood may not increase measurably. They compared the rate of intravenous infusion of $PGF_{2\alpha}$ needed to induce labour with estimates of the rate at which endogenous $PGF_{2\alpha}$ is released (calculated from the plasma concentration of PGFM and the rate of its clearance). The rate of uterine secretion of $PGF_{2\alpha}$ estimated in this way is about 100 ng/min, and the rate at which infused $PGF_{2\alpha}$ reaches the uterus is about half this value. Although these approximations involve a number of assumptions, it appears that sufficient $PGF_{2\alpha}$ is released in early labour to be responsible for its onset. Whether the source of $PGF_{2\alpha}$ is decidua or myometrium is uncertain, but decidua is favoured because levels of 6-keto-$PGF_{1\alpha}$ in maternal plasma or amniotic fluid do not rise in parallel with PGFM, as would be expected if myometrium was the source. The possibility that decidual PGF_2 arises from amniotic PGE_2 converted by the enzyme 9-keto-reductase can be ruled out because the specific activity of the enzyme in decidua is much lower than that of 15-keto-PG dehydrogenase, which would result in inactivation of PGE_2 rather than conversion to $PGF_{2\alpha}$ (Niesert *et al.*, 1986).

The decidual stromal cells in which phospholipids are highly enriched with arachidonic acid are generally considered to be the cell type mainly responsible for the synthesis of $PGF_{2\alpha}$, although epithelial cells also have this capacity. Decidual stromal cells may be

macrophage-like, derived in part from bone marrow cells (Bulmer and Sutherland, 1983; Casey and MacDonald, 1988), because both are sites of 1-hydroxylation of 25-OH-vitamin D_3 and of production of β-endorphin and both respond to exposure to bacterial endotoxin by releasing quantities of PGs and cytokines. An inconsistency is the predominant production of $PGF_{2\alpha}$ by decidua but of PGE_2 by macrophages. More than one source and more than one prostanoid may be involved in the initiation of labour; for example, amniotic PGE_2 may enhance formation of various receptors in decidua and decidual $PGF_{2\alpha}$ may activate the myometrium.

(c) Control of PG synthesis

Evidence for many aspects of the system regulating PGs in pregnant human uterine tissues is missing or uncertain, making a coherent description impossible. To provide some orderliness to the fragments that are available, the following review will refer each section to Figure 9.1, with an appended numeral referring to a numeral on the diagram, i.e. Figure 9.1.1, etc.

Arachidonic acid is stored in fetal membranes and decidua (Figure 9.1.1), mainly in the *sn*-2 position of the glycerophospholipids, phosphatidylcholine, phosphatidylethanolamine and phosphatidylinositol, all of

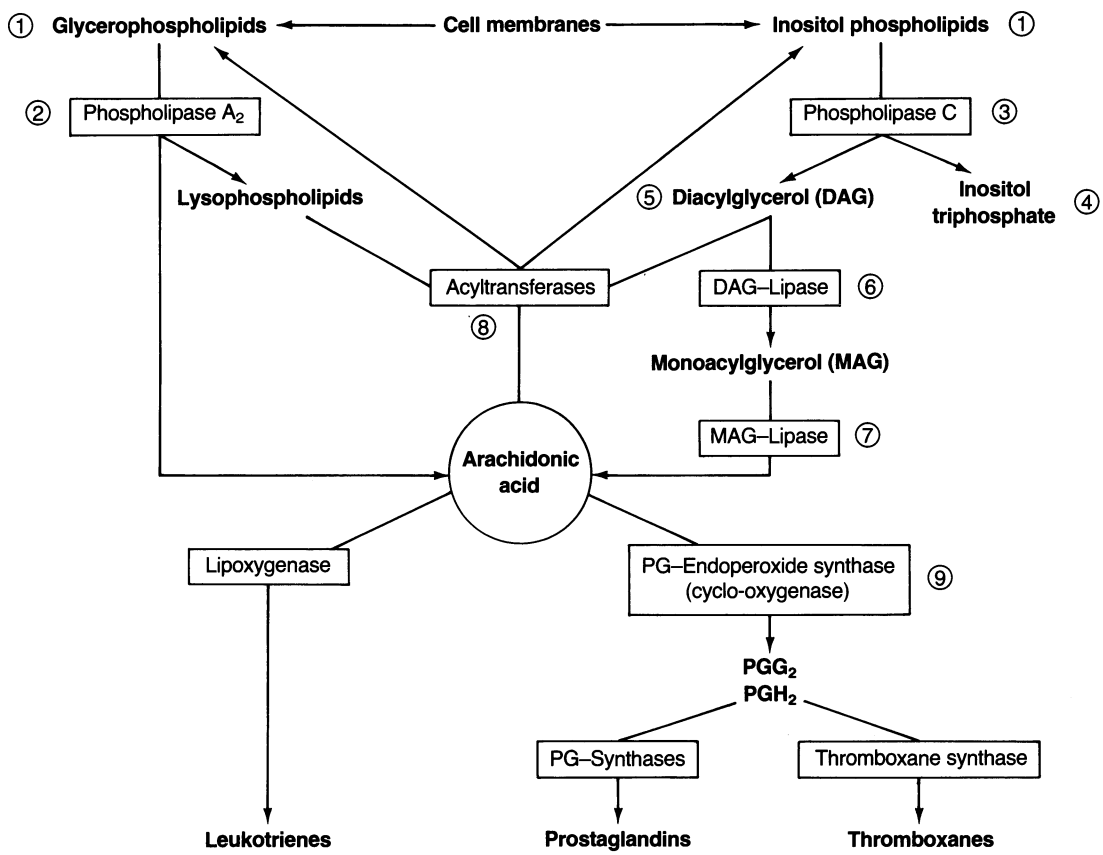

Figure 9.1 The arachidonic acid cascade. See text for details.

which are enriched with arachidonic acid relative to other tissues (Okita *et al.*, 1982a) for reasons that are uncertain but possibly due to an effect of P_4. Triglycerols in the membranes are not enriched and do not become depleted of arachidonic acid in labour. The release of arachidonic acid is controlled by one of two phospholipases. Many studies of PL activity have been in fetal membranes and there is a dearth of information about decidua. Phospholipase A_2 activity (Figure 9.1.2) in fetal membranes is relatively specific for phosphatidylethanolamine substrates (Okazaki *et al.*, 1978) and is a microsomal enzyme that is activated by Ca^{2+} at neutral pH, unlike lysosomal PLA_2, which is activated at acid pH independently of Ca^{2+}. The rate of release of arachidonic acid from 1-palmitoyl, 2-arachidonyl glycerophosphoethanolamine by PLA_2 is approximately four times that from the corresponding form of phosphatidylcholine. In addition, PLA_2 has specificity for glycerophospholipids containing arachidonic acid rather than oleic acid at the *sn*-2 position. Phospholipase C (PLC), which has specificity for phosphatidylinositol (Figure 9.1.3), is the first in a series of enzymes that release arachidonic acid from amnion and is Ca^{2+} dependent (DiRenzo *et al.*, 1981). Phospholipase C effects the release of inositol triphosphate (IP_3) (Figure 9.1.4), giving rise to diacylglycerol (DAG) (Figure 9.1.5), which becomes the substrate for DAG diacylglycerol lipase (Figure 9.1.6) with liberation of the fatty acid from the *sn*-1 position. A monoacylglycerol lipase (Figure 9.1.7) catalyses the final step, liberating arachidonic acid from the *sn*-2 position. DAG lipase and monoacylglycerol lipase are present in fetal membranes and decidua (Okazaki *et al.*, 1981c). The concentration of free arachidonic acid is determined not only by the activity of the PLs and the rate at which it is metabolized but also by the rate at which it is reincorporated into glycerophospholipids by lysophosphatide acyltransferase activity (Figure 9.1.8) and at which DAG is recycled through diacylglycerol kinase activity to phosphatidic acid and thence back to phosphatidylinositol. The increase in the concentration of DAG observed in in-labour amnion (Okita *et al.*, 1982b) is consistent with activation of the PLC pathway during labour and with the finding that the specific activity of DAG lipase in amnion, chorion and decidua does not increase from early to late pregnancy (Okazaki *et al.*, 1981a), suggesting that the production of arachidonic acid through the PLC pathway may be limited to some extent by DAG lipase activity. However, the relative importance of PLC-mediated and PLA_2 -mediated release of arachidonic acid as substrate for PG synthesis in labour is unknown. Prostaglandin synthesis may be initiated by agonist-activated PLC activity, leading to subsequent liberation of arachidonic acid from DAG, and the secondary release of PGs then results from activation of PLA_2 by-products (DAG and IP_3) of the PLC pathway, but studies of human uterine tissues to assess such a hypothesis are lacking.

In general, PG production is rate limited by arachidonic acid availability determined by PL activity, but some evidence in animal species suggests that PGH synthase (PGHS) (Figure 9.1) may also impose restraint on the rate at which arachidonic acid is metabolized to prostanoids in intrauterine tissues (J.S. Robinson *et al.*, 1978; Risbridger *et al.*, 1985). In women, the concentration of PGHS in placental and myometrial microsomes (Keirse *et al.*, 1984) increases threefold in pregnancy, which is consistent with the enzyme being rate limiting in early pregnancy. At term, however, the extremely rapid release of $PGF_{2\alpha}$ into the maternal circulation and amniotic fluid after amniotomy or cervical stimulation (Turnbull *et al.*, 1977) does not suggest low capacity for metabolism of arachidonic acid. *In vitro* experiments in which arachidonic acid is added to homogenized tissues or cell cultures are difficult to interpret because the release of endogenous arachidonic acid may already be high. Even so, prep-

arations of chorionic membrane and decidua *in vitro* respond to the addition of arachidonic acid with increased production of PGE_2 (Lopez-Bernal *et al.*, 1987b). Present evidence points to the rate-limiting step in prostanoid synthesis at term as being phospholipase activity, but this does not exclude PGHS activity as a limiting factor in earlier pregnancy. Indeed, Marshall *et al.* (1987) estimated that the capacity of the human body for the synthesis of PGs is 1000 times greater than the amount actually produced (as measured by urinary excretion), and they argued that the biosynthetic system must be restrained under normal circumstances by factors in addition to availability of arachidonic acid. They postulate the natural self-destruction of PGHS and the destruction by peroxidases of the hydroperoxides formed by the enzyme on which its activity is dependent as two of these factors. Presumably, PGHS activity places a ceiling on the magnitude of the response in PG production that can be elicited by arachidonic acid release.

The activity of PGHS may be subject to regulation by protein kinase C. Phorbol esters and synthetic DAG, both of which stimulate protein kinase C, also stimulate PGHS in dispersed amnion, and this action as well as that of epidermal growth factor (EGF) and glucocorticoids is blocked by staurosporine, an inhibitor of protein kinase C (Zakar and Olson, 1988, 1989).

(d) Stimuli of prostanoid synthesis

Various agents, of maternal and fetal origin, stimulate arachidonic acid release and are thought to activate PLs, but little detail is available from studies of human tissues. A role for oxytocin in stimulating PG synthesis is supported by clinical and biochemical observations. Oxytocin receptors in the myometrium and decidua increase with the start of labour. Infusion of oxytocin to induce labour in women at term is associated with a sustained increase in concentrations of PGFM in the circulation of those in whom the infusion is successful but a transient increase only in those in whom labour does not become established (Fuchs *et al.*, 1983a). The decidua or the myometrium is the likely source of the PG release in response to oxytocin because the response persists for at least 2 h after delivery of the placenta and membranes (Fuchs *et al.*, 1982b). Oxytocin stimulates release of PGE and $PGF_{2\alpha}$ from incubated portions of term decidua but not from myometrium (Fuchs *et al.*, 1981). Perfusion of a dispersed decidual cell preparation pulse labelled with [^{3}H]-arachidonic acid showed that oxytocin (and histamine and bradykinin) stimulates an immediate release of arachidonic acid and PGF_2 which is greater from cells obtained after labour than before labour (T. Wilson *et al.*, 1988). The response to oxytocin is presumably mediated by oxytocin receptors, and certain post-receptor responses in myometrial and decidual cells have been described by Schrey *et al.* (1987): oxytocin and vasopressin stimulated the accumulation of inositol phosphates (Figure 9.1.4) and DAG (Figure 9.1.5), thereby demonstrating activation of PLC. Both the binding of oxytocin to its receptor and the release of inositol phosphates by hydrolysis of phosphatidylinositol are inhibited by the oxytocin antagonist CAP 440 (Lopez Bernal *et al.*, 1989). Guanosine triphosphate-binding proteins (G proteins) that are thought to transduce receptor-mediated signals have yet to be studied in uterine tissues.

The roles of oestrogen and P_4 in stimulating prostanoid release in human pregnancy are indeterminate because of the difficulty in manipulating hormonal actions *in vivo*. The P_4 receptor antagonist, mifepristone, is relatively ineffective in inducing mid-term labour unless supplemented by PG (Baulieu *et al.*, 1987), and this suggests that P_4 withdrawal may not be involved in promoting PG release. Production of PGs is increased slightly but not significantly in decidual cell cultures in response to P_4 and

mifepristone compared with that to P_4 alone (Kelly and Smith, 1987).

Oestradiol-17β stimulates the production of $PGF_{2\alpha}$ by incubated dispersed cell preparations of non-pregnant endometrium (S.J.M. Skinner *et al.*, 1984; Schatz *et al.*, 1987) and by endometrial explants (Leaver and Richmond, 1984), but studies of tissues from pregnant women have not been reported.

Amniotic fluid contains a number of constituents that stimulate prostanoid production, but most remain uncharacterized and the site of action undetermined. Platelet-activating factor (PAF; 1-O-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine) is known to stimulate the synthesis of prostanoids in various tissues (Hanahan, 1986). Amniotic fluid from women before the onset of labour contains no measurable PAF, but amniotic fluid from about half a group of women in labour contained PAF activity detected by chromatography and platelet aggregation (Billah and Johnston, 1984). Similar findings were reported by Nishihira *et al.* (1984), who identified PAF by mass spectrometry. PAF stimulates contractions of human myometrium *in vitro* (Tetta *et al.*, 1986), and this effect is thought to be caused by an increase in cytosolic Ca^{2+}. Several possible sources of PAF have been suggested. PAF is detectable in the urine of newborns (Billah and Johnston, 1984) and is formed in organ cultures of fetal lung and may enter the tracheal fluid to reach the amniotic fluid (D.R. Hoffman *et al.*, 1986). Amnion contains PAF and its precursors and has the capacity to synthesize PAF, but Billah *et al.* (1985) were unable to demonstrate its release. The production of PGE_2 by amnion is stimulated by PAF, probably by increasing cytosolic Ca^{2+} and activating PLC and PLA_2. Angle *et al.* (1988) proposed that the release of prostanoids and the onset of labour is stimulated by PAF entering amniotic fluid from the maturing lung, but the normal duration of pregnancy in association with fetuses with complete tracheal atresia (which prevents the passage of lung fluid) weighs against this hypothesis. A similar hypothesis was proposed by Lopez-Bernal *et al.* (1988), who showed that the production of PGE by incubated discs of amnion was stimulated by human pulmonary surfactant. The fatty acids of surfactant glycerophospholipids are composed of about 2% arachidonic acid, and surfactant may provide substrate for prostanoid synthesis.

Casey *et al.* (1983b) identified a protein or protein-associated substance in fetal urine that markedly stimulated PGE_2 synthesis in amnion cells in monolayer culture and suggested that it was of renal origin. Strickland *et al.* (1983) showed that unextracted fetal urine in a concentration of 20% or greater stimulates PGE_2 synthesis by bovine seminal vesicle microsomes. The activity was heat stable and of molecular weight <12 kDa but was not purified. Hypotheses proposing a fetal urinary constituent as a trigger to labour are not supported by experiments of nature since fetuses that are unable to urinate because of lack of kidneys or obstruction of the renal tract are delivered spontaneously at term.

A fraction of amniotic fluid which passes through a membrane with a molecular weight exclusion of 1000 stimulates PGE_2 production by bovine seminal vesicle microsomes (Cohen *et al.*, 1985). The stimulatory activity increases throughout pregnancy and is greatest in labour. The relationship of this activity to the activity described in fetal urine is unclear, but both are of low molecular weight. Rehnstrom *et al.* (1983) demonstrated that crude amniotic fluid from late pregnancies in an unspecified concentration increases production of PGE and PGF by decidua and myometrium. The possibility that the active material is arachidonic acid was not excluded.

Schrey *et al.* (1987) used the ability of the phorbol ester, 12-O-tetradecanoylphorbol 13-acetate (TPA) to bind to and activate protein kinase C (thereby mimicking the action of

DAG) to explore the role of DAG in stimulating prostanoid production in decidual cells. TPA rapidly stimulated release of arachidonic acid from phosphatidylcholine, accompanied by a fall in phosphatidylcholine, extracellular accumulation of choline and cellular accumulation of phosphorylcholine. Schrey *et al.* (1987) interpret their observations as consistent with a model in which protein kinase C activation leads to arachidonic acid mobilization from decidual cell phospholipid by a mechanism involving PLA_2 -mediated phosphatidylcholine hydrolysis and PLC-mediated phosphatidylinositol hydrolysis, coupled with further hydrolysis of the DAG product. This study incidentally raises the possibility that decidua differs from amnion in that phosphatidylcholine rather than phosphatidylethanolamine may be the major source of arachidonic acid for metabolism to prostanoids. Schrey *et al.* (1987) did not suggest a mechanism linking protein kinase C with activation of phospholipases but it may inactivate a phospholipase inhibitory protein.

EGF, which is present in amniotic fluid, stimulates the production of PGE_2 and lipoxygenase products by confluent cultures of amnion cells (M.D. Mitchell, 1987), but there is no evidence that the concentration of EGF or its receptor undergoes changes at term. Amnion discs release PGE_2 into the incubation medium when exposed to low concentrations of isoproterenol (DiRenzo *et al.*, 1984). The response is inhibited by propanolol and reproduced by dibutyryl cyclic AMP, which supports beta-adrenergic stimulation.

Various non-physiological agents presumed to stimulate PG release are used as methods of inducing abortion or labour or arise as a consequence of pathological states in pregnancy. They include intra-amniotic hypertonic or irritant solutions, extra-amniotic fluids or foreign bodies and amnionitis. The concentration of $PGF_{2\alpha}$ in amniotic fluid is raised 24 h after the intra-amniotic injection of hypertonic saline when uterine activity is beginning (Gustavii and Greén, 1972). The effects of amnionitis, which is an important cause of preterm labour, have been studied extensively. Bacterial endotoxin (a lipopolysaccharide), released into the amniotic fluid in substantial quantities during infection (Romero *et al.*, 1987b), stimulates the production of cytokines by decidua (Romero *et al.*, 1989a–c). Three of these cytokines, interleukin 1α, interleukin 1β and tumour necrosis factor, which accumulate in amniotic fluid, are potent stimuli of $PGF_{2\alpha}$ by decidua (Casey and MacDonald, 1988; M.D. Mitchell *et al.*, 1990) and are thought to mediate the effect of amnionitis in provoking preterm labour. The mechanism by which cytokines stimulate prostanoid synthesis in decidua has not been studied.

(e) Inhibitors of prostanoid synthesis

Increased prostanoid synthesis at term could reflect either the activity of various stimuli, the withdrawal of tonic inhibition or both of these. Several putative inhibitors are present in pregnancy, but evidence of a reduction in effect at term is lacking for most of them.

Abel *et al.* (1980) measured the concentration of PGE and $PGF_{2\alpha}$ in the endometrium of women with intrauterine or ectopic (tubal) pregnancies and found that the concentrations are significantly less than in the endometrium throughout the normal menstrual cycle. Because the effect on the endometrium is the same whether the conceptus is inside or outside the uterus, Abel *et al.* (1980) concluded that the suppression of endometrial synthesis of PGs in early pregnancy may be mediated systemically rather than through a local action of the conceptus. The obvious candidate for a circulating inhibitor is P_4, which reduces the production of $PGF_{2\alpha}$ by secretory endometrium in organ cultures over a period of days (Kelly and Smith, 1987). However, the concentration of PGs is raised in mid-luteal endometrium, when P_4 levels are as high as in early preg-

nancy (Levitt *et al.*, 1975; Mathius and Kelly, 1978), and the production rate of $PGF_{2\alpha}$ in perfused endometrium is maximal in the late luteal phase (S.J.M. Skinner *et al.*, 1984). The apparent conflict between the known inhibitory effect of P_4 and the high concentration of PGs present in secretory endometrium is probably reconciled by reports from animal studies showing that although P_4 inhibits synthesis it also increases the capacity for synthesis *in vivo* (Kelly and Smith, 1987). The concentration of PGs in excised tissues probably reflects the capacity for synthesis rather than the actual levels present *in vivo* because of rapid production by the traumatized tissue. The contrast of the concentrations in endometrial tissue in the mid-luteal phase (which are high) with the production rates in perfused tissues at the same time in the menstrual cycle (which are low) (Liggins *et al.*, 1980), suggests that the capacity for synthesis of PGs is impaired in early pregnancy by a circulating agent that is unlikely to be P_4. The addition of 10^{-6} M progesterone to dispersed decidual cells reduces the rate of release of arachidonic acid within 15 min, although it has no effect on PLA_2 activity in a cell-free system (T. Wilson *et al.*, 1986), suggesting a direct physical action rather than an effect mediated by nuclear receptors and transcription of mRNA. A similarly rapid effect of P_4 on contractions of the monkey vas deferens stimulated by Ca^{2+} was noted by Moroshita (1986).

Various unidentified compounds with inhibitory effects on PG synthesis have been located in amniotic fluid or incubation media conditioned by decidua or amnion. Saeed *et al.* (1982) studied the effect of crude amniotic fluid on the rate of conversion of arachidonic acid to PGE_2 by bovine seminal vesicle microsomes and found that inhibitory activity is greatest in early pregnancy, is less at term and falls further in labour. The inhibitory activity is directed against PG synthase and may be proteinaceous (Brennecke *et al.*, 1983). A preliminary report by Reddi and Norman (1985) described inhibition of microsomal PGE and PGF production by amniotic fluid from about one-third of women not in labour, but PGF was not inhibited during labour. Culture medium conditioned by decidua from women at term but not in labour has marked inhibitory effects on the production of PGE_2 by amnion cells in monolayer culture (Romero *et al.*, 1987c), but Manzai and Liggins (1984) reported inhibition of endometrial production of PGE and PGF by medium conditioned by incubation with dispersed amnion cells from non-labouring women: the inhibitory action was absent when amnion cells from women in labour were used. The inhibitory effect is not reversed by arachidonic acid, suggesting that the site of action may be on PG synthase.

An endogenous inhibitor of PG synthase (EIPS) identified in plasma of human and other animals was postulated as playing a part in parturition (Saeed *et al.*, 1977), but measurements of plasma concentrations of EIPS by radioimmunoassay throughout pregnancy and labour show no trends consistent with lessening of inhibitory activity with the onset of labour (Brennecke *et al.*, 1984). A protein known as pregnancy-associated prostaglandin synthase inhibitor (PAPSI) was identified in human amniotic epithelium by immunohistochemistry using an uncharacterized antibody against PAPSI (Mortimer *et al.*, 1985); although the protein was present in most of the tissues of 15 women at term, none was found in five women in labour.

Recent interest has centred on proteins with PLA_2 inhibitory activity belonging to the lipocortin family, which were first identified by Hirata *et al.* (1980) and Blackwell *et al.* (1980). The glucocorticoid-dependent lipocortins have molecular weight of 15–37 kDa. They are polar glycoproteins containing about 10% carbohydrate. Lipocortin I (M_r 37 000) has been sequenced and cloned (Wallner *et al.*, 1986) and has partial homology with kinases and their substrates. Lipocortin mRNA is present in large amounts

in lung, thymus, spleen and placenta. Short stretches of internal hydrophobic residues may be involved in binding Ca^{2+}. Analysis of genomic DNA reveals only one unique gene, which suggests that other PLA_2-inhibitory proteins in the same family are products of proteolytic cleavage or of aggregation. The physiological role of lipocortins I and II (M_r 37 000) is not known, and it is possible that PLA_2 inhibitory activity is not their main function. The lipocortin molecule is inactivated by phosphorylation (Hirata, 1983), which is probably catalysed by protein kinase C because activation of protein kinase C by phorbol ester stimulates PLA_2 activity, presumably through reduced inhibitory activity of the lipocortins.

Confirmation of the relevance of lipocortins to the initiation of human parturition comes from the isolation from amniotic fluid of a protein with inhibitory activity against PLA_2 (T. Wilson *et al.*, 1985). A molecular weight of 80 kDa distinguishes it from the smaller lipocortins I and II, but in other respects the physical characteristics are similar. The protein is liberated during incubation of chorion, amnion and decidua, particularly from chorion (T. Wilson *et al.*, 1989). The activity of this protein, named gravidin, evident in medium from incubates of chorion taken before the start of labour, disappears in labour. Gravidin is a potent inhibitor of PLA_2, being active at concentrations as low as 10^{-10} M in dispersed whole-cell preparations of decidua as well as in cell-free preparations of porcine pancreatic PLA_2. It is not yet known whether gravidin is glucocorticoid dependent like lipocortin I and II, but the high concentrations of cortisol (10^{-5} M) required to inhibit the synthesis of $PGF_{2\alpha}$ in the endometrium (S.J.M. Skinner *et al.*, 1984) and the absence of effects of large doses of corticosteroids on the initiation of labour (Casey *et al.*, 1985) suggest that it is not. A possibility yet to be investigated is that gravidin is progesterone dependent, thereby providing an additional mechanism by which uterine quiescence and impeded PG synthesis is maintained by P_4 throughout pregnancy.

A P_4-dependent protein, blastokinin (Krishnan and Daniel, 1967) or uteroglobin (Beier, 1968), is a low molecular weight (15 kDa) molecule first found in the rabbit uterus in early pregnancy but is also present in other reproductive and non-reproductive tissues. It inhibits both chemotaxis of human neutrophils and thrombin-induced platelet aggregation. These effects depend, at least in part, on potent PLA_2 inhibitory activity, but the protein is genetically distinct from the lipocortins. A uteroglobin-like protein identified in late-luteal phase human endometrium and characterized both biochemically and immunologically (Kikukawa *et al.*, 1988) has yet to be studied in pregnancy. In the non-pregnant endometrium, the concentrations of uteroglobin and tissue PGE_2 and $PGF_{2\alpha}$ are inversely related and vary according to whether the endometrium is oestrogen or P_4 dominated. Another protein, interferon, has the potential for involvement in the control of prostanoid synthesis in pregnancy. Members of the interferon family, ovine trophoblastic protein 1 and bovine trophoblastic protein 1, are implicated in the inhibition of endometrial $PGF_{2\alpha}$ synthesis in early pregnancy in sheep and cattle that prevents luteolysis and permits implantation (sections 9.5 and 9.7). Recombinant 2α-interferon inhibits the production of PGE_2 and $PGF_{2\alpha}$ in explants of placenta and chorioamnion (G.E. Rice and S.P. Brennecke, personal communication) but has no effect on arachidonic acid-stimulated production, suggesting that the site of inhibitory action may be on a phospholipase.

9.2.9 SUMMARY – A MODEL

A soundly based model is not yet possible and the following proposal is necessarily speculative but may serve as a useful framework in which to incorporate future developments.

The earliest identifiable events in labour are increases in the production of $PGF_{2\alpha}$ and in the concentration of uterine oxytocin receptors; a relatively small increase in prostanoid production, perhaps PGE_2 by amnion, may stimulate oxytocin receptor formation, which leads in turn to a response to circulating oxytocin manifested in the myometrium by contractility and in the macrophage-like decidual stromal cells by PLC-mediated stimulation of $PGF_{2\alpha}$ production. The latter involves two pathways, one mediated by inositol triphosphate, which increases cytosolic Ca^{2+}, thereby activating PLA_2, and the other mediated by diacylglycerol, which activates protein kinase C, leading to activation of PGHS and to the phosphorylation and inactivation of gravidin, thereby enhancing further the activity of PLA_2. Positive-feedback loops involving prostanoid-enhanced oxytocin responsiveness and oxytocin-stimulated prostanoid synthesis in particular, lead to rapidly escalating release of $PGF_{2\alpha}$ from the abundant stores of arachidonic acid in the fetal membranes and decidua.

The signal to the foregoing events is unknown. Although, by analogy with experimental animals, the idea that the signal emanates from the fetus is appealing, no convincing evidence of fetal involvement, either by a circulating hormone or by a substance entering the amniotic fluid, has been forthcoming. The wide range but normal mean length of gestation in anencephalic pregnancies uncomplicated by polyhydramnios suggests that the fetus has, at most, a permissive role. Available evidence points strongly to the mechanism initiating labour being an intrauterine, paracrine system and consequently to the signal arising in the placenta/chorion. Local changes in oestrogen and P_4 metabolism could then alter the ratio of the two hormones to promote prostanoid release, but evidence that this occurs *in vivo* and of how it is regulated is lacking. Alternatively, the initiating system may be activated by a chorionic genetic clock transduced by protein kinases yet to be identified.

The release of $PGF_{2\alpha}$ from the decidua has multiple consequences for the uterus. The myometrium is stimulated not only by a direct action but also by potentiating the response to oxytocin and possibly by promoting the formation of gap junctions. The connective tissue of the cervix and uterine body undergoes complex biochemical changes that lead to softening and distensibility identical to the changes in response to relaxin; indeed, although circulating relaxin concentrations are unchanged at term, locally formed relaxin may mediate the action of prostanoids on connective tissues.

9.3 MONKEY

9.3.1 INTRODUCTION

Studies relevant to parturition have been made mainly of the rhesus monkey (*Macaca mulatta*) with a few of baboons (*Papio papio*), cynomolgus monkeys (*Macaca fascicularis*), the sooty mangabey (*Cercocebus atys*) and the common marmoset (*Callithrix jacchus*). The following account refers to rhesus monkeys unless otherwise specified.

The initiation of parturition in the monkey shares many features in common with human pregnancy, but human and non-human primates differ in the extent to which C_{18} and C_{19} steroids are 16α-hydroxylated in the fetus. The human fetus has very active 16α-hydroxylation, and consequently the major oestrogen entering the maternal circulation is oestriol with relatively small amounts of oestrone and oestradiol-17β, whereas non-human primate fetuses have low 16α-hydroxylase activity (Heinricks and Colas, 1970) and the major oestrogens are oestrone and oestradiol-17β. The physiological significance of this difference remains unexplained. Another consequence of the lack of placental 17α-hydroxylase (Ainsworth *et al.*, 1969) is the absence in primates of either a sharp fall

in P_4 production or rise in oestrogen production as the rate of conversion of P_4 to oestrogen is unresponsive to fetal cortisol concentrations.

9.3.2 ROLE OF THE FETUS

Maternal hypophysectomy is associated with normal parturition at term (Smith, 1954; Chez *et al.*, 1970), lending support to the generally held view that control of parturition in the monkey is intrauterine rather than a maternal endocrine function. As in human pregnancy, however, available evidence points to the fetus as having no more than a permissive or modulating role, implying that the controlling mechanism lies in the placenta and/or fetal membranes, although there is much less direct evidence to support this supposition than there is for human pregnancy.

Fetal hypophysectomy, performed by implanting radioactive capsules in the pituitary fossa (Chez *et al.*, 1970), is followed by labour at term. Surgical removal of the fetal head does not alter the mean duration of pregnancy (163 days *vs.* 167 days in controls) but alters the distribution, with births spread fairly evenly over a period of 50 days from 137 days onwards (Novy *et al.*, 1977). This pattern of deliveries is similar to that in human pregnancies complicated by anencephaly (W.M. Honnebier and Swaab, 1973). Fetal adrenalectomy has not been performed successfully, but continuous administration of glucocorticoids to the mother for 2–3 weeks before term in doses that inhibit fetal adrenal function as evidenced by low oestrogen production and adrenal hypoplasia is associated with normal-term delivery (Challis *et al.*, 1974a). More prolonged treatment with dexamethasone (for 5 weeks before term) leads to prolonged pregnancy in most, but not all, animals (Novy and Walsh, 1983; Mitchell *et al.*, 1984), which is consistent first with the non-involvement of fetal cortisol in the initiation of parturition and, second, with oestrogen having a permissive role.

Fetectomy is associated with placental retention to approximately term. Van Wagenen and Newton (1943) claimed that fetectomy did not alter the normal timing of placental delivery, but Lanman *et al.* (1975) found that fetectomy resulted in placental expulsion around term with a distribution similar to that occurring after fetal decapitation. Five baboons in which fetectomy was performed at 100–109 days delivered the placentas on day 168/9 (term 184 days) (Albrecht *et al.*, 1980). By contrast, Nathanielsz *et al.* (1990) reported that five monkeys fetectomized at 120–130 days' gestation retained the placenta for 21–32 days beyond term except for one delivered by hysterotomy at term because of cord prolapse. The results of the fetectomy and hypophysectomy experiments are consistent with a signal initiating parturition arising in the placenta and/or fetal membranes and with refinement of the precision of the signal being provided by the fetus, perhaps via the fetal zone of the adrenal.

9.3.3 PROGESTERONE

Progesterone (P_4) is secreted throughout pregnancy by both the placenta and the CL. Indeed, the concentration of P_4 in the uteroovarian vein is at least as high as that in the uterine vein (Walsh *et al.*, 1977a), but this does not reflect the relative production rates because of the much higher blood flow in the uterine veins. The CL continues to secrete P_4 after removal of both the fetus and placenta by Caesarean section in hypophysectomized monkeys, although at a much reduced rate (Walsh *et al.*, 1977b). Since fetectomy alone does not cause a fall in uterine vein or peripheral P_4 concentrations, it is likely that CL function throughout pregnancy is normally maintained by a product of the placenta, probably chorionic gonadotrophin. Luteolysis preceding parturition is unlikely in view of the persistence of P_4 secretion from the CL after Caesarean section.

The mean concentration of P_4 in maternal

plasma shows little change throughout most of pregnancy (Figure 9.2).

Immediately prepartum, the concentration either remains unchanged (Stanczyk *et al.*, 1986) or rises inconsistently (Challis *et al.*, 1974b). P_4 concentrations follow a similar pattern in baboons (Albrecht, 1980; Albrecht *et al.*, 1980), cynomolgus monkeys (Stabenfeldt and Hendrickx, 1973a; Hodgen *et al.*, 1977), bonnet monkeys (*Macaca radiata*) (Stabenfeldt and Hendrickx, 1972) and the sooty mangabey (Stabenfeldt and Hendrickx, 1973b). In none of these species is there evidence of a fall in plasma P_4 concentrations before parturition. There is a different pattern of concentrations of P_4 and oestradiol-17β in common marmosets (Chambers and Hearn, 1979; and Torii *et al.*, 1989; Figure 9.3).

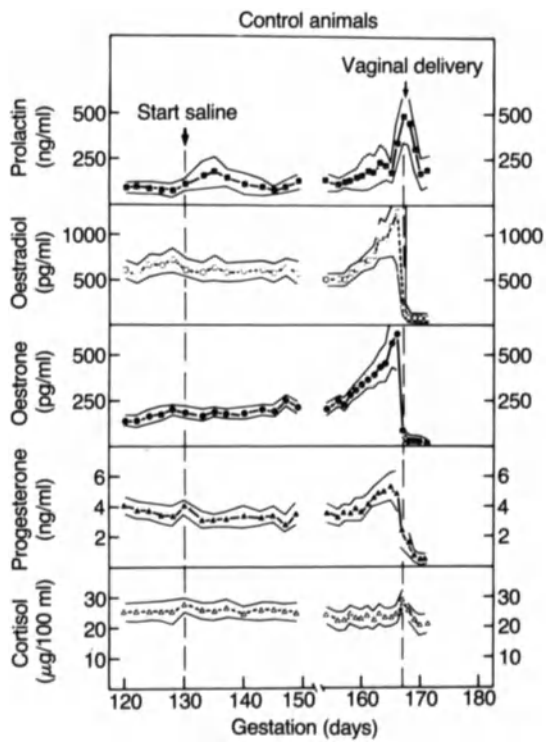

Figure 9.2 Maternal venous concentrations of hormones in rhesus monkeys from Day 120 of gestation until spontaneous delivery at term. (Reproduced with permission from Novy and Walsh, 1983.)

P_4 remains at levels similar to the luteal phase until about 90 days of pregnancy, when values increase rapidly to a peak at 110–130 days (term 144 days). Concentrations then fall steeply to values approximating those of early pregnancy 4–10 days before term and to undetectable levels at parturition. The marmoset is the only primate in which a marked prepartum fall in plasma P_4 concentrations has been reported. The marmoset placenta secretes P_4 from early pregnancy (Hodges *et al.*, 1983). The high levels in late pregnancy are considered by Torii *et al.* (1989) to be of placental origin, and the prepartum fall probably results from reduced synthesis of P_4.

Both the mother and the fetal monkey show marked diurnal variations (up to 100%) in plasma P_4 concentrations with a peak at 22:00–24:00 h and a trough at 08:00–10:00 h (Walsh *et al.*, 1984), which is the reciprocal of the diurnal rhythm of cortisol concentrations in the maternal plasma (Figure 9.4).

The changes in P_4 concentration are thought to be due in part to alterations in the rate of secretion of pregnenolone by the fetal adrenal and in part to displacement of P_4 from cortisol-binding globulin by high concentrations of cortisol in the morning. A similar diurnal variation in the fetal levels of DHEAS coincides with that of P_4, and both are thought to be a passive response of the fetal adrenal to inhibition of fetal ACTH secretion by the maternal diurnal rhythm of plasma cortisol, which readily crosses the monkey placenta (Novy and Haluska, 1988). Uterine activity also exhibits a diurnal rhythm during the week before term with an increase during the hours of raised P_4 and DHEAS concentrations from 22:00–02:00 h. However, the association is not causal since the fluctuations in P_4 and DHEAS are abolished by infusing the fetus with ACTH, but the diurnal rhythm of uterine activity persists although it is abolished by maternal adminis-

tration of dexamethasone (Ducsay *et al.*, 1983; Walsh *et al.*, 1984).

Haluska *et al.* (1987a) found that oral administration of mifepristone (20 mg/kg/day) for three doses at about 130 days of gestation was followed by a sustained increase in uterine activity until Caesarean section was performed after 48 h. Uterine activity (predetermined by intra-amniotic pressure and EMG) differed from normal labour in that the contractions were of longer duration (38 min) and lower frequency (5/h). The concentration of $PGF_{2\alpha}$, 6-keto-$PGF_{1\alpha}$, PGFM and bicyclo-PGE_2 in amniotic fluid increased, but not until 40 h after the onset of uterine activity. The cervix did not soften or dilate. These results differ from those of Wolf *et al.* (1989), who gave a single oral dose of mifepristone (25 mg) to 19 cynomolgus monkeys on day 160 of pregnancy (term 167 days): they observed slight (0.5–1.0 cm) cervical dilatation in 15 animals, but uterine activity (by manual palpation) was noted in only two animals, both of which delivered within 48 h. The reason for these disparate results is uncertain but is unlikely to be attributable to the difference in species or to differing gestational ages. It is clear, however, that withdrawal of P_4 action in late pregnancy fails to induce normal parturition in either species although P_4 receptors are blocked and oestradiol receptors increase after treatment with mifepristone (Haluska *et al.*, 1990a).

9.3.4 OESTROGEN

The fetal monkey has a functional fetoplacental unit in which oestrogen synthesis by the placenta depends on a supply of androgens (androstenedione and DHEAS) by the fetal adrenal (Walsh *et al.*, 1980). Inhibition of adrenal activity by maternal dexamethasone administration decreases oestrogen and androgen concentrations in the mother and fetus. Conversely, stimulation of the fetal adrenal with exogenous ACTH while endogenous ACTH is inhibited by dexamethasone sharply increases androgen and oestrogen levels. Oestrone is the major oestrogen in the fetal circulation and oestradiol-17β predominates in the mother (Challis *et al.*, 1974b; Resko *et al.*, 1975). The concentrations of oestrone and oestradiol-17β remain constant during the last third of pregnancy until the last few days, when the concentration of both oestrogens rise by approximately 10% (Walsh *et al.*, 1979) (Figure 9.2). Similar patterns of oestrone and oestradiol-17β in the maternal circulation are present in the baboon (Albrecht *et al.*, 1980) and cynomolgus monkey (Hodgen *et al.*, 1977). Like P_4, plasma concentrations of oestradiol-17β in marmosets differ from those of other monkeys in that values do not rise immediately prepartum (Torii *et al.*, 1989): There are very low

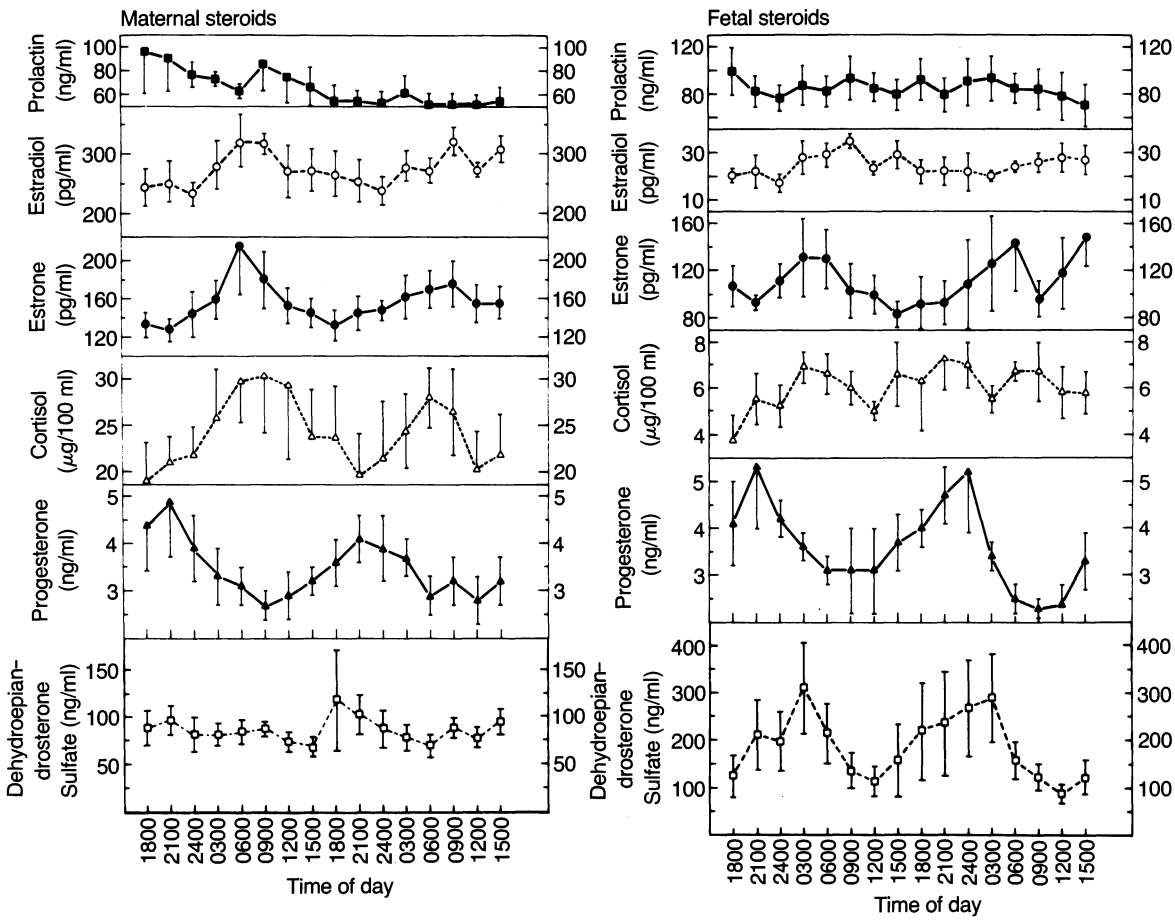

Figure 9.4 Hormone fluctuations in maternal and fetal peripheral plasma every 3 h during a 48 h period in long-term catheterized rhesus monkeys. (Reproduced with permission from Walsh *et al.*, 1984.)

concentrations before 90 days, peak values at 110–130 days and a trend to falling levels in some animals at term (Figure 9.3). Walsh *et al.* (1980) proposed that the terminal rise in oestrogen concentrations in rhesus monkeys provides a mechanism for a fetal effect on the timing of parturition. Experimental anencephaly reduces oestrogen concentrations and disturbs the distribution of pregnancy lengths (Novy *et al.*, 1977) and the administration of oestrogen induces delivery in monkeys with prolonged pregnancies and low oestrogen levels as a result of fetal death. Subsequent experiments by these and other workers make it unlikely that the preparturient rise in oestrogen triggers parturition, although it probably reflects an increase in adrenal activity and cortisol secretion that has an important role in promoting the final maturation of the fetal lungs and other organs. Inhibition of the rise in oestrogen by maternal dexamethasone treatment does not alter pregnancy length (Challis *et al.*, 1974a). Raising circulating oestrogen concentrations to very high levels by maternal treatment with oestradiol fails to initiate labour (Novy and Walsh, 1983). Insertion of Silastic capsules loaded with oestradiol into the amniotic sac is also ineffective (Novy and Haluska, 1988). When fetal monkeys were infused with ACTH from 125–135 days of gestation until delivery, there were several-fold increases in the concentrations of cortisol, DHEAS and oestradiol-17β, but delivery occurred normally at term (Novy and Haluska, 1988). In baboons, prolonged administration of the anti-oestrogen, ethamoxytriphetol, does not alter pregnancy length (Albrecht, 1980). However, the concomitant increase in maternal plasma concentrations of oestradiol-17β and fall in P_4 suggest that (1) oestrogen synthesis in the baboon placenta is subject to feedback regulation and (2) oestrogen is required for sustained high production of P_4.

9.3.5 OXYTOCIN

The concentrations of oxytocin are low in maternal plasma and amniotic fluid throughout the second half of pregnancy in rhesus monkeys and show no upward trend towards term (M.D. Mitchell *et al.*, 1980b).

A diurnal rhythm of oxytocin in maternal plasma coincides with that of P_4 and of uterine activity (M.B.O.M. Honnebier *et al.*, 1989a). The nocturnal uterine activity is abolished by a single bolus of a competitive oxytocin antagonist, suggesting a causal relationship between oxytocin concentrations and uterine activity at 98–117 days' gestation. Moreover, sensitivity to exogenous oxytocin is greatest at the time of nocturnal uterine activity (M.B.O.M. Honnebier *et al.*, 1989b).

In baboons, oxytocin concentrations in maternal peripheral plasma are similar to those in rhesus monkeys but are more variable and show a weak positive correlation with gestational age (Dawood *et al.*, 1979b). The concentration in uterine vein plasma is significantly higher than that in peripheral plasma, and the values in umbilical vein blood and fetal jugular blood sampled at the time of Caesarean section (three animals near term) are substantially higher than in maternal blood. Maternal infusion of oxytocin at a rate of 1–40 miu/min near term causes a dose-related increase in uterine activity beginning with the smallest dose. A bolus dose of 10 miu of oxytocin injected into the umbilical vein at the time of Caesarean section is followed within 15 min by a transient increase in concentration in maternal plasma and a rise in concentration in amniotic fluid. A massive intravenous bolus of oxytocin (20 U) given to cynomolgus monkeys near term failed to induce labour (Wolf *et al.*, 1989).

Hirst *et al.* (1991) did not confirm fetomaternal passage of oxytocin even when infused into the fetus in large amounts. The concentration of oxytocin in maternal plasma increased from 136 days, but only in samples

taken at night, and a further increment was noted in labour. Oxytocin receptors increased fourfold from 130 days to the early postpartum period. Hirst *et al.* (1991) concluded that a combination of increased concentrations of plasma oxytocin and myometrial oxytocin receptors facilitates delivery.

9.3.6 RELAXIN

In the rhesus monkey (Weiss *et al.*, 1981) and the baboon (Castracane *et al.*, 1985), relaxin becomes detectable in the circulation early in pregnancy and persists at constant levels to term. Although the source of circulating relaxin in these species is the CL (Ottobre *et al.*, 1984), relaxin remains detectable in decidua, placenta and myometrium after luteectomy (Castracane *et al.*, 1985), suggesting that local production may contribute to the physiological role of relaxin.

9.3.7 EICOSANOIDS

A role for PGs in the initiation of parturition in monkeys is supported by evidence similar to that in human pregnancy. Administration of PGE_2 or $PGF_{2\alpha}$ induces premature labour or abortion in rhesus monkeys (Kirton *et al.*, 1970; Challis *et al.*, 1974b), although extra-amniotic injection of arachidonic acid fails to do so (J.S. Robinson *et al.*, 1978). Daily intramuscular injections of $PGF_{2\alpha}$ at 142–151 days of gestation is followed by delivery in 2–6 days. Conversely, treatment with the PG synthase inhibitor, indomethacin, prolongs pregnancy (Novy *et al.*, 1974). However, few studies that systematically investigated eicosanoids in monkeys at term and in labour have been reported and information is fragmented and incomplete. The most detailed report is that of M.D. Mitchell *et al.* (1976), who measured PGF and PGFM in peripheral plasma and amniotic fluid of rhesus monkeys in late pregnancy. The concentration of PGFM in plasma is similar to that in non-pregnant animals (Cornette *et al.*, 1974) and falls significantly in the last 5 days of pregnancy. At least up to 24 h before parturition no increase in circulating PGFM is present. In amniotic fluid, however, both PGF and PGFM increase fourfold in the last 5 days of pregnancy (M.D. Mitchell *et al.*, 1976; Dubin *et al.*, 1988). When pregnant monkeys were treated with betamethasone for 2 weeks from 120 days, the low concentration of amniotic fluid PGFM at 133 days in controls was unaffected by treatment, but at 160 days, when PGFM had increased substantially in controls, the concentrations in betamethasone-treated animals remained low (Dubin *et al.*, 1988). Oestrone, oestradiol-17β and P_4 concentrations were unaffected by treatment, whereas cortisol levels were markedly reduced. Cortisol concentrations had returned to control values at 160 days. Maternal plasma levels of oestradiol-17β were suppressed during treatment but did not differ from controls at 160 days. The authors speculate that the low amniotic fluid concentrations of PGFM 4 weeks after discontinuing treatment with betamethasone may be due to induction of a protein that inhibits PLA_2 or PG synthase. The fetal adrenals failed to recover from suppressed growth.

Walsh (1991) found that $PGF_{2\alpha}$ in amniotic fluid was undetectable until 1–2 weeks before delivery and increased in association with a nocturnal pattern of strong uterine activity in two of five animals; two other animals began labour and delivered with very little increase in $PGF_{2\alpha}$ levels. In contrast, the concentrations of 5-HETE and LTC_4 were higher and rose markedly and consistently up to 7 days before the start of labour. There is a rise in amniotic fluid levels of 5-HETE and a similar increase in LTB_4 but no change in 15-HETE; similar but not significant changes in these lipoxygenase metabolites were observed after the maternal administration of mifepristone. Walsh (1991) suggests that 5-HETE and LTC_4 may stimulate uterine contractions or have chemotactic effects. LTC_4 may lack oxytocic effects in monkeys since it is ineffective in

stimulating human myometrial strips *in vivo* (Bryman *et al.*, 1985; Lopez-Bernal *et al.*, 1989), but 5-HETE stimulates human myometrial tissue in a dose-dependent manner (Bennett *et al.*, 1987) and could contribute to the initiation of labour in monkeys.

Amnion, chorion, decidua and myometrium obtained by Caesarean section at 140–168 days of pregnancy all release PGs in a superfusion system (M.D. Mitchell *et al.*, 1978d). The major product at all gestational ages is PGE from amnion. Decidua parietalis releases increased quantities of PGF and PGFM towards term, their total approximating half that of PGE from amnion at 168 days. In all tissues, the ratios of PGE/PGF and PGF/PGFM increase at term.

The role of eicosanoids in determining the types of uterine activity immediately preceding the onset of parturition remains unclear. Uterine contractility in pregnant monkeys is of two types:

1. Periods of EMG activity lasting for at least 3 min at least throughout the second half of pregnancy and showing no diurnal rhythm; and
2. contractions of <1 min in duration make their appearance in late pregnancy.

The latter have a strong diurnal rhythm with peak activity between 22:00 and 02:00 h (Ducsay *et al.*, 1983), which coincides with the peaks in the concentrations of P_4 and DHEAS in the fetal circulation. At approximately 1 week before parturition the nocturnal periods of uterine activity increase progressively to a crescendo 48–72 h before delivery. Novy and Haluska (1988) suggest that parturition in this species is an extension of a normally occurring nocturnal pattern of uterine activity in late pregnancy. The diurnal rhythm of uterine activity persists in animals in which the diurnal pattern of secretion of DHEAS is abolished by fetal infusion of ACTH, thus excluding the fetal adrenal as the source of the rhythm. In monkeys treated with RU486, an exaggerated diurnal rhythm of uterine activity was observed during the first 24 h but thereafter activity increased steadily without evidence of diurnal variation (Haluska *et al.*, 1987a). The cause of the diurnal rhythm is unknown, although it probably has important implications for understanding the mechanism initiating parturition in non-human primates.

9.3.8 SUMMARY

Many aspects of parturitional physiology in monkeys have features in common with human pregnancy, and it seems likely that a paracrine mechanism is involved in both species. The monkey fetus seems to have little more than a permissive role, as evidenced by a lack of consistent effects on pregnancy of length of hypophysectomy, decapitation, corticosteroid treatment or stimulation of the fetal adrenals with ACTH. Oestrogen and P_4 show no pronounced changes prepartum, and experimental manipulation of their concentration has no consistent effects in initiating or delaying parturition. The postulated paracrine system is further supported by the tendency of the placenta to remain *in situ* after removal of the fetus until approximate term or later in monkeys and 2 weeks before term in baboons. Overall, however, ignorance of the mechanism initiating parturition in non-human primates is even greater than that in humans.

9.4 PIG

9.4.1 INTRODUCTION

The commercial importance of the pig industry in most countries has ensured that considerable research funds have been directed into pig research. The relatively high perinatal mortality in this species has led to an emphasis on parturitional research. Not only is the pig a CL-dependent species, but it is also polytocous and so, if more than one of

the fetuses initiates parturition, how are their actions coordinated?

In ruminants, activation of the hypothalamic–pituitary–adrenal axis increases fetal plasma cortisol concentrations, initiating parturition and causing the synchronous maturation of the key organs essential for post-natal survival. In pigs, the two processes may be separate but, if so, they must be linked in some way to ensure that the piglets are mature at the time of birth. The pig represents a great technical challenge for fetal physiologists; not only are the fetuses small (smaller than fetal lambs) but there are so many. Moreover, relaxin is found in pigs; it is easily measured, is released from the CL and inhibits uterine activity.

9.4.2 PROGESTERONE

(a) Corpus luteum

The maintenance of gestation in the sow depends on the continued secretion of P_4 by the ovary. The placentas may make a small contribution to P_4 production during late pregnancy but ovariectomy performed at any time during gestation rapidly terminates pregnancy, indicating that placental P_4 production is inadequate for the maintenance of pregnancy (du Mesnil du Buisson and Dauzier, 1957). Progesterone replacement therapy will prevent abortion after ovariectomy (Fèvre *et al.*, 1968; First and Staigmiller, 1973), and the induction of additional CL on day 103 or 107 prolongs gestation (Bosc *et al.*, 1974; Martin *et al.*, 1977). Between four and six CL are needed for the production of sufficient P_4 to maintain late pregnancy (Martin *et al.*, 1977). Abortion occurs if maternal P_4 falls below 4 ng/ml (Ellicott and Dziuk, 1973; Nara *et al.*, 1981).

The length of gestation in the sow is 112–116 days. Maternal plasma P_4 concentrations fall slowly over the last 10–14 days of gestation before decreasing rapidly in the final 24–36 h before farrowing (Robertson and King, 1974; Baldwin and Stabenfeldt, 1975; Silver *et al.*, 1979a).

(b) Placental synthesis

There is clear evidence that the placenta produces P_4 during late pregnancy. Fetal P_4 concentrations are higher than maternal concentrations (Barnes *et al.*, 1974; Silver *et al.*, 1979a; Hagen *et al.*, 1983). The maintenance of high fetal P_4 concentrations in fetuses in ovariectomized sows (Randall *et al.*, 1986) and in sows after luteolysis induced with cloprostenol (Silver *et al.*, 1983) indicates that uterine uptake and placental transfer of P_4 from the mother are unlikely. There is a negative arteriovenous difference for P_4 across the umbilical vessels, suggesting placental production of P_4 (Hagen *et al.*, 1983; Nase *et al.*, 1985), and the fetal placenta can synthesize P_4 from P_5 *in vitro* (Craig, 1982). This confirmed histochemical (Christie, 1968; Dufour and Raeside, 1969) and biochemical (Ainsworth and Ryan, 1966) evidence of 3β-HSD in the pig placenta. The source of P_5 is not known: cholesterol may be synthesized *in situ* or taken up from the maternal circulation and then converted to P_5, or P_5 may be derived from the maternal or fetal circulations. There is no information on the circulating concentrations of P_5 in the sow.

When the luteal source of P_4 is removed (by ovariectomy) and replaced by medroxyprogesterone acetate (MPA) (Craig, 1982), there is a negative arteriovenous difference for P_4 across the maternal placental vessels. Maternal P_4 concentrations increased from day 104 to 110 and then decreased until the expected day of delivery (day 114). There are potential problems with the use of MPA because it depresses ovarian production of P_4 during the luteal phase in human (Johansson, 1971; Shinada *et al.*, 1978) and rats (Sunde *et al.*, 1982). However, the administration of MPA to sows in late pregnancy did not suppress P_4 production as judged by maternal P_4 concentrations (Whitely *et al.*, 1990),

and there is a negative arteriovenous difference for P_4 in the umbilical vessels of fetuses of ovariectomized sows (Randall *et al.*, 1986).

The major source of P_4 in the fetal circulation therefore appears to be the fetal placenta. The contribution of the fetal adrenal to the fetal P_4 pool would seem to be minimal (MacDonald *et al.*, 1980). However, in the last 24 h of gestation, when there is a sharp fall in maternal P_4 levels, fetal P_4 concentrations rose in both arterial and umbilical venous blood, presumably due to increased synthesis not decreased metabolism of P_4. Flint *et al.* (1979) noted a decrease in the formation of polar metabolites (pregnanetriols and pregnanediols) from P_4 by the term placenta, but the presence of high P_4 concentrations in samples taken from piglets at birth suggests that the P_4 may be derived from the adrenal which is maximally stimulated at this time (Silver *et al.*, 1979b). High concentrations of P_4 are also seen in neonatal pigs after premature delivery induced with cloprostenol (Silver *et al.*, 1983), suggesting that in piglets (as in foals) cortisol induction of 17α-hydroxylase activity in the fetus occurs late in gestation, but is not complete in premature newborn (Thorburn, 1993).

(c) Placental metabolism

Despite the ability of the placenta to produce P_4 during late pregnancy, it does not significantly contribute to maternal P_4 concentrations and cannot maintain the pregnancy in the absence of the CL. Indeed, there is a marked positive arteriovenous difference across the maternal placental vessels (6–8 ng/ml) which indicates that the uterus clears a large amount of P_4 from the maternal circulation. The fate of this P_4 is unknown, but it is presumably metabolized by the placenta, endometrium and myometrium. The major products of P_4 metabolism by the endometrium (maternal tissue) *in vitro* were 5β-reduced pregnanediols (3α,20α-diol) and pregnanetriols (3α,17α,20α-triol) together with 5β-pregnan-3α-ol-20-one (5β-pregnanolone). Less than 10% of the metabolites were 5α-reduced (Craig, 1982). In contrast, the products of placental (maternal or fetal tissues) metabolism were predominantly 5α- and 5β-pregnanolones (3α-hydroxy-5-pregnan-20-one). 17α-Hydroxylated products accounted for <5% of the metabolites isolated. Since the placenta produces mainly 5α- and 5β-pregnanolones, it presumably lacks the 20α-reductase enzyme. This study suggests that in the maternal endometrium the initial reduction of P_4 is to the 5β derivatives by an NADPH-requiring enzyme and the subsequent reduction of the 3-ketone is predominantly to the 3α-hydroxysteroid (5β-pregnenolone). A further reduction of the 20-ketone function to a 20α group leads to the formation of pregnanediol. The endometrium can also convert the 17α-hydroxylated derivative of P_4 through the above steps to pregnanetriol (5β-pregnane-3α,17α,20α-triol).

Whether these pathways operate *in vivo* to metabolize the large amounts of P_4 secreted by the CL into is not known. It is assumed that P_5 (and P_4) are metabolized via the Δ_4 pathway (Craig, 1982), although the Δ_5 pathway is primarily operative in the sheep (Nathanielsz *et al.*, 1982; Mason *et al.*, 1989), suggesting that the Δ_5 is the major pathway. However, the Δ_4 pathway may be functional close to term because the placenta shows increased ability to metabolize P_4 to 17α-OH-P_4 at this time.

The magnitude of the placental production of P_4 and its metabolites is still not clear. In the goat, Sheldrick *et al.* (1981) have proposed that the placental production of P_4 increases progressively from day 60 of gestation and reaches high levels but, in contrast to the sheep, most of this P_4 is metabolized to metabolites such as 5β-pregnanediol. Based on the plasma concentrations of unconjugated oestrone and oestradiol-17β in the pregnant sow, placental steroid biosynthesis commences about Day 80 of gestation. Craig

(1982) implied that increasing amounts of 5β-reduced metabolites are secreted by the pig placenta, but this has not been confirmed. Steroidogenic activity in the pig placenta may be low, with most of the P_4 synthesized by the placenta being directly converted to oestrogens. The placenta (and the endometrium) may play a much greater role in the clearance and metabolism of CL-derived P_4. There is a need to undertake with pigs the experiments undertaken with goats, whereby pregnancy is maintained after ovariectomy with MPA and P_4 and its major metabolites measured by specific radioimmunoassays.

9.4.3 LUTEOTROPHINS

(a) Protein hormones

Pituitary stalk section of hysterectomized sows, or sows in early pregnancy, results in luteal regression and abortion (L.L. Anderson *et al.*, 1967), indicating that continuous secretion of pituitary luteotrophin is necessary to maintain the CL and that the possible secretion of a placental luteotrophin is inadequate to replace the function of the pituitary. In hypohysectomized/hysterectomized sows, the CL can be maintained by LH alone and LH, but not prolactin, can prevent luteal regression (L.L. Anderson *et al.*, 1966). Administration of antiserum to LH causes luteal regression (Spies *et al.*, 1967). LH is therefore important for CL maintenance during the first half of pregnancy. However, prolactin may play a role in CL maintenance during mid- to late pregnancy: pituitary stalk section after day 70 of gestation or hypophysectomy resulted in regression after about 20 days (du Mesnil du Buisson, 1966), and hypophysectomy in late pregnancy terminated the pregnancy (Kraeling and Davis, 1974). Injections of bovine prolactin, but not LH, maintain luteal function (weight and P_4 content) after hypophysectomy of sows between days 70 and 80 (du Mesnil du Buisson and Denamur, 1969).

The administration of bromocriptine, a dopamine agonist, to late pregnant (day 111) sows reduced prolactin concentrations to <2 ng/ml, and caused the early onset of luteolysis in two out of three animals, again suggesting a luteotrophic role for prolactin in late pregnancy (Taverne *et al.*, 1982). There is also an increasing density of prolactin binding sites in luteal cells during the first half of pregnancy in the sow (Rolland *et al.*, 1976). It is not known whether antiserum to prolactin antiserum after day 70 would cause abortion.

The sudden decrease in P_4 secretion just before parturition may be related to the removal of a pituitary luteotrophic stimulus. The most likely pituitary luteotrophin in late pregnancy is prolactin, but there is no evidence of a preparturient decrease in plasma prolactin concentrations. Indeed, an increase in the maternal prolactin concentration has been reported (van Landeghem and van der Wiel, 1978; Taverne *et al.*, 1979a, 1982; Dusza and Krzymowska, 1981).

(b) Oestrogens

Administration of oestrogens during the oestrous cycle prolongs luteal function in pigs (Kidder *et al.*, 1955; Gardner *et al.*, 1963; Kraeling *et al.*, 1975) and increases plasma P_4 concentration (Ford *et al.*, 1982). One possible mechanism is that oestrogen reduces $PGF_{2\alpha}$ release into the circulation, thereby blocking the normal luteolytic action of the uterus (see Bazer *et al.*, 1986); such a mode of action has been suggested for the luteotrophic effect of endogenous oestrogen secreted by the conceptus early in gestation (Bazer and Thatcher, 1977). Oestrogen administered on day 12 after oestrus, apart from extending the lifespan of the CL in non-pregnant gilts, also increased the level of unoccupied LH receptors (Garverick *et al.*, 1982). Since maintenance of the CL is dependent on LH in the pig from about day 14 after oestrus (du Mesnil du Buisson, 1966, 1973; L.L. Anderson *et al.*, 1967; Spies *et al.*, 1967), the luteotrophic

action of oestrogen may be manifested by increasing numbers of LH receptors and thus LH action. This would be consistent with the lack of action of oestrogens in maintaining CL after hypophysectomy (du Mesnil du Buisson, 1966) or pituitary stalk section (L.L. Anderson *et al.*, 1967).

Conley and Ford (1989) demonstrated a direct luteotrophic effect of oestrogen on the pig CL *in vivo* by the intraluteal implantation of oestradiol. However, the dose of oestradiol used was much higher than that necessary to stimulate CL function when administered by an intrauterine route (Ford *et al.*, 1982). Conley and Ford (1989) concluded that the systemic effect of oestradiol noted in their study was due to an effect on the uterus by reducing $PGF_{2\alpha}$ release into the utero-ovarian vein as described by Frank *et al.* (1977) and Ford *et al.* (1982). This supports the proposal by Bazer *et al.* (1986) that the primary effect of oestrogen that results in maintenance of luteal function is a decrease of the luteolytic signal. Against a direct action of oestrogen on the CL was the finding that oestrogens did not increase the lifespan of CLs of pituitary stalk-sectioned sows (L.L. Anderson *et al.*, 1967), although it is possible that there were low LH values in these animals. Consistent with a direct action of oestrogen on the CLs was the stimulatory action of oestrogen on P_4 production by pig granulosa cells in culture (Goldenberg *et al.*, 1972; Veldhuis *et al.*, 1981) and of stilboestrol on binding of LH by isolated pig granulosa cells (Nakano *et al.*, 1977).

Garverick *et al.* (1982) suggested the following sequence of events. Firstly, before day 12 of gestation, the small amounts of oestrogen secreted by the conceptus act directly to inhibit endometrial $PGF_{2\alpha}$ synthesis and thus reduce the luteolytic signal. Secondly, the increasing concentrations of oestrone sulphate in maternal plasma during early pregnancy (Robertson and King 1974; Heap *et al.*, 1981) would explain the rise in luteal LH receptors between days 20 and 30 of gestation (Ziecik *et al.*, 1980).

It is not known whether oestrogens are luteotrophic after day 70 of gestation in the pig. Administration of oestradiol-17β to two pregnant gilts (days 102 and 105 of gestation) (Flint *et al.*, 1979) had no luteolytic or luteotrophic effects, but it is not clear how the luteotrophic effect was assessed because hormone concentrations are not indicated.

Oestrogen concentrations increase in the maternal circulation from day 70 to term (Robertson and King, 1974) and may act with prolactin to maintain luteal function. There appears to be neither a placental lactogen nor a chorionic gonadotrophin in the pig in early or late pregnancy (P.A. Kelly *et al.*, 1976; Flint *et al.*, 1979; A.P.F. Flint and P. Saunders, unpublished observations).

Considerable evidence is available indicating that fetuses may play a part in maintaining the CL of pregnancy to term (summarized by First and Bosc, 1979). At least four fetuses are required to maintain a pregnancy (Polge *et al.*, 1966), but when one uterine horn is removed, two fetuses are sufficient (Dhindsa and Dziuk, 1968). Pregnancy can be maintained for only one fetus when all the uterus except that portion occupied by the fetus is removed by day 14 of pregnancy (du Mesnil du Buisson and Rombauts, 1963). When all fetuses were killed after day 30, CL and P_4 concentrations were maintained until day 60 (Webel *et al.*, 1975) or from days 100 to 120 of gestation (Coggins and First, 1977) if the fetuses had not been resorbed. However, removal of all fetuses at day 102 caused delivery of the placentas in less than 48 h (Chiboka *et al.*, 1976). First and Bosc (1979) concluded that fetal tissue or a product of the intact conceptus, such as oestrogen (Bazer and Thatcher, 1977), must be present *in utero* to prevent the uterus from initiating luteolysis. Embryo extracts are luteotrophic when infused into the uterine lumen of unilaterally pregnant sows: luteal function is maintained and $PGF_{2\alpha}$-induced luteal regression is retarded (Longenecker and Day, 1972; Ball and day, 1982a). Ball and Day (1982b) used intra-

luteal implants containing pig embryonic extracts to maintain the function of an individual CL in an ovary, suggesting that the embryo extract can (also) directly prevent the luteolytic effects of the uterus at the level of the CL. The active principle(s) was heat stable and charcoal extractable, indicating that it was of low molecular weight, possibly a steroid (e.g. oestradiol). However, PGE_2 is another luteotrophic factor produced by the pig embryo (Akinlosotu *et al.*, 1986) as in sheep (Henderson *et al.*, 1977).

(c) Prostaglandin E_2

PGE_2 has been proposed as one of the signals for maternal recognition of pregnancy in sheep and cows (sections 9.5 and 9.7). In contrast, when intrauterine infusions of PGE_2 are started on days 12–14 of the oestrous cycle in cyclic pigs, luteal function is not prolonged (Schneider *et al.*, 1983), but if the infusion is started earlier in the cycle (day 7) and continued through to day 23 the decrease in plasma P_4 concentrations that normally occurs around day 15 is delayed and luteal function extended (Akinlosotu *et al.*, 1986). In the PGE_2-infused gilts, peak P_4 concentrations remained high from day 9 until day 23, and rapidly declined to <1 ng/ml by day 26.

The exact mechanisms of action of PGE_2 in maintaining luteal function are still unknown. Like LH, PGE_2 stimulates P_4 secretion and cyclic AMP production by bovine luteal cells *in vitro* (Speroff and Ramwell, 1970; Marsh, 1971) but the PGE_2 analogue, sulproston, is neither luteotrophic nor luteolytic in the cyclic pig (Sander *et al.*, 1982). This analogue is believed to act via the EP_1-type PGE_2 receptor and stimulate IP_3 turnover (R.A. Coleman *et al.*, 1985) and not via the EP_2 receptor, which activates adenylate cyclase and increases cAMP. In cycling ewes, PGE_2, by arterial infusion, induces luteolysis (section 9.5).

The luteotrophic effect of the intrauterine infusion of PGE_2 (Akinlosotu *et al.*, 1986) may be mediated by an action on the endometrium, inhibiting the release of the luteolysin $PGF_{2\alpha}$ into the uterine venous drainage, or by a direct luteotrophic action on the CL of pregnancy. The putative luteotrophic action of PGE_2 on the CL would require that, for the latter, adequate levels of PGE_2 would need to reach the CL, but information is lacking on the plasma concentrations of PGE_2 in the early pregnant pig.

Does PGE_2 continue to exert a luteotrophic role throughout pregnancy and does it act locally on the endometrium to inhibit $PGF_{2\alpha}$ release? The placenta is an important source of PGE during late gestation in the pig. PGE_2 is secreted into the fetal circulation [mean PGE concentration in the umbilical vein at birth being 11.3 ± 3.3 ng/ml (34 nmol/l) compared with 3.0 ± 0.3 ng/ml in the arterial plasma], and in catheterized fetuses from late pregnant sows PGE_2 levels are high in the umbilical vein (Silver *et al.*, 1979a). Significant amounts of PGE_2 are present in the maternal uterine vein at farrowing (4.0 ng/ml, 12.0 nmol/l) (Silver *et al.*, 1979a). Considering the high placental blood flow at that time, the production rate of PGE_2 by the late pregnant uterus is very high. PGE_2 is also found in the maternal artery during late pregnancy (1.4 ± 0.3 ng/ml, 4.2 nmol/l), indicating that considerable amounts of PGE_2 had escaped the lungs and could be exerting a luteotrophic effect on the CL of pregnancy. PGE_2 may also exert a stimulatory action on the myometrium and may explain the increase in uterine activity during the last 3 weeks of pregnancy in the sow (Taverne *et al.*, 1979b). However, the action of PGE_2 on the pig myometrium is unknown and further information is needed on the plasma concentrations of PGE_2 in the maternal uterine vein and artery during gestation in the pig.

Rice *et al.* (1989) have characterized the gestational profile of PGE_2 release from chorioamnion and chorioallantois in sows between 47 and 112 days' gestation. PGE_2

release from explants of the combined chorioallantois and chorioamnion under basal conditions is low (i.e. 13.7 ± 2.8 pmol/100 mg/h) up to 89 days (0.7 gestation). Release significantly increased by 3.5-fold over the next 22 days and reached a maximum of 176.5 ± 34.9 pmol PGE_2/100 mg/h. The addition of arachidonic acid significantly increased the release of PGE_2 at all stages of gestation, but when expressed as a percentage of basal PGE_2 release this effect decreased with increasing gestational age. Thus, with increasing gestational age, arachidonic acid became less rate limiting, implying an increase in phospholipase activity. However, the marked increase in PGE_2 synthesis in the presence of arachidonic acid between 80 and 110 days indicates a marked increase in PGH synthase activity in the pig placenta. Whether this is due to an increase in the tissue content of the PGH synthase enzyme, an increase in the rate of catalytic conversion or an increase in the half life of the enzyme is still to be determined (Rice *et al.*, 1989). Changes in the maternal plasma pattern and placental production of PGE_2 in the sheep are described in section 9.5. The pig may follow a similar pattern, and if so, PGE_2 may play a luteotrophic role in the pig.

9.4.4 LUTEAL REGRESSION AND HORMONAL CHANGES AT BIRTH

Parturition in the pig is preceded by a complex pattern of hormonal changes (reviews by First and Bosc, 1979; Taverne, 1982). A decrease in P_4 concentrations (Robertson and King, 1974; Ash and Heap, 1975) caused by the regression of the CL plays an essential role in the onset of parturition because P_4 treatment after ovariectomy prevents premature delivery (First and Staigmiller, 1973; Sherwood *et al.*, 1978) and induction of additional CL on days 103 or 108 of pregnancy prolongs gestation (Bosc *et al.*, 1974; Martin *et al.*, 1977). There is some debate about the exact timing of the decrease in P_4 levels and whether it precedes or follows the increase in relaxin concentrations, depending partly on the frequency of sampling and what is interpreted as a significant increase. Watts *et al.* (1988), using hourly sampling for the last 48 h, reported that the first change detected was a decrease in P_4 concentrations, which began at about 30 h prepartum and progressed to term. At about 20 h before delivery, plasma PGFM concentrations increased sharply, rising more slowly thereafter, and there was a surge in plasma relaxin concentrations 15–12 h prepartum, reaching a maximum of 55–329 ng/ml. The maternal plasma concentrations of oestradiol-17β varied within and amongst gilts over a relatively wide range, but in all animals an increase was observed during the last 30 h.

In contrast, Whitely *et al.* (1990) reported that relaxin concentrations increased before P_4 concentrations started to decline, as found by Taverne *et al.* (1982), who considered that maternal plasma prolactin and relaxin concentrations started to rise almost simultaneously between 57 and 47 h before the first piglet and that both hormones reached peak values when the plasma concentrations of P_4 had started to decline rapidly.

There is, however, marked variation between animals in the timing of the relaxin increase and the P_4 decrease. A study of individual sows (Sherwood *et al.*, 1981) showed that relaxin concentrations rose steadily from 2.7 ng/ml on day 110 to 15.8 ng/ml on day 112 and during the 2 days preceding parturition there was a further marked increase, with values reaching a peak 15 h before the birth of the first piglet. During days 110–112 small peaks of relaxin were detected, and these are probably in response to small amounts of $PGF_{2\alpha}$ released from the uterus. $PGF_{2\alpha}$ is known to be released in a pulsatile manner (Gleeson *et al.*, 1974), but these pulses can only be detected satisfactorily by high-frequency sampling from the uterine vein. The measurement of PGFM in peripheral plasma is a relatively insensitive means of

measuring $PGF_{2\alpha}$ release from the uterus. The administration of indomethacin to the preparturient sow not only blocks parturition but also prevents the increase in plasma concentrations of relaxin and prolactin (Taverne *et al.*, 1982), indicating that $PGF_{2\alpha}$ is involved in the triggering process for these changes.

If $PGF_{2\alpha}$ is the luteolysin in the pig, then only very low concentrations of $PGF_{2\alpha}$ would be needed in the arterial blood to initiate luteolysis. The efficacy of $PGF_{2\alpha}$ as a luteolysin is dependent not only on the concentration achieved but also on the time the CL is exposed to the $PGF_{2\alpha}$ the longer the better (Thorburn and Nicol, 1971). The efficacy of the $PGF_{2\alpha}$ analogues relates to their relatively long biological half-life, because they are not metabolized as rapidly by the lungs. A small initial release of $PGF_{2\alpha}$ causes a small decrease in P_4 concentrations, which in turn causes a further release of $PGF_{2\alpha}$. Thus, as the P_4 levels fall, greater amounts of $PGF_{2\alpha}$ are released, causing further decreases in P_4. If a luteolytic dose of a $PGF_{2\alpha}$ analogue (e.g. cloprostenol) is given to sows to induce farrowing, it is some 6 h before the initial increase in endogenous $PGF_{2\alpha}$ release occurs, and the $PGF_{2\alpha}$ concentrations continue to increase over the next 20 h, reaching very high values similar to those found at spontaneous delivery (Silver *et al.*, 1979a, 1983).

Further evidence in favour of $PGF_{2\alpha}$ being the luteolysin in the sow is provided by the studies of Martin *et al.* (1977). When CL were induced in pregnant gilts on day 83 or 103, and the original CL removed 6 days later, pregnancy was maintained. CL induced on day 83 had no effect on the length of gestation, and remained functional for 30 days rather than 15 days, as do the CL of the oestrous cycle, or 114 days, as do the CL of gestation. These results suggest that there was no circulating $PGF_{2\alpha}$ (or other luteolysin) in the pregnant sow before normal term because the CL persisted despite being sensitive to the luteolytic action of $PGF_{2\alpha}$. These observations also show that these CL are responsive to $PGF_{2\alpha}$ because they regress at term. The CL induced on day 102 remained functional for 15 days and prolonged gestation beyond the usual 114 days (to 119 days), exhibiting an intrinsic lifespan as in the oestrous cycle (du Mesnil du Buisson and Léglise, 1963). The CL of the oestrous cycle are resistant to luteolytic doses of $PGF_{2\alpha}$ during the first 12 days of the cycle, and presumably the new CL induced on day 103 are resistant to the parturient luteolysin.

$PGF_{2\alpha}$ treatment causes the regression of the old CL, but CL induced less than 12 days previously are resistant; plasma P_4 levels decreased but not sufficiently to cause parturition (Coggins *et al.*, 1977). $PGF_{2\alpha}$ and its analogues are potent luteolytic agents in the sow, and the fall in maternal plasma P_4 and rise in PGFM follow the same patterns as those seen before spontaneous labour at term (First and Bosc, 1979; Silver *et al.*, 1979a, 1983; Nara and First, 1981). Indomethacin prevents the preparturient increase in PGFM, luteal regression, the decrease in maternal P_4 concentrations and parturition (Nara and First, 1977). In indomethacin-treated sows, exogenous $PGF_{2\alpha}$ caused a decrease in P_4 concentrations and delivery, but very high doses given over long periods were required to increase the concentration of $PGF_{2\alpha}$ metabolites in the blood equal to those found at delivery (Nara and First, 1977). These results again indicate that only very low concentrations of $PGF_{2\alpha}$ are needed to initiate luteal regression at term in the sow.

The luteolytic agent in the sow is of uterine origin because hysterectomy at day 112 prolongs the life of old CL and new CL that have been induced about 7 days before the expected term (Bosc *et al.*, 1974; First and Bosc, 1979). The luteolysin travels from the uterus to the ovaries, at least in part by the systemic route. Parturition occurs at the expected time after ovaries are transplanted to the uterus or the body wall, thus surgically disrupting the normal anatomical relationship between the uterus and ovaries and pre-

venting any countercurrent transfer of the luteolysin between the uterine vein and ovarian arteries (Martin *et al.*, 1978). If $PGF_{2\alpha}$ is the luteolysin, these results would suggest that the lungs of the pregnant pig are not fully effective in clearing $PGF_{2\alpha}$ from the blood during its passage through the lungs.

Maternal plasma P_4 concentrations decrease slowly over the last 10–14 days of gestation before decreasing rapidly over the last 24–36 h associated with luteal regression (Robertson and King, 1974) caused by withdrawal of trophic support during the last 2 weeks of gestation or release of very small amounts of the $PGF_{2\alpha}$. Whatever the cause, the gradual decrease in P_4 concentrations over the last 10 days may also initiate the release of small amounts of $PGF_{2\alpha}$, which in turn initiate the final luteolytic mechanism.

9.4.5 THE EVOLUTION OF MYOMETRIAL ACTIVITY BEFORE PARTURITION

During the last 3 weeks of gestation, when circulating concentrations of P_4 are relatively high, myoelectric activity in the uterus is minimal and restricted to episodes of several minutes' duration, principally in areas of muscle overlying the fetuses (Taverne *et al.*, 1979b). Uterine EMGs consist of irregular episodes (<3.5/h) of prolonged phases of activity (>3.5 min duration) in uterine segments containing a fetus. Empty parts of the uterus remain relatively inactive (Taverne *et al.*, 1979b). Plasma oxytocin concentrations remain below 1.2 μu/ml between 12 and 2 days before parturition (Forsling *et al.*, 1979). Between 24 and 10 h before expulsion of the first piglet, mean concentrations of P_4 significantly fall and those of oestrogens increase. This coincides with behavioural changes of the sow (nest building), but myometrial activity at this stage is similar to that recorded on the previous days (Taverne *et al.*, 1979b). It was only between 9 and 4 h before the first piglet is born that the pattern of the EMGs changes and regular phases of electrical discharges appear with increasing frequency (7–12/h in all parts of the uterus). At the same time, oxytocin concentrations in peripheral plasma are elevated. During delivery of the piglets the mean frequency of the phases of electrical discharges increases further (18–20/h, their duration being significantly shorter than in the previous few hours). Oxytocin concentrations reach their highest levels at this stage, oestrogen concentrations are already falling and P_4 is <4 ng/ml in all sows (Taverne *et al.*, 1979b). Watts *et al.* (1988) found that total EMG activity did not change between 20 and 10 h prepartum, despite a marked increase in circulating PGFM concentrations, but in ovariectomized gilts, which therefore lacked relaxin, EMG activity increased steadily from about 15 h after the last P_4 injection when plasma P_4 titres were falling below 40 ng/ml. Watts *et al.* (1988) suggested that the difference between these two groups might be the sharp increase in plasma relaxin titres which occurred in control animals as P_4 concentrations waned. Consistent with this view was their finding that the progressive rise in EMG activity observed in the ovariectomized gilts after the last P_4 injection was virtually abolished in another group of animals by the administration of relaxin. These studies agreed with those of Porter and Watts (1986), who suggested that relaxin appears to maintain myometrial quiescence as the P_4 block wanes. When relaxin concentrations decrease, EMG activity increases progressively up to birth, as reflected by significant negative correlation between relaxin and mean total duration of electrical activity, suggesting that relaxin inhibits the myometrium while P_4 titres are falling and while circulating levels of $PGF_{2\alpha}$ are increasing (Watts *et al.*, 1988), as found for rats (Porter *et al.*, 1979).

Progesterone is a potent inhibitor of myometrial activity in the ovariectomized nonpregnant pig, and the ability of P_4, or synthetic progestagens (Craig, 1982) to maintain pregnancy in the sow after bilateral ovari-

ectomy, at least in part, may be due to inhibition of myometrial contractions by P_4 (Porter and Watts, 1986). As in rabbits (Csapo *et al.*, 1963) and sheep (Lye and Porter, 1978), the effect of P_4 is gradual in onset, the reduction in the frequency of pressure cycles occurring progressively over a period of 6–24 h. In contrast to relaxin, P_4 abolishes the myometrial responsiveness to oxytocin, and at least partial withdrawal of P_4 is a prerequisite for parturition (Taverne, 1982).

9.4.6 RELAXIN

The CL of pregnant pigs synthesize relaxin and store it in membrane-bound vesicles. The content of relaxin in the CL increases from about day 28, reaching peak levels at day 110 of gestation and, then decrease (Belt *et al.*, 1971; L.L. Anderson *et al.*, 1983), markedly so between 44 and 26 h before parturition when relaxin is discharged into the blood (Belt *et al.*, 1971). Plasma concentrations are markedly elevated only during the 2 days before parturition: peak values (50–300 ng/ml) occur 14–22.5 h before parturition, and concentrations then decrease rapidly to low levels (1 ng/ml) by 1 day after farrowing (Sherwood *et al.*, 1975, 1981). The high levels of relaxin in plasma are associated with high plasma concentrations of PGFM and the regression of the CL (Sherwood *et al.*, 1979; Nara and First, 1981; Taverne *et al.*, 1982; Watts *et al.*, 1988). It is thought that $PGF_{2\alpha}$ acts on the CL to cause the secretion of relaxin, concentrations increasing sharply after a luteolytic dose of exogenous $PGF_{2\alpha}$ (Sherwood *et al.*, 1976, 1979). Moreover, relaxin concentrations peaked 10 min after a small dose of $PGF_{2\alpha}$ (50 μg i.v.) which did not cause luteolysis and was not sufficient to decrease maternal P_4 concentrations (Nara *et al.*, 1982). Inhibition of PG synthesis by indomethacin prevented the release of relaxin, while simultaneous treatment with exogenous $PGF_{2\alpha}$ induced release of relaxin from the CL (Nara and First, 1981). Before parturition in the sow, maternal plasma prolactin and relaxin concentrations start to increase at about the same time (Taverne *et al.*, 1982). Although a common stimulus may evoke the relaxin and prolactin spikes, they are independent because abolition of the prolactin spike with bromocriptine did not prevent the occurrence of the relaxin spike (Taverne *et al.*, 1982). In bromocriptine-treated sows, normal preparturient changes in relaxin and P_4 were observed and parturition was unaffected, indicating that increasing prolactin concentrations were not an essential component of parturition. The prepartum changes in plasma prolactin, relaxin and P_4 concentrations were prevented by indomethacin but occurred apparently unchanged after the treatment ended, suggesting a primary role for $PGF_{2\alpha}$ in the prepartum hormone changes and the initiation of parturition.

The significance of the prepartum increase in relaxin concentrations is still uncertain, but it may be involved in the softening of the cervix (Kertiles and Anderson, 1979) and in myometrial coordination (Downing *et al.*, 1980). The main role of relaxin in the pig would appear to be as a myometrial inhibitor (Porter and Watts, 1986; Watts *et al.*, 1988).

Relaxin appears to maintain uterine quiescence as the P_4 block (Csapo, 1956) wanes. Porter and Watts (1986) demonstrated that P_4 is a potent inhibitor of myometrial activity in the ovariectomized non-pregnant pig, and suggested that the ability of P_4, or synthetic progestagens (Craig, 1982), to maintain pregnancy in the sow after bilateral ovariectomy, at least in part, is due to its inhibition of myometrial contractions. They found that, as in the rabbit (Csapo *et al.*, 1963) and the ewe (Lye and Porter, 1978), the effect of P_4 was gradual in onset since the reduction in the frequency of pressure cycles occurred progressively over a period of 6–24 h. In contrast to relaxin, P_4 abolished the myometrial responsiveness to oxytocin. Porter and Watts (1986) concluded that the pig is like the rabbit (Csapo *et al.*, 1963) and sheep (Lye and

Porter, 1978), in that a classic P_4 block 'can be demonstrated, a conclusion which is consistent with the reports that at least partial withdrawal of the action of the steroid is a prerequisite for parturition' (Taverne, 1982).

Purified porcine relaxin is a powerful myometrial inhibitor in the pig *in vivo* (Porter and Watts, 1986). Relaxin lowers the frequency of intrauterine pressure cycles without reducing the amplitude. A single dose of relaxin that produces plasma concentrations similar to those found normally prepartum is able to reduce myometrial activity almost to zero. Relaxin inhibition of the uterus in pigs does not affect the responsiveness of that organ to oxytocin (Porter and Watts, 1986). It appears that (1) relaxin is able to inhibit myometrial contractility of the gravid pig uterus *in vivo* and (2) the evolution of labour activity in the sow is inversely correlated with plasma relaxin concentrations (Porter, 1979; Porter and Watts, 1986; Watts *et al.*, 1988).

9.4.7 MATURATION OF THE FETAL PITUITARY–ADRENAL AXIS

In the pig, fetal adrenal weight increases during late gestation (Dvorak, 1972) and plasma cortisol concentrations in chronically catheterized fetuses increase during the last 4–9 days of gestation (Silver *et al.*, 1979a; Randall, 1983; Silver and Fowden, 1989). Therefore, activation of the fetal pituitary–adrenal axis presumably initiates parturition in pigs in a way similar to that in ruminants (Liggins *et al.*, 1973; Thorburn and Challis, 1979). Decapitation (Stryker and Dziuk, 1975) or hypophysectomy (Bosc *et al.*, 1974; Kendall *et al.*, 1983; Randall and Tsang, 1986) of the entire litter at an early stage of pregnancy results in a prolongation of pregnancy and eventual death of the fetuses *in utero*, emphasizing the importance of the fetal pituitary (and the brain) in the initiation of labour in pigs. When the litter contained one intact fetus plus three or four headless fetuses, parturition was delayed to day 124 or 125. When more than one intact fetus was present in a litter containing some headless fetuses, parturition was not delayed and two intact fetuses were needed to induce labour at term (Stryker and Dziuk, 1975). However, these studies did not point specifically to ACTH and the hypothalamic–pituitary–adrenal axis.

A single transuterine injection of a large dose of long-acting ACTH to each fetus, or all except two, at 103 days' gestation marginally shortened gestation to 110–112 days compared with controls, 113–114 days (Bosc, 1973). Dexamethasone (100 mg/day) administered to pregnant sows on days 101–104 also shortened the length of gestation to 110.5 days as compared with 115 days in controls (Coggins and First, 1977). A similar delay between injection of dexamethasone (75 mg/day on days 101–103) to the pregnant sow and the time of delivery (112.6 ± 0.6 days compared with 114.7 ± 0.2 days) was observed by North *et al.* (1973). Dexamethasone (6 mg) administered to seven fetuses of a litter also resulted in premature delivery some 7–8 days later (North *et al.*, 1973).

Although these findings are consistent with the suggestion that the initiation of parturition may be actively triggered by the fetal pituitary–adrenal axis (First *et al.*, 1982), this conclusion has been criticized (Silver and Fowden, 1989; Randall *et al.*, 1990). Randall *et al.* (1990) consider that these experiments are inconclusive because large doses were used and were superimposed on the stress response associated with surgical procedures. Furthermore, studies in ruminants have shown that when dexamethasone is used in pharmacological doses to induce premature parturition, the increase in placental 17α-hydroxylase activity occurs rapidly in the first 12–24 h and parturition occurs within 48–72 h (Thorburn and Challis, 1979). The delay observed in the pig experiments suggests that dexamethasone may be working by a mechanism other than a direct action on placental 17α-hydroxylase. Studies in pregnant cows have shown that if dexamethasone

(possibly because the dose was inadequate) does not induce parturition within a few days, it still initiates premature parturition, but delivery occurs some 7–10 days later (Fairclough *et al.*, 1981). However, studies in sheep suggest that glucocorticoid treatment may increase the responsiveness of the fetal hypothalamic–pituitary–adrenal axis or act at some other site(s) to provoke another parturient mechanism independent of the fetal pituitary–adrenal axis (Liggins *et al.*, 1977). There is some compelling evidence to indicate that the fetal pituitary–adrenal system is not directly involved in initiating parturition in the pregnant sow.

Early hypophysectomy by coagulation of the fetal pituitary between days 68–84, selectively alters the growth and maturation of individual organs. Hypophysectomy (before day 70) resulted in a significant reduction in the weights of the thyroid, adrenal and the testes but the spleen and kidneys increased (Randall, 1989). Differences occur between fetal lambs hypophysectomized late (115–125 days' gestation) and early (70–75 days' gestation) (Deayton *et al.*, 1993). Ewes carrying fetuses hypophysectomized earlier (days 70–75) failed to show the normal increase in placental oestrogen and PGE_2 biosynthesis between days 90 and 125 (Deayton *et al.*, 1993). They suggested that the fetal pituitary, perhaps by the synthesis and release of gonadotrophins, may influence placental steroid and PGE_2 synthesis. It is not known whether fetal infusion of dexamethasone or ACTH will induce premature labour in ewes carrying fetuses hypophysectomized early in gestation (day 75 or earlier). It is possible, therefore, that in pigs, in which the fetuses have been decapitated or hypophysectomized early in gestation (Stryker and Dziuk, 1975; Coggins and First, 1977), the maturation of the placenta and other key organ systems may also be delayed (Randall, 1989). This suggestion is consistent with the observation of the inability of dexamethasone to induce delivery in sows carrying decapitated fetuses (Coggins and First, 1977) and its failure to reduce maternal P_4 concentrations (Coggins *et al.*, 1977).

The parturition-inducing ability of glucocorticoids increases with advancing gestation in a number of species (Adams and Wagner, 1970; Bosc, 1972; Coggins and First, 1973) and may be dependent on a maturational process also controlled by the fetal pituitary or at least some portion of the fetal brain (Coggins and First, 1977). Furthermore, in the sow, as in the sheep (Chapter 10, this volume), fetal hypophysectomy (or decapitation) prevents the increase in placental PGE_2 production during the last 0.3 of gestation, and so the lack of PGE_2 may interfere with parturient mechanisms.

Randall *et al.* (1990) measured the fetal and maternal hormone changes in plasma from gilts in which all fetuses were infused with ACTH (2 μg/h) or saline continuously from day 103 of gestation. Litter size had been reduced to four earlier in gestation. The fetal adrenals were significantly heavier in fetuses receiving ACTH, and their plasma cortisol values increased rapidly in response to the ACTH infusion, although there was a marked variation in individual piglets. The fetal plasma cortisol concentrations were similar to those seen in the last few days of gestation (Silver *et al.*, 1979a; Randall, 1983). The fetal adrenal is fully responsive *in vitro* to ACTH by about 90 days' gestation (Lohse and First, 1981). A rise in fetal plasma cortisol in response to ACTH can be elicited by fetal manipulation as early as 70 days (0.65 gestation): infusion of ACTH (125 μg/day), over a 4-day period, elicited a cortisol response (Silver and Fowden, 1989) similar to that observed by Randall *et al.* (1990).

In chronically catheterized fetuses, Silver and Fowden (1989) noted a gradual rise in both cortisol and ACTH in fetal plasma from day 100 to term. There was a significant correlation between plasma cortisol and log plasma ACTH values ($r=0.81$, $P<0.001$). Analysis of basal values from younger (day

70–100) fetuses showed a positive correlation between cortisol and log ACTH, but the slope of the regression line was significantly less than for the older fetuses, indicating a greater adrenocortical response to a given level of ACTH nearer term.

In neither of the two studies in which ACTH was infused into chronically catheterized fetuses was premature parturition induced. In the experiments of Randall *et al.* (1990), all fetuses were infused with ACTH (2 μg/h) from day 103, whereas in the study of Silver and Fowden (1989), a continuous infusion of ACTH (0.125 mg/day) for 4–5 days was given to only 1–2 fetuses per litter (total size 7–12). Both studies caused an increase in fetal cortisol to parturient levels. It is difficult to reconcile these findings with the earlier studies, which suggested that activation of the fetal pituitary–adrenal axis initiated parturition in the pig (First and Bosc, 1979; First *et al* 1982).

These results indicate that the fetal pituitary axis is not involved in parturition *per se*, but that it probably plays a very important role in the maturation of the fetal lung and many other systems essential for post-natal survival of the neonate. It seems unlikely that the same mechanism is operative in the sow as in the goat since, in the goat, oestrogen is luteolytic (Currie and Thorburn, 1976), whereas in the sow, oestrogen is luteotrophic (Flint *et al.*, 1979).

In sheep and goats, the main action of glucocorticoids is to increase oestrogen biosynthesis by increasing placental 17α-hydroxylase activity (A.B.M. Anderson *et al.*, 1975; Flint *et al.*, 1978). Increased placental production of oestrogens would serve little purpose in sows because oestrogens are not luteolytic (Flint *et al.*, 1979). It appears that some other mechanism is involved in stimulating $PGF_{2\alpha}$ release from the pig placenta, if $PGF_{2\alpha}$ is the likely luteolysin in the pig.

Pituitary factors (e.g. gonadotrophins) may be required for the placental production of PGs in sows (Silver *et al.*, 1979b). Methallibure, an inhibitor of hypothalamic function (Mueh *et al.*, 1975) and specifically LH release, causes prolonged pregnancy when administered to the pregnant sow (First, 1972; Coggins and First, 1977). The fetal pituitary may therefore be responsible (Rice *et al.*, 1989), as in the sheep (Thorburn *et al.*, 1989; Deayton *et al.*, 1993), for a progressive increase in PGH synthase (cyclooxygenase) activity in the placenta but the final trigger may depend on the massive release of substrate (arachidonic acid) for $PGF_{2\alpha}$ synthesis and the presence of the enzyme ($PGF_{2\alpha}$ isomerase) which converts PG endoperoxides to $PGF_{2\alpha}$, or the enzyme 9 keto-reductase, which converts PGE_2 to $PGF_{2\alpha}$. The nature of this trigger is unknown.

9.4.8 OESTROGENS

Oestrogen concentrations increase in maternal (Robertson and King, 1974) and fetal (A.A. Macdonald *et al.*, 1979) circulations during the last month of gestation, with a more rapid increase during the last week. The rapid decrease after parturition suggests that oestrogens are produced by the placenta (Fèvre *et al.*, 1968; Robertson and King, 1974), supported by the finding that negative arteriovenous differences for conjugated oestrone and oestradiol-17β exist across both the uterine and umbilical circulations (Silver *et al.*, 1979a; Randall and Tsang, 1986). The high oestrogen content of the placental tissue (Choong and Raeside, 1974) and the demonstration that fetal placental tissue can convert androstenedione or P_5 to oestrogens (Ainsworth and Ryan, 1966; Craig, 1982) are additional evidence for the placental synthesis of oestrogens.

Progesterone concentrations are significantly higher and oestrogen concentrations significantly lower in hypophysectomized fetuses (Kendall *et al.*, 1985; Randall and Tsang, 1986) than in intact fetuses. When fetuses in one uterine horn only were hypophysectomized, oestrogen concentrations in

the uterine vein draining the horn containing intact fetuses were higher than those from the contralateral vein (Randall and Tsang, 1986), indicating that fetal and maternal oestrogen concentrations are influenced by the fetal pituitary. These observations are consistent with the earlier findings in sheep (Kendall *et al.*, 1977) in which fetal hypophysectomy also resulted in low fetal and maternal oestrogen concentrations and which have been recently confirmed (Thorburn *et al.*, 1989; Deayton *et al.*, 1993).

In the absence of the fetal pituitary, the placenta still produced a small amount of oestrogens since a negative arteriovenous difference still existed between the umbilical vessels (Randall and Tsang, 1986). The nature of the pituitary factor(s) is unknown. The higher fetal P_4 concentrations in the hypophysectomized pig fetuses suggest that P_4 is not being metabolized to oestrogens and that there is a low level of 17α-hydroxylase in the placenta of the hypophysectomized fetus. This would account for the low oestrogen levels found in these sows and their fetuses (Randall and Tsang, 1986). The high oestrone concentrations in hypophysectomized fetuses after surgery were thought to be due to some other steroid (possibly androstenedione derived from the adrenals) being converted to oestrogens.

The fetal placenta of the pig has the ability to convert P_4 to oestrogens and 17α-hydroxylase increases between days 106 and 114 of gestation (Craig, 1982), a period when fetal cortisol concentrations are rising (Silver *et al.*, 1979a; Randall, 1983; Silver and Fowden, 1989; Randall *et al.*, 1990). Craig (1982) suggested that, as in sheep and goats (Thorburn and Challis, 1979), fetal cortisol may be responsible for the increase in 17α-hydroxylase. However, infusion of dexamethasone into hypophysectomized fetuses for 96 h did not cause significant alterations in P_4 or oestrogen concentrations (Randall and Tsang, 1986), despite the concentration infused being higher than that previously used to suppress endogenous cortisol production in intact fetuses (Randall *et al.*, 1984). When ACTH or dexamethasone was infused into intact fetuses oestrone concentrations did not increase markedly but P_4 concentrations decreased after about 6 days of infusion (Randall and Tsang, 1986). No consistent changes were seen in the maternal oestrogen or P_4 concentrations during the course of ACTH infusions into all fetuses, but fetal plasma P_4 values fell during the infusion both of ACTH and saline (Randall *et al.*, 1990). The available data would suggest that, if fetal cortisol does increase 17α-hydroxylase activity in the porcine placenta, the increase is not great and its action on fetal and maternal steroid levels is also not significant. The need for oestrogen in the pig seems more obscure since oestrogens are not luteolytic in the pregnant sow (Flint *et al.*, 1979). Oestrogens may play a less obligatory role by raising oxytocin receptor concentrations in the placenta, endometrium and myometrium.

9.4.9 OXYTOCIN

In the pig, plasma oestrogen concentrations increase slowly over the last 3 weeks before parturition to reach peak values at delivery. In other species, oestrogens are known to stimulate the release of oxytocin (Roberts and Share, 1969; Roberts, 1975) and increase the sensitivity of the uterus to the hormone (Theobald, 1970), and myometrial sensitivity to oxytocin might therefore be enhanced by oestrogens during the last 3 weeks of pregnancy. This increased sensitivity may be due to an increase in the number of oxytocin binding sites (Soloff, 1975) present in the pig uterus (Soloff and Swartz, 1974). Myometrial activity increases and continues until completion of delivery; this coincides with elevated concentration(s) of oxytocin in the maternal plasma (Forsling *et al.*, 1979; Taverne *et al.*, 1979b). During delivery of the piglets the frequency of contractions in-

creases and oxytocin concentrations reach their highest values (Taverne *et al.*, 1979b), when oestrogen concentrations are already falling and P_4 has reached values below 4 ng/ml. Forsling *et al.* (1979) concluded that the only steroid that seemed to relate to oxytocin release was the negative correlation with P_4. Taverne *et al.* (1979b) noted with some reservations that the raised oxytocin concentration may precipitate the rather sudden onset of the regular pattern of uterine activity observed between 9 and 4 h before delivery of the first piglet.

There is a massive release of $PGF_{2\alpha}$ from the pregnant uterus during labour (Silver *et al.*, 1979a). Since $PGF_{2\alpha}$ stimulates the release of oxytocin in the sow (Ellendorff *et al.*, 1979), there is a possibility that $PGF_{2\alpha}$ and oxytocin may exhibit a positive-feedback effect on their own release (Thorburn *et al.*, 1977a,b; Ellendorff *et al.*, 1979), leading to the evolution of myometrial activity adequate to ensure safe delivery of the piglets and their placentas.

9.4.10 SUMMARY

The maintenance of pregnancy in the sow depends on the continued function of the CL and its ability to secrete P_4. During the second half of pregnancy trophic support for the CL seems to depend on prolactin (and to a lesser extent LH) from the maternal pituitary, but there appears to be no decrease in plasma concentrations of prolactin to account for the decrease in P_4 concentrations during the last 10–14 days before delivery.

We propose that PGE_2, derived from the placenta, may be luteotrophic during late pregnancy, but information is lacking on the plasma concentrations of PGE_2 in the pig and whether it is luteotrophic to the late pregnant pig CL. Oestrogens secreted by the placenta may provide a further luteotrophic stimulus to the CL. The relative importance of these factors needs to be evaluated. It is possible that one or more of these substances may act indirectly to suppress the release of $PGF_{2\alpha}$, the ultimate luteolysin in the sow.

The gradual decrease in P_4 concentrations during the 10–14 days before delivery suggests that there is a gradual decrease in the trophic support for the CL. If the fetus(es) is to play a primary role in the initiation of parturition in this species, it would seem that some mechanism must exist for the fetus(es) to switch off this trophic support. Maternal pituitary hormones such as prolactin and LH are unlikely to be involved. There is no evidence of a decrease in oestrogen secretion by the placenta. A switch in the synthetic pathway for PGs from E_2 to $F_{2\alpha}$, that is from a luteotrophin to luteolysin, would seem an effective mechanism which theoretically might be achieved by the fetus.

As in the sheep, PGE_2 may be synthesized in the fetal placenta and membranes and $PGF_{2\alpha}$ produced by the endometrium and maternal placenta, with oxytocin stimulating the secretion of $PGF_{2\alpha}$ but not PGE_2. The chorion (trophoblast) may secrete a substance which inhibits $PGF_{2\alpha}$ synthesis in the maternal endometrium and placenta, the inhibition being directed at the phospholipase or PGH synthase steps of PG synthesis, or both. This inhibition could be switched off at an appropriate time by the fetus increasing $PGF_{2\alpha}$ release and initiating luteal regression.

The present data strongly indicate that $PGF_{2\alpha}$ is the luteolysin that precipitates CL regression and parturition in the sow. Some days before delivery small amounts of $PGF_{2\alpha}$ are released from the uterus and act on the CL to cause the initial small pulses of relaxin and to initiate regression of the CL. The initial decrease in P_4 concentrations enhances the release of $PGF_{2\alpha}$ which, in turn, acts back on the CL to decrease P_4 release further and stimulate relaxin release. Thus, the interaction of $PGF_{2\alpha}$ and P_4 forms a positive feedback (Figure 9.5).

In the parturient sow, increasing relaxin and oestrogen concentrations and decreasing P_4 values may stimulate the release of oxy-

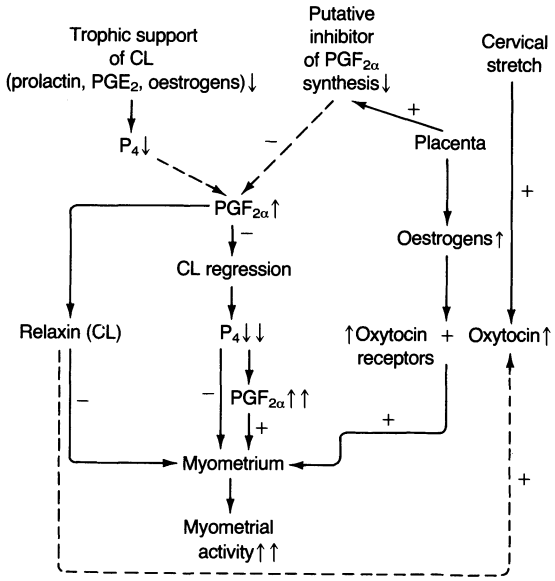

Figure 9.5 The pathways involved in the initiation of parturition in the pig.

tocin from the posterior pituitary. With the birth of the first piglet, the Ferguson reflex would stimulate further oxytocin release. Preliminary data indicate that significant levels of PGE_2 escape metabolism in the lungs and appear in the arterial circulation and may account for the increase in uterine activity during the last three weeks of pregnancy in the sow. With the decrease in P_4 concentrations, the high arterial levels of PGE_2 may account in part for the uterine activity at parturition. It is known that PGE_2 can act via either the IP_3 or the adenylate cyclase pathway, and theoretically could stimulate or inhibit uterine activity dependent on the nature of the PGE_2 receptors present on the myometrium at any time. However, PGF_α has to be transported by the systemic route to cause CL regression in the pig, and it is more likely that in the pig, as in other species, $PGF_{2\alpha}$ synthesized in the endometrium and maternal placenta may diffuse directly into the myometrium to stimulate activity. Only small amounts of PGs may be required to stimulate myometrial activity as P_4 values decrease. The increase in oestrogen concentrations before parturition is probably an expression of increased activity of the fetal pituitary–adrenal axis. Oestrogens increase oxytocin release and increase the number of oxytocin receptors in the endometrium, myometrium and placenta, and thus facilitate the release of PGs and the direct action of oxytocin.

9.5 SHEEP

9.5.1 INTRODUCTION

Most research in the past 25 years on the mechanism of parturition has been on the sheep. There are many reasons for this: sheep are important economically in many countries and farmers and governments actively contribute to research on them; sheep withstand surgery well and are therefore excellent experimental models in pregnancy, allowing the development of new techniques for maintaining vascular catheters in the fetus and sophisticated surgical techniques, such as hypophysectomy, pituitary stalk section, thyroidectomy, bilateral nephrectomy and hypothalamic–pituitary disconnections. The relatively large size of the section on the sheep testifies to the scope of the literature on parturition in this species and the importance of these studies.

The sheep, like the human, is a species in which the placenta is a major site of P_4 production. In this respect, the sheep contrasts with the goat and cow and most other ruminant species (Heap *et al.*, 1977) in which the CL constitutes the major site of P_4 synthesis. In all ruminants, P_4 exerts a profound inhibitory influence on myometrial activity. The initiation of parturition in these species is mainly directed at removing this inhibitory action of P_4. It is instructive to compare the mechanisms by which the fetus initiates its own delivery by inhibiting P_4 secretion,

whether this P_4 is produced in the placenta or CL (Figure 9.6).

9.5.2 PROGESTERONE

P_4 is essential for the maintenance of pregnancy in sheep. During the first half of pregnancy, the concentration of P_4 gradually increases from luteal phase levels, but at approximately day 90 its concentration increases markedly, reaching a peak at about day 125 of gestation (Basset *et al.*, 1969; Thorburn *et al.*, 1977a), before decreasing in the last few days before parturition at 145 days (Bassett *et al.*, 1969; Stabenfeldt *et al.*, 1972).

(a) Site of production

The CL is the major site of P_4 production during the first third of pregnancy, ovariectomy of the ewe before day 50 of pregnancy resulting in abortion (Casida and Warwick, 1945; Denamur and Martinet, 1955). The *in vitro* studies of R.V. Short and Moore (1959) and Ainsworth and Ryan (1967) suggested that the ovine placenta was the site of P_4 synthesis during late pregnancy. This was later confirmed by Linzell and Heap (1968),

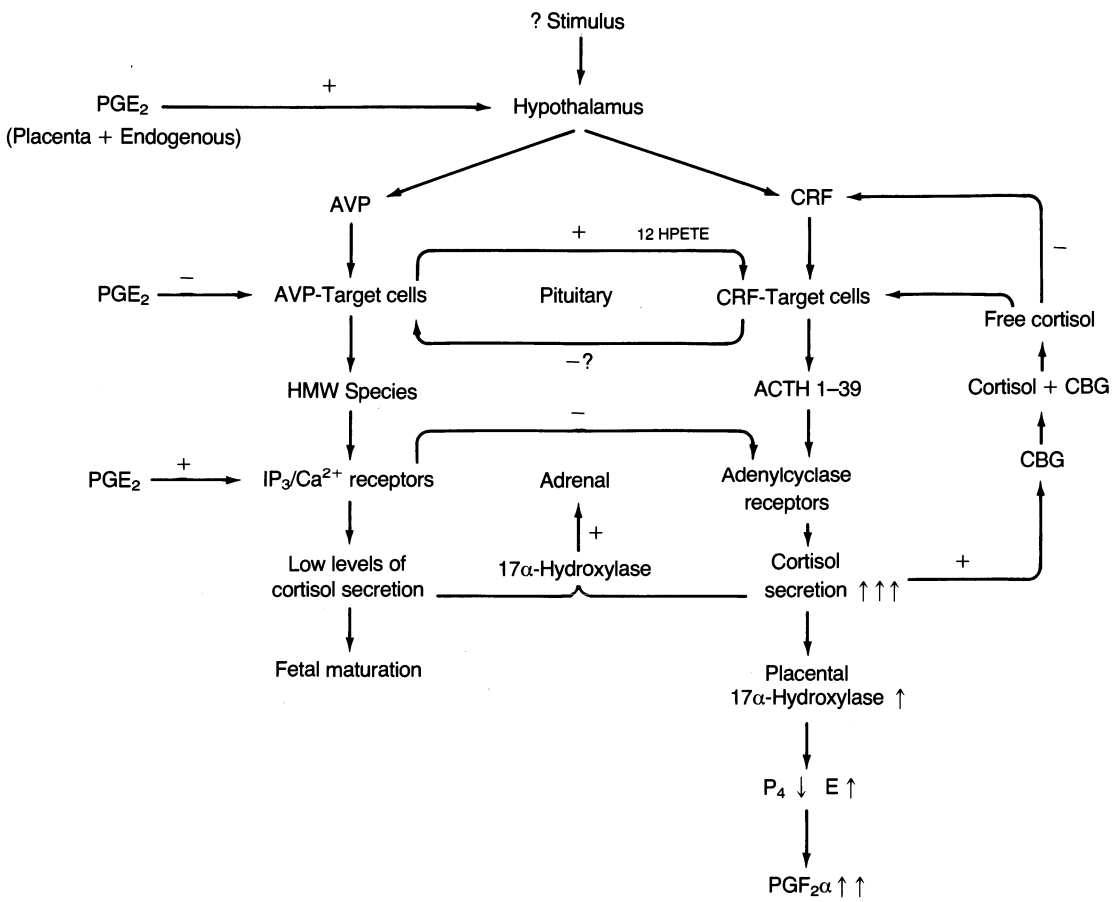

Figure 9.6 The pathways involved in the initiation of parturition in the sheep.

who monitored uterine venous blood concentrations of P_4 in late pregnant ewes. Thorburn *et al.* (1977a) measured plasma concentrations of P_4 in the utero-ovarian vein after ovariectomy on day 55–60: P_4 concentrations decreased to low levels (0.5–1.0 ng/ml), but were sufficient to maintain the pregnancy. From days 55 to 90, there was a progressive increase in P_4 levels in the utero-ovarian plasma, indicating placental P_4 production which was markedly decreased in the few days before delivery. The extra-ovarian contributions to P_4 levels in the circulation have also been measured in ovariectomized ewes in which pregnancy was maintained by treatment with medroxyprogesterone acetate (Ricketts and Flint, 1980): placental production of P_4 rose initially between 50 and 70 days of gestation, with a second phase of increase between 90 and 120 days of gestation, thus confirming the earlier results.

(b) Biosynthesis

Although information is not yet available, it seems likely that in sheep the increase in placental P_4 production between days 90 and 125 of gestation is associated with the placental uptake of lipoprotein from the maternal circulation, as occurs in man (Van Leusden and Villee, 1965; Hellig *et al.*, 1970; Cummings *et al.*, 1982; Simpson, 1984). Lipoproteins, particularly high-density lipoprotein (HDL), stimulated P_4 production in ovine luteal cells in a dose-dependent manner (Diskin *et al.*, 1989) and HDL from the maternal circulation may be the major source of cholesterol for P_4 synthesis. Confirming the results of Flint *et al.* (1974a), Battista *et al.* (1989) showed, using short-term incubation of placental explants from ewes of 133–138 days' gestation, that P_4 synthesis was stimulated by catecholamines via β-adrenoreceptors and adenylate cyclase. LH and the P_4 precursor 25-hydroxycholesterol failed to stimulate basal or agonist-stimulated P_4 synthesis, consistent with the *in vivo* data of J.S. Robinson *et al.* (1977), who showed that fetal hypophysectomy after day 125 of gestation did not affect maternal plasma concentrations of P_4.

In isolated ovine binucleate cells (BNCs), PGE_2, but not LH or cAMP, stimulated P_4 secretion, suggesting that PGE_2 acts through a cAMP-independent mechanism, e.g. the inositol triphosphate (IP_3)/protein kinase C pathway (Wango *et al.*, 1988). The ovine placenta secretes increasing amounts of PGE_2 during the last third of gestation (Fowden *et al.*, 1987), and maternal plasma PGE_2 and P_4 concentrations increase in parallel (Thorburn *et al.*, 1989), but BNCs are not the site of PG synthesis in the ovine placenta. Boshier *et al.* (1991), using immunohistochemical techniques, showed that BNCs did not contain PGHS and uninucleate cells of the trophoblast and the fibroblasts of the ovine placentome in culture did not produce PGs (X. Ralph, unpublished data) (Figure 9.7).

These studies suggest that, once P_4 production is fully established in the ovine placenta (at about 120 days' gestation), P_4 synthesis can be maintained by the combined action of the uninucleate and binucleate cells and that PGE_2, produced in the uninucleate cells via a cAMP-dependent mechanism, acts on the BNCs via a cAMP-independent pathway to stimulate P_4 synthesis. It is possible that, once the HDL receptors and the steroidogenic enzymes are present, they require no further trophic support.

(c) Ovine placental lactogen

There is a parallel increase in maternal plasma concentrations of P_4 and ovine placental lactogen (oPL) (J.S.D. Chan *et al.*, 1978; Taylor *et al.*, 1983). Apoprotein constituents of HDL stimulate a dose-dependent increase in the release of placental lactogen from human trophoblast explants and trophoblast cells (Handwerger *et al.*, 1987), and in pregnant ewes HDL, but not lipoprotein-free

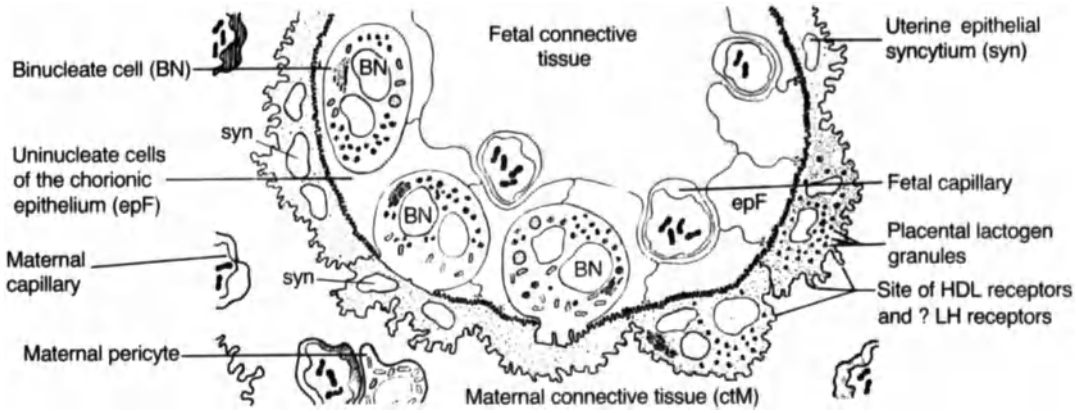

Figure 9.7 The ovine placenta. (Modified from Steven, 1977.)

plasma proteins, stimulates an increase in plasma oPL (Grandis *et al.*, 1989).

Battista *et al.* (1989) reported that oPL secretion was stimulated via the protein kinase C pathway. Since HDL stimulates the release of oPL (Grandis *et al.*, 1989) and oPL is derived from the BNCs (Wooding, 1981), this suggests that there are specific receptors for HDL on the BNCs and that these receptors act via the protein kinase pathway to release oPL. If HDL receptors are present on the maternal surface of the BNCs, it would facilitate delivery of maternal cholesterol directly into the BNCs as substrate for P_4 biosynthesis. Furthermore, the parallel increase in maternal plasma concentrations of P_4 and oPL between 90 and 125 days of gestation would be explained by an increase in HDL receptors on the BNCs. Indeed, as in the human, the major determinant of placental P_4 synthesis may be the number of HDL receptors (Figure 9.8).

The factor(s) that increases the putative lipoprotein receptors on the ovine BNCs is unknown. It has been suggested that hCG/LH may be responsible for inducing low-density lipoprotein (LDL) binding sites in the human CL and thus increase P_4 secretion and that adrenocorticotrophic hormone (ACTH) induces LDL receptors in bovine adrenal cells (Ohashi *et al.*, 1982). It is possible, therefore, that LH may be responsible for the increase in placental P_4 synthesis between 90 and 125 days of gestation by inducing placental lipoprotein receptors and thereby increasing cholesterol delivery to the placenta for P_4 biosynthesis.

(d) Hormonal regulation of placental synthesis

It is not clear whether LH or any other trophic hormone is needed for placental P_4 biosynthesis in the sheep, although LH receptors are present in the placenta. Fetal hypophysectomy at day 100–130 of gestation did not reduce maternal P_4 concentrations, which remained high (Kendall *et al.*, 1977; J.S. Robinson *et al.*, 1977; Ricketts *et al.*, 1980), and it was concluded that P_4 production by the placenta was independent of fetal pituitary control. The *in vitro* studies of Battista *et al.* (1989) and Wango *et al.* (1988) are consistent with that view and suggest that, once P_4 synthesis is established in the placenta, LH is not needed for the maintenance of P_4 synthesis.

Thorburn *et al.* (1989) proposed that fetal pituitary hormones may be needed to initiate the increase in placental steroidogenesis between days 90 and 125 of gestation. After hypophysectomy of fetal lambs between 70 and 75 days of gestation, the increase in P_4

concentrations in maternal plasma between days 90 and 125 of gestation was not significantly affected, but the predicted increase in the plasma concentrations of oestrone sulphate and PGE_2 did not occur (Deayton *et al.*, 1993). These results suggest that fetal pituitary hormones are not essential for the increase in P_4 production but that they are for oestrogen and PGE_2 synthesis by the placenta. If LH is required, an endogenous LH-like substance (?ovine CG) may substitute for fetal pituitary LH. However, if the major determinant of the increase in placental P_4 production is the delivery of cholesterol to the placenta, rather than the regulation of steroidogenic enzymes, then the regulatory factor may be the number of lipoprotein receptors. It is possible, therefore, that HDL and LH receptors are present on the maternal surface of the syncytium (formed from the BNCs) and are exposed to HDL and LH in the maternal circulation. Although maternal hypophysectomy did not affect the normal maintenance of pregnancy (Denamur and Martinet, 1961), P_4 concentrations were not measured.

It is not yet known how the LH receptors are induced, but oPL may be involved: J.S. Chan *et al.* (1980) have shown that oPL can maintain LH receptors in the ovary of the pseudopregnant rat.

A working model may help explain the close relationship between placental oPL and P_4 production. This model predicts that the HDL and LH receptors are both present in the maternal syncytium (derived from BNCs). It suggests that LH of maternal origin may be needed but that it may be replaced by oCG. It is interesting to speculate whether a characteristic of the placental P_4-producing

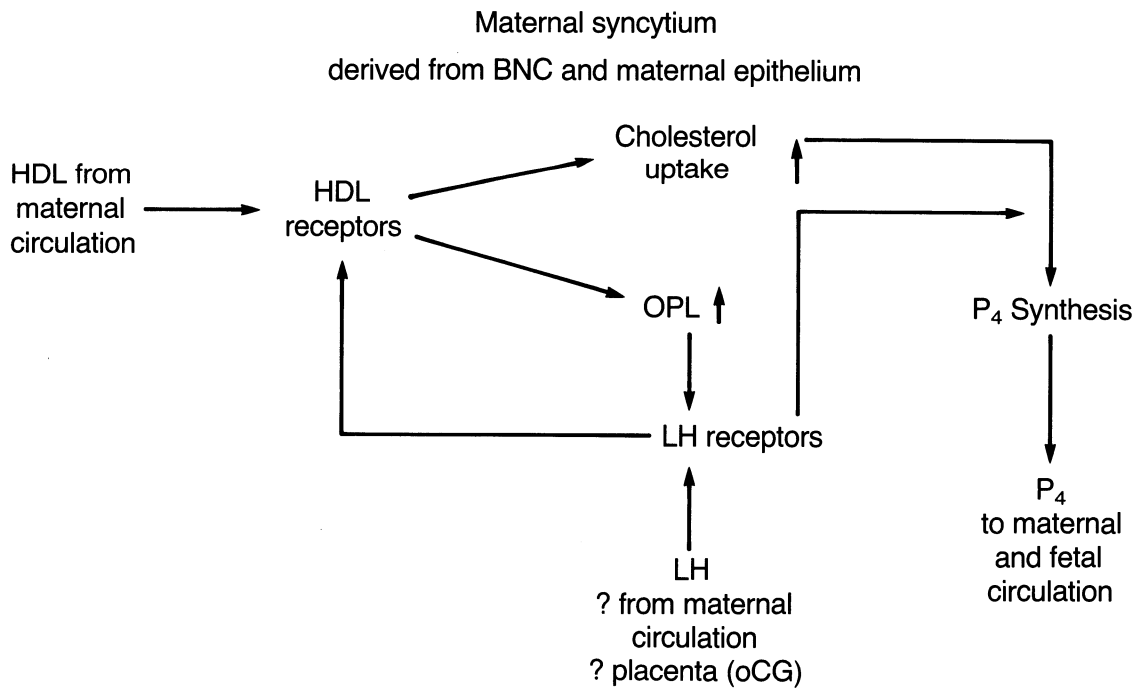

Figure 9.8 The putative mechanisms involved in progesterone biosynthesis in the sheep placenta. The maternal syncytium is thought to be formed by fusion of BNCs derived from the fetal trophoblast and the cells of the maternal epithelium.

species as compared to those in which the CL is the main site of P_4 production, is the development of lipoprotein binding sites on the placenta and their ability to derive cholesterol from the maternal circulation as a substrate for P_4 synthesis.

(e) Chorionic gonadotrophin

Using a radioreceptor assay, Lacroix and Martal (1979) detected hCG-like activity in the ovine placenta and amniotic fluid but not in maternal plasma. This substance first appeared in the placenta as early as day 15, reaching a peak concentration at day 80, and remained constant until near term, when it decreased rapidly (Lacroix and Martal, 1979). Further work is required to establish the presence of CG in the ovine placenta and to determine whether it plays a significant role in placental P_4 production. The significance of large quantities of a GnRH-like material in the ovine placenta (Rice and Smirnis, 1990) has yet to be established.

(f) Prepartum decrease in concentrations

The concentration of P_4 in the plasma of pregnant ewes decreases in the last few days before parturition (Bassett *et al.*, 1969; Fylling, 1970, Stabenfeldt *et al.*, 1972). Concentrations of P_4 and 20α-dihydroprogesterone (20α-P_4) in fetal and maternal plasma fall with increasing gestational age, the mean time of onset of the fall for maternal P_4 being 3.5 ± 0.5 days and for maternal 20α-P 3.4 ± 0.3 days before delivery (Elsner *et al.*, 1980; Magyar *et al.*, 1981; Nathanielsz *et al.*, 1982; Yu *et al.*, 1983). Consistent with earlier reports (Nancarrow and Seamark, 1968; Strott *et al*, 1974) maternal concentrations of P_4 were 10-fold higher than fetal concentrations. Mean fetal 20α-P_4 concentrations were two-/fourfold higher than maternal concentrations. The time courses of the decreases in 20α-P_4 and P_4 were similar (Elsner *et al.*, 1980). An active 20α-reductase exists in the placenta and fetal erythrocytes (Nancarrow and Seamark, 1968), and therefore these results indicate that P_4 is metabolized in the placenta to 20α-P_4 and is subsequently secreted into the fetal and maternal circulations with P_4. Some of the P_4 secreted into the fetal circulation is rapidly converted to 20α-P_4 by the 20α-reductase in the fetal erythrocytes.

The metabolic clearance rate (MCR) of P_4 in blood is high (3.5 l/min) and rises slightly towards the end of pregnancy (Bedford *et al.*, 1972a). The conversion ratio (Longcope *et al.*, 1968) of P_4 to 20α-P_4 is 77.2%. When P_4 is administered in large amounts to pregnant ewes to block parturition, it is rapidly converted to 20α-P_4 and virtually none is converted to oestrogen (Nathanielsz *et al.*, 1988). This is consistent with the observation that the ovine placental pathway is ineffective (Mason *et al.* 1989) and that C_{19} steroids, which become the aromatizable substrates for oestrogen formation, are produced principally from P_5 via 17α-hydroxypregnenolone (17α-P_5) and dehydroepiandrosterone (DHEA), the so-called Δ_5-pathway, rather than 17α-hydroxyprogesterone, which is inefficiently converted to androstenedione (Mason *et al.*, 1989). This would explain why the exogenously added P_4 was not a substrate for ovine placental oestrogen production but was rapidly metabolized to 20α-P_4 and other metabolites (Jenkin *et al.*, 1985a,b; Nathanielsz *et al.*, 1988). Mason *et al.* (1989) have suggested that, contrary to the general opinion, the preparturient decline in P_4 concentrations is due to diversion of P_5 metabolism away from 3β-HSD action to 17α-P_5 and DHEA formation.

Pregnenolone therefore emerges as a key steroid in the ovine placenta. Elsner *et al.* (1980) have emphasized the high levels of P_5 and its sulphoconjugate in maternal and fetal plasma. The relative concentrations (ng/ml) of these steroids in maternal and fetal (in parentheses) plasma at approximately 125 days' gestation are as follows: P_5-S 169 (200);

P_5 2.5(5.0); P_4 18.0 (1.5); 20α-P_4 9 (20.0) (Elsner *et al.*, 1980; Nathanielsz *et al.*, 1982). Clearly the ovine placenta secretes considerable amounts of P_5 , which is metabolized to the sulphoconjugate by the sulphotransferase (Rosenfeld *et al.*, 1980) in the placenta and maternal and fetal liver. Nathanielsz *et al.* (1982) suggested that because P_5-S levels decreased before parturition the high concentrations of P_5 -S in the maternal compartment may contribute to the preparturient rise in oestrogen. However, Mason *et al.* (1989) have shown that steroid sulphatase activity is undetectable in the ovine placenta and that sulphated steroids, such as P_5-S, are not substrates for steroid 17α-hydroxylase/C-17,20-lyase. The decreases in P_5-S concentrations observed in maternal and fetal plasma (Nathanielsz *et al.* 1982) are therefore probably due to the metabolism of P_5 into 17α-P_5 and DHEA rather than its sulphation (Mason *et al.*, 1989).

At day 125 of gestation the high circulating concentrations of P_4, 20α-P_4, P_5 and particularly P_4-$_5$S are due to the marked increase in P_5 production from cholesterol between 90 and 125 days. The large amounts of Δ_5 steroids secreted by the placenta indicated that 3β-HSD activity is rate limiting to some extent. However, the profound changes in placental steroid metabolism observed in the last 2–5 days before delivery, resulting in a dramatic decrease in maternal P_4 concentrations, are believed to be a consequence of the prepartum rise in the plasma concentration of cortisol in the fetal circulation (Bassett and Thorburn, 1969; Magyar *et al.*, 1980). Increases in the activities of steroid 17α-hydroxylase (A.B.M. Anderson *et al.*, 1975; N.G. Anderson *et al.*, 1978a) and steroid C-17, 20 lyase (Steele *et al.*, 1976; N.G. Anderson *et al.*, 1978b) are involved.

Between 118 and 140 days of gestation, P_5 and P_4 17α-hydroxylase activities in placental microsomes were undetectable (France *et al.*, 1988; Mason *et al.*, 1989). Only minor metabolism of carbon-labelled P_5 or P_4 substrate occurred with these preparations under the described assay conditions (Trilostane, a 3β-HSD inhibitor, was present). The radiolabelled products did not exceed 4% of the total radioactivity and appeared to be predominantly 20α-reduced products. In these *in vitro* conditions, precise quantification of the low basal activity of steroid 17α-hydroxylase was impeded by the presence of 20α-HSD activity, but this may not occur *in vivo*. A low level of 17α-hydroxylase activity may account for the low level of oestrogen production by the ovine placenta at this stage of gestation. In normal and glucocorticoid-induced parturition there was a marked increase in 17α-hydroxylase activity and it was associated with a marked accumulation of cytochrome $P450_{17\alpha}$ protein. The mechanism of glucocorticoid action in natural ovine parturition may therefore be to increase cytochrome $P450_{17\alpha}$ synthesis either by stabilizing the mRNA for cytochrome $P450_{17\alpha}$ or by acting as a stimulus to transcription of the steroid 17α-hydroxylase gene. Much higher levels of 17α-hydroxylase activity were present in placentae from ewes in which labour was induced with dexamethasone than in those in normal labour, and the level of activity increased with the time in labour. Mason *et al.* (1989) concluded that the differences in activity were due to the dosage and duration of exposure of the placenta to glucocorticoid, whether endogenous or exogenous.

This suggestion is consistent with results of other studies in which premature parturition, secondary to a fetal infusion of cortisol, was blocked by medroxyprogesterone acetate or exogenous P_4 (Thorburn, 1983; Jenkin *et al.*, 1985a,b; Nathanielsz *et al.*, 1988) and maternal and fetal oestrone sulphate concentrations continued to increase to high levels, indicating a progressive increase in 17α-hydroxylase activity. Based on the data of Magyar *et al.* (1980), a fetal cortisol concentration of about 20–30 ng/ml over 2–5 days would be needed to induce the necessary

17α-hydroxylase activity and then delivery. Presumably the 17α-hyroxylase activity would continue to increase with the increasing fetal cortisol levels. Mason *et al.* (1989) provided direct evidence that the preparturient decrease in P_4 concentrations is caused not only by metabolism of P_4 to 17α-OH-P_4 and-pregnen-17α,20α-diol-3-one but primarily by diversion of P_5 metabolism from 3β-HSD action to 17α-OH-P_5 and DHEA formation. The substrate specificity of the ovine placental steroid 17α-hydroxylase/C-17,20-lyase is similar to that of bovine and human $P450_{17\alpha}$ and uses P_5, P_4 and 17α-OH-P_5 as substrates, but inefficiently converts 17α-OH-P_4 to androstenedione.

One of the most compelling arguments against P_4 withdrawal being a prerequisite for the initiation of parturition in sheep was the failure of exogenous P_4 administered in physiological amounts to block labour (Liggins, 1973). Bengtsson and Schofield (1963) reported that P_4 (80 mg/day) did not delay the onset of labour at term. Liggins *et al.* (1972) showed that P_4 (100 mg/day for 4 days), in amounts which restored plasma P_4 levels, failed to delay the onset or the progress of labour, a result consistent with earlier observations (Hindson *et al.*, 1969). When the amount of P_4 was increased to 150 mg/day, cervical dilatation was blocked, and only when larger doses of P_4 (e.g. 200 mg/day) were administered was uterine activity blocked and normal or induced delivery period prevented. This amount of P_4 is more than twice the normal production rate for late pregnancy (Bedford *et al.*, 1972a).

When dexamethasone (or cortisol) is administered, the placental 17α-hydroxylase is markedly increased and endogenous P_5 metabolism is diverted away from P_4 formation towards oestrogen synthesis. Exogenous P_4, instead of supplementing endogenous placental P_4, represents the sole source of P_4 in the maternal circulation and is in turn rapidly metabolized to 20α-P_4 and other metabolites (Thorburn, 1983; Jenkin *et al.*, 1985a,b; Nathanielsz *et al.*, 1988). Moreover, the metabolism of the endogenous P_5 to oestrogens leads to high plasma oestrogen concentrations. It is only when the exogenous P_4 is increased to 200 mg/day that the blocking activity of P_4 on the myometrium is successful in the face of high oestrogen concentrations. Consistent with this view was the finding that the expected release of $PGF_{2\alpha}$ into the utero-ovarian vein in response to diethylstilboestrol administration was blocked by the same dose of P_4 (200 mg/day). Clearly the release of $PGF_{2\alpha}$ (and hence uterine activity) from the placenta is encouraged by an increase in the oestrogen–P_4 (E/P_4) ratio. The administration of glucocorticoids dramatically increases the E/P_4 ratio, by increasing 17α-hydroxylase activity, and leads to $PGF_{2\alpha}$ release, uterine activity and labour. Large amounts of exogenous P_4 are needed to return the E/P_4 ratio to preparturient levels because the endogenous P_5 is being converted to oestrogen. The mechanism by which P_4 inhibits $PGF_{2\alpha}$ release is unknown. In experiments wherein P_4 withdrawal was induced by inhibitors of 3α-HSD (Taylor *et al.*, 1982; Jenkin and Thorburn, 1985; Ledger *et al.*, 1985), which converts P_5 into P_4, decrease in plasma P_4 concentration for 6 h was sufficient to provoke an increase in the metabolite of $PGF_{2\alpha}$ in the maternal circulation and premature delivery in a majority of animals. Again, there was a relative increase in the E/P ratio and an increase in $PGF_{2\alpha}$ release and uterine activity.

(g) Metabolism of progesterone and pregnenolone

The half-time clearance of radioactive P_4 in pregnant sheep is 10 min and the MCR about 3.5 l/min (Tsang and Hackett, 1979), within the range previously reported (Bedford *et al.*, 1972a). Tsang and Hackett (1979) found that 20α-P_4 accounted for only 10% of the total radioactive metabolites and that the major mechanism of P_4 metabolism is by 5α-

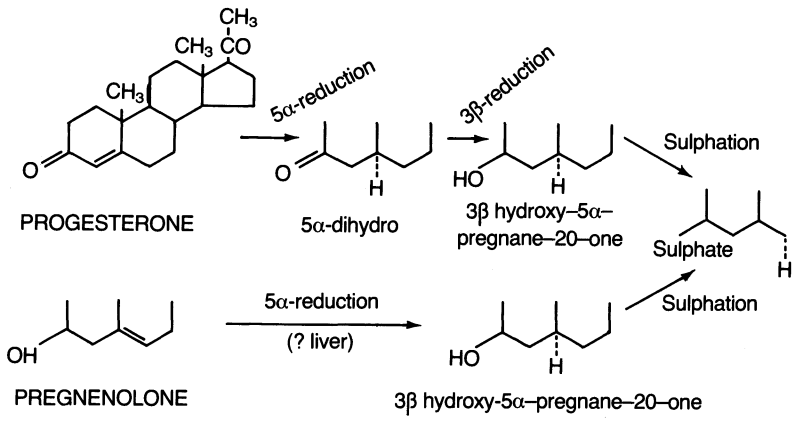

Figure 9.9 Metabolic pathways of progesterone and pregnenolone.

reduction of ring A followed by sulphoconjugation at the 3 position (Figure 9.9).

There appears to be a rapid conversion of the free metabolites to sulphates, which are then slowly cleared from the circulation, possibly due to protein binding, as has been suggested for other steroid sulphates (Wang *et al.*, 1967). The bulk of the metabolites was found in the sulphate fraction, the major one being 3β-hydroxy-5α-pregnan-20-one. While the conversion of P_4 into 20α-P_4 was confirmed, its further metabolism to pregnanediol (5β-pregnane-3α,20α-diol), the prominent human and goat (Schulster *et al.*, 1976) pregnancy metabolite, was not evident either as the free steroid or as the sulphoconjugate (see Figure 9.9). However, small amounts of 5α-pregnane-3β, 20α-diol were found in the sulphate fraction. Although the metabolism of P_5 has not been studied in the sheep, it seems likely that P_5 is sulphoconjugated directly, leading to the high levels of P_5-S measured in the maternal and fetal circulation (Nathanielsz *et al.*, 1982). Some P_5 may undergo initial reduction to its 5α-metabolite, 3β-hydroxy-5α-pregnan-20-one, and then sulphoconjugation. The 5α-reduction is thought to take place in the liver, whereas sulphoconjugation can take place either in the placenta or the liver.

Despite one of their animals being in labour and the other just 2 days before delivery, when it might be expected that placental 17α-hydroxylase activity would be increased, Tsang and Hackett (1979) found no conversion of the labelled P_4 to oestrogens and considered that this may have been due to a failure of P_4 to cross the placenta. Thorburn (1983) and Nathanielsz *et al.* (1988) also found that P_4, when given to block labour, was not converted to oestrogens. However, Mason *et al.* (1989) reported that 17α-OH-P_4 is an unsatisfactory substrate for ovine placental C-17,20-lyase and it will be necessary to inject labelled P_5 to parturient sheep and determine the efficiency of P_5 to oestrogen to clarify this anomaly. It seems unlikely that P_4 failed to 'cross' the placenta (or, more accurately, gain access to the key enzymes) since DHEA when given to the mother is rapidly converted to oestrogens (Rosenfeld and Worley, 1978). The studies of Jenkin *et al.* (1985a,b) indicate that neither P_4 nor 20α-P_4 is transferred from the ewe to the fetus to any great extent.

It has been suggested (Tsang and Hackett, 1979) that 5α-reduction of P_4 may have physiological implications and that this may be related to its biological activity in target organs (Nuti and Karavolas, 1977): 5α-

pregnane-3,20-dione is retained by the ovine endometrium after P_4 infusion (Bedford *et al.*, 1974) and there is a considerable amount of the sulphoconjugate of 5α-pregnan-3β-ol-20-one in sheep pregnancy plasma (Tsang and Hackett, 1979). The biological activity of these steroids needs to be assessed, particularly in relation to the regulation of PG synthesis.

In contrast to the pregnant ewe, 5β-pregnanediols are the major metabolites of P_4 in the fetus. P_4 is produced by the fetal adrenal glands as well as the placenta (Nancarrow, 1969; Cox, 1975; Dolling and Seamark, 1979). The amount of P_4 produced by the ovine placenta near term is about 40–50 mg/day (Bedford *et al.*, 1972a), although the amount entering the circulation is unknown. The three major metabolites of P_4 found in fetal sheep blood are 5β-pregnane-3β,20β-diol, 5β-pregnane-3β, 20α-diol and 5β-3α,20α-diol, all were present as sulphates in μg/ml amounts (Dolling and Seamark, 1979). *In vivo* studies with radioactive tracers have shown these three 5β-pregnanediols to be end products of P_4 metabolism (Nancarrow and Seamark, 1968; Nancarrow, 1969). The enzymes involved include two specific oxidoreductases which catalyse the reversible reduction of the 3-oxo and 20-oxo groups, a 4-ene-5β reductase which catalyses the reversible reduction of the A ring of P_4, and the specific alkyl sulpha-transferases in the conjugate formation. These enzymes are widely distributed in both fetal and placental tissues including blood (Nancarrow and Seamark, 1968; Seamark *et al.*, 1970: Cox, 1975; Dolling and Seamark, 1979). The blood of fetal sheep possesses a remarkable ability to metabolize P_4; the main enzymes include 20α-hydroxysteroid dehydrogenase and 3α-reductase (Seamark *et al.*, 1970). The placenta and other fetal tissues are potent sources of steroid sulphatase activity (Ainsworth, 1972). In control fetuses, the plasma concentrations of both 5β-pregnane-3β, 20β-diol and 5β-pregnane-3β, 20α-diol showed a steady four-fold increase between 105 and 143 days' gestation; a more marked increase was observed in fetuses which came into premature labour following infection or bilateral nephrectomy (Dolling and Seamark, 1979). In this study, the concentrations of these 3β-hydroxy metabolites were higher than those of 5β-pregnane-3α,20α-diol. These results suggest the fetal adrenal glands may be a major source of P_4 in the fetal lamb and that P_4 derived from the adrenal glands is mainly metabolized to these 3β-hydroxy, 5β-pregnane derivatives, whereas P_4 derived from the placenta is metabolized to 5β-pregnane-3β, 20α-diol (5β-pregnanediol). *In vitro* studies with fetal adrenal tissues (A.B.M. Anderson *et al.*, 1970; Glickman *et al.*, 1979) have shown that trophic stimulation of the fetal adrenal before about 130 days' gestation causes an increase in the synthesis of progestagen rather than cortisol, the capacity to synthesize cortisol developing after this time (see Dolling and Seamark, 1979). With the rapid increase in cortisol concentration in the four to five days before labour, there is an associated decrease in fetal concentration of the 3β-hydroxy, 5β-pregnanes (Dolling and Seamark, 1979), suggesting that 17α-hydroxylase activity has increase in the fetal adrenal cortex. These studies confirm that the fetal adrenal glands are producing considerable amounts of P_4 (as well as corticosterone (Madill and Bassett, 1973) and possibly some pregnenolone) for some time before it commences secreting cortisol. It would appear that using plasma cortisol concentration as the sole criterion of fetal adrenal steroidogenic activity may be misleading.

A similar situation exists in the fetal foal, where it has been shown that the fetal adrenal glands secrete pregnenolone (and possibly P_4) for some weeks before delivery and only in the last one to two days do the plasma cortisol levels increase (Thorburn, 1993). Administration of synthetic ACTH to immature fetal foals causes an increase in the maternal and fetal plasma levels of 5β-pregnane

metabolites of pregnenolone and P_4 (see Thorburn, 1993).

9.5.3 OESTROGENS

In 1958, Velle reported that urine from late pregnant sheep contained significant quantities of oestradiol-17α and oestrone. Fèvre and Rombauts (1966) confirmed that these were the major oestrogens excreted during pregnancy and found that oestrogens first appeared in the urine at about day 70 and their excretion increased significantly from about day 90 to term. Ovariectomy after day 60 did not markedly affect the pattern of oestradiol-17α excretion, although oestrone excretion was reduced (Fèvre, 1967), indicating that these oestrogens are mainly derived from the fetoplacental unit. Until day 120, oestrogen sulphoconjugates in fetal plasma (largely oestrone and oestradiol-17α) increased in a similar pattern but then decreased (Findlay and Cox, 1970; Findlay and Seamark, 1973; Carnegie and Robertson, 1978) before undergoing a massive increase in the last 2–4 days before delivery (Currie *et al.*, 1973; Nathanielsz *et al.*, 1982).

The concentration of oestrogen sulphoconjugates in maternal plasma provides a better index of placental oestrogen biosynthesis. Carnegie and Robertson (1978) described three distinct stages of oestrogen biosynthesis by the ovine placenta. The first stage covers the period day 0–55, the second day 55–140 and the third the last 2–4 days of gestation. The major oestrogens present in maternal plasma are the sulphoconjugates of oestrone and oestradiol-17α and their concentrations increase progressively from day 70 to term (Currie *et al.*, 1973; Carnegie and Robertson, 1978). Nathanielsz *et al.* (1982), in a detailed study of the preparturient hormone profiles, observed a fall in fetal and maternal oestrone sulphate concentrations from 10 to 5 days before birth followed by a terminal rise over the last 24–48 h that was a mirror image of the fall in plasma P_5, P_5-S and P_4 values. The preponderance of sulphotransferase over sulphatase activity in the fetoplacental tissues of the sheep results in rapid sulphoconjugation of oestrogens (Currie *et al.*, 1973; Findlay and Seamark, 1973; Thorburn *et al.*, 1977a) and accounts for the predominance of oestrogen sulphoconjugates over unconjugated oestrogens in fetal and maternal plasma.

The maternal plasma concentrations of unconjugated oestrogens (oestrone and oestradiol-17β) are low until day 120 then increase gradually before undergoing a sudden and rapid rise in the 24 h before parturition (Challis, 1971; Challis *et al.*, 1971; Bedford *et al.*, 1972b; Thorburn *et al.*, 1972a; Robertson and Smeaton, 1973; Challis and Patrick, 1981). This dramatic increase in free oestrogens coincides with the major increase in the oestrogen sulphoconjugates in fetal and maternal plasma at that time. Since the oestrogen MCR did not change (Challis *et al.*, 1973a), the preparturient increase in free oestrogen concentrations may simply be an expression of a massive increase in the production rate of oestrogen by the ovine placenta in the 24–48 h before delivery, although an increase in placental sulphatase or aromatase activities cannot be excluded.

The prepartum rise in fetal plasma concentrations of cortisol increases the activity of steroid 17α-hydroxylase (A.B.M. Anderson *et al.*, 1975; N.G. Anderson *et al.*, 1978a; France *et al.*, 1988; Mason *et al.*, 1989) and steroid C-17,20-lyase (Steele *et al.*, 1976). In microsomes of placental cotyledons obtained from pregnant ewes at 118–140 days' gestation, in which there was no evidence of active or impending labour, steroid 17α-hydroxylase activity was below the sensitivity of the assay (France *et al.*, 1988), but administration of dexamethasone to the fetus for 45 h dramatically increases the amounts of 17α-hydroxylase. The activity of 17α-hydroxylase is increased in placenta from ewes in labour (Mason *et al.*, 1989), but dexamethasone is a more potent stimulus for increasing 17α-

hydroxylase activity than are the cortisol concentrations in normal labour. The increased 17α-hydroxylase activity in dexamethasone-induced parturition presumably explains the higher circulating oestrogen values in this type of premature labour. The 17α-hydroxylase activity is determined not only by the dosage but also by the duration of exposure of the placenta to the glucocorticoid (France *et al.*, 1988; Mason *et al.*, 1989). If parturition is blocked by the maternal administration of medroxyprogesterone acetate or P_4 there is almost a complete diversion of P_5 metabolism through to oestrogens, and P_4 and 20α-P_4 virtually disappear from the fetal and maternal circulations and oestrogen concentrations (particularly oestrone sulphate) reach very high levels (Thorburn, 1983; Jenkin *et al.*, 1985a,b; Nathanielsz *et al.*, 1988). In these studies the fetal infusion of cortisol was maintained for several days and the oestrogen concentrations progressively increased with time.

Therefore, like the plasma oestrogen concentrations, 17α-hydroxylase activity only reaches measurable levels in the last 2–4 days before delivery, whereas P_4 and P_5 concentrations decrease over the same period. Fetal cortisol concentrations must therefore reach high levels to induce sufficient 17α-hydroxylase activity to cause a decrease in P_4 and an increase in oestrogen levels. Dexamethasone, apart from being a potent glucocorticoid, is not bound to protein whereas, at term, about 85–90% of the circulating cortisol is bound to protein (Ballard *et al.*, 1982). Therefore, only about 6 ng/ml 'free' cortisol is needed in the fetal circulation to induce sufficient 17α-hydroxylase activity to induce parturition. The gradual increase in fetal cortisol concentrations before the last 4–5 days, i.e. up to day 140 of gestation, may play a key role in the maturation of a number of organ systems, including the fetal pituitary and adrenal.

It has been generally accepted that oestrogen synthesis in late gestation is largely an intraplacental function and that sheep, unlike primates, do not have a fetoplacental unit for oestrogen biosynthesis (B.F. Mitchell *et al.*, 1986). However, these experiments have not excluded a role for C_{19} steroids of fetal adrenal origin in oestrogen synthesis (Liggins *et al.*, 1972, 1973; Thorburn *et al.*, 1977a; Thorburn and Challis, 1979; Challis and Olson, 1988). The concentrations of androstenedione and testosterone in fetal sheep plasma rise before parturition (Findlay and Seamark, 1973; Yu *et al.*, 1983), and it is possible that circulating androgen precursors could contribute to the increasing oestrogen production. B.F. Mitchell *et al.* (1986) showed that androstenedione is cleared rapidly from the fetal circulation and that it has an extremely high MCR. In these studies, pulsatile ACTH administration to the fetus did not alter the high clearance rate of androstenedione but caused significant increases in its production rate and whole blood concentration. The production rate for androstenedione was significantly increased even when the rise in fetal cortisol had effectively been blocked by concomitant administration of metyrapone, an 11β-hydroxylase inhibitor. This experiment suggests that the increase in production rate of androstenedione was due to activation of the fetal adrenal. Furthermore, when tritiated androstenedione was infused into chronically catheterized fetal sheep, radioactive oestrogen conjugates were isolated and identified from fetal and maternal circulations (B.F. Mitchell *et al.*, 1986). It was estimated that up to 30% of maternal oestrogens at term might be formed in the placenta from fetal adrenal precursors (Challis and Olson, 1988). Collagenase-dispersed fetal adrenal cells secrete androstenedione, (B.F. Mitchell *et al.*, 1986) and the output by these cells, when treated with $ACTH_{1-23}$ *in vitro*, was significantly greater when the tissue was obtained from animals that had previously received an ACTH infusion *in vivo* than from saline-treated controls. Currie *et al.* (1973) had

shown that the infusion of androstenedione into a fetal lamb provoked an increase in maternal unconjugated oestrogen levels and precipitated premature parturition, although DHEAS infused into the fetus in similar amounts was ineffective. In such experiments high levels of oestrogen need to be produced to induce parturition because placental P_4 production would be maintained. Further experiments are needed to confirm these observations.

A bolus injection of DHEA (10 mg) into the mother resulted in an increase in unconjugated oestrogen in both the fetal and maternal compartments (Pupkin *et al.*, 1975). Rosenfeld *et al.* (1977) similarly showed that an infusion of DHEA into the fetus resulted in the placental production of oestrogen.

In summary, it seems likely that both the adrenal and the placenta provide C_{19} steroids as precursors for placental aromatization and that both contribute to the preparturient oestrogen surge.

9.5.4 AROMATASE

Ovine placental aromatase is principally located in the microsomes (Ainsworth and Ryan, 1966), however France *et al.* (1987) concluded that, although the endoplasmic reticulum of the ovine placental cells is a major site of aromatase, other membrane structures in the cell also appear to contain the aromatase enzyme system and may be of more importance overall to a total aromatase activity. Sheep placental microsomes metabolize C_{19} steroids to oestrone and oestradiol *in vitro* (Ainsworth and Ryan, 1966; Pierrepoint *et al.*, 1971; Findlay and Seamark, 1973; Mann *et al.*, 1975; France *et al.*, 1987, 1988; Mason *et al.*, 1989). Basal levels of placental aromatase are relatively constant between 118 and 140 days' gestation and a two- to threefold increased in the placentas of ewes in normal or dexamethasone-induced labour (Mann *et al.*, 1975; Mason *et al.*, 1989). Aromatase activity increases in placental explants when cortisol is added to the culture medium (Ricketts *et al.*, 1980; Flint, 1983), and glucocorticoids in high concentration may induce a modest increase in aromatase activity. Mason *et al.* (1989) questioned the significance of the preparturient increase in aromatase activity, because earlier studies (Rosenfeld *et al.*, 1980; France *et al.*, 1987) suggested that aromatase did not appear to be a rate-limiting enzyme with regard to oestrogen production; the basal levels of the enzyme found between 118 and 140 days' gestation appeared adequate to accommodate the rise in oestrogen production which occurs in the last 48 h of pregnancy.

Information is lacking on the level of aromatase activity in the placenta of the sheep during the critical phase between days 70 and 120 when placental oestrogen biosynthesis is increasing and there is a steady increase in the concentration of oestrone sulphate in fetal and maternal plasma. Thorburn *et al.* (1989) have suggested that fetal pituitary FSH may regulate placental aromatase because fetal hypophysectomy at day 70–75 prevented the increase in maternal oestrone sulphate levels that normally occurs between 90 and 120 days' gestation. Kendall *et al.* (1977) found that, when parturition was induced by administering ACTH to hypophysectomized fetuses, there was no increase in maternal unconjugated oestrogen concentrations, although there was a fall in P_4 and a rise in PG output. They suggested that some pituitary factor may be required for placental oestrogen biosynthesis, and the results of Thorburn *et al.* (1989) would be consistent with the proposal that FSH may be the fetal pituitary factor.

The discussion so far has centred around the rapid increase in oestrogen concentrations in the last 2–4 days before delivery (Currie *et al.*, 1973; Nathanielsz *et al.*, 1982), but little attention has been directed towards the gradual increase in placental oestrogen production from day 70 to day 120–130 (Fèvre and Rombauts, 1966; Currie *et al.*, 1973;

Carnegie and Robertson, 1978). Although the placental 17α-hydroxylase activity is low between 118 and 140 days' gestation (France *et al.*, 1988), it is possible that sufficient P_5 is metabolized by the low levels of 17α-hydroxylase to explain the progressive increase in oestrogen production. It is also possible that C_{19} steroids, derived from the fetal or the maternal adrenal, may act as substrates for oestrogen biosynthesis. However, the pattern of increase of maternal plasma oestrone sulphate levels so closely follows that of P_4 it would favour the former suggestion that there is a leak in the placental steroidogenic pathway and that some P_5 is diverted through to oestrogens.

The progressive increase in the oestrone sulphate concentrations in the maternal plasma is of particular importance to the development of the myometrium. Oestradiol-17β stimulates synthesis of the contractile protein, actomyosin, and lowers the threshold of stimulation of the myometrial cell to oxytocin. Sulphatase, sulphotransferase and 17α- and 17β-HSD are present in sheep myometrium, and oestradiol-17β is the major product formed from oestrone and oestrone sulphase (Fitzpatrick, 1960; Kuriyana, 1961; Knifton, 1967; Brinsfield, 1968; Rossier and Pierrepoint, 1974). In addition, oestrone sulphate is converted to oestrone and oestradiol by ovine endometrium (Dwyer and Robertson, 1980; Power and Challis, 1987). The concentrations of oestrogens (pg/g) in myometrium and endometrium exceed those in plasma (pg/l) (Challis and Patrick, 1981), indicating that enzymatic interconversions and tissue concentrating mechanisms, including specific receptor uptake, affect tissue oestrogen concentrations with the possibility of producing local changes that may not be apparent in plasma measurements (Power and Challis, 1987). The concentration of oestrone and oestradiol in myometrium increases between day 130–135 and term in animals in spontaneous labour or after ACTH-induced labour (Power and Challis, 1987). Oestrogens may promote gap junction formation between myometrial cells (Garfield *et al.*, 1987) and stimulate the formation of oxytocin receptors (Alexandrova and Soloff, 1980a–c) and the output of stimulatory PGs (Liggins *et al.*, 1973) in the uterus. These observations confirm and extend the previous measurements of total oestrogen by Rawlings and Ward (1976). Power and Challis (1987) showed that the concentrations of oestrone and oestradiol in the fetal membranes were higher than in the endometrium and myometrium. In the amnion there was no consistent change in oestrone concentrations with gestation, although oestradiol concentrations increased between day 130 and term. Concentrations of oestrogen in the chorion after day 100 were the highest of all tissues, but did not change between day 130–135 and term (Power and Challis, 1987), although the chorion is a major site of PG production and metabolism (C.A. Evans *et al.*, 1982). Oestrone sulphatase is present in the sheep chorion and the chorion is also able to aromatize C_{19} steroids; local enzymatic regulation of chorionic oestrogens may therefore be important in the control mechanisms of pregnancy and parturition (Power and Challis, 1987).

9.5.5 PROSTAGLANDINS

(a) Plasma concentrations of $PGF_{2\alpha}$ and PGFM

Normal parturition in sheep is associated with a marked increased in concentrations of $PGF_{2\alpha}$ in uterine venous plasma (Liggins and Grieves, 1971; Thorburn *et al.*, 1972a). Concentrations of PGE_2, PGFM (the major metabolic of $PGF_{2\alpha}$) and 6-keto-$PGF_{1\alpha}$ (the major metabolite of prostacyclin, PGI_2) are also increased before spontaneous labour (M.D. Mitchell *et al.*, 1979a; C.A. Evans *et al.*, 1981) and before labour induced by intrafetal infusion of ACTH or glucocorticoids (Currie *et al.*, 1973; Thorburn *et al.*, 1977b; M.D.

Mitchell *et al.*, 1979a). Similarly, the concentrations of PGE_2 in fetal plasma (Challis *et al.*, 1976a) and of PGE_2 , $PGF_{2\alpha}$ and 6-keto-PGF_1 α in amniotic fluid (Challis *et al.*, 1978; M.D. Mitchell *et al.*, 1978e; Olson *et al.*, 1985) increase before delivery.

Detailed information on the plasma concentrations of $PGF_{2\alpha}$ and PGFM throughout pregnancy is lacking. PGFM concentrations in the utero-ovarian vein accurately reflect those of $PGF_{2\alpha}$ (Burgess *et al.*, 1989), and Burgess (1991) showed that basal concentrations of PGFM in utero-ovarian vein plasma are low (0.36 ± 0.05 nM) on days 60–63 of gestation but then gradually increase to 1.78 ± 0.28 nM by days 135–138, and 3.48 ± 0.35 nM in preparturient ewes (140–147 days) before reaching high levels at parturition (19.2 ± 2.5 nM). The arterial concentrations of PGFM were much lower than those in the utero-ovarian vein; at days 60–63 PGFM was undetectable in arterial plasma, and by days 135–138 its concentration had only reached 0.82 ± 0.07 nM. The arteriovenous differences showed that PGFM is secreted by the uterus in concentrations equimolar to those of $PGF_{2\alpha}$. The production of $PGF_{2\alpha}$, as judged from PGFM values, was low at mid-gestation, before increasing gradually during the late gestation and then dramatically in the last 24 h before delivery.

The arteriovenous difference for PGFM across the uterus confirms the earlier studies of M.D. Mitchell *et al.* (1980c) and Fowden and Silver (1983) and demonstrates that the ovine uterus metabolizes some of the $PGF_{2\alpha}$ it produces *in vivo* and secretes it as its metabolite PGFM. PGFM appearing in the uterine vein is therefore derived from $PGF_{2\alpha}$ delivered to the uterus in its arterial circulation plus PGFM synthesized in the uterine tissues (Keirse *et al.*, 1976; M.D. Mitchell and Flint, 1978a).

In the pregnant uterus, 83% of the uterine blood flow is distributed to the cotyledons, 3–4% to the myometrium and 13–14% to the endometrium (Makowski *et al.*, 1968). Since the $PGF_{2\alpha}$ production rate by the myometrium *in vitro* is only about 25% of that of the maternal cotyledon (M.D. Mitchell and Flint, 1977), the maternal cotyledons appear to be the major contributor to $PGF_{2\alpha}$ concentrations in the utero-ovarian vein (Thorburn and Challis, 1979).

It has been assumed that most of the PGF produced by the uterine tissues will be metabolized in the lungs (Vane, 1978) and that little, if any, would appear in the arterial circulation. However, Fowden *et al.* (1987) and Andrianakis *et al.* (1989a) have shown that some PGE_2 escapes metabolism in the lungs and appears in significant amounts in the arterial circulation. Small amounts of $PGF_{2\alpha}$ are present in maternal arterial plasma during ACTH-induced preterm labour (Olson *et al.*, 1985). More information is needed on arterial concentrations of $PGF_{2\alpha}$; if $PGF_{2\alpha}$ does not reach the myometrium by a systemic route, it must be produced locally by the membranes and endometrium and reach the myometrium by diffusion (Thorburn and Challis, 1979). Alternatively, the increasing amounts of PGE_2 in the arterial circulation (see below) may exert a direct stimulatory action on the myometrium or be converted locally to $PGF_{2\alpha}$ by 9-keto-reductase.

(b) Prostaglandin E_2

Using a new indirect assay for PGE_2, in which the more stable methyloxime derivative of PGE is formed (R.W. Kelly *et al.*, 1986), Fowden *et al.* (1987) reported that the concentrations of PGE_2 in the maternal carotid artery, uterine vein and the fetal carotid artery increase progressively during the last third of gestation. An arteriovenous difference for PGE_2 on the maternal and fetal sides of the placenta (Fowden *et al.*, 1987; Andrianakis *et al.*, 1989a,b) indicates that the increasing plasma concentrations are an expression of increased PGE_2 production by the placenta.

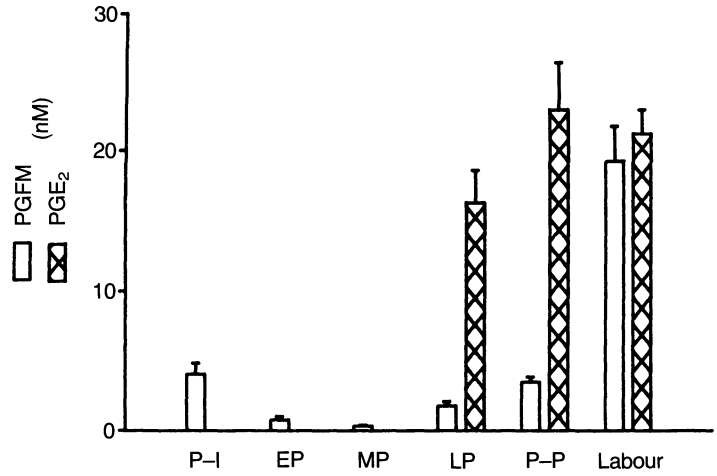

Figure 9.10 Mean (± SEM) basal utero-ovarian (UOV) venous plasma concentrations of PGFM and PGE_2 during preimplantation (P-I; day 14 p.c.), early pregnancy (EP; day 21–23 p.c.), mid-pregnancy (MP; day 60–63 p.c.), late pregnancy (LP; day 135–138 p.c.) and before (P-P; >day 140 p.c.) and during active labour. Concentrations of PGE_2 in UOV plasma of P-I, EP and MP ewes were below the lower limits of sensitivity of the PGE_2 assay. (Reproduced with permission from Burgess *et al.*, 1991.)

The temporal pattern of PGE production by the uterus differs from that of $PGF_{2\alpha}$: concentrations in the utero-ovarian vein are undetectable in mid-gestation (63–65 days), but reach high levels (16.21 ± 0.83 nM) by late gestation (135–138 days) (Burgess, 1991). The basal PGE_2 concentration in preparturient ewes (22.90 ± 3.4 nM >140 days' gestation) and parturient ewes (32.25 ± 1.7 nM) are not significantly greater than those in the late pregnant ewes, as found by Fowden *et al.* (1987) and Andrianakis *et al.* (1989a). The arterial concentration of PGE_2 at 135–138 days gestation was 4.93 ± 0.24 nM (Burgess, 1991) which is in agreement with the earlier studies. The difference in the temporal pattern of placental PGE_2 and $PGF_{2\alpha}$ production (Figure 9.10) and the vastly different response of PGE_2 and $PGF_{2\alpha}$ to an oxytocin challenge suggests different rates of production and modes of regulation.

(c) Sites of production

Concentrations of $PGF_{2\alpha}$ are higher in maternal cotyledons and myometrium than in fetal cotyledons (Liggins and Grieves, 1971), but there are high levels of PGE_2 in fetal cotyledons, but not myometrium or maternal cotyledons, after delivery (M.D. Mitchell and Flint, 1977). Subsequent work has confirmed these early studies. Using a superfusion system, M.D. Mitchell and Flint (1978b) showed that PGE_2 output from the combined fetal and maternal cotyledons exceeded that of $PGF_{2\alpha}$, a finding consistent with the observation of C.A. Evans *et al.* (1981) that the concentration of PGE in whole cotyledons exceeded that of $PGF_{2\alpha}$.

C.A. Evans *et al.* (1981) concluded that the cotyledons and the chorioallantois were the major sites of PG synthesis: in control animals, the chorioallantois contained the highest concentrations of $PGF_{2\alpha}$ and 6-keto-$PGF_{1\alpha}$, and $PGF_{2\alpha}$ and 6-keto-$PGF_{1\alpha}$ but not PGE_2 were elevated by fetal ACTH treatment. C.A. Evans *et al.* (1981) also proposed that the fetal membranes are major sites of PG production in late pregnancy and during induced labour. The chorioallantois is anatomically close to the endometrium and PGs

synthesized in the chorion might be expected to diffuse readily into the amniotic and allantoic fluids and the concentrations of PGs in these fluids might be an expression of PG synthesis by the chorion. Information on the PG concentrations in allantoic fluid is unavailable. The amniotic fluid becomes more viscid during late gestation, making it more difficult to sample, but concentrations of PGE_2, $PGF_{2\alpha}$ and 6-keto-$PGF_{1\alpha}$ in amniotic fluid are elevated before delivery (M.D. Mitchell *et al.*, 1977a,b; Challis *et al.*, 1978). During ACTH-induced labour, PGs increase in fetal fluids before the increased mechanical activity of the uterus begins (Olson *et al.*, 1985), providing further evidence that PGs initiate uterine activity rather than result from it.

The placenta has been clearly identified as a major site of PG production, with the maternal placenta being suggested as the major source of $PGF_{2\alpha}$ (Liggins and Grieves, 1971) and the fetal placenta (trophoblast) of PGE_2 production (M.D. Mitchell and Flint, 1977). The synthesis of PGs by the placenta throughout the pregnancy has been investigated in detail.

PG synthesis by dispersed ovine cotyledonary cells, mostly uninucleate trophoblast cells, is low during early and mid-gestation but increases markedly from day 110–120 onwards (Risbridger *et al.*, 1985). The addition of arachidonic acid to incubations of cotyledonary cells did not significantly enhance PG synthesis, suggesting that the concentration of PGHS in the trophoblast varies during gestation, increasing only after 110 days' gestation.

Microsomes from ovine cotyledons represent a PGHS-enriched subcellular fraction (Leach-Harper and Thorburn, 1984; Risbridger *et al.*, 1985; Rice *et al.*, 1987, 1988) and their capacity to synthesize PGE_2 and $PGF_{2\alpha}$ from radiolabelled arachidonic acid increases 25-fold between 20 and 140 days' gestation, the greatest increase being after 120 days (Rice *et al.*, 1988). This was considered to be the result of an increase in PGHS activity or content in the placenta but could have been due to an increase in the activity or content of the E-isomerase (which converts the product of PGHS activity to PGE_2). This possibility was excluded by studies of the amount of oxygen consumed by the PGHS-catalysed conversion of arachidonic acid to PGs (Rice *et al.*, 1990). Microsomal oxygen consumption increased 22-fold between 74 and 147 days' gestation; it was stimulated by the addition of arachidonic acid and inhibited by inhibitors of PGHS activity such as indomethacin and 4-aminoantipyrine. The increase did not occur after fetal hypophysectomy at 70–80 days' gestation (Rice *et al.*, 1990), consistent with the finding that placental PGE_2 production did not increase during late gestation in such pregnancies (Thorburn *et al.*, 1989). It has been suggested that some fetal pituitary factor may be needed for the induction of PGHS activity, mRNA translation or PGHS gene expression (Thorburn *et al.*, 1989; Rice *et al.*, 1990).

The *in vitro* measurements of the gestational changes in PG-forming capacity (Risbridger *et al.*, 1985), cotyledonary PGHS activity (Rice *et al.*, 1988, 1990) and *in vivo* measurements of plasma concentrations of PGE_2 during gestation (Fowden *et al.*, 1987) show a similar profile: low during early to mid-gestation but increasing rapidly from 110–120 days of gestation to term. Studies of the synthesis of PGs by intrauterine tissues of animals of other species (see Rice *et al.*, 1990) are consistent with the observations in sheep and suggest a common governing mechanism. Thorburn *et al.* (1988, 1991) and Thorburn and Rice (1990) propose that the increased PG production by the placenta during the last 0.25–0.30 of gestation corresponds to the rapid growth phase of the fetus, which commences at about 110–120 days' gestation in the sheep. Reducing the food intake of late pregnant ewes increases placental PGE_2 production, (Fowden *et al.*,

1987), and the increase in substrate demand by the fetus on the placenta during its phase of rapid growth might provide a stimulus for the placenta to increase PGE_2 production with this increased PGE_2 concentration in turn facilitating transport of substrate for the increase in growth of the fetus. Thorburn (1991) has also proposed that the increased concentration of PGE_2 in fetal plasma may provide a stimulus for the fetal hypothalamo-pituitary–adrenal axis, and this may be part of the trigger mechanism for parturition.

Since the pattern of growth of a fetus is genetically determined and is common to most species, it may explain why placental PG production follows a similar pattern in the sheep, pig, rabbit, guinea pig and goat. Under various adverse conditions (e.g. fetal and placental hypoxaemia, maternal undernutrition, placental trauma, hyperthermia) placental PGE_2 production is increased and may lead to premature labour. It is not clear at the present time whether the mechanism (placental PGE_2 production) represents the 'trigger' for parturition or an amplifying system in the activation of the HPA axis (see Chapter 10, this volume).

(d) Differential regulation of release of PGE_2 and $PGF_{2\alpha}$

The belief that PGE_2 and $PGF_{2\alpha}$ are not only synthesized in different sites (Liggins and Grieves, 1971; Mitchell and Flint, 1977) but that their release is regulated in different ways is supported by the studies of Burgess *et al.* (1989) and Burgess (1991). Administration of oxytocin to the ewe significantly increased the release of $PGF_{2\alpha}$ into the utero-ovarian vein but failed to stimulate PGE_2 release. Oxytocin, acting via oxytocin receptors and the IP_3 pathway, may therefore increase the production of $PGF_{2\alpha}$ from the maternal placenta. The failure to stimulate PGE_2 release may be due to the inability of oxytocin to cross the maternal syncytium to gain access to the trophoblast (fetal placenta) and/or to a lack of oxytocin receptors on the trophoblast (Jenkin *et al.*, 1989). The release of $PGF_{2\alpha}$ from the maternal placenta therefore appears to be regulated by the prevailing oxytocin concentrations in maternal plasma and the density of the oxytocin receptors in the placenta. The influence that the fetus has on PGF release into the maternal circulation is by varying the concentrations of oestrogens and P_4 in the maternal plasma, an increase in the E/P ratio causing an increase in the number of oxytocin receptors. Administration of mifepristone, a P_4 antagonist, to a pregnant ewe led to increased concentrations of PGE_2 and $PGF_{2\alpha}$, but only $PGF_{2\alpha}$ increased in response to oxytocin (Burgess *et al.*, 1991), again suggesting a differential response.

The influence of steroid hormones on oxytocin receptors is well documented (Soloff, 1975; Hsueh *et al.*, 1976; Roberts *et al.*, 1976; Nissenson *et al.*, 1978). Oestrogen promotes the synthesis of its own receptor and that of oxytocin (Hsueh *et al.*, 1976; Pavlik and Coulson, 1976; Clark *et al.*, 1977), and this action is antagonized by P_4. The release of PGFM into the utero-ovarian vein in response to oxytocin varies in relation to the prevailing E/P ratio, the higher the ratio the greater the release of $PGF_{2\alpha}$ (Burgess, 1991). The prepartum increase in the E/P_4 ratio in the pregnant ewe might therefore be expected to cause an increase in oxytocin receptors in the maternal placenta in a manner similar to that described in the non-pregnant ewe (Hixon and Flint, 1987). Such an increase has been demonstrated indirectly by the increase in the release of PGFM but not PGE_2 in response to oxytocin after treatment with mifepristone in late pregnant ewes (Burgess *et al.*, 1992). This result is more meaningful than measuring oxytocin receptors *per se* because Sheldrick and Flint (1986) demonstrated that oxytocin receptor numbers were increased even when release of $PGF_{2\alpha}$ in response to oxytocin was inhibited, and Vallet *et al.* (1990) have demonstrated a dissociation between oxytocin receptor concentrations

and release of $PGF_{2\alpha}$ in response to oxytocin in the ewe. Oxytocin concentrations in maternal and fetal plasma rise at parturition (Glatz *et al.*, 1981; M.D. Mitchell *et al.*, 1982a; Dawood *et al.*, 1983), the maternal concentrations increasing significantly during the second stage of labour (Glatz *et al.*, 1981). $PGF_{2\alpha}$ release into the maternal circulation is therefore determined by changes in the concentration of oestrogens, P_4, oxytocin and its receptors, whereas the release of PGE_2 is regulated in a different way and is insensitive to the action of oxytocin.

(e) Route of transfer of PGs to myometrium

The cotyledons represent the major site of PG production in the uterine tissue, but it is still not clear to what extent the PGs arising from the cotyledons reach the myometrium and to what extent they contribute to uterine activity. From the anatomy, Thorburn and Challis (1979) considered it unlikely that PGs could diffuse from the cotyledons to the myometrium and a countercurrent mechanism to transport $PGF_{2\alpha}$ selectively from the uterine vein to the uterine artery (and thus to the myometrium) could not be demonstrated (Liggins *et al.*, 1973). The systemic route of transfer of PGs from the cotyledons to the myometrium would appear inefficient in view of the ability of the lung to metabolize and clear most PGF_2 in the pulmonary circulation (Vane, 1978). However, there is still a lack of information on $PGF_{2\alpha}$ concentrations in maternal arterial plasma during late pregnancy and parturition. An intra-aortic infusion of $PGF_{2\alpha}$ (5–10 μg/min) in pregnant sheep, which Thorburn and Challis (1979) calculated should achieve plasma arterial concentrations of 2–4 ng/ml, increased uterine activity and myometrial sensitivity to oxytocin (Liggins *et al.*, 1973) despite high P_4 concentrations. Thorburn and Challis (1979) proposed that during the last 24 h before delivery, when the sensitivity of the myometrium to $PGF_{2\alpha}$ had increased markedly, due to the decrease in P_4 levels (and a removal of the 'P_4 block') and an increase in oestrogen levels, the myometrium may respond to quite low arterial $PGF_{2\alpha}$ concentrations (Thorburn *et al.*, 1977a). PGs in the arterial circulation may also stimulate oxytocin secretion, thereby reinforcing the reflex-stimulated oxytocin release that occurs at this time in response to cervical and vaginal stretching (Roberts and Share, 1968; Gillespie, 1973; Flint *et al.*, 1975).

Concentrations of PGE_2 in arterial plasma increase during the last third of gestation, reaching high levels at term (Fowden *et al.*, 1987; Burgess, 1991), suggesting that the lungs may be less effective at clearing PGE_2 or that the amounts of PGE_2 presented to the lungs are greater. Nevertheless, the myometrium, cervix and other tissues are exposed to increasing concentrations of PGE_2, which may explain the evolution of uterine activity, and the appearance of the so-called 'contractures' (Nathanielsz *et al.*, 1977), during this time. The pattern of prolonged uterine contractions ('contractures') is thought to be due to the myometrium being stimulated by an agonist while the blocking action of P_4 on the myometrium is present (Thorburn *et al.*, 1983). The propagation of electrical activity in the myometrium is probably blocked by P_4. With the preparturient decrease in P_4 concentrations, the uterine sensitivity to PGs increases markedly (Jenkin *et al.*, 1982; Thorburn *et al.*, 1983; Jenkin and Thorburn, 1985; Burgess *et al.*, 1991). It is not known whether PGE_2 would be equally effective in stimulating uterine activity in sheep.

(f) Endometrium and fetal membranes

In sheep the myometrium is lined by the intercotyledonary endometrium to which the chorion is closely apposed. PGs produced in these tissues can readily diffuse into the myometrium. In the non-pregnant ewe, the endometrium represents a major site of PG production and the PGF_2 produced by the

endometrium is responsible for the increased uterine activity at the end of the oestrous cycle. In the late pregnant ewe, the endometrium can also produce PGs, although *in vitro* studies indicate that the synthetic capacity of the endometrium is less than that of the chorioallantois or cotyledons (Mitchell and Flint, 1977, 1978a; C.A. Evans *et al.*, 1981, 1982; Olson *et al.*, 1985). Nevertheless, the proximity of the endometrium to the myometrium would ensure an efficient transfer of PGs so that as the inhibitory influence of P_4 at the myometrium wanes, PGs produced locally may play a key role in stimulating uterine activity.

In the late pregnant sheep the chorion is extensive and on one surface is in close proximity to the endometrium while on the other it is in close apposition to the allantois and amnion. The chorioallantois contained the highest concentrations of $PGF_{2\alpha}$ and 6-keto-$PGF_{1\alpha}$ in late pregnant sheep, and $PGF_{2\alpha}$ and 6-keto-$PGF_{1\alpha}$ but not PGE_2, were increased after infusion of ACTH to the fetus to induce premature labour (C.A. Evans *et al.*, 1981). It seems likely that PGs produced in the endometrium or chorioallantois can diffuse into the myometrium to stimulate activity. PGs injected into the amniotic or allantoic sacs of sheep during mid-pregnancy can induce abortion (Thorburn, 1977). Extra-amniotic infusion of $PGF_{2\alpha}$ causes a rapid elevation of maternal and fetal plasma and amniotic fluid PGFM concentrations in excess of those found at normal term (Jenkin *et al.*, 1982). When a 3β-HSD inhibitor was injected during extra-amniotic infusion of $PGF_{2\alpha}$ there was a precipitous decline in maternal plasma P_4 concentrations and parturition began within 24 h. They concluded that a substantial decrease in plasma P_4 concentrations is necessary to render the myometrium sensitive to $PGF_{2\alpha}$ in late pregnant sheep. These studies also demonstrate the ability of $PGF_{2\alpha}$ injected extra-amniotically to diffuse widely and to initiate uterine activity.

The relative importance of the various sites of production of PGs in relation to the initiation of parturition in sheep is still unclear. The sensitivity of the myometrium to stimulation with PGs increases so markedly, following removal of the P_4 influence, that small amounts of PGs, whatever their source, may be sufficient to stimulate uterine activity. It is possible that in sheep the massive release of $PGF_{2\alpha}$ into the maternal uterine vein during the last 24 h before delivery is not essential for parturition, since most of the circulating PG is metabolized in the lungs. However, in other ruminants (e.g. goat and cows) this release of $PGF_{2\alpha}$ into the uterine vein may be of key importance since the countercurrent diffusion of $PGF_{2\alpha}$ from the utero-ovarian vein to the ovarian artery may be responsible for causing the regression of the CL of pregnancy and a decrease in maternal P_4 levels. This, in turn, would enhance the further release of PGs and render the myometrium more sensitive to the action of PGs.

9.5.6 REGULATION OF PG SYNTHESIS AND RELEASE

(a) Oestrogens

The close temporal relationship between the preparturient increases in oestrogen and $PGF_{2\alpha}$ in the utero-ovarian vein is consistent with the thesis that increasing plasma concentrations of oestrogen may stimulate the release of $PGF_{2\alpha}$ (Thorburn *et al.*, 1972a; Currie *et al.*, 1973; Challis *et al.*, 1982). Moreover, the evolution of uterine activity during the last 24 h of pregnancy (Ward, 1968; Thorburn *et al.*, 1984) coincides with the increase in maternal plasma $PGF_{2\alpha}$ (and free oestrogens), suggesting that $PGF_{2\alpha}$ may be responsible for initiating myometrial activity associated with labour. The administration of oestrogen induces premature delivery in sheep (Hindson *et al.*, 1967) and, within 24 h of treating pregnant sheep with diethylstilboestrol, concentrations of $PGF_{2\alpha}$ increase in

the maternal cotyledons and myometrium, but not in the fetal cotyledons (Liggins, 1973). These changes are associated with a marked increase in $PGF_{2\alpha}$ concentrations in the utero-ovarian vein and a 90% decrease in the threshold response to oxytocin, despite the absence of any change in peripheral or utero-ovarian P_4 concentrations.

Because oestradiol-17β was considered the primary trigger coming from the fetus to initiate $PGF_{2\alpha}$ release and parturition, oestradiol was infused into sheep during late pregnancy in amounts which produced physiological (parturient) levels in the maternal circulation and premature delivery was induced in three of four experiments (Currie *et al.*, 1973; Currie, 1974; Thorburn *et al.*, 1977a). Labour and an increased release of $PGF_{2\alpha}$ was observed in the absence of any change in circulating P_4. The concentrations of oestrogens relative to those of P_4 were considerably lower than those observed normally at parturition. Earlier in pregnancy (day 125) oestradiol (Currie *et al.*, 1973; Currie, 1974) or stilboestrol (Hindson *et al.*, 1967; Liggins *et al.*, 1973) stimulated an increase in uterine activity and $PGF_{2\alpha}$ release, but cervical relaxation and delivery did not occur.

Oestradiol given as short- or long-term (overnight) systemic infusions failed to stimulate $PGF_{2\alpha}$ release in day 15 nonpregnant ewes (Burgess *et al.*, 1990; Burgess, 1991), contrary to the results of Barcikowski *et al.* (1974), who used non-pregnant sheep bearing an autotransplanted uterus. Even doses of oestradiol 100 times greater than that used by Barcikowski *et al.* (1974) failed to induce significant increases in PGFM concentrations in the utero-ovarian vein, Burgess (1991) also found that oestradiol failed to stimulate the release of PGFM or PGE_2 from the uteri of mid-pregnant (day 60–65) and late pregnant (day 135–140) animals. These studies suggest that the action of oestradiol to stimulate PG release was blocked until day 140 of pregnancy.

It was proposed that the high P_4 concentrations throughout pregnancy may inhibit the action of oestrogen on oxytocin receptors and the PG synthetic mechanism to prevent increased PG release and that, in the days before delivery when P_4 concentrations decrease and its inhibitory effect is withdrawn, oestrogen stimulates $PGF_{2\alpha}$ release via an induction of oxytocin receptors and an increase in PG synthetic capacity (Burgess, 1991; Burgess *et al.*, 1991). The results of the early studies, in which the release of $PGF_{2\alpha}$ and uterine activity was observed, may be explained by the use of large (pharmacological) amounts of synthetic oestrogens. It is apparent from a number of studies that if sufficient oestrogen is given to increase the E/P_4 ratio to parturient levels, $PGF_{2\alpha}$ will be released irrespective of the P_4 concentrations prevailing at the time. It would seem that P_4 and oestrogen may exert opposing actions on the key enzymes in the PG synthetic pathway, i.e. PLA_2 and cyclo-oxygenase.

(b) Progesterone

In sheep, P_4 exerts a marked inhibitory influence on the myometrium and the cervix. Indeed, withdrawal of this P_4 'block' is a prerequisite for successful delivery in sheep (Thorburn, 1983; Thorburn *et al.*, 1983, 1984; Jenkin and Thorburn, 1985). The concentration of P_4 decreases 3–4 days before parturition (Nathanielsz *et al.*, 1982), before the increase in $PGF_{2\alpha}$ release (Bassett *et al.*, 1969).

The profound inhibitory action of P_4 on the ovine myometrium has been demonstrated in the non-pregnant, ovariectomized, oestrogen-primed ewe (Lye and Porter, 1978). Oxytocin and $PGF_{2\alpha}$, given in amounts sufficient to cause pronounced myometrial activity in the oestrogen-primed uterus, failed to stimulate activity in the P_4-blocked uterus, indicating that the inhibitory action of P_4 is directly on the myometrium and not simply due to the suppression of $PGF_{2\alpha}$ re-

lease. Progesterone can inhibit labour at term in sheep (Bengtsson and Schofield, 1963), although prolonged pregnancy occurred only after the administration of large amounts of P_4. The administration of P_4 in doses below 100 mg/day, sufficient to maintain physiological concentrations of P_4 (i.e. in the normal preparturient range), did not delay the initiation of parturition (Liggins *et al.*, 1973). However, high doses of P_4 (100 mg/day) were able to inhibit uterine activity and labour during fetal infusion of dexamethasone. Thorburn (1979) suggested two reasons why such large amounts of P_4 are needed to block premature or term labour in sheep. Firstly, exogenous P_4 is cleared rapidly by the placenta as a result of the increased placental blood flow in late pregnancy and the ability of the placenta to metabolize P_4. Secondly, because of the high circulating levels of oestrogen achieved at parturition due to the quantitative conversion of endogenous P_4 to oestrogen, large amounts of exogenous P_4 are needed to lower the E/P_4 ratio to preparturient levels. Subsequent studies have confirmed these ideas (Thorburn, 1983; Thorburn *et al.*, 1983; Jenkin *et al.*, 1985a,b; Nathanielsz *et al.*, 1988). Progesterone (200 mg/day) or MPA (250 mg) significantly delayed the initiation of parturition induced by cortisol infusion. Fetal and maternal plasma PGFM levels were increased, but myometrial activity, as judged by intrauterine pressure and electromyographic recordings, did not increase (Thorburn *et al.*, 1983). These studies showed that P_4, when administered in adequate amounts, is able to inhibit uterine activity in the pregnant ewe and prevent parturition despite high levels of PGs (Thorburn *et al.*, 1983; Jenkin *et al.*, 1985a,b). These experiments also confirmed that P_4, and particularly MPA, also inhibit the release of $PGF_{2\alpha}$ from the uterus, but that supraphysiological amounts of exogenous P_4 are needed to overcome the stimulatory effects of high levels of oestrogen that are generated by the fetal cortisol induced metabolism of placental P_4 to oestrogen (Thorburn *et al.*, 1983; Jenkin *et al.*, 1985a,b; Nathanielsz *et al.*, 1988).

9.5.7 SENSITIVITY OF THE MYOMETRIUM TO $PGF_{2\alpha}$

The importance of P_4 inhibiting both myometrial activity and the stimulatory action of $PGF_{2\alpha}$ on the myometrium has been explored in the following ways. Administration of competitive inhibitors of 3β-HSD (Taylor *et al.*, 1982; Jenkin and Thorburn, 1985) causes a decrease in maternal plasma P_4 concentrations and an increase in PGFM concentrations. If maternal P_4 concentrations are decreased to sufficiently low levels, parturition occurs despite oestrogen concentrations being unchanged. However, if P_4 decreases to about 30% of the preinjection levels, despite a marked increased in PGFM concentrations in maternal plasma (up to 4 ng/ml), and a gradual increase in myometrial (EMG) activity, delivery does not occur.

The ovine myometrium when under the influence of P_4, is insensitive to PGs (Thorburn *et al.*, 1972a) and so P_4 withdrawal alone, without any associated increase in oestrogens, may therefore be enough to induce $PGF_{2\alpha}$ release and parturition. When $PGF_{2\alpha}$ was infused extra-amniotically in late pregnant ewes (132.4 ± 0.24 days' gestation) in a dose sufficient to cause $PGF_{2\alpha}$ concentrations in excess of those found in fetal and maternal plasma and in amniotic fluid at parturition (Thorburn *et al.*, 1983), there was no change in P_4 concentrations or myometrial (EMG) activity in three out of five animals and only a small increase in frequency in the other two animals. However, concomitant injection with a 3β-HSD inhibitor produced a profound decrease in maternal P_4 concentrations, a marked increase in uterine activity and parturition within 24 h.

Liggins *et al.* (1973) found that prolonged intra-aortic infusions of $PGF_{2\alpha}$ increased uterine activity and increased the sensitivity of

the myometrium to oxytocin in late pregnant ewes, but this may have been due to a longer duration and different route of administration and by the $PGF_{2\alpha}$ concentrations achieved at the myometrium. Acute administration of high doses of $PGF_{2\alpha}$ will also overcome the P_4 block and induce uterine activity in late pregnant sheep (M.D. Mitchell *et al.*, 1977b).

Local P_4 withdrawal can also be achieved by the administration of P_4 analogues (e.g. mifepristone), which can compete with endogenous P_4 for uterine binding sites but lack P_4-like activity. Administration of mifepristone to late pregnant ewes does not alter P_4 or oestrogen concentrations, and the changes in PG release and uterine sensitivity to oxytocin mimic those in preparturient animals (Burgess, 1991): basal concentrations of PGFM and PGE_2 were increased compared with values in late pregnant ewes. The ability of oxytocin to elicit uterine PGFM release was also enhanced in the treated animals (Burgess, 1991; Burgess *et al.*, 1991). These results are consistent with the proposal that P_4 withdrawal is essential in the pregnant sheep for the increased release of PGs at term.

The key role of PGs in the initiation of premature labour in sheep was clearly demonstrated by the studies of M.D. Mitchell and Flint (1978a). The administration of meclofenamate (an inhibitor of PGHS and a $PGE_{2\alpha}$ antagonist) to pregnant sheep prevented the delivery of a live fetus in response to an intrafetal dose of dexamethasone. Despite the anticipated rise in oestradiol and fall in P_4 concentrations, parturition did not occur if PG synthesis was blocked. The pretreatment contracture pattern of uterine activity persisted although the frequency of the contractures increased, possibly due to the high oestrogen levels. After cessation of meclofenamate treatment, uterine activity (labour-like contractions) commenced within 1–2 h, but $PGF_{2\alpha}$ release only occurred during second-stage labour. Presumably, only low levels of $PGF_{2\alpha}$ are needed to induce delivery in the presence of very low P_4 levels and high oestrogen concentrations.

9.5.8 OXYTOCIN

There is still no evidence that oxytocin, at least that of maternal pituitary origin, is a prerequisite for parturition in sheep. The studies of Denamur and Martinet (1961) and Bosc (1974) showed that normal parturition occurred at term after maternal hypophysectomy at days 50–134 of pregnancy, although some regrowth of neurosecretory tissue cannot be excluded in these animals (Swaab *et al.*, 1977). An oxytocin receptor antagonist which successfully blocks the action of exogenous oxytocin in pregnant sheep failed to block uterine activity at term (Jenkin *et al.*, 1990). These results suggest either that endogenous oxytocin is not responsible for causing the uterine activity associated with parturition in sheep or that, once oxytocin has exerted its action, it cannot be reversed by the administration of an antagonist. However, human fetal membranes (and/or decidua) have the potential to synthesize oxytocin (Chibbar *et al.*, 1991) and a local paracrine (and/or autocrine) action by oxytocin in the membranes, endometrium and decidua of the sheep could allow for the local generation of PGs and a direct action of oxytocin on the myometrium, the release of oxytocin being mediated by local changes in the E/P_4 ratio.

Glatz *et al.* (1981) concluded that oxytocin did not stimulate the onset of labour in sheep, but did facilitate delivery of the fetus and placenta by inducing forceful uterine contractions, confirming suggestions that oxytocin plays an important role during second- and third-stage labour in the sheep (Currie *et al.* 1973). Vaginal distension provokes the reflex release of oxytocin (Ferguson, 1941; Debackere *et al.*, 1961; Roberts and Share, 1968) and $PGF_{2\alpha}$ (Flint *et al.*, 1974b) and P_4 can inhibit this response in nonpregnant ewes (Roberts and Share, 1968).

When the vagina is distended in late pregnant ewes, an increase in plasma oxytocin concentrations is followed 1 min later by an increase in PGF concentrations (Flint *et al.*, 1975); the response increases as delivery approaches and is most pronounced in the immediate post-parturient animal, indicating that the sensitivity of the posterior pituitary to vaginal distension in the periparturient ewe is influenced by the prevailing P_4 concentration (Flint *et al.*, 1975; M.D. Mitchell *et al.*, 1977b). The infusion of oxytocin into late pregnant ewes also causes the release of $PGF_{2\alpha}$ into the utero-ovarian vein, and this response increases towards term (M.D. Mitchell *et al.*, 1975; Burgess, 1991), paralleling the increasing ability of oxytocin to cause uterine contractions nearer delivery (Hindson *et al.*, 1969). The recent studies of Burgess (1991) have confirmed and extended the earlier observations of Mitchell *et al* (1975). She found that oxytocin stimulated the uterine release of PGFM and that the response was greater in preparturient (day 140 term) than in late pregnant (130–135 days) ewes and concluded that the capacity of the PG secretory system to respond to oxytocin increased markedly near term. The increased response to oxytocin is dependent not only on the plasma concentration of oxytocin but also on the affinity and concentration of its receptors in the target tissue (Alexandrova and Soloff, 1980a; Fuchs *et al.*, 1983b). In endometrial explants from non-pregnant ewes, the ability of oxytocin to stimulate $PGF_{2\alpha}$ release was correlated with the oxytocin receptor concentration, and the oxytocin receptor concentration varied directly with the E:P_4 ratio, high levels being found at oestrus (Roberts *et al.*, 1976). It seemed likely that the increased $PGF_{2\alpha}$ secretory response to oxytocin preceding delivery was due to an increased concentration of oxytocin receptors in the endometrium and maternal placenta resulting from the progressive increase in the E/P_4 ratio (Burgess, 1991). Intra-arterial oxytocin injection significantly increases the release of PGFM into the utero-ovarian vein during mid- and late pregnancy in the sheep, but oxytocin fails to stimulate the release of PGE_2 (Burgess *et al.*, 1989; Burgess, 1991), indicating that an endogenous inhibitor of PGE_2 release may be present in the ovine endometrium during late pregnancy. Fetal injection of oxytocin during late pregnancy fails to stimulate PGE_2 release (Jenkin *et al.*, 1989), thus supporting the contention that the PGE_2-secreting cells do not possess oxytocin receptors. These results provide further evidence that PGE_2 and $PGF_{2\alpha}$ are synthesized in different sites and suggest that the massive release of $PGF_{2\alpha}$ during labour is mainly derived from the endometrium, which is highly responsive at that time to oxytocin.

9.5.9 SUMMARY

This section should be read in conjunction with Chapter 10, this volume, on the development of the fetal hypothalamo-pituitary–adrenal axis. The studies described emphasize the importance of P_4 in the maintenance of pregnancy in the sheep. P_4 is essential for maintaining myometrial quiescence during gestation and a decrease in maternal P_4 concentrations (i.e. the removal of the so-called P_4 block) is a prerequisite for dilation of the cervix and the explosive myometrial activity associated with labour. The decrease in maternal P_4 concentrations is caused by increasing concentrations of cortisol in the fetal circulation acting on the placenta to induce the enzyme 17α-hydroxylase. In the late pregnant sheep, the placenta is the major site of P_4 production and the increased activity of the 17α-hydroxylase increases the metabolism of P_4 to oestrogens, and thus decreases the plasma levels of P_4, while increasing those of oestrogens, resulting in a marked increase in the E/P ratio. This profound change in the hormonal environment of the myometrium enhances its sensitivity to agonists such as $PGF_{2\alpha}$, PGE_2 and oxytocin.

The decrease in P_4 concentration (and the increase in oestrogen levels) not only increases the sensitivity of the myometrium to $PGF_{2\alpha}$ and oxytocin, but also favours their release. As P_4 concentrations fall, $PGF_{2\alpha}$ release from the maternal placenta, endometrium and fetal membranes increases. Some $PGF_{2\alpha}$ diffuses directly from the endometrium and fetal chorioallantois to the myometrium, whereas some is transported via the systemic circulation to the myometrium, the relative importance of the two pathways has yet to be determined.

Oxytocin is released from the fetal posterior pituitary in second-stage labour by the stretching of the cervix by the fetal head (the so-called Ferguson reflex) and by the high concentration of $PGF_{2\alpha}$ released from the uterus at this time. Oxytocin, apart from stimulating uterine activity directly, causes the further release of $PGF_{2\alpha}$. The increase in the E/P ratio favours the release of oxytocin. Recent studies suggest that oxytocin may be synthesized and released locally from the membranes and myometrium, and can therefore act directly on the myometrium. These findings, if confirmed, would explain how oxytocin may play a role in the initiation of parturition without being detected in the maternal circulation.

The recent findings of increasing production of PGE_2 during the last third of gestation, adds a new dimension to the discussion of the initiation of parturition. The increase in placental PGE_2 production appears to be under fetal pituitary control. It has been suggested that the increasing concentration of PGE_2 in the fetal circulation may play an important role in maintaining high fetal concentration of cortisol, and therefore in initiating the decrease in maternal P_4 concentrations. Large amounts of PGE_2 are secreted into the maternal circulation, and since it is not completely cleared by the lungs, increasing concentrations of PGE_2 are found in the maternal arterial circulation during the last few weeks of gestation. This arterial PGE_2 may act on the cervix to initiate cervical ripening and on the mammary gland to initiate lactogenesis; in both cases P_4 withdrawal may be an important element. The PGE_2 in the arterial circulation also provides a continuous stimulus to the myometrium and may be responsible for the appearance of the uterine 'contractures' observed during the latter part of pregnancy in the ewe. These 'contractures' may represent the effect of a P_4 -blocked myometrium responding to a potent challenge from PGE_2 in the arterial circulation. When P_4 concentrations decrease in the days preceding parturition, the PGE_2 in the arterial circulation may become a more potent stimulus to the myometrium, causing a more profound increase in myometrial activity and the initiation of labour. PGE_2 may also provide a stimulus for the release of oxytocin from the posterior pituitary and, possibly, the membranes and myometrium.

Thus, the initiation of parturition in sheep is the successful accomplishment of a continuous dialogue between the fetus and its placenta so that the fetus is delivered at an appropriate time, and an appropriate size, with its key organ systems mature and fully prepared for post-natal life.

9.6 GOAT

9.6.1 INTRODUCTION

Compared with the sheep and pig, there is a relative paucity of information on the initiation of parturition in goats. This is due to both a lack of industry funds and importance of the goat industry in most countries.

From a scientific point of view, the goat is an excellent experimental animal and is representative of animals which are dependent on the corpus luteum of pregnancy as a source of progesterone. In this species, the continued function of the corpus luteum is essential for the maintenance of pregnancy and the factors (luteotrophins) regulating its function are clearly of great importance. Early

in pregnancy the maternal pituitary hormones, prolactin and luteinizing hormone (LH) play this role, whereas in the latter part of pregnancy the nature of the luteotrophins is still a matter requiring further study, although several placental factors have been proposed including caprine placental lactogen (cPL), prostaglandin E_2 (PGE_2), a putative caprine chorionic gonadotrophin (cCG) and oestrogens. The goat is also a classical example of a species in which P_4 inhibits myometrial activity throughout pregnancy and its withdrawal (i.e. a decrease in maternal plasma P_4 concentrations) is an essential prerequisite for the onset of labour.

In both the goat and sheep, a major decrease in maternal plasma P_4 concentrations is needed to remove the inhibitory effects of P_4 on the myometrium and to allow increased myometrial activity and delivery of the fetus. In the sheep, the placenta is the major site of progesterone production during late pregnancy, whereas in the goat the corpus luteum serves this function.

As in sheep, activation of the fetal pituitary–adrenal axis appears to play a primary role in the initiation of parturition in the goat but, unlike sheep, in which fetal plasma cortisol acts directly on the placenta to decrease placental P_4 to the low levels necessary for parturition (at 150 days of gestation), fetal cortisol acts indirectly to cause regression of the maternal CL of pregnancy and thereby reduces circulating P_4 concentrations (by increaseing the level of 17α-hydroxylase). In the goat, fetal cortisol must act indirectly to cause regression of the CL of pregnancy, therby reducing circulating P_4 concentrations. Oestrogen at low levels may exert a direct trophic action on the CL, whereas at high concentrations, and particularly when P_4 concentrations start to fall, oestrogen exerts a luteolytic action by stimulating the release of $PGF_{2\alpha}$ from the endometrium and maternal placenta. Thus, the fetus, by means of its placenta and the secretion of oestrogen, initially maintains the CL, P_4 secretion and the pregnancy and then, by increasing oestrogen secretion, contributes to the regression of the CL and the termination of the pregnancy.

It has also been proposed that the initial decrease in P_4 concentrations may result from withdrawal of luteotrophic support of the corpus luteum due to a cortisol-induced decrease in cPL production by the placenta. The initial decrease in progesterone concentrations may then precipitate the release of luteolytic amounts of $PGF_{2\alpha}$. Recently, it has been shown, both in sheep and goats, that the placenta secretes increasing amounts of PGE_2 into the fetal and maternal circulations during the last third of gestation. In the goat, PGE_2 may play an important role as a luteotrophin during the last third of gestation until the demise of the corpus luteum is brought about by the release of large amounts of $PGF_{2\alpha}$ from the 'maternal' placenta during the one to two days before delivery.

9.6.2 THE FETAL PITUITARY–ADRENAL AXIS

The infusion of synthetic ACTH into fetal goats induces premature parturition (Thorburn *et al.*, 1972a), the maternal endocrine changes during which are similar to those before parturition at term (Currie *et al.*, 1973; Currie and Thorburn, 1977a,b). The concentration of corticosteroids in fetal plasma increases gradually between 4 and 11 days before term and then more rapidly during the last 4 days of pregnancy (Currie *et al.*, 1973; Currie and Thorburn, 1977a,b). Pregnancy was prolonged beyond term after ablation of the fetal pituitary by electrocoagulation (Currie and Thorburn, 1977a).

These studies led to the suggestion that a raised cortisol concentration in the fetus caused the onset of labour through effects on maternal steroid concentrations (Currie and Thorburn, 1977a). Infusion of oestradiol-17β into pregnant goats caused luteal regression (Currie and Thorburn, 1976) and, because

the concentration of oestrogen in maternal plasma rises before P_4 falls, it seemed likely that the primary effect of increased fetal adrenal activity in the goat was to induce increased oestrogen synthesis (Currie and Thorburn, 1977a).

Flint *et al.* (1978) proposed two mechanisms by which increased fetal adrenal activity might increase placental oestrogen biosynthesis: (1) that the fetal adrenal not only secretes cortisol but also androgens, which are aromatized to oestrogens by the placenta and (2) that fetal cortisol induces in the placenta the enzymatic capacity to synthesize oestrogens *de novo*. Intrafetal infusion of dexamethasone induces premature parturition in the goat (Flint *et al.*, 1978), indicating that a glucocorticoid is the only product of the adrenal essential for this process. The infusion of dexamethasone suppresses the fetal pituitary–adrenal axis as judged by the low fetal cortisol concentrations. The fetal glucocorticoids induce 17α-hydroxylase activity in the goat placenta and thus play an important role in initiating parturition in this species.

It has been proposed that a luteotrophic complex may maintain the CL of pregnancy in the goat (Thorburn, 1979) and that withdrawal of this trophic support may lead to a fall in maternal P_4 levels which, in turn, may enhance the release of $PGF_{2\alpha}$ from the maternal placenta (Thorburn, 1979; Thorburn and Challis, 1979). The placental secretion of placental lactogen (cPL), which forms part of this putative luteotrophic complex, would appear to be regulated by the levels of fetal cortisol (Currie *et al.*, 1977). During the last 15 days before delivery when fetal cortisol concentrations were rising, cPL values progressively decreased when synthetic ACTH was infused into the fetus. Maternal cPL levels decreased more abruptly. Thus, increased activity of the fetal pituitary–adrenal axis may switch off the production of cPL and decrease the trophic support of the CL. The consequent decrease in P_4 concentrations, together with the increased oestrogen synthesis resulting from activation of the fetal pituitary–adrenal axis, may produce a sufficient change in the E/P_4 ratio in the maternal placenta to cause the release of small amounts of $PGF_{2\alpha}$ and to initiate luteal regression. As P_4 concentrations decrease further, $PGF_{2\alpha}$ release is enhanced causing the further demise of the CL. This second mechanism may prove to be most important because the preparturient increase in oestrogen biosynthesis, as judged by plasma oestradiol-17β concentrations, is not marked (Flint *et al.*, 1978).

9.6.3 MAINTENANCE OF THE CORPUS LUTEUM OF PREGNANCY

The goat is representative of many species in which the CL is the major site of P_4 production throughout pregnancy. Parturition is preceded by regression of the CL and a decrease of the concentration of P_4 in the maternal plasma (Meites *et al.*, 1951; Linzell and Heap, 1968; Irving *et al.*, 1972a; Thorburn and Schneider, 1972). Removal of the CL at any time during pregnancy results in abortion, but the pregnancy can be maintained by replacement therapy with P_4 (Meites *et al.*, 1951; Irving *et al.*, 1972b) or MPA (Sheldrick *et al.*, 1980, 1981). Luteal regression and premature parturition can be induced by administration of $PGF_{2\alpha}$ to the mother (Currie and Thorburn, 1973). Premature parturition can also be induced by maternal administration of oestradiol-17β, which probably acts by stimulating uterine production of PGs (Currie and Thorburn, 1976). An understanding of the initiation of parturition in the goat therefore requires a knowledge of factors maintaining the CL during pregnancy and those causing its regression at term.

Goats, hypophysectomized between 38 and 120 days of pregnancy or pituitary stalk sectioned between 44 and 120 days, aborted 3–9 days later, indicating that the maternal pituitary gland is essential for the maintenance of the CL (Cowie *et al.*, 1963). Pregnancy

was maintained in goats hypophysectomized after day 90, by the administration of P_4 (20 mg/day) or LH (1 mg/day) but not prolactin (1–5 mg/day). When LH treatment was stopped, P_4 concentrations fell and the animals aborted. Because LH treatment was able to maintain P_4 secretion and pregnancy in two out of four goats hypophysectomized at day 60, Buttle (1978) concluded that, after day 90 of gestation, LH but not prolactin was an essential part of the luteotrophic complex. Buttle (1978, 1983) proposed that cPL could replace prolactin for CL maintenance in late pregnancy.

Malecki (1989) suggested that surgical stress, trauma and preoperation fasting, rather than removal of the pituitary hormones, may have resulted in abortion. Other workers have reported a tendency for goats to abort when subjected to surgical (Flint *et al.*, 1978) and environmental stress (van Heerden, 1961; van Rensburg, 1971). In an attempt to protect the pregnant goat against surgical stress, and assuming that luteolysis occurred in association with surgery, P_4 was administered for the first 9 days after surgery. Despite the P_4 treatment, abortions still occurred at 13.5–17.5 days after surgery, suggesting that regression of the CL had occurred around the time of surgery. The ability of administered LH to prevent abortion in hypophysectomized goats in the studies of Buttle (1978, 1983) was presumably due to the maintenance of P_4 concentrations by the exogenous LH. While this study demonstrated that LH was luteotrophic it did not conclusively demonstrate that LH was essential for pregnancy maintenance.

Although the exact mechanisms of stress-induced abortions are not known in the goat, some studies provide a clue to possible mechanisms involved. The infusion of synthetic ACTH into a pregnant goat not only produced a marked increase in maternal cortisol concentrations but also a significant increase in fetal cortisol values (Thorburn *et al.*, 1972a). If maintained for some days, high fetal cortisol concentrations are likely to induce premature parturition in the goat. While investigating post-surgical abortion in mares, Silver *et al.* (1979b) noted that presurgical food restriction caused an elevation in maternal $PGF_{2\alpha}$ concentrations and that this in turn led to luteal regression and premature labour. In other species, LH has been shown to antagonize the luteolytic action of $PGF_{2\alpha}$, and this may explain the protective action of the LH treatment in the studies of Buttle (1978, 1983).

In the studies of Malecki (1989), one goat hypophysectomized at day 84 of pregnancy was able to maintain the pregnancy and P_4 production within the range expected for unoperated goats until near term. Although hypophysectomy in this goat was not anatomically complete and prolactin was present in the peripheral circulation, LH could not be detected in any blood sample after hypophysectomy or after infusion of 200 mg LHRH on two separate occasions. It would appear that in this animal hypophysectomy was functionally complete with respect to LH, and Malecki (1989) concluded that LH may not be essential for the maintenance of pregnancy after day 84 of gestation in the goat.

To avoid the side-effects of surgical hypophysectomy, Malecki *et al.* (1987) used passive immunization against LH to study the effect of LH deprivation during pregnancy: infusion of antiserum against oLH in goats between 13 and 120 days of gestation resulted in abortions in five out of five goats immunized up to day 35 and in 24% of goats between days 42 and 120 of gestation. All goats immunized after day 35 of gestation displayed a significant drop in peripheral plasma P_4 levels regardless of whether abortion occurred. This indicates that maternal pituitary LH is essential for pregnancy maintenance up to at least day 35 of pregnancy, although LH still has a substantial luteotrophic role between days 42 and 120, as suggested by Currie and Thorburn (1974), who studied the effect on CL function of hysterec-

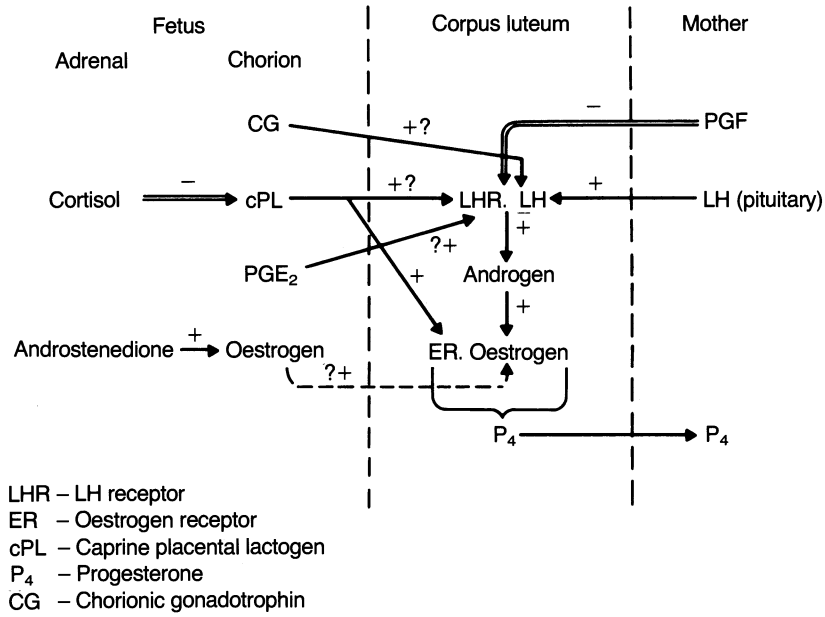

Figure 9.11 The putative mechanisms involved in trophic regulation of the CL of pregnancy in the goat. (Modified from Thorburn, 1978.)

tomy (between days 30 and 50) in pregnant goats.

The evidence in favour of the luteotrophic action of cPL has been summarized by Malecki (1989) as follows:

1. cPL becomes detectable by radioreceptor assays in the peripheral plasma at about day 50 of gestation and reaches peak levels at days 110–130 (Currie *et al.*, 1977).
2. An increase in peripheral P_4 concentrations occurs between days 30 and 50 of pregnancy (Thorburn and Schneider, 1972) which corresponds to the appearance of cPL in the maternal circulation.
3. Hysterectomy of goats between 30 and 50 days of pregnancy results in a decline in peripheral P_4 to less than half presurgery levels, suggesting that a luteotrophin originating from the conceptus has been removed (Currie and Thorburn, 1974).
4. Two out of four goats hypophysectomized at day 60 of gestation aborted despite replacement therapy with 1 mg of LH per day, suggesting that cPL production at this stage of pregnancy may be too low to maintain CL function.

Based on the observations of Currie and Thorburn (1974) and Buttle (1978, 1983) it was suggested that cPL and LH may form a luteotrophic complex around day 50 of pregnancy in the goat (Figure 9.11).

A more detailed description of a possible caprine luteotrophic complex is given by Thorburn (1979), but there is still no direct evidence that cPL plays a luteotrophic role in the pregnant goat and cPL has not yet been isolated and purified. It would be of interest to repeat the passive immunization experiments of Malecki *et al.* (1987) using antiserum to cPL as well as oLH.

(a) Chorionic gonadotrophin

Material showing activity in an hCG radioimmunoassay and bovine granulosa cell radioreceptor assay has been detected (prob-

ably a large molecular weight glycoprotein) in placentas from goats at 61, 69, 74 and 143 days of pregnancy (Malecki, 1989). This material did not cross-react in an LH radioimmunoassay, suggesting that it was not LH of pituitary origin bound to cotyledonary tissue.

An hCG-like material was also tentatively identified in the urine of pregnant (60–140 days' gestation) but not non-pregnant goats. The urinary CG-like material could be the same as the high molecular weight form identified in the placenta because the glycosylated side chains could be removed to permit filtration by the kidney. It was difficult to estimate accurately the level of CG-like material in goat placental tissue as the degree of cross-reaction of the hCG RIA in the radioreceptor assay was unknown, but the quantity appeared to be very low compared with that found in the placentas of other species (Malecki, 1989). However, Malecki (1989) suggests that cPL together with CG (i.e. a placental LH-like substance) may form a luteotrophic complex, together with maternal pituitary LH and prolactin, during the second half of pregnancy in the goat.

(b) Oestrogens

There is strong evidence that oestrogens are luteotrophic in some species, e.g. rabbit (Bill and Keyes, 1983; Gadsby *et al.*, 1983) and rat (Bugdanove, 1966). There appears to be no direct evidence of a luteotrophic action of oestrogens in the pregnant goat. In fact, the administration of oestradiol-17β to pregnant goats provoked $PGF_{2\alpha}$ release from the uterus and caused luteolysis with subsequent abortion (Currie and Thorburn, 1976), although oestrogens of fetoplacental origin may play a luteotrophic role during pregnancy. Ovariectomy during pregnancy maintained by a synthetic progestagen did not alter oestradiol-17β concentrations, indicating that the conceptus and not the ovary is the major source of oestrogen (Currie and Thorburn, 1977a,b; Sheldrick *et al.*, 1980). It has not yet been demonstrated whether oestrogen is part of the luteotrophic signal from the conceptus.

(c) Prostaglandin E_2

PGE_2 is the major PG produced by the goat placenta and membranes (M.D. Mitchell *et al.*, 1978f). Like the sheep (Fowden *et al.*, 1987) the goat placenta produces increasing amounts of PGE_2 (G.D. Thorburn, unpublished) and it is possible that placental PGE_2 may provide a luteotrophic stimulus for the CL of pregnancy during the last third of gestation. (For discussion on the potential luteotrophic action of PGE_2 in the pig see section 9.4.3.)

9.6.4 OESTROGEN AND THE FETAL PITUITARY-ADRENAL AXIS

In the goat, unconjugated oestrogens increase steadily in the maternal plasma throughout pregnancy before undergoing a more rapid increase over the last 4–5 days before delivery (Challis and Linzell, 1971; Thorburn *et al.*, 1972a; Umo *et al.*, 1976; Currie and Thorburn, 1977a; Flint *et al.*, 1978). The major oestrogens in maternal plasma are oestrone and oestradiol-17α, both considered relatively weak biologically. However, $E_{2\beta}$ can be formed from oestrone in maternal tissues (Challis and Linzell, 1973) and is probably the active oestrogen, plasma concentrations following a similar time course throughout pregnancy (Challis and Linzell, 1971; Flint *et al.*, 1978; Meinecke-Tillmann *et al.*, 1986). The concentrations in blood of unconjugated oestrone and oestradiol-17α are approximately one-third those of the corresponding sulphoconjugates (Thorburn *et al.*, 1972a; Currie *et al.*, 1973). Oestradiol-17α does not induce labour (Currie and Thorburn, 1976).

Active aromatase activity is present in the

goat placenta (Ainsworth and Ryan, 1970) and the progressive increase in maternal oestrogen concentrations could result from placental aromatization of C_{19} precursors derived from the fetal adrenal gland (Thorburn and Challis, 1979) because infusion of synthetic ACTH into fetal goats causes an increase in fetal and maternal oestrogen levels and premature parturition (Thorburn *et al.*, 1972a). These results could be explained in at least two ways: (1) that the fetal adrenal secretes not only corticosteroids, but also androgens, which are aromatized to oestrogen by the placenta; and/or (2) that the fetal corticosteroids induce in the placenta the enzymes needed to synthesize oestrogens *de novo*. The studies of Flint *et al.* (1978) suggested that increased production of fetal adrenal androgens is not essential for the increased oestrogen production before delivery and that, as in the sheep, high fetal levels of cortisol induce or activate placental steroid 17α-hydroxylase which increases the endogenous production of C_{19} precursors in the placenta for oestrogen biosynthesis.

In late pregnancy the goat placenta may produce small amounts of P_4 (Sheldrick *et al.*, 1980), but substantial amounts of oestrogens are secreted and plasma levels concentrations increased progressively from day 40 of pregnancy onwards; these levels are considerably higher than those found in sheep. The goat placenta also produces substantial amounts of 5β-pregnane-3α,20α-diol (Sheldrick *et al.*, 1981), which increases in the peripheral circulation between days 40 and 140 of gestation, reaching levels of 80 to 100 ng/l before decreasing rapidly before term. The main circulating products of placental steroid synthesis are therefore 5β-pregnane-3α,20α-diol, oestrone, oestradiol-17α and their sulphoconjugates. Considering the dramatic decrease in the plasma concentrations of 5β-pregnane-3α,20α-diol before parturition it is surprising that there is not a more dramatic increase in oestrogen values at this time. The possibility must exist that some other product which is synthesized in considerable amounts has been missed.

In the studies of Sheldrick *et al.* (1981), it had been assumed that the precursor of 5β-pregnane-3α,20α-diol synthesis was P_4 and that P_5 was converted by 3β-HSD to P_4, which was then reduced by 5β-reductase to 5β-reduced derivatives. However, the goat may lack a placental 3β-HSD and possess a 5β-reductase instead, leading to direct reduction of P_5 by 5β-reductase before reduction by 20α-hydroxylase through to the 20α-ol derivative. However, the major metabolite found in the circulation of the pregnant goat was the 3α-ol derivative (Sheldrick *et al.*, 1981) suggesting that it may be derived from P_4 (perhaps produced in the CL and metabolized in the placenta) or that P_5 is converted to the 3α derivative before 5β reduction.

In vitro studies (Wango *et al.*, 1988) showed that the goat does not synthesize P_4 but converts labelled P_5 to 5β-pregnanediol, which was the major metabolite. This direct route of metabolism is consistent with the hypothesis that a major difference between the sheep and the goat is that the sheep placenta contains 3β-HSD, which allows the conversion of P_5 through to P_4 (section 9.5.2), whereas in the goat there is a relative deficiency of this enzyme and the goat placenta contains a 5β-reductase which converts P_5 through to the inactive 5β-reduced derivatives. There is no information on whether the goat placenta secretes P_5, and the circulating concentrations of P_5 and P_5 sulphate in the goat are not known, but they are likely to be high.

Sheep and goats are sufficiently close phylogenetically to allow interspecies crosses to survive until approximately day 40 of pregnancy (Hancock *et al.*, 1968). This may be because the goat placenta is unable to synthesize C_{21} steroids, although this appears unlikely in view of the low uterine production of P_4 in ovariectomized or luteectomized goats in which pregnancy is maintained with MPA (Sheldrick *et al.*, 1980). However, the main difference between the

two species may relate to the presence (or not) of placental 5β-reductase or the relative activities of 5β-reductase to 3β-HSD. In species which contain 5β-reductase and metabolize P_5 to inactive metabolites, it would seem essential for the CL to remain functional and secrete significant amounts of P_4. There is an added need for the placenta to secrete luteotrophic substances to maintain the CL functional for the rest of pregnancy.

Although glucocorticoids may increase 3β-HSD activity and *de novo* placental P_4 biosynthesis from P_5, Flint *et al.* (1978) failed to find any conversion of androstenedione to oestradiol-17β by placental explants of the goat and suggested that the raised levels of oestradiol-17β in the maternal circulation at term may not be placental in origin. The mammary gland of the goat produces oestradiol-17β in late pregnancy (Maule Walker and Peeker, 1978), accounting for over 90% of the increase in peripheral plasma concentrations of oestradiol-17β near term. It is possible that oestrone or oestradiol-17α produced by the uterus may be converted into oestradiol-17β by mammary 17-dehydrogenase.

9.6.5 LUTEOLYSIS

Oestrogens are luteolytic in pregnant goats. Infusion of oestradiol-17β, but not oestradiol-17α, into late pregnant goats resulted in PGF release into the uterine vein, leading to regression of the CL (Currie and Thorburn, 1976). It was therefore proposed that increased oestrogen biosynthesis by the fetal placenta was responsible for the initiation of parturition of the goat (Currie and Thorburn, 1977a; Thorburn, 1979; Thorburn and Challis, 1979): oestradiol-17β produced by the fetal placenta would traverse the placental barrier and act on the oestrogen receptors in the maternal placenta which respond by increased production of $PGF_{2\alpha}$. Currie and Thorburn (1976, 1977a) proposed that oestrogen increased the number of oxytocin receptors, whereas P_4 acted at the nuclear locus to repress synthesis of oxytocin receptors, as occurs in sheep (Roberts *et al.*, 1976).

When premature parturition was induced with oestradiol-17β, the placenta and membranes were delivered within 12 h of the fetus, perhaps because of the oestrogen causing breakdown of the lysosomes and the release of hydrolase enzymes, causing dissolution of the maternal placenta and placental separation (Currie and Thorburn, 1977a).

Activation of fetal pituitary–adrenal function may provide a stimulus to the final increase in oestrogen concentrations before parturition (Currie *et al.*, 1973; Currie and Thorburn, 1977a; Thorburn *et al.*, 1977a,b; Thorburn, 1979). Premature parturition resulting from ACTH infusion to the fetus is associated with elevated oestrogen concentrations in fetal and maternal plasma and increased release of $PGF_{2\alpha}$ into the uterine vein (Thorburn *et al.*, 1972a; Currie and Thorburn, 1977a), suggesting that oestrogens synthesized in the fetal cotyledons crossed the placental barrier to stimulate $PGF_{2\alpha}$ production by the maternal cotyledons.

When CL regression is induced by the infusion of $PGF_{2\alpha}$ into the pregnant goat during late pregnancy, plasma P_4 concentrations decline, and 30–40 h later there is a major release of endogenous $PGF_{2\alpha}$ into the uteroovarian vein. The concentration of $PGF_{2\alpha}$ is maximal at the time of delivery of the kid (Currie and Thorburn, 1973). Similarly, endogenous $PGF_{2\alpha}$ is released 24–36 h after CL regression induced during the mid-luteal phase of the sheep oestrous cycle by $PGF_{2\alpha}$ analogues (Challis *et al.*, 1976b). In both instances P_4 withdrawal has been proposed as the stimulus for the increase in $PGF_{2\alpha}$, which is consistent with the major action of P_4 in suppressing PG release. Abortion in goats after ovariectomy or luteectomy can be prevented by exogenous P_4 (Meites *et al.*, 1951; Irving *et al.*, 1972b). When P_4 was administered to ovariectomized pregnant goats in a manner that caused large fluctuations in the

plasma P_4 concentrations, there was a significant increase in $PGF_{2\alpha}$ concentrations in the uterine vein with each fall in P_4 (Thorburn *et al.*, 1972a). After cessation of treatment, the P_4 concentrations fell and $PGF_{2\alpha}$ values rose to a plateau of about 7 ng/ml that was maintained for about 10 h before a further large increase occurred with labour itself. These experiments clearly indicate that P_4 suppresses the release of $PGF_{2\alpha}$ and suggested that the release mechanism is labile and quickly responds to variations in the plasma P_4 concentration (Thorburn *et al.*, 1972a; Currie and Thorburn, 1977b).

In contrast, when premature parturition was induced with oestradiol-17β the goats displayed striking mammary engorgement which was evident within 24 h of the start of treatment. The lactogenic response seen in these animals is in contrast to the agalactia observed in premature parturition induced with luteolytic doses of $PGF_{2\alpha}$ but is similar to that observed with fetal ACTH infusion (Thorburn *et al.*, 1972a; Currie and Thorburn, 1976). These doses of oestradiol-17β presumably stimulated the release of prolactin from the maternal pituitary which acted with the elevated oestradiol and low P_4 concentrations to give the observed lactogenic response.

9.6.6 SUMMARY

It seems likely that the following sequence of events is involved in the initiation of parturition in goats. Activation of the fetal hypothalamo-pituitary–adrenal axis causes a progressive increase in fetal cortisol concentrations during the last 10 days before delivery. Activation of the fetal adrenal may also increase the plasma concentrations of androstenedione (and other substrates) for aromatization to oestrogens by the placenta. Fetal cortisol induces 17α-hydroxylase activity in the placenta, facilitating the conversion of endogenous P_5 to oestrogens within the placenta (and chorion?). Oestrogens, in turn, act locally in the placenta (and maternal endometrium?) to stimulate increased production of $PGF_{2\alpha}$, which is released into the uterine vein. The countercurrent mechanism facilitates transfer of $PGF_{2\alpha}$ from the utero-ovarian vein to the ovarian artery and the $PGF_{2\alpha}$ initiates regression of the CL. The initial decrease in P_4 enhances the release of further $PGF_{2\alpha}$, ensuring rapid and complete regression of the CL (Figure 9.12).

High fetal cortisol concentrations also decrease maternal PL values and may thus reduce trophic support for the CL and lower maternal P_4 concentration. The decrease in P_4 levels may enhance the release of $PGF_{2\alpha}$ from the maternal placenta, and might be expected to work in concert with the high oestrogen values. The increase in the E/P_4 ratio in the placenta may increase the number of oxytocin receptors. The change in the E/P_4 ratio in maternal plasma, together with hypothalamic stimulation via the Ferguson reflex, would ensure release of oxytocin from the maternal posterior pituitary, the oxytocin causing a massive release of $PGF_{2\alpha}$ during labour.

The mammary gland also produces oestradiol-17β in late pregnancy and may contribute to the increase in the E/P_4 ratio and provide a further stimulus for $PGF_{2\alpha}$ release. The myometrium is exposed to $PGF_{2\alpha}$ indirectly from the maternal placenta and directly by diffusion from the endometrium. The relative importance of these two routes has not been established. The sensitivity of the myometrium to $PGF_{2\alpha}$ increases with the fall in P_4 concentrations. It is not yet known whether PGE_2 exerts a stimulatory action on the caprine myometrium or the exact site of its synthesis. However, using the sheep analogy, PGE_2 is probably synthesized in the chorion and fetal placenta and may reach the myometrium by the same route as $PGF_{2\alpha}$.

9.7 CATTLE

The major endocrine changes associated with parturition (days 277–290) in cattle are mostly

clearly defined. Some features are similar to those of other ruminants such as the sheep and goat, but differences are apparent particularly in the source of P_4.

9.7.1 ROLE OF THE FETUS

Studies of prolonged pregnancy in cattle yielded the first clear evidence of an essential role for the fetus in the initiation of parturition in any species. Genetic analysis of inbred stock (Jasper, 1950; Kennedy *et al.*, 1957) showed that, although the patterns of inheritance are similar, there are at least two distinct genetically controlled syndromes (Kennedy *et al.*, 1957, 1967). Since a cow that is heterozygous for the mutant gene may have normal or abnormal pregnancies in any sequence when bred to a heterozygous bull, Holm (1967) postulated that the bovine fetus

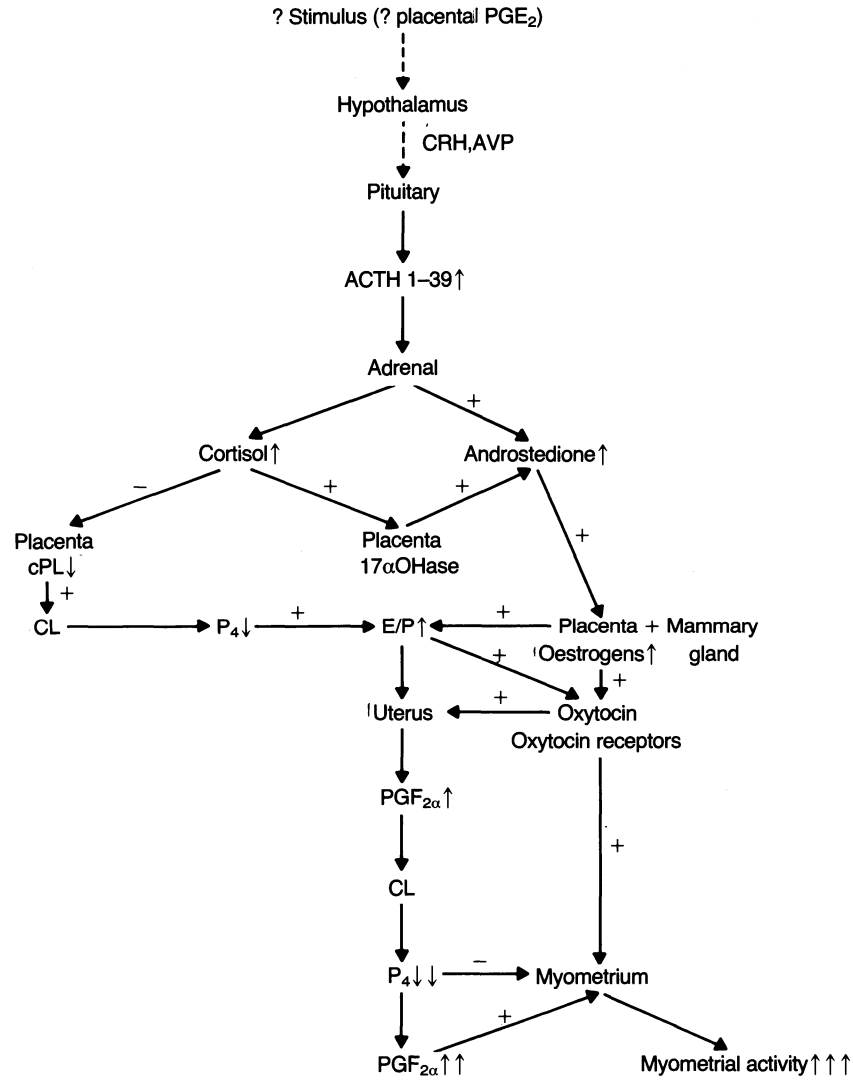

Figure 9.12 The pathways involved in the initiation of parturition in the goat.

interacting with the maternal organism controls the length of its intrauterine life. The circumstantial evidence derived from study of the malformed calves points strongly to the anterior pituitary as the primary defect causing prolonged pregnancy, with adrenocortical insufficiency as the next step in the chain. Although the roles of the fetal pituitary and adrenal have not been investigated directly by experimental ablation in cattle, much evidence is available to support the hypothesis that parturition in cattle is initiated, as it is in sheep, by activation of the fetal pituitary–adrenal system. The concentration of cortisol in fetal plasma rises prepartum, but there is some disagreement as to the magnitude of the increase. Comline *et al.* (1974), who studied 10 chronically cannulated fetuses, reported that the concentration of cortisol was usually <5 ng/ml before 250 days of gestation, rising to about 10 ng/ml in fetuses 7–10 days before parturition and to a mean value of 61 ng/ml within 1 h of birth, which was premature at a mean of 264 days. In the series of five animals described by Hunter *et al.* (1977), values up to 7 days before parturition were similar to those reported by Comline *et al.* (1974), but the higher mean prepartum value (74 ng/ml) was attributed to delivery at term. Takeishi *et al.* (1989) reported similar findings in late pregnancy but did not sample close to term. However, the concentration of 88 ng/ml found in neonates immediately after delivery agrees with that of 94 ng/ml found by Comline *et al.* (1974). ACTH concentrations rise from 60–70 pg/ml at 210 days to 240 pg/ml at 240 days and to 400 pg/ml at 270 days (Takeishi *et al.*, 1989), but values in the neonates fell to 180 pg/ml, a finding interpreted as evidence that the prepartum increase in cortisol concentrations may be due to an increase in the sensitivity of the adrenal to ACTH.

Intramuscular or intravenous injections of ACTH into chronically cannulated fetuses but not the mother cause premature parturition (Welch *et al.*, 1973) after a delay of about 6 days. The concentration of cortisol increases during treatment in a pattern similar to that at normal term and is associated with changes in maternal plasma oestrogen and P_4 concentrations that mimic the normal pattern. Fetal treatment with cortisol has been investigated in only one animal (Comline *et al.*, 1974): 100 mg of cortisol were injected four times daily intravenously and premature parturition at 257 days was observed after 5[1/2] days. The relatively long latent period in the cow compared with that in sheep (about $2\frac{1}{2}$ days) may be attributable to the intermittent nature of the administration because parturition can be induced in as short a time at 3 days by continuous fetal infusion of dexamethasone (Fairclough *et al.*, 1981). Fairclough *et al.* (1981) described a dose relationship to latent period which was 12, 9 and 3 days respectively for daily infusion rates of dexamethasone of 0.1, 1.0 or 10.0 mg. The lowest dose was associated with a 10-fold increase in cortisol concentration during the 3 days before calving. These observations are consistent with the existence of negative feedback 6 weeks before term in the bovine fetus and also with a maturational effect of glucocorticoid on the hypothalamus–pituitary whereby the threshold of negative-feedback is progressively raised. A dose-related response in fetal oestrogen concentration also was found: with <2.2 mg of dexamethasone per day, no change in conjugated oestrogen concentration occurred, but at a dose of 10 mg/day fetal oestrogen values rose sharply before the rise in maternal oestrogen concentrations. Fairclough *et al.* (1976) postulated that fetal corticosteroids not only stimulate placental production of oestrogen but also influence the relative amounts of oestrogen secreted into the fetal and maternal circulations.

Maternally administered corticosteroids for inducing parturition have been extensively studied because of their commercial utility in inducing calving in dairy cattle that would

otherwise calve late in the milking season. In general, the patterns of concentrations of P_4, oestrogen and PGs in the maternal circulation after corticosteroid administration closely resemble those at normal term. However, the time course of the changes is strongly dependent on the gestational age, the latency to delivery ranging from 13 days at 240 days (Hunter *et al.*, 1974) to as short as 36 h at 272 days (B. Hoffman *et al.*, 1973).

Little work has been done in the past 15 years with chronically cannulated fetal preparations (probably because of the cost of experimental animals) and knowledge of the hypothalamo-pituitary–adrenal axis in fetal calves does not match that in fetal sheep. Although it is likely that many of the observations made in fetal sheep can be extrapolated to the bovine fetus, there is a need to apply recently developed techniques to a relatively few well-planned experiments to confirm the validity of extrapolation.

9.7.2 PROGESTERONE

The changes in P_4 concentrations in maternal peripheral plasma follow a well-defined pattern on which there is general agreement (R.V. Short, 1958; Gomes *et al.*, 1962; G.S. Pope *et al.*, 1969; Donaldson *et al.*, 1970; Edqvist *et al.*, 1970; Stabenfeldt *et al.*, 1970; Robertson, 1972; Schrams *et al.*, 1972; R.E. Short *et al.*, 1989). During the last 28 days of pregnancy, concentrations remain steady in the range 5–15 ng/ml until about 7 days before parturition, when they decline steadily to 3 ng/ml at 48 h before parturition. This fall coincides temporally with rising concentrations of cortisol in the fetus (Hunter *et al.*, 1977). During the final 48 h, P_4 values fall rapidly to <1 ng/ml. The maternal administration of dexamethasone in doses of 10 or 20 mg is associated with a sharp fall in P_4 concentration to about 1 ng/ml (Edqvist *et al.*, 1972) immediately before premature parturition.

The source of P_4 in bovine pregnancy has been controversial. The placenta can synthesize P_4, as demonstrated by incubations of homogenized tissue (Ainsworth and Ryan, 1967) or dispersed heterogeneous populations in culture (Shemesh *et al.*, 1984b), but the amounts are small compared with those released by placental tissue in other species. The cell type responsible for P_4 is the BNC (Reimers *et al.*, 1985) which, although of fetal origin, migrates into the maternal epithelium (Wooding and Wathes, 1980). However, there is no clear evidence that the placenta secretes P_4. Indeed, the concentration of P_4 in uterine venous plasma is lower than in peripheral venous or arterial blood (Comline *et al.*, 1974; Fairclough *et al.*, 1975), although S.M. Pimentel *et al.* (1986) found higher concentrations of P_4 in uterine venous blood than in arterial blood at 250 days and no difference at 270 days. Early ovariectomy experiments attempting to resolve the question of the relative roles of the placenta and CL suggested that the placenta might secrete P_4 in substantial amounts in late pregnancy because bilateral ovariectomy caused abortion only when performed before 200 days. However, when ovariectomy was performed after 200 days (Estergreen *et al.*, 1967) there was a fall in the concentration of P_4 to >10% of preoperative values (Edqvist *et al.*, 1973a), confirmed by Wendorf *et al.* (1983). These findings undoubtably show that the CL is the major source of P_4 in bovine pregnancy but leave unanswered the question of the source of the 10–20% of P_4 remaining in the plasma after bilateral ovariectomy. Fairclough *et al.* (1975) postulated that the maternal adrenal might be the source because Balfour *et al.* (1957) reported that the concentration of P_4 concentration in adrenal venous blood in pregnant cows at 210 and 240 days of gestation was 10–100 times greater than in adrenal arterial blood. Wendorf *et al.* (1983) compared the effects of bilateral ovariectomy, bilateral maternal adrenalectomy and a combination of the two procedures performed at

215 days: the duration of pregnancy in adrenalectomized animals compared with intact controls was unaffected, whereas ovariectomy was associated with delivery 8 days earlier than in controls: ovariectomized/adrenalectomized animals aborted within 4 days of operation. Plasma P_4 concentrations fell slightly after adrenalectomy, to 20% after ovariectomy and to undetectable levels after the combined operation. Wendorf *et al.* (1983) therefore concluded that, at least after 215 days of gestation, the placenta does not secrete P_4 and that the CL is the major source, and that the adrenal secretes sufficient P_4 to maintain pregnancy until rising oestrogen concentrations near term cause a marked shift in E/P_4 ratio. Nevertheless, the results of S.M. Pimentel *et al.* (1986) leave open the possibility that the placenta secretes small amounts of P_4 at 250 days.

The prepartum fall in P_4 appears to be obligatory for the initiation of parturition at term since administration of P_4 or MPA can prolong pregnancy by 7–10 days (L.E. McDonald *et al.*, 1953; Nellor, 1963). However, the prolongation is unpredictable and fetal death is not uncommon. McDonald and Hays (1958) treated cows with P_4-in-oil starting 33 days before term with a regimen that was able to prevent abortion after luteectomy, but observed no prolonged pregnancies. However, the dose of P_4 was probably insufficient to prevent a substantial fall in plasma P_4 at term. In other studies using similar doses of P_4, pregnancy was either not prolonged (Holm, 1967) or prolongation occurred in some but not all animals (Kiesel and Autrey, 1961). Fairclough *et al.* (1984) examined the effect of progestagens on premature parturition induced by intrafetal infusion of dexamethasone: the cows were infused intravenously with P_4 or megestrol acetate. Treatment with P_4 prevented the fall in P_4 concentrations in untreated cows. Parturition was prevented in all treated animals although concentrations of $PGF_{2\alpha}$ in utero-ovarian venous blood increased as in untreated animals. Delivery occurred within 2 days of stopping treatment with progestagen.

9.7.3 OESTROGENS

The concentration of unconjugated oestrone in plasma exceeds that of oestradiol-17β by 3–5 times, but the ratio is fairly constant throughout the second half of pregnancy. Oestrone concentrations are >100 pg/ml from 140 days of gestation until 260 days, when levels began to rise steadily to reach a peak at term of about 2000 pg/ml oestrone and about 200 pg/ml of oestradiol-17β (Edqvist *et al.*, 1973b). In general, these changes have been confirmed by others using radioimmunoassays (Robertson and King, 1974; B. Hoffmann *et al.*, 1977; Hunter *et al.*, 1977), but opinions differ as to whether a fall in concentration occurs during the 24 h before parturition. Peterson *et al.* (1975) and Hunter *et al.* (1977) reported well-defined peaks of both oestrone and oestradiol-17β beginning 7–10 days before term and reaching maximal values about 3 days before term before falling sharply during the 24 h before parturition (Figure 9.13).

There was no increase in fetal oestrogens accompanying the peak in maternal plasma. Maternal plasma also contains oestradiol-17β but in much lower concentrations than in fetal plasma, where it is the dominant oestrogen. Unconjugated oestrogens form only 1–10% of total oestrogens (B. Hoffmann *et al.*, 1977).

The source of oestrogen in the maternal circulation is probably the placenta; neither fetectomy (B. Hoffmann *et al.*, 1979) nor bilateral ovariectomy and bilateral adrenalectomy (Wendorf *et al.*, 1983) causes a fall in oestrogen values. The concentration of oestrogen in utero-ovarian venous blood is higher than that in peripheral blood (Robertson, 1972; Peterson *et al.*, 1975; G. Evans and Wagner, 1981). The nature and site of synthesis of oestrogen precursors remain uncertain, but the experiments described above make it

likely that they are derived largely, if not entirely, from C_{21} steroids synthesized in the placenta. Whether the precursors are Δ_4 or Δ_5 steroids derived from P_4 or P_5 respectively is also uncertain. Fetal placental minces and enriched preparations of BNCs convert P_5 primarily to P_4 in late pregnancy, but the product becomes predominantly oestrogens prepartum (Gross and Williams, 1988). The rate of conversion of P_5 to androstenedione

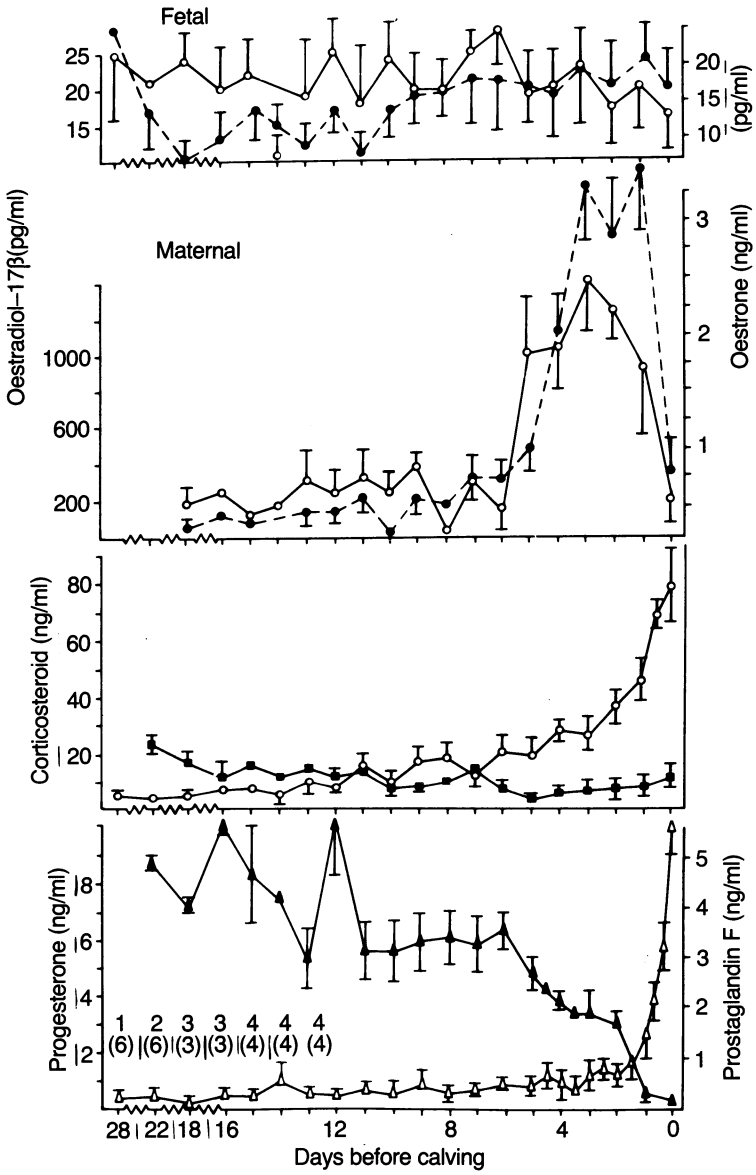

Figure 9.13 Plasma concentrations of fetal and utero-ovarian oestrone (●) and oestradiol-17β (○), fetal (○) and maternal (■) jugular corticosteroids, maternal jugular progesterone (▲) and utero-ovarian $PGF_{2\alpha}$ (△) preceding parturition in the cow. (Reproduced with permission from Fairclough *et al.*, 1976; 1984.)

and oestrogen is increased by exposure to dexamethasone. These findings *in vitro* are consistent with the observations *in vivo* that treatment of the pregnant cow or the fetus with glucocorticoids is associated with a marked peak in the concentration of plasma oestrogens (Fairclough *et al.*, 1981) and suggest that the prepartum rise in oestrogens is the result of activation by fetal cortisol of 17α-hydroxylase and C17,20-lyase, as it is in sheep. This is supported by the demonstration that exposure of placental tissue *in vitro* to glucocorticoids enhances the activity of 17α-hydroxylase (Flint *et al.*, 1979) and by the observation that maternal oestrogen concentrations increase in corticosteroid-treated, ovariectomized cows despite suppressed maternal and fetal adrenal activity (B. Hoffman *et al.*, 1977). The question of the relative importance of the Δ_4 and the Δ_5-pathways was investigated by Hoedemaker *et al.* (1990), who incubated fetal villi with various tritiated steroids. They confirmed a dose-dependent, stimulatory action of cortisol on the conversion of androstenedione and P_5 to oestrogen and found that androstenedione, P_5 and 17α-OH-P_4 were the preferred substrates. The relative conversion rates of androstenedione and DHEA to oestrogen were not investigated.

9.7.4 PROSTAGLANDINS

The concentration of $PGF_{2\alpha}$ in utero-ovarian venous plasma remains low (1 ng/ml) throughout the last month of pregnancy until 36–48 h before parturition. A gradual rise then occurs until 24 h prepartum, when the concentration rises sharply to reach 5–7 ng/ml (Fairclough *et al.*, 1975; Hunter *et al.*, 1977; Gimenez *et al.*, 1983) (Figure 9.13). The concentration of PGFM in peripheral blood follows a similar pattern (Edqvist *et al.*, 1978). Although there is no correlation of PGF or PGFM concentrations with the slow decline in P_4 concentrations during the last week of pregnancy, the final sharp fall in P_4 values during the final 24 h prepartum coincides in onset with the marked increase in PGF_2 in utero-ovarian plasma and of PGFM in peripheral plasma, suggesting a luteolytic role for $PGF_{2\alpha}$. Luteectomy on day 250 after infusion of oestrone for 4 days fails to stimulate secretion of $PGF_{2\alpha}$, indicating that the fall in P_4 production in normal cows is more likely to be a consequence of the sharp increase in $PGF_{2\alpha}$ than its cause (C.A. Pimentel *et al.*, 1986). Furthermore, the infrequent blood sampling regimens in all studies to date leave open the possibility that the final rise in $PGF_{2\alpha}$ is preceded by brief spikes of release of $PGF_{2\alpha}$, as occurs during luteolysis in the oestrous cycle.

The stimulus of $PGF_{2\alpha}$ secretion at term remains uncertain. Neither oestrone infusion at 246 days nor removal of the major source of P_4 by luteectomy at 250 days stimulates secretion (C.A. Pimentel *et al.*, 1986) but it is possible that an increase in E/P_4 ratio nearer term could be effective. Nevertheless, the increase in $PGF_{2\alpha}$ concentrations normally associated with the marked increase in E/P_4 ratio before parturition induced by intrafetal infusion of dexamethasone is not impaired by large doses of progestagen that block parturition (Fairclough *et al.*, 1984). In addition, increased concentrations of oestrogen in maternal blood are not obligatory for release of $PGF_{2\alpha}$ since intrafetal infusion of low doses of dexamethasone are effective in inducing release of $PGF_{2\alpha}$ and parturition although oestrogen levels are unchanged (Fairclough *et al.*, 1981). However, plasma oestrogen concentrations may be an insensitive indicator of concentrations within the endometrium close to the site of synthesis in the placenta.

An endometrial inhibitor of synthesis may also contribute to the regulation of PG release. Shemesh *et al.* (1984a) described an endogenous, heat-labile inhibitor extracted from maternal caruncular tissue of placentomes. The activity was present in extracts from 120–0 day placentomes but was not de-

tectable after 260 days. Co-cultures of 120-day tissue (but not term tissue) with fetal cotyledonary cells inhibited PG synthesis. Nothing is known of the factors responsible for the disappearance of inhibitory activity in late gestation. On the whole, while the evidence that release of $PGF_{2\alpha}$ is determined mainly by the E/P_4 ratio is inconclusive, it seems to be the likeliest mechanism. Studies with inhibitors of P_4 synthesis and P_4 receptors such as epostane and mifepristone respectively are needed to resolve the issue.

The source of PGs released into the uteroovarian vein is thought to be mainly the placenta. Synthesis of labelled PGs from tritiated arachidonic acid was greater in the fetal villus than the maternal crypt component of late gestation placentomes and increased prepartum in both components, the predominant product being PGE_2 from fetal tissue (Gross *et al.*, 1987). The latter observation is not consistent with the concentrations of PGE_2 in fetal blood reported by Gimenez *et al.* (1983): blood samples were obtained acutely from 80 to 260 days of pregnancy and the concentration of PGE_2 in the umbilical artery and vein was less than half that of $PGF_{2\alpha}$ or PGFM. Whether PGE_2 increases prepartum in the fetal calf circulation as it does in the sheep fetus is unknown. Highly enriched suspensions of BNCs produce PGE_2 and, to a lesser extent, PGI_2 (Reimers *et al.*, 1985), but the production of PGF_2 was not measured. Dispersed fetal binucleate cells, rather than fetal principal cells, were the major site of synthesis of PGs, and PGE_2 predominated (Gross and Williams, 1988).

The above studies do not appear to have clarified the source of the large quantity of $PGF_{2\alpha}$ released into the maternal circulation immediately prepartum. By analogy with other species, it is most likely to be maternal tissues, but incubation of minces of maternal caruncles are not confirmatory; the possibility that intercaruncular endometrium is more active in production of $PGF_{2\alpha}$ has not been explored.

9.7.5 OXYTOCIN

The concentration of oxytocin in peripheral plasma in late pregnancy is low (1–3 pg/ml), and no increase is found until the forelegs of the calf distend the vagina late in the second stage of labour (Landgraf *et al.*, 1983), confirming the early observations made with bioassays (Fitzpatrick and Walmsley, 1965). Maximal values of 60–116 pg/ml are reached at the time of delivery. Intravenous or intramuscular injections of pig relaxin near term stimulate oxytocin release within 30 min (Musah *et al.*, 1989), but the significance of this observation is unclear. The concentration of oxytocin receptors and the interrelationships of oxytocin and PGs have not been studied for cattle.

9.7.6 RELAXIN

Relaxin has been isolated from CL late pregnant cows (M.J. Fields *et al.*, 1980), but the concentration in the circulation has not been described. When pig relaxin is administered into the cervical canal in late pregnancy there is marked cervical dilatation, relaxation of the pelvic ligaments and shortening of the duration of pregnancy by about 2 days (Perez-grovas and Anderson, 1982; Musah *et al.*, 1986). There was also a sharp fall in P_4 values and a rise in oestrogen levels within 24 h of treatment, but the reasons are unknown. Intramuscular treatment with relaxin is ineffective (Caldwell *et al.*, 1990).

9.7.7 SUMMARY

The bovine placenta does not secrete P_4 in significant amounts and the source of circulating P_4 is mainly the CL, but the maternal adrenal may secrete sufficient P_4 to maintain pregnancy after ovariectomy. Parturition is initiated by luteolysis, probably induced by $PGF_{2\alpha}$ from a uterine source that remains undefined. The release of $PGF_{2\alpha}$ is stimulated by a sharp prepartum increase in concen-

trations of fetal cortisol, but the mechanism is uncertain since neither increased oestrogen levels nor reduced P_4 concentrations (or both) stimulate release. The roles of oxytocin and relaxin have not been elucidated. In many respects, the mechanism of initiation of parturition in cattle resembles that in goats.

9.8 HORSE

Information relating to parturition in the horse is insufficient to propose a coherent hypothesis for the mechanism of initiation of parturition. Available evidence makes it clear, however, that the horse differs markedly from ruminants and also differs in many respects from primates.

9.8.1 ROLE OF THE FETUS

The classical demonstration that the duration of pregnancy is determined by the genotype of the fetus was cross-breeding experiments in equids. The duration of pregnancy in the horse (stallion × mare) is 340 days and of the donkey (jack × jenny) is 365 days; the stallion × jenny cross is 350 days and the jack × mare cross is 355 days. However, these experiments cannot be interpreted as proving that the fetus itself plays the major part since the genes that are expressed may lie not in the fetus but in the placenta and/or fetal membranes, as they may in human pregnancy. The technical difficulties of obtaining surgical access to the fetal horse and of maintaining chronic preparations has prevented critical experiments such as fetal hypophysectomy and adrenalectomy. Experiments of nature in which the fetus lacks hypothalamic–pituitary tissue or adrenal glands have not been reported. The plasma concentrations of cortisol in the fetal horse are unusual in showing no increase until 48 h before parturition and a marked increase in concentration only during parturition. Rossdale and Silver (1982) point out the wide range of gestation lengths that are compatible with mature foals when the onset of labour is spontaneous and yet the likelihood of delivery of an immature fetus when labour is induced with PG analogues within the term range. They suggest that 'readiness for birth' is linked to fetal adrenal activity and occurs close to the natural time of delivery. These observations and the infrequency of premature birth under natural conditions suggest that a signal, whether endocrine or paracrine, must pass from the fetus to the mother to indicate the foal's readiness for birth. Whether the signal is dependent on heightened activity of the fetal hypothalamic-pituitary–adrenal system is unknown, but the ability of dexamethasone administered to the mare to shorten pregnancy (Alm *et al.*, 1975) is consistent with the notion. However, labour does not start for several days after dexamethasone treatment is stopped, which makes it unlikely that the corticosteroid acts directly as it does in sheep and goats.

Corticosteroid treatment accelerates maturation of the fetal horse (G.C. Liggins, unpublished observations) and it is possible that the effect of dexamethasone on the timing of parturition is expressed by advancing fetal maturation. The observation of Alm *et al.* (1975) that P_4 treatment was as effective as dexamethasone in shortening pregnancy length is unexplained.

9.8.2 PROGESTERONE

Ovariectomy in pregnant mares up to 70 days of gestation causes abortion unless followed by P_4 treatment but is compatible with continuing pregnancy when performed at 140 days (Holtan *et al.*, 1979), indicating that the placenta is a major source of P_4 throughout the second half of pregnancy. The pattern of plasma concentrations differs from that in other species. Peripheral concentrations increase early in pregnancy, peak at 60–120 days and subsequently fall to low (Holtan *et al.*, 1975; Seamans *et al.*, 1979; Seren *et al.*,

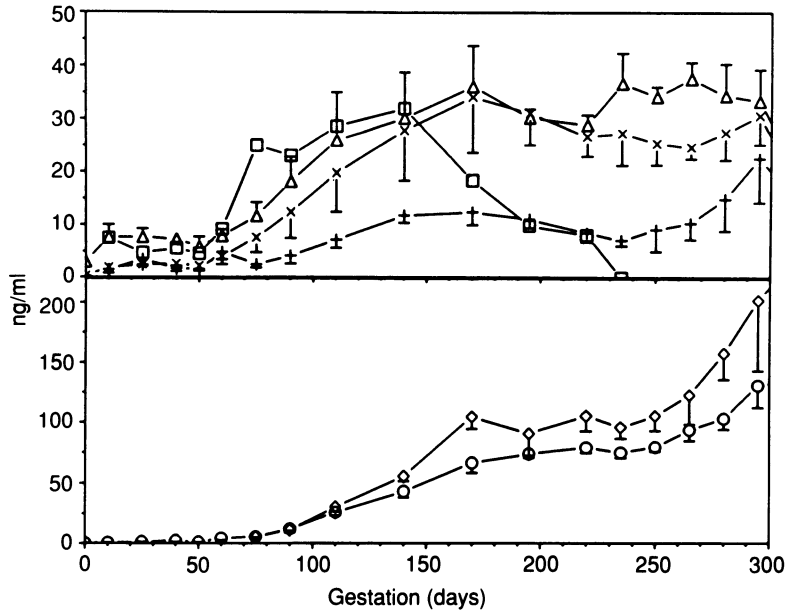

Figure 9.14 Plasma progestagens measured by GC–MS in pregnant pony mares. (□) = progesterone; (△) = 5α-pregnane-3,20-dione; (×) = 3β-hydroxy-5α-pregnan-20-one; (+) – 5α-pregnane-3β,20β-diol; (◇) = 20α-hydroxy-5α-pregnan-20-one; ( ) = 5α-pregnane-3β, 20α-diol. Means, ± SEM. (Reproduced with permission from Holtan *et al.*, 1991.)

1981; N.S. Pope *et al.*, 1987) or undetectable (Holtan *et al.*, 1991) values. Holtan *et al.* (1991), using highly specific gas chromatography–mass spectrometry (GS–MS), found no detectable P_4 after 240 days but substantial quantities of 5α-reduced metabolites, illustrating the problems associated with the use of less specific methods by earlier workers (Figure 9.14).

The predominant steroids are 20α-hydroxy-5α-pregnan-3-one (400–2100 ng/ml) and 5α-pregnane-3β,20α-diol (100–350 ng/ml). These first appear in the plasma between 30 and 60 days and increase gradually until about 30 days prepartum, when concentrations rise more rapidly until 2–3 days prepartum, when a slight fall occurs. Four other mono and dihydroxy-5α-pregnanes identified by Holtan *et al.* (1991) are present in relatively low concentrations (30–100 ng/ml). It is difficult to reconcile the results obtained by GC–MS with those of Seamans *et al.* (1979) using chromatography/radioimmunoassay (RIA), who observed marked falls prepartum in both 5α-dihydroprogesterone (from 130 to 10 ng/ml) and total hydroxy-5α-pregnanes (from 1400 to 100 ng/ml). Present evidence suggests that circulating P_4 is not required for the maintenance of pregnancy after 200 days but the role that 5α-pregnane metabolites might play remains uncertain until information about their biological activities becomes available.

Fowden and Silver (1987) investigated the effects of inhibiting P_4 synthesis by administering epostane, a 3β-HSD inhibitor, for 9 days at 292 days of pregnancy. Although plasma P_4 concentrations (measured by RIA) fell rapidly and remained depressed throughout treatment, none of the mares delivered prematurely. The results of similar experiments with the P_4 receptor blocker, mifepristone, may help resolve the question of whether progesterone or its metabolites have

a significant place amongst the hormones maintaining pregnancy and controlling parturition.

9.8.3 OESTROGENS

The equine placenta lacks 17α-hydroxylase and requires androgen as substrate for synthesis of oestradiol-17β and oestrone (Ainsworth and Ryan, 1969). The fetal gonad rather than the fetal zone of the adrenal is the source of DHEAS metabolized by the equine placenta (Raeside *et al.*, 1979). Regression of the fetal gonads in late pregnancy is reflected in falling concentrations of plasma oestrogens including biologically inert equilin and equilenin in the mare. This suggests that the gonads are the source of substrate for oestrone and equilin, but the nature of the substrate for equilin is unknown because administration of labelled DHEA to the fetus yields labelled oestrone but not equilin (Pashen *et al.*, 1982). The concentration of oestradiol-17β in maternal plasma rises from very low values after 108 days until 153 days, when levels rise rapidly to peak values at 198 days then decline progressively after 279 days, but the interval from peak values to parturition varies greatly (Haluska and Currie, 1988). No significant changes in the concentration of oestradiol-17β occur near parturition.

Fetal gonadectomy results in an immediate and sustained fall in maternal plasma oestrogen concentrations, but P_4 values are unaffected. Dysmature foals are delivered at term (Pashen and Allen, 1979). Parturition can therefore occur normally despite the maintenance of a very high P_4–oestrogen ratio. The administration of large doses of stilboestrol to mares from 321 days to foaling has no effect on the length of gestation, although softening and dilatation of the cervix occurs soon after the start of treatment (Alm *et al.*, 1975). These observations indicate that oestrogen is unlikely to play a significant part in initiating parturition, even permissively.

9.8.4 OXYTOCIN

The myometrium of the pregnant horse is very sensitive to oxytocin near term and parturition can be induced rapidly by a single dose of oxytocin (Hillman, 1975; Rossdale *et al.*, 1984), which presumably reflects a high concentration of oxytocin receptors. It is likely that the ability of oxytocin to induce rapid delivery is dependent on prior changes in the cervix that render it distensible, but this has not been studied. Nothing is known of the sensitivity to oxytocin earlier in pregnancy or of the factors that influence the formation of oxytocin receptors. The patterns of P_4 and oestrogen concentrations in late pregnancy do not encourage the view that the sensitivity to oxytocin is determined by these steroids.

The concentration of oxytocin in the peripheral circulation remains at very low values throughout pregnancy (Haluska and Currie, 1988) until the expulsive stage of labour, when peaks of variable magnitude are found (Allen *et al.*, 1973; Haluska and Currie, 1988).

Mares have an usually high degree of maternal control over the expulsive phase of labour, suggesting that the high sensitivity to oxytocin coupled with the low circulating concentrations provides a means for the maternal control of parturition by inhibiting release of oxytocin through neural mechanisms (Haluska and Currie, 1988). The administration of oxytocin is followed immediately by the release of $PGF_{2\alpha}$ (Barnes *et al.*, 1978; Rossdale *et al.*, 1979), although manual dilatation of the cervix is not, indicating that a cervical reflex stimulating oxytocin release is absent in the horse.

9.8.5 RELAXIN

Relaxin in peripheral plasma assayed by heterologous RIA shows no change prepartum or until the expulsive stage of labour, when there is a sharp increase (Stewart *et al.*,

1982), probably due to a response to oxytocin because it can be reproduced by an intravenous bolus of oxytocin, but mediation by the release of $PGF_{2\alpha}$ cannot be excluded. The source of relaxin is likely to be the placenta; relaxin concentrations in the blood persist after delivery while the placenta is retained but fall after expulsion, and release of relaxin can be stimulated by oxytocin while the placenta is retained but not after expulsion (Stewart *et al.*, 1982).

The function of relaxin in equine parturition has not been studied and there is no direct evidence that it is involved in the connective tissue changes in the cervix and pelvic ligaments associated with parturition or with myometrial contractility. The nonpregnant cervix is notable for its unusual distensibility, having longitudinal folds rather than annular rings, as in other farm species, and readily permits the passage of large instruments (Ginther, 1979). This suggests that relaxin may be relatively unimportant in relation to prepartum cervical function.

However, studies of EMG activity in the myometrium in two pony mares led Haluska *et al.* (1987a) to propose that the unusual pattern of myometrial activity in equine parturition is attributable to the effects of relaxin. During the week before parturition, uterine activity has a diurnal rhythm with infrequent contractions during the day and increased activity at night. On the day before parturition, increased activity is present during the day and becomes persistently increased during the early daylight hours of the day of parturition. However, a phase of myometrial quiescence lasting 2–4 h separates labour from rupture of the membranes and the expulsive phase of labour, a pattern that appears to be unique to the mare. The quiescent phase precedes the sharp increase in relaxin concentrations during the expulsive phase. Immediately after delivery, myometrial quiescence returns and persists until the placenta is expelled.

When the photoperiod was reversed for 40 days before expected term, 58% and 16% of mares delivered at 08:30–16:30 h and 22:30–08:30 h, respectively, compared with 13% and 80% of control mares at these times (Bosc *et al.*, 1988).

9.8.6 EICOSANOIDS

Daily intramuscular injections of 12 mg of $PGF_{2\alpha}$ in mares in late pregnancy does not induce labour (Alm *et al.*, 1975), possibly because of inadequate dosage. The synthetic analogue, fluprostenol, is very effective, stimulating labour and delivery within 90 min in most animals (Rossdale *et al.*, 1979). The administration of fluprostenol is associated with an almost immediate increase in plasma concentrations of PGFM, which rise to very high levels at delivery if foaling occurs within 90 min. In mares foaling after >90 min, PGFM values fall rapidly at the time of delivery, suggesting that the release of PGFM is not directly related to uterine activity or distension of the birth canal. Measurements of oxytocin have not been made, and it is not known whether fluprostenol stimulates release of oxytocin, which could mediate the effect of fluprostenol on release of $PGF_{2\alpha}$. Rossdale *et al.* (1979) considered this to be unlikely because of the variable time (up to 60 min) from injection of fluprostenol to the release of $PGF_{2\alpha}$. These experiments cannot be interpreted as unequivocal evidence that $PGF_{2\alpha}$ acts on the myometrium or has an obligatory role in parturition. The effects of cyclo-oxygenase inhibitors such as indomethacin on the time of parturition in horses have not been reported.

The concentration of PGFM in maternal plasma is low until after 200 days, when a progressive rise occurs to a plateau about 15 days before term, which is maintained until parturition (Barnes *et al.*, 1978; Stewart *et al.*, 1984; Haluska and Currie, 1988) (Figure 9.15).

PGFM concentrations rise sharply in labour but not until a few minutes before rupture of

the membranes and at least 2 min after an eightfold increase in the concentration of oxytocin has occurred (Haluska and Currie, 1988). The release of $PGF_{2\alpha}$ may therefore be a consequence of the rise in oxytocin concentration since administration of oxytocin is followed within a brief interval by a marked increase in PGFM values. The existence of significant arteriovenous differences in PGFM across the uterine circulation in late pregnancy strongly suggests uterine tissues as the source of PGFM, but the precise tissue is unknown (Silver *et al.*, 1979a).

Concentrations of PGE_2 and $PGF_{2\alpha}$ increase in fetal plasma and allantoic fluid 2–6 days before parturition. The source of the PGs and the cause of the increase are uncertain, although they may be related to a fall in P_4 concentration in fetal plasma that occurs over the same period (Barnes *et al.*, 1978).

An unusual feature of PG metabolism in the horse is the marked increase in the output of PGFM from the uterus during fasting for 20–30 h (Silver and Fowden, 1982). The increase in plasma concentration of PGFM correlates with the fall in plasma glucose and the rise in free fatty acids. The levels of PGFM fall promptly after refeeding or glucose infusion, reaching basal levels within 1–3 h. Despite maintenance of normal nutrition after fasting there is a strong tendency to premature parturition within 1 week. These observations indicate that a mechanism might exist whereby the fetus or placenta can recognize nutritional deprivation and respond by setting in motion the means to escape from an unfavourable intrauterine environment. However, it is surprising that the response should occur after such a brief period of undernutrition.

9.8.7 SUMMARY

The horse shows a remarkable sensitivity of the myometrium to oxytocin and the speed with which delivery can be induced after a single intravenous injection of oxytocin. The late onset of raised oxytocin concentrations only minutes before the expulsive phase of labour is difficult to reconcile with the increased uterine activity present for several hours before delivery unless the myometrial sensitivity to oxytocin is increasing during this period. Studies of oxytocin receptor concentrations are needed.

Convincing evidence that oestrogen, P_4 or prostanoids play a significant part in the initiation of parturition in the horse is lacking (Thorburn, 1993). The oestrogen–P_4 ratio is unimportant. The effects of oxytocin antagonists on PG release and of cyclo-oxygenase inhibitors on oxytocin release and parturition need to be investigated. At present, the most likely sequence is that oxytocin receptor concentrations rise progressively in the final days of pregnancy, perhaps in response to release of minimal quantities of an eicosanoid, allowing the myometrium to respond to the low levels of circulating oxytocin. Eventually a mechanical stimulus triggers a massive release of oxytocin, which in turn stimulates the synthesis of $PGF_{2\alpha}$; rapid expulsion of the fetus is then assured by the combined effects of the two hormones. However, this hypothesis begs the question of how the fetus communicates its readiness for birth to the parturitional mechanism. This precocial species has a remarkably wide range of pregnancy lengths yet fetal maturation compatible with extrauterine survival seems to be attained only near the time of birth.

9.9 RAT

9.9.1 INTRODUCTION

Pregnancy in the rat is maintained by P_4 secreted by the CL and parturition is preceded by a fall in circulating concentrations of P_4. Although the pregnant rat is the subject of more reports than any species other than man, the factors determining the fall in the secretion rate of P_4 are unknown. The onset of parturition in the rat and probably other murids has several features that are unique to the species and make it unsuitable as a model with relevance to parturition in primates.

9.9.2 ROLE OF THE FETUS

Implantation of fertilized ova in lactating rats does not take place at the normal time but is delayed for several days. Administration of P_4 or oestrogen shortens the delay (Yoshinaga and Hosi, 1958). This phenomenon was exploited by Yoshinaga (1961) to study the effect of the fetus on the time of parturition by inducing early implantation of some of the blastocysts with local injections of oestradiol, thus creating pregnancies containing fetuses of two different ages. Delivery of all the fetuses takes place at one time in this preparation and the time depends on the ratio of old fetuses to young fetuses. When the ratio is more than 0.3, parturition occurs at normal term (23–24 days), but if the ratio is less than 0.3 parturition is delayed until 28 days, when the older fetuses are born dead and the younger fetuses are born alive. Decapitation of the older fetuses when the ratio is more than 0.3 results in parturition at 28 days. The results were interpreted as evidence that the fetal brain or pituitary secretes a hormone that initiates parturition. However, the fetus could be secreting a hormone that maintains placental production of a luteotrophin.

No evidence that the fetal brain or pituitary plays a part in initiating labour was found by Swaab *et al.* (1977), who removed the brain and pituitary by aspiration at 19 days of pregnancy. Brain-aspirated and sham-operated animals did not differ in the length of pregnancy, although both groups had longer pregnancies than unoperated controls. Brain-

aspirated animals had more protracted labours than sham-operated controls, suggesting that the fetus may contribute to the course of labour although not to its initiation. Schriefer *et al.* (1982) proposed that parturition is triggered by oxytocin release from the fetus, but Higuchi *et al.* (1985a) found no evidence of a fall in pituitary content of oxytocin or increased plasma oxytocin in newborn animals compared with fetuses near term.

9.9.3 PROGESTERONE

The major source of P_4 in pregnancy is the CL and ovariectomy at any stage of pregnancy is followed by abortion in 12–24 h (Csapo and Wiest, 1969; Clabaut *et al.*, 1988) which can be prevented by the administration of P_4. Abortion is also induced by treatment with P_4 antiserum (Csapo *et al.*, 1975) and by the inhibitors of P_4 synthesis, azastene (Creange *et al.*, 1978) or isoxazole (Carnathan *et al.*, 1981) and by mifepristone (Bosc *et al.*, 1987). The concentration of P_4 in the uterine vein is higher than that in arterial blood, suggesting placental secretion, but very much lower than that in ovarian venous effluent (Sanyal, 1978). Homogenates of mid-pregnancy placentas produce P_4 during incubation but the production rate in placentas obtained in later pregnancy is low (Matt and Macdonald, 1984). The abortifacient effect of ovariectomy leaves no doubt that the placenta secretes insufficient P_4 to maintain pregnancy. The concentration of circulating P_4 falls sharply beginning about 36 h before the onset of parturition (Bartholomeusz *et al.*, 1976; Clabaut *et al.*, 1988). In animals of other species, the mechanism causing reduced P_4 secretion is luteolysis, but the fall in P_4 secretion by the rat CL is due, at least in part, to a sharp 72-fold increase in ovarian metabolism of P_4 to 20α-hydroxypregn-4-en-3-one (20α-P_4) (Weist, 1970). The prepartum fall in P_4 concentrations is associated with an equally large rise in 20α-P_4 levels due to a marked increase in the activity of ovarian 20α-hydroxysteroid dehydrogenase (Weist *et al.*, 1968).

Induction of a new crop of CL after 12 days of pregnancy by injections of pregnant mare serum gonadotrophin followed by LH prolongs pregnancy to 25–27 days and usually results in death of the mothers or fetuses (Takahashi *et al.*, 1979). Plasma P_4 concentrations are maintained after term and the normal increase in 20α-P_4 is greatly attenuated. These results were interpreted as evidence that the secretion of placental luteotrophin continues beyond term and that the new CL remain responsive to placental luteotrophin, the difference being attributable to low levels of LH at the time when the new CL were formed.

The prepartum fall in P_4 levels is accompanied by an equally sharp fall in the concentrations of myometrial nuclear P_4 receptors and a sharp rise in nuclear oestrogen receptors (Saito *et al.*, 1985). This pattern of changes is consistent with P_4 promoting the formation of its own receptors and inhibiting formation of oestrogen receptors, thus amplifying the effects of lowered P_4 concentrations on target tissues.

Contractile activity in the rat uterus continues throughout pregnancy despite high concentrations of P_4 (Fuchs, 1969). Paradoxically, quiescence develops during the period of 24–36 h before parturition at a time when P_4 values are falling. Administration of P_4 12 h before term is followed by normal labour at the expected time (Bernard and Ruttner, 1985). These observations suggest that P_4 may lack a direct inhibitory action on the myometrial smooth muscle. Porter and Challis (1974) found no lessening of uterine activity post partum during intrauterine treatment with P_4 for 24 h. Because oestrogen inhibits uterine activity but promotes propagation and P_4 inhibits oestrogen receptor formation, Fuchs (1978) suggested that the observed actions of P_4 are best explained as anti-oestrogen effects. According to this hypothesis, falling concentrations of P_4 at

term are associated at first with uterine quiescence due to increased expression of oestrogen, but this gives way to labour contractions as gap junctions, oxytocin receptors and PG synthesis increase in response to oestrogen. *In vitro* studies of the effects of P_4 on longitudinal and circular muscle strips show that the acute effects are complex (Osa and Ogasawara, 1984). In late pregnancy, P_4 potentiates contractions of longitudinal muscle but inhibits those of circular muscle; post partum, the action on longitudinal muscle is biphasic and on circular muscle is inhibitory.

9.9.4 OESTROGEN

The rat placenta lacks aromatase activity and does not synthesize oestrogens (Matt and MacDonald, 1984). The evidence so far suggests that the luteotrophic action of oestradiol-17β in the rat is dependent on stimulation of intraluteal oestradiol production by LH and maintenance of oestradiol receptors by prolactin or a decidual luteotropin, probably rat placental lactogen, depending on the stage of pregnancy (Gibori *et al.*, 1978, 1981; Basuray *et al.*, 1983). The ovaries are the sole source of oestrogen in pregnancy, but luteal and non-luteal tissues have limited ability to synthesize oestrogen *in vitro* in the absence of added androgen substrate in the second half of pregnancy (Taya and Greenwald, 1981).

There is good evidence that the placenta is the major source of androgen for ovarian oestrogen synthesis and that androstenedione is the preferred substrate. Although activities of 17α-hydroxylase and 17,20-lyase are absent from the placenta in early pregnancy, activities of both enzymes increase steadily from 11 days and peak at 18 days' gestation (Warshaw *et al.*, 1986). The total capacity of the placenta for androgen production greatly exceeds that of the ovaries. Peripheral plasma concentrations of androstenedione and testosterone follow the same pattern as the activity of placental 17α-hydroxylase, rising from 12 days and peaking at 18 days (Jackson and Albrecht, 1985). The lack of effect on pregnancy length of aspirating the fetal brains in entire litters (which presumably prevents only prepartum increase in cortisol levels) does not support this possibility that placental 17α-hydroxylase is inducible by rising concentrations of fetal cortisol, as in other species, thereby providing the fetus with the means of controlling steroidogenesis. However, further studies of the regulation of placental 17α-hydroxylase are needed. Concentrations of oestrone and oestradiol-17β rise progressively from about 16 days of pregnancy and peak at 21 days before falling slightly before parturition starts (Labsethwar and Watson, 1975; Fuchs, 1978). Although circulating concentrations of oestrone are higher than those of oestradiol-17β, the reverse is true in the ovarian vein (Shaik, 1971). The secretion rate of the oestrogens follow a pattern similar to concentrations in plasma and reaches 100 ng of oestradiol-17β per 24 h.

Oestrogen has an essential role in pregnancy and parturition. After ovariectomy in late pregnancy, oestrogen administration maintains pregnancy and normal parturition occurs at term, whereas untreated animals have prolonged delivery with a high fetal mortality (Catala and Deis, 1973), probably because formation of oxytocin receptors and gap junctions is impaired by lack of oestrogen. Although oestrogen is luteotrophic in rats and delays luteolysis and parturition when given at 20 days at the start of luteolysis (Behrman *et al.*, 1971), parturition is advanced by administration at 21 days when luteolysis is established (Dukes *et al.*, 1974). Daily injections of oestradiol starting at 16 days induces premature delivery at 19 days (Mackenzie and Garfield, 1986). Oestrogen may therefore advance or delay delivery depending on the timing of treatment. The mechanism by which oestrogen stimulates premature delivery is uncertain but is likely

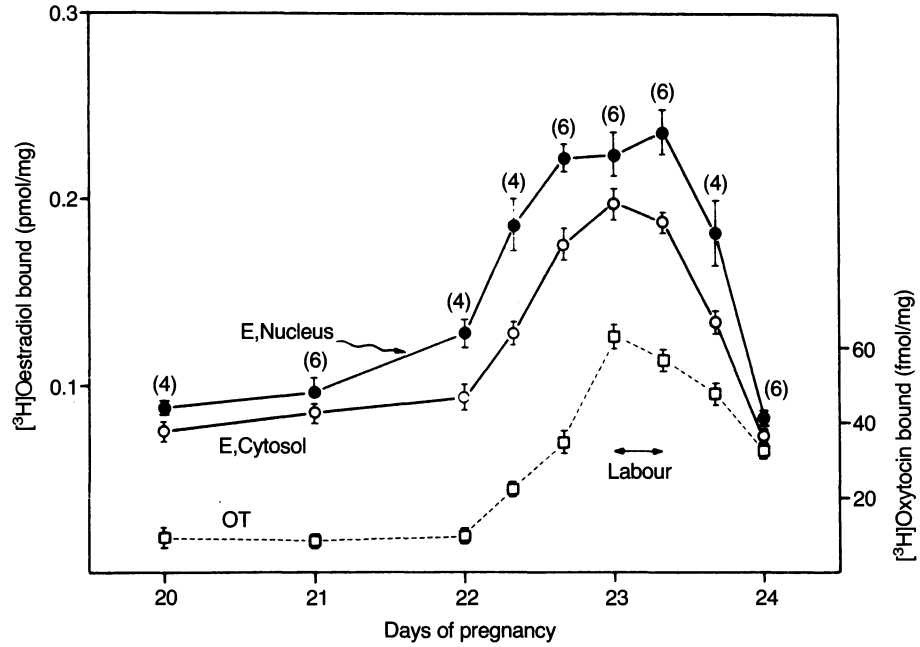

Figure 9.16 Concentrations of oxytocin receptors (□) and oestrogen receptors in the nuclear (●) and cytosolic (○) fraction of rat myometrium. (Reproduced with permission from Alexandrova and Soloff, 1980a.)

to be an indirect action since oestrogen inhibits uterine contractility *in vivo* and *in vitro* (Saldivar and Melton, 1966; Osa and Ogasawara, 1984). In ovariectomized puerperal rats, actinomycin D interferes with the inhibitory effects of oestradiol on spontaneous activity, suggesting that the mechanism involves the synthesis of protein (Downing and Porter, 1978).

9.9.5 OXYTOCIN

The myometrium is refractory to oxytocin throughout pregnancy until 6–8 h before delivery, when sensitivity increases markedly (Fuchs and Poblete, 1970). At that time, parturition is readily induced by infusion of oxytocin in very small amounts and the pattern of contractions mimics that during spontaneous delivery. Concentrations of oxytocin in maternal plasma are low until the first pup is delivered, when there is a modest rise (Higuchi *et al.*, 1985a,b). The rapid increase in sensitivity to oxytocin is attributable to a corresponding increase in the concentration of high-affinity oxytocin binding sites in the gravid and non-gravid uterine horns (Alexandrova and Soloff, 1980a,b). Attempts to establish increased oxytocin receptors as the major factor initiating parturition have not been successful. Passive immunization with an oxytocin antibody that impairs lactation is ineffective in preventing normal parturition at term (Schriefer *et al.*, 1982). Experiments with competitive antagonists of oxytocin are needed.

The concentration of oxytocin receptors correlates closely with that of nuclear oestradiol receptors, which increase as the concentration of P_4 falls prepartum (Alexandrova and Soloff, 1980b) (Figure 9.16).

The relationship to oestradiol is probably direct but it may be mediated indirectly, at least in part, by $PGF_{2\alpha}$ because adminis-

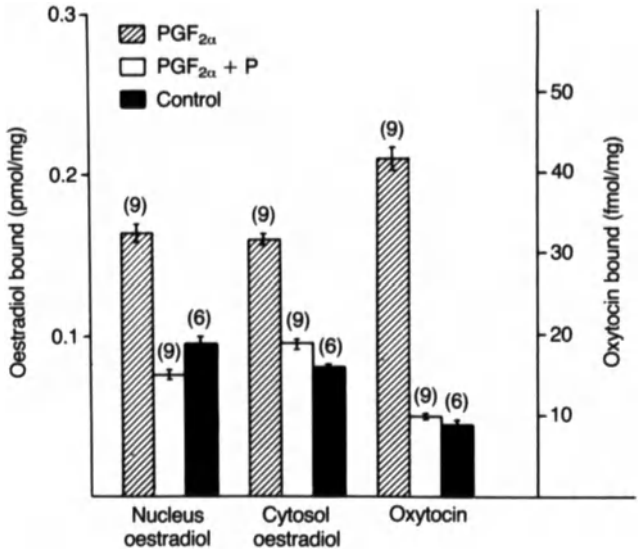

Figure 9.17 Effect of $PGF_{2\alpha}$ at day 18 on the concentration of oestradiol receptors in the nuclear and cytosol fraction and of oxytocin receptors in rat myometrium at labour on day 20. One group of $PGF_{2\alpha}$-treated animals was treated with progesterone. (Reproduced with permission from Alexandrova and Soloff, 1980c.)

tration of the cyclooxygenase inhibitor, naproxen, inhibits both the sensitivity to oxytocin and the increase in oxytocin receptors (W.Y. Chan *et al.*, 1988). However, in non-pregnant rats, treatment for 5 days with $PGF_{2\alpha}$ or indomethacin is without effect on oxytocin receptor concentrations (Engstrom *et al.*, 1988). The layers of the myometrium have different sensitivities to oxytocin: the longitudinal layer is as sensitive at 10 days of pregnancy as at term whereas the circular layer is refractory until 21 days (Crankshaw, 1987). A difference in the spontaneous contractile activity and response to oxytocin of the distal and proximal portions of the uterine horn correlates directly with differences in the concentrations of oxytocin receptors in the respective horns and inversely with the concentration of P_4 in the respective tissues (Gorodeski *et al.*, 1990). The administration of $PGF_{2\alpha}$ at 18 days induces delivery at 20 days accompanied by increased oxytocin and oestradiol receptors, both of which are inhibited by the administration of P_4 (Alexandrova and Soloff, 1980c) (Figure 9.17).

Whether the response is caused directly by $PGF_{2\alpha}$ or indirectly by inducing luteolysis remains uncertain. The administration of mifepristone causes fetal death about 12 h later. Oxytocin receptor concentrations rise sharply at this time but abortion is delayed for a further 12 h (Gorodeski *et al.*, 1990), suggesting that oxytocin may be insufficient to cause coordinated contractions and another factor, possibly PG, is essential for delivery.

Pelvic neurectomy impairs the release of oxytocin during parturition by interrupting the afferent pathways of a reflex stimulated by vaginal distension. Rats in which the increase in oxytocin is partly inhibited begin labour at term but delivery is slowed, whereas those showing no rise fail to deliver, but signs of labour such as stretch movements, vaginal bleeding and passage of mucus occur at term (Higuchi *et al.*, 1986).

These observations are consistent with increased oxytocin concentrations being obligatory for expulsion of the fetuses but not for the initiation of parturition.

9.9.6 RELAXIN

Relaxin in pregnancy arises from the ovary and disappears from the circulation after ovariectomy. Serum concentrations increase prepartum in two phases, the second of which occurs between 36 and 24 h before birth and coincides with the onset of functional luteolysis (Sherwood *et al.*, 1980). Concentrations fall during the final 24 h of pregnancy. Relaxin is required for normal delivery at term. Pregnant rats ovariectomized at 9 days and given maintenance P_4 (withdrawn at 21 days) and oestrogen (Downing and Sherwood, 1985a) or at 21 days and given oestrogen alone (Cheah and Sherwood, 1988) have prolonged pregnancies and durations of labour. Addition of relaxin to the treatment schedule restores pregnancy length and labour to normal. Treatment of intact rats with relaxin from 19 to 23 days prolongs pregnancy but not labour unless delivery occurs during treatment when labour is prolonged (Jones and Summerlee, 1986a). When delivery occurs after treatment is finished, labour is shortened. This may be attributable to a central effect of relaxin on oxytocin release since infusion of relaxin lowers circulating oxytocin concentrations (Jones and Summerlee, 1986a). The opioid antagonist, naloxone, prevents the fall in oxytocin values and the prolonged labour associated with relaxin treatment, suggesting that the effect of relaxin on oxytocin release is mediated by an opioid system (Jones and Summerlee, 1986b). However, naloxone treatment is ineffective in preventing delayed onset of labour in stressed rats although it shortens the interval between the birth of successive pups (Long *et al.*, 1985). Passive immunization with monoclonal antibodies specific for rat relaxin has no effect on the timing of luteolysis or initiation of parturition but prolongs labour (Guico-Lamm and Sherwood, 1988) due to failure of the cervix to undergo the normal prepartum increase in distensibility (Hwang and Sherwood, 1988).

The second phase of relaxin release that coincides with luteolysis can be induced prematurely by administration of $PGF_{2\alpha}$ (Gordon and Sherwood, 1983). Indomethacin protracts luteolysis, delays or prevents delivery and delays the increase in relaxin concentrations until indomethacin treatment is stopped.

In addition to effects on the cervix, relaxin inhibits myometrial activity. The frequency of contractions in ovariectomized animals maintained on oestrogen and P_4 is reduced by treatment with relaxin (Downing and Sherwood, 1985a). Relaxin inhibits spontaneous activity of circular muscle *in vitro* as well as activity induced by low concentrations of oxytocin and PGF but does not inhibit longitudinal muscle contractility (Downing and Sherwood, 1985b). Another potential route by which relaxin may influence myometrial activity is by its action in inhibiting myometrial synthesis of PGI_2 which stimulates myometrium *in vitro* (Gimeno *et al.*, 1983).

9.9.7 CATECHOLAMINES

Adrenaline and noradrenaline inhibit contractile activity of the longitudinal muscle from pregnant rats *in vitro*, whereas circular muscle is inhibited by adrenaline but stimulated by noradrenaline in low concentrations, particularly in late pregnancy (Chernaeva, 1984). The latter response probably reflects the concentration of α_1-adrenoreceptors, which increases sharply in the last 6 h of pregnancy (Legrand *et al.*, 1987) for reasons that are uncertain. The occupancy of α_1-adrenoceptors may make an important contribution to the overall excitability of the myometrium at the onset of labour because

chemical sympathectomy with 6-hydroxydopamine blocks parturition and markedly lowers the concentration of noradrenaline in both plasma and myometrium (Legrand *et al.*, 1987). Administration of a bolus of prazosin delays delivery for a period equal to the half-life of the drug. The relationship of α-adrenoceptors mediating these responses to the adrenergic nervous system is unclear in view of the progressive degeneration of the nerves during pregnancy.

9.9.8 EICOSANOIDS

Intravenous infusion of $PGF_{2\alpha}$ for 6 h at a rate of 20 g/h at 18 days or later induces irreversible luteolysis, as indicated by a fall in plasma P_4 concentration within 3 h and parturition 36–48 h later (Dukes *et al.*, 1974; Fuchs *et al.*, 1974). This suggests that release of $PGF_{2\alpha}$ at about 20 days of pregnancy is the normal luteolytic signal that initiates parturition, but there is little direct evidence to support this hypothesis. The anti-inflammatory agent, fenclozic acid, given at 20 days is ineffective in delaying labour (Dukes *et al.*, 1974). Treatment with indomethacin delays parturition by about 24 h (Aitken, 1971; Chantharaksri *et al.*, 1974; Fuchs *et al.*, 1976), which probably results from a reduced rate of decline of P_4 concentrations. Nevertheless, rising levels of 20α-P_4 show that luteolysis occurs despite indomethacin treatment. A delay of 24 h in the onset of parturition is associated also with passive immunization with anti-$PGF_{2\alpha}$ antibodies (Dunn *et al.*, 1973). Cavaille and Maltier (1978) demonstrated in unilaterally pregnant rats that removal of the ovary on the side of the gravid horn caused delayed parturition, whereas unilateral ovariectomy had no effect on pregnancy length in bilaterally pregnant animals. Their suggestion that the gravid horn generates a luteolytic factor that reaches the ovary by a direct route was supported by the observation that deliveries were delayed or incomplete in half the bilaterally pregnant animals in which unilateral ovariectomy was combined with ligation of the uterine artery and vein on the opposite side.

Although aspirin and indomethacin inhibit both spontaneous and oxytocin-induced contractions *in vitro*, indomethacin is ineffective in inhibiting contractions *in vivo* (Fuchs *et al.*, 1976). Furthermore, infusion of $PGF_{2\alpha}$ or PGE_2 within 24 h of term fails to induce delivery, whereas oxytocin is highly effective (Dukes *et al.*, 1964). These observations suggest that the rat differs from many other species in the relative refractoriness of the myometrium to PGs close to term. Progesterone enhances and oestrogen inhibits the myometrial response to PGs in ovariectomized rats (Fuchs, 1964); if this also occurs in the pregnant animal, the sharp prepartum fall in P_4–oestrogen ratio should inhibit the response to PGs.

In view of the doubt about the luteolytic role of endogenous $PGF_{2\alpha}$ and the refractoriness of the myometrium, the question arises as to the function of the rapidly increasing concentrations of prostanoids in the uterus near term (Gu and Rice, 1991). The withdrawal of P_4 in the presence of maintained oestrogen concentrations in ovariectomized pregnant rats maintained by steroid administration causes a specific increase in PGF concentration in uterine tissue and oestrogen alone stimulates PGF, PGE, TXB_2 and 6-keto-$PGF_{1\alpha}$ (L. Wilson and Lindsey, 1987), thus reproducing the marked increase in uterine PGs found after luteolysis at term in intact animals (L. Wilson and Freinkel, 1982). P_4 treatment blocks the stimulatory effects of oestrogen. Neither treatment increases the concentration of any of the prostanoids in uterine venous plasma (L. Wilson and Huang, 1984).

The major prostanoid produced by the myometrium is PGI_2, but experiments to determine its actions are inconclusive. Kawano and Mori (1988) observed that PGI_2 concentrations were highest where the uterine wall was most stretched and postulated

that PGI_2 maintained uterine relaxation. However, PGI_2 stimulates myometrium *in vitro*.

Although the prostanoids appear to have little direct oxytocic activity at term, they may play an important part in the mechanism causing the marked increase in concentration of oxytocin receptors that precede the onset of parturition (Alexandrova and Soloff, 1980c; W.Y. Chan *et al.*, 1988).

9.9.9 SUMMARY

The onset of parturition in rats is precipitated by functional luteolysis, which is unusual in that the fall in P_4 secretion is caused mainly by metabolism to 20α-P_4 rather than by reduced synthesis of P_4. Another unusual feature of steroid metabolism is the dependence of ovarian oestrogen synthesis on substrate (androstenedione) secreted by the placenta. The luteolytic signal arises from the gravid uterus, but whether it is the result of withdrawal of luteotrophin or release of a luteolysin ($PGF_{2\alpha}$) is uncertain. The resulting fall in P_4 values while ovarian oestrogen secretion is maintained is associated with a sharp rise in oxytocin receptors, α_1-adrenoceptors and relaxin, all of which are necessary for the timely onset and progress of parturition. Delivery of the litter is dependent on release of oxytocin during the expulsive phase of labour. The role of prostanoids in the onset of parturition is uncertain because they have little oxytocic activity *in vivo* and the part they play in luteolysis is not established, but they may contribute to the formation of gap junctions, oxytocin receptors and α_1-adrenoceptors and to the release of relaxin.

9.10 GUINEA PIG

9.10.1 INTRODUCTION

Pregnancy in the guinea pig has many features in common with human pregnancy and the mechanism of initiation of parturition (65 days) is likewise unknown. The paracrine hypothesis that is currently under active investigation in humans remains unexplored in the guinea pig.

9.10.2 ROLE OF THE FETUS

The results of experiments attempting to establish a fetal role in parturition are conflicting and cannot be fitted into a plausible hypothesis. The concentration of cortisol in fetal plasma increases markedly in the last week of pregnancy due to both rising levels of cortisol-binding globulin and increased rate of secretion (Dalle and Delost, 1980). The fraction of free cortisol is proportionately greater, suggesting that it could serve as a stimulus to parturition. However, a daily injection of a large dose of dexamethasone into each fetus in three animals during the last week of pregnancy did not advance the time of parturition (Illingworth *et al.*, 1974). Furthermore, destruction of the fetal pituitary or pituitary stalk has no effect on pregnancy length (Donovan and Peddie, 1973), although fetal adrenal growth is impaired. The placenta is freely permeable to cortisol and the rise in fetal levels of cortisol parallels that in the maternal plasma (Dalle and Delost, 1976). The administration of dexamethasone to the mother has no effect on the time of parturition, although passage into the fetus is likely (Illingworth *et al.*, 1974). Paradoxically, preliminary experiments in which the fetal midline basal hypothalamus was lesioned were followed by abortion (Donovan and Peddie, 1973). Available evidence makes it clear that the prepartum increase in fetal cortisol values does not trigger parturition, but the role of the fetal hypothalamus and pituitary is ambiguous.

9.10.3 PROGESTERONE

Pregnancy becomes independent of the CL in mid-pregnancy when placental production of

P_4 is sufficient to maintain pregnancy. Ovariectomy before 30 days causes abortion but delivery at term occurs when ovariectomy is performed after 30 days (Csapo *et al.*, 1981). However, the CL remains functional throughout pregnancy and circulating concentrations of P_4 fall by 40% after ovariectomy at term (Batra and Thorbert, 1981). High P_4 concentrations, with much P_4 bound to a unique binding globulin, are maintained to term and do not fall before the onset of labour (Heap and Illingworth, 1974).

Doubt has been expressed that progesterone is a myometrial regulatory agent in the guinea pig. Myometrial activity continues throughout pregnancy despite high levels of P_4. Exogenous P_4, even when placed in the uterus, is without effect on the duration of pregnancy or on the mechanical activity of the uterus (Porter, 1970, 1971). However, the refractoriness of the uterus could be attributable to full occupancy of P_4 receptors. P_4 inhibits and oestrogen stimulates receptor formation (Sumida *et al.*, 1988); accordingly, the very high P_4–oestrogen ratio prevailing throughout pregnancy is likely to be associated with a low concentration and a high occupancy of receptors. Experiments with P_4 antagonists leave little doubt that the maintenance of pregnancy is dependent on placental P_4 because such treatment causes abortion after 40 days' gestation (Elger *et al.*, 1986). This does not necessarily imply a direct action of P_4 on the myometrium as the effect of P_4 antagonists could be mediated, for example, by the release of PGs.

9.10.4 OESTROGENS

Concentrations of oestrogen in the maternal circulation are very low in the second half of pregnancy and fall during the week before term (Illingworth *et al.*, 1974). The levels are unchanged by bilateral ovariectomy (Batra and Thorbert, 1981), suggesting that the site of oestrogen synthesis is within the uterus. The placenta has little aromatase activity (Ainsworth and Ryan, 1966) and the site of synthesis appears to be intrafetal because Challis and Illingworth (1972) demonstrated that the concentration of labelled oestrogen after injection of radioactive androstenedione was higher in the umbilical artery than in the umbilical vein. Much of the radioactivity was associated with the 16α-hydroxylated products, oestriol and epioestriol.

Administration of oestrogen does not induce labour; indeed, implants of oestradiol or stilboestrol delay the onset of labour and cause a high incidence of fetal death (Illingworth *et al.*, 1974). The mechanism of delayed delivery is uncertain but could be attributable to induction of P_4 receptors (Sumida *et al.*, 1988) by oestrogen. The concentration of nuclear oestrogen receptors expressed per mg of DNA in the myometrium increases from 50 days to term but remains unchanged when expressed per mg of protein (Alexandrova and Soloff, 1980d).

9.10.5 OXYTOCIN

Oxytocin is undetectable in the maternal circulation before the expulsive phase of labour, when it is released in substantial amounts (Burton *et al.*, 1974). The plasma of the firstborn fetus contains no oxytocin, but subsequent fetuses have concentrations approaching those of the mother. Since the placenta is permeable to oxytocin, this suggests a maternal origin for the oxytocin in the fetal circulation. Oxytocin receptor concentrations in the myometrium rise throughout pregnancy to 60 days and plateau thereafter until term (Alexandrova and Soloff, 1980d). This pattern is mirrored by sensitivity to oxytocin, which increases 50-fold from early to late pregnancy (Bell, 1941). The absence of detectable oxytocin in plasma or an increase in myometrial oxytocin receptors before parturition is inconsistent with a role for oxytocin in the initiation of parturition, but until decidua has been studied the

possibility of a prepartum increase in receptors in that tissue cannot be ruled out.

9.10.6 RELAXIN

Relaxin immunoreactivity in guinea pig plasma (measured by RIA using an antibody against pig relaxin) during late pregnancy does not show any consistent pattern between animals. Relaxin concentrations rise in mid- to late pregnancy in some animals, and in others values rise shortly before parturition (Boyd *et al.*, 1981). Lengthening of the pubic ligaments is preceded by increased plasma concentrations of relaxin in most, but not all, animals.

Circulating relaxin may arise from the endometrial glands, where increasing quantities can be demonstrated by immunocytochemistry as pregnancy progresses (Pardo *et al.*, 1980). Treatment of ovariectomized guinea pigs with oestrogen and P_4 not only induces accumulation of relaxin in endometrial glands but also reproduces the marked relaxation of the pelvic ligaments that occurs in response to treatment with relaxin (Pardo and Larkin 1982). Injections of pig relaxin inhibit spontaneous uterine activity in non-pregnant guinea pigs and, because P_4 apparently lacks inhibitory effects, Porter (1972) suggested that relaxin is the hormone mainly responsible for uterine quiescence in this species.

9.10.7 CATECHOLAMINES

The total content of myometrial α_1-adrenoceptors increases 34-fold in pregnancy, but this is attributable to growth of the uterus and not to an increase in concentration (Arkinstall and Jones, 1989). Together with the observation that the excitatory response to noradrenaline declines towards term (Carter, 1985), this suggests that α_1-adrenergic stimulation is unlikely to contribute to the initiation of parturition in the guinea pig.

9.10.8 EICOSANOIDS

Information about the synthesis of prostanoids in the pregnant guinea pig is almost completely lacking. Plasma concentrations of PGF in peripheral plasma remain unchanged with the onset of parturition, but there is a twofold increase in PGF and 6-keto-$PGF_{1\alpha}$ in vena caval plasma (Kendall, 1977). PGE_2 and its metabolites have not been measured. The endometrium produces significant quantities of PGs at least in early pregnancy (Poyser, 1984) which may be important in activating the myometrium; strips of circular muscle from pregnant animals become quiescent *in vitro* unless the endometrium is left intact (H.A. Coleman and Parkington, 1988). Daily subcutaneous injections of $PGF_{2\alpha}$ or PGE_2 at 43 days induce abortion, but a high proportion of fetuses are dead when expelled (Elger, 1979); PGs therefore differ from oxytocin, which induces the abortion of living fetuses.

9.10.9 SUMMARY

It is difficult to construct a satisfactory hypothesis for the mechanism that initiates parturition in guinea pigs. Clearly, parturition is not dependent on luteolysis, and available evidence does not support an active role for oxytocin. Insufficient information is available to assess the possible role of prostanoids.

9.11 DOG

9.11.1 INTRODUCTION

Reported studies of pregnancy and parturition are almost exclusively related to laboratory-bred beagles. P_4 and oestrogen levels in Labrador bitches are similar to those of beagles, and there is no reason to expect major differences in the mechanism of parturition within the canine species. The dog belongs to the large group of mammals in which parturition is preceded by luteolysis.

9.11.2 ROLE OF THE FETUS

The contribution of the fetus to the onset of parturition has not been studied. Pregnancy and pseudopregnancy are of the same duration (65–66 days) but, although differences in the endocrine milieu of the two are rather subtle, it is clear that the presence of the conceptus is expressed in CL function. Fetal corticosteroids are unlikely to play a part because administration of dexamethasone from 45 days leads to fetal death but not parturition (Austad *et al.*, 1976).

9.11.3 PROGESTERONE

Maintenance of pregnancy is dependent on P_4, and ovariectomy at 50–55 days is followed by parturition (Sokolowski, 1971). In both the pregnant and pseudopregnant animals, P_4 concentrations rise to high values (25 ng/ml) by 25 days and then fall progressively to about 3 ng/ml 3 days before parturition (Concannon *et al.*, 1975). The concentration continues to fall slowly in the pseudopregnant bitch, whereas it falls abruptly in the pregnant animal to about 1 ng/ml on the day of parturition (Figure 9.18).

P_4 implants at 60 days prevents parturition at term and results in prolonged pregnancy and death of the mother (Concannon *et al.*, 1977). Pregnancy is maintained when plasma P_4 concentrations exceed 2 ng/ml. Luteolysis terminates luteal function abruptly about 48 h before parturition. The rapid withdrawal of progestational activity immediately preceding parturition is apparent in hypothermia and a sharp rise in plasma prolactin, both of which begin shortly after the fall in P_4 levels (Concannon *et al.*, 1978).

9.11.4 OESTROGEN

Oestrogen concentrations remain steady through the second half of pregnancy at

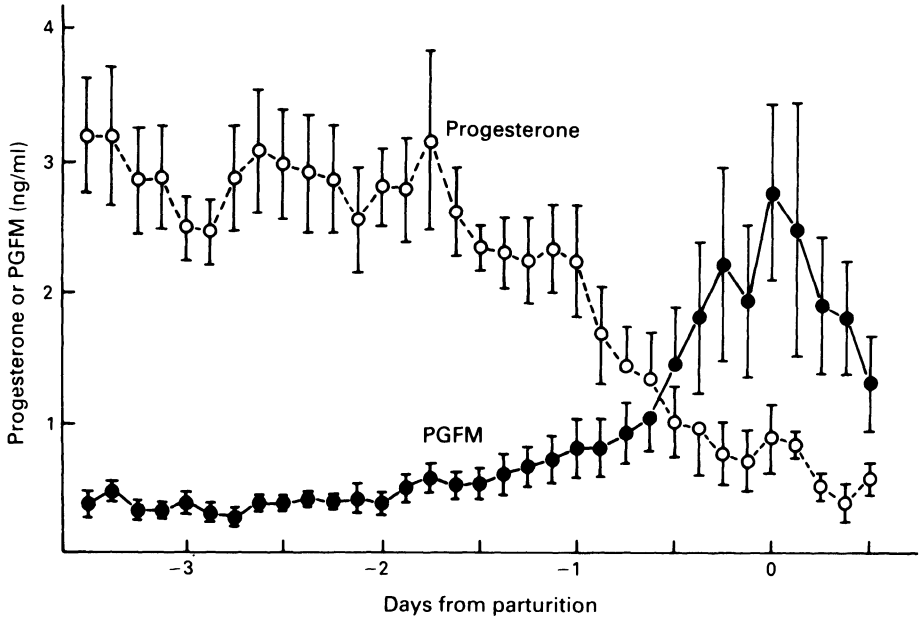

Figure 9.18 Concentrations of progesterone and 13,14-dihydro-15-keto-prostaglandin $F_{2\alpha}$ (PGFM) in peripheral plasma of bitches around parturition. (Reproduced with permission from Concannon *et al.*, 1988.)

about twice the values of the non-pregnant cycle (Concannon *et al.*, 1975) then fall sharply during the 2 days prepartum to reach non-pregnant values by the day of parturition. Immunoreactive plasma oestrogen is mainly oestradiol-17β (Austad *et al.*, 1976). The source of oestrogen is unknown, but the prepartum fall in concentrations which coincides with a similar fall in P_4 points strongly to the ovary.

9.11.5 RELAXIN

Plasma relaxin concentrations rise in the second half of pregnancy in intact and ovariectomized animals in which pregnancy is maintained with injections of 17α-ethyl-19-nortestosterone, although values are lower in the latter group (Steinetz *et al.*, 1989). These findings suggest that relaxin is secreted by the ovaries and the uterus. Parturition is not heralded by any marked changes in relaxin values.

9.11.6 PROSTAGLANDINS

The concentration of PGFM in peripheral plasma increases fivefold during the 3 days before parturition (Concannon *et al.*, 1988). The close temporal relationship of rising PGFM and falling P_4 values is consistent with a luteolytic role for $PGF_{2\alpha}$. Administration of $PGF_{2\alpha}$ induces luteolysis (Concannon and Hansel, 1977), but whether PG antagonists prevent luteolysis is unknown.

9.11.7 SUMMARY

The initiation of parturition in the dog is almost certainly a consequence of luteolysis, and the luteolytic agent is probably $PGF_{2\alpha}$, but the stimulus to release of $PGF_{2\alpha}$ is unknown. The hormonal changes at parturition are unusual in that both P_4 and oestrogen fall sharply at luteolysis and there is little or no change in the oestrogen–P_4 ratio. The trigger to parturition therefore appears to be exclusively a fall in P_4 concentrations.

9.12 RABBIT

The maintenance of pregnancy to term (31 days) in rabbits has been known to depend on the presence of functional CL secreting P_4 since the classical experiments of Fraenkel (1910) and Corner (1928). Luteolysis precedes parturition and is its cause, but the factors leading to luteolysis, which must be considered to be the primary step in the mechanism initiating parturition, remain uncertain.

9.12.1 ROLE OF THE FETUS

Bauman and Dziuk (1975) decapitated all fetuses in the litter at 18–21 days: pregnancy length was shortened by 2 days in the does carrying decapitated fetuses, but only about 10% of the fetuses were subsequently recovered and no sham operations were included, making interpretation of the results difficult. Chiboka *et al.* (1977) removed the fetuses at 25 days and observed normal delivery of placentas at term preceded by normal nest-building behaviour. When fetectomy was performed at 21 days, placentas were retained until 36 days. The results were interpreted as indicating that the fetuses programme the placenta before 25 days of gestation but thereafter the placenta is autonomous in determining the time of parturition.

9.12.2 PROGESTERONE

The contribution of the placenta to the raised concentration of P_4 in the maternal circulation was investigated by Thau and Lanman (1974). Pregnant does were ovariectomized at 21 days and pregnancy was maintained by injections of MPA, which does not cross-react in the RIA of P_4. The concentration of P_4 fell promptly to non-pregnant values, indicating that the CL is the only significant source of the raised levels of P_4 in pregnancy.

The concentration of P_4 in maternal peripheral plasma follows a well-defined pattern for which there is general agreement (Kendall and Liggins, 1972; Challis *et al.*, 1973b; Singh and Adams, 1978; Lau *et al.*, 1982): values rise rapidly during the first 8 days of pregnancy, reach peak values at 14 days, fall slightly to a plateau until 29 days then decline rapidly to reach low levels a few hours before parturition. The concentration of 20α-P_4 is approximately the same as that of P_4 and follows the same pattern through pregnancy (Fuchs, 1978). The concentration of P_4 in the myometrium closely parallels that of the plasma throughout pregnancy and the ratio of myometrial–plasma concentration approximates unity throughout most of pregnancy but falls slightly below unity near term. The concentration of P_4 receptors in myometrium and endometrium has been studied by Quirk and Currie (1984), who found that the nuclear P_4 receptor concentration in myometrium is inversely related to the plasma concentration of P_4, and attributed this surprising result to stimulation of P_4 receptor formation by the rising ratio of oestrogen–P_4 as plasma concentrations of P_4 (but not of oestrogen) fall prepartum. The concentration of receptors in endometrium does not rise as P_4 levels fall. Quirk and Currie (1984) concluded that the level of P_4 receptors in rabbit myometrium does not reflect the physiological response to P_4. Evidence that the secretion of P_4 by the CL is dependent on luteotrophin(s) secreted by the placenta has been provided by experiments in which fetectomy was performed at 15 days and the placentas were left in place (Klein, 1967). At necropsy at 20 days, the CL had not regressed. Transplantation of placentas to the body wall or abdominal cavity prolongs the lifespan of the CL nearly to term (Chu *et al.*, 1946). The nature of the placental luteotrophin and the extent to which maternal pituitary LH is part of the luteotrophic complex in the rabbit are uncertain, as also is whether luteolysis normally results from withdrawal of luteotrophic support, from the action of a luteolysin or from both effects. Dislocation of the placentas is followed by luteolysis and abortion (Csapo, 1969). Although this experiment is open to several interpretations, including release of prostanoids resulting from trauma, loss of placental luteotrophin is probably the most likely explanation since leaving a single placenta intact maintains pregnancy yet is unlikely to reduce significantly the extent of trauma.

Inhibition of P_4 synthesis by oral administration of isoxazol, a 3β-HSD inhibitor, at 25 days is followed by increasing sensitivity to oxytocin and oxytocin-induced abortion in most animals within 2 days (Bernard *et al.*, 1980). The claim that P_4 concentrations in the uterine vein in these experiments fell as a result of treatment is doubtful since the post-treatment blood sample was collected at post-partum autopsy. The study needs to be repeated with other inhibitors and improved sampling procedures.

9.12.3 OESTROGEN

The placenta probably does not secrete oestrogen (Ainsworth and Ryan, 1966) and the ovarian follicles are the sole source. Loss of the follicles either by their removal, by inducing ovulation or by hypophysectomy causes abortion which can be prevented by the administration of oestrogen (Gadsby *et al.*, 1983). Withdrawal of oestrogen is followed rapidly by a fall in circulating progesterone to low levels which can be fully reversed by oestrogen treatment 24 h after oestrogen withdrawal provided that abortion is prevented by administering medroxyprogesterone (Gadsby *et al.*, 1983). Thus, it appears that the putative placental luteotrophin depends on follicular oestrogen for either its action or its production.

A fall in oestrogen production is a potential physiological mechanism for initiating luteolysis and parturition, but studies of plasma oestrogen concentrations are not supportive.

Both oestrogen and oestradiol-17β levels remain within a narrow range throughout pregnancy and show no significant trend at term (Challis *et al.* 1973b; Lau *et al.*, 1982).

9.12.4 OXYTOCIN

The sensitivity to oxytocin increases dramatically prepartum (Fuchs, 1964; Porter and Schofield, 1966), and a small single intravenous dose of oxytocin leads to rapid expulsion of the litter after 30 days, although the uterus is refractory to oxytocin until 25 days. Myometrial contractions occur during delivery in the non-pregnant horn of unilaterally pregnant animals (Fuchs, 1964), suggesting a circulating stimulus, presumed to be oxytocin. Further support for a systemic stimulus was reported by Wagner (1974) who observed electrical activity synchronous with parturitional uterine activity in myometrial transplants in ear chambers. Electrical stimulation of the infundibulum and the median eminence causes parturition provided that the pregnancy is within 24 h of term (Lincoln, 1971). Milk ejection accompanying the electrical stimulation lends strong support to oxytocin release as the stimulus to parturition. The extracellular electrical activity of magnocellular neurones was recorded in unanaesthetized rabbits during parturition by O'Byrne *et al.* (1986). Oxytocin neurones were differentiated from vasopressin neurones by their response to suckling. During parturition, 5–14 discrete bursts of firing were seen, representing a three- to 100-fold increase in the rate of firing compared with prepartum. The increased electrical activity was accompanied by a marked increase in circulating oxytocin, leaving no doubt that the expulsive phase of labour is the consequence of oxytocin release. An obligatory role of oxytocin release to complete parturition is suggested by the prolongation of pregnancy that is associated with high cervical cord transection (Beyer and Mena, 1970).

The mechanism underlying the rapid increase in the sensitivity of the prepartum uterus to oxytocin was elucidated by Reimer *et al.* (1986). They measured the oxytocin receptor concentrations in myometrium each day near term after determining the sensitivity to injections of oxytocin. In addition, they measured contractile responses to oxytocin *in vitro* at 30 days. The response to oxytocin increased at least fourfold between 30 and 31 days of pregnancy, and this increased sensitivity was accompanied by a 10-fold increase in oxytocin binding sites in both decidua and myometrium. The stimulus to the formation of oxytocin receptors in rabbits has not been investigated but may be similar to that in the rat, i.e. inhibited by P_4 and stimulated by oestrogen (Fuchs *et al.*, 1983b). Whether the effects of ovarian hormones are direct or are mediated by other agents such as prostaglandins is uncertain. In the ovariectomized, non-pregnant rabbit, oxytocin stimulates the release of $PGF_{2\alpha}$ from endometrium but not from myometrium (Small *et al.*, 1978). Treatment with oestrogen increases oxytocin-stimulated release of $PGF_{2\alpha}$ and P_4 completely inhibits the response to oestrogen.

9.12.5 CORTICOSTEROIDS

The concentration of cortisol in fetal plasma rises progressively from 24 days to term, raising the possibility that fetal cortisol is an important signal to the initiation of parturition (Mulay *et al.*, 1973; Baldwin and Stabenfeldt, 1974). When cortisol (Nathanielsz and Abel, 1972, 1973; Abel *et al.*, 1973) or dexamethasone (Adams and Wagner, 1969; Kendall and Liggins, 1972; Challis *et al.*, 1975) was given to does at 21–25 days of pregnancy, delivery of pups after 72 h accompanied by nest-building activity and lactation was noted consistently. Induced parturition is preceded by a fall in P_4 concentrations of a similar magnitude to that at normal term, but a rise in plasma concentration of $PGF_{2\alpha}$, which nor-

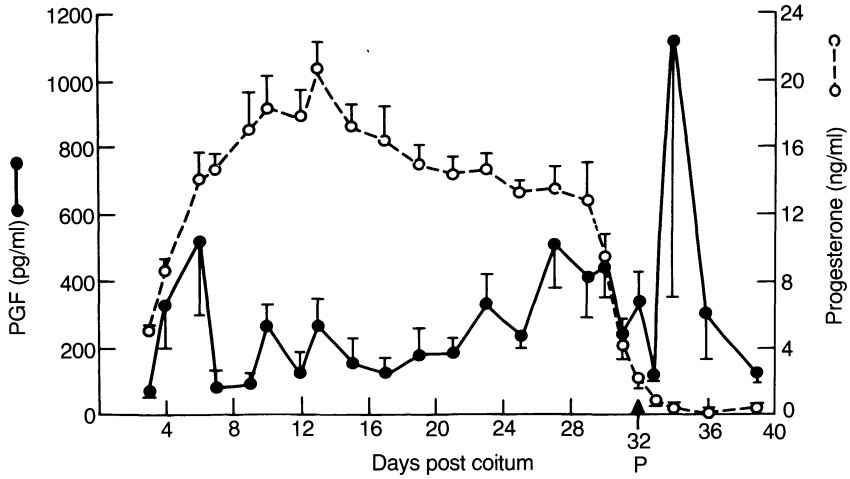

Figure 9.19 Concentration of progesterone and PGF in the peripheral plasma of pregnant rabbits. (Reproduced with permission from Challis *et al.*, 1973a.)

mally accompanies or precedes the fall in P_4, is not present and the response to dexamethasone is not inhibited by concurrent treatment with indomethacin (Challis *et al.*, 1975). Challis *et al.* (1975) proposed that the findings are consistent with a direct action of corticosteroid on the ovary, which would rule out a physiological role for fetal cortisol since it does not have access to the maternal ovary. An alternative explanation is that corticosteroid suppresses the putative placental luteotrophin, which could be influenced by fetal cortisol, but administered corticosteroids might have a physiological or pharmacological action on the placenta. Further experiments, including stimulation of the fetal adrenals with ACTH, are required before a role in parturition can be confidently attributed to rising concentrations of fetal cortisol before term.

9.12.6 RELAXIN

Relaxin has been purified from the placenta (P.A. Fields *et al.*, 1982) but the source of circulating relaxin is unknown.

9.12.7 EICOSANOIDS

Information about the maternal plasma concentrations of prostanoids preceding parturition is limited. Assays of PGFM or a stable metabolite of PGE_2 in serial samples near term have not been reported. Challis *et al.* (1973a) found that the peripheral concentration of PGF increased significantly from 21 to 30 days in samples taken on alternate days (Figure 9.19).

In three animals sampled daily from 29 days values were raised on days 27–30 in two and not in the third, in which P_4 levels did not fall until 30 days. These results were not confirmed by Lytton and Poyser (1982), who found a peak of $PGF_{2\alpha}$ in uterine vein blood at 25 days, but concentrations remained low in arterial and peripheral venous blood to term. A physiological role of $PGF_{2\alpha}$ in luteolysis is not supported by experiments in which pregnant rabbits were given indomethacin in late pregnancy (Challis *et al.*, 1975). The treatment prolonged pregnancy by 1 day but did not prevent luteolysis and P_4 concentration fell over the same time course as it did in controls. While there is doubt

whether release of $PGF_{2\alpha}$ precedes luteolysis, and that endogenous $PGF_{2\alpha}$ is luteolytic, infusion of $PGF_{2\alpha}$ causes an irreversible fall in P_4 within 2 h (Challis *et al.*, 1974c; Laudanski *et al.*, 1979). Continuous intra-aortic infusion of $PGF_{2\alpha}$ for a minimum period of 8 h at 21 days is followed by delivery after a mean latent period of 38 h (Nathanielsz *et al.*, 1973). Inhibition of P_4 synthesis by administering trilostane, a 3β-HSD inhibitor, as a single intravenous bolus at 28 days causes an immediate fall in P_4 and delivery after 30 h but the concentration of PGFM in peripheral blood remains low until labour starts, when it rises sharply (Makimura *et al.*, 1984).

M.H. Block *et al.* (1985) showed that placental microsomes in late pregnancy efficiently metabolize labelled arachidonic acid to PGE_2 and $PGF_{2\alpha}$, PGD_2 and TXA_2, but little PGI_2, and the cytosolic fraction generates a variety of lipoxygenase products.

9.12.8 SUMMARY

Parturition is immediately preceded by luteolysis and a marked fall in P_4 concentrations, but the cause of luteolysis is not known. Although administered $PGF_{2\alpha}$ causes luteolysis, indomethacin fails to block luteolysis, suggesting that luteolysis is not normally initiated by release of $PGF_{2\alpha}$. Parturition is readily provoked by oxytocin at term but the uterus is insensitive to oxytocin earlier in gestation. The increased sensitivity to oxytocin is probably due to a marked increase in oxytocin receptors that accompanies luteolysis and is likely to result from the fall in P_4. Luteolysis is probably due to withdrawal of luteotrophic support rather than the release of a luteolysin, but the nature of the luteotrophin(s) and the stimulus to its withdrawal are unknown.

9.13 CONCLUSIONS

The past 25 years have seen enormous strides in the understanding of the mechanism of initiation of parturition. In some species, sheep in particular, knowledge has reached a level of sophistication similar to that in many other physiological systems. In others, primates in particular, understanding of how the system does **not** work is substantial, but solid hypotheses capable of being tested are lacking. Clearly, wide diversity is a characteristic of mammalian parturition and it is difficult to discern an evolutionary pathway. To some extent, the needs of the newborn can be linked teleologically to the type of mechanism in a given species; precocial species having a mature newborn capable of fending for itself immediately after birth are well served by a system where the fetus has firm control of the time of birth, whereas the more immature newborn dependent for survival on prolonged mothering tolerates systems that are less tightly tied to the fetus and maternal influences are more readily seen. Even in sheep, however, maternal circadian rhythms probably contribute to the hour of birth if not the day. In evolutionary terms, whether the degree of maturity at birth is a cause or a consequence of a particular system of determining the time of birth is moot.

The widely differing systems across the species tend to converge towards the end of their respective pathways so that the roles played by agents such as prostaglandins and oxytocin that activate the uterus have much in common. The extent to which the pathways share a common origin is less clear. In general, opinions are divided on whether the signal is complex and multifactorial, deriving from input from many maturing organs or comes from one or more specific genes that function as a clock. Such a clock need not be absolutely accurate since the signal may not only initiate parturition but also accelerate maturation of those organs on which postnatal survival is most dependent.

For the moment, it seems that classic endocrine and physiological techniques have nearly reached their limit and that further progress is likely to come from investigations

at a cellular level. Hopefully, however, the wheel will turn full circle and it will be possible in due course to return to the whole animal armed with testable hypotheses derived from the study of cells.

ACKNOWLEDGEMENTS

The authors wish to thank Ms Jan Deayton for her assistance with collating the references, Ms Judi Herschell for typing the manuscript and Dr Jeffery Schwartz for helpful discussions during the preparation of the manuscript.

10.1 HISTORICAL ASPECTS

The concept that the fetus initiates its own delivery dates from 460 BC, when Hippocrates suggested that, at the appointed hour, the fetus puts its feet on the fundus of the uterus and pushes to effect its own delivery. It was not until the tenth century that the Italian anatomist, Fabricius ab Aquapendente, proposed that the chief agent in the initiation of parturition was the muscular action of the uterus. In 1882, Spiegelberg re-emphasized the role of the fetus when he wrote in a German textbook of midwifery that, '. . . the reason why labour occurs at a definite time must be sought for, not in the uterus and its changes, but in the fetus. It is the **maturity** of the latter that gives the signal.'. In 1933, Malpas reported a series of cases of prolonged pregnancy associated with fetal anencephaly. Malpas concluded that 'the time of the onset of labour is determined by the foetus', and 'the foetal adrenal, pituitary, or nervous system, perhaps in combination, are suggested as tissues possibly concerned in the actual excitation of the neuromuscular expulsive mechanisms'.

Prolonged pregnancy in cattle has long been recognized as a clinical entity. Most inbred breeds of dairy cattle produce genetically defective calves. Investigation of affected fetuses provided the first definitive evidence for the fetal pituitary–adrenal axis playing a primary role in the initiation of parturition. Prolonged gestation in Holstein–Friesian (Jasper, 1950) and Guernsey (Kennedy *et al.*, 1957) breeds was due to a homozygous recessive autosomal gene in the fetus that resulted in fetal endocrinopathies (reviewed by Holm, 1967). In the cows carrying affected fetuses, the corpus luteum (CL) of pregnancy did not regress, and, rather than decreasing at term, progesterone (P_4) concentrations were maintained throughout gestation (Holm and Short, 1962). The affected calves of the Guernsey breed were premature in development, failing to grow beyond the size of a 7-month fetus, and always exhibited adenohypophyseal aplasia. Although the adrenal cortex and medulla were distinguishable, the adrenal glands were small and the cortical architecture was undeveloped. Gestation in these animals ranged from 292 to 526 days (normal term, 280 days). The affected calves of the Holstein–Friesian breed continued to grow during their prolonged gestation and were unusually large, but they failed to initiate labour and died *in utero* about 100 days past term (Holm, 1967). The adenohypophysis, although present, was smaller than normal (Holm, 1967).

Naturally occurring prolonged gestation has also been observed in sheep. In 1963, a congenital cyclopian-type malformation associated with prolonged pregnancy was identified in fetuses of range sheep in Idaho (Binns *et al.*, 1963, 1964). The teratogenic effect resulted from the ingestion of skunk cabbage (*Veratrum californicum*) on the fourteenth day of gestation. The toxic principle was 11-deoxyjervine, a steroidal alkaloid. The affected lambs had pituitary glands, although the neural connections were either missing or abnormal (Kennedy, 1971). In 1969, Basson *et al.* reported cases of prolonged pregnancy in sheep due to the ingestion of the shrub *Salsola tuberculata* during the second half of gestation: gestation was prolonged for about 2 weeks, and at delivery the lambs were found to have atrophic adrenal cortices.

Clinical syndromes of non-infectious cause characterized by premature delivery are rare. The syndrome of recurrent abortion in highly inbred Angora goats has been studied by van Rensburg (1971), who demonstrated fetal adrenal hyperplasia in the aborted fetuses and suggested that premature activation of the fetal pituitary–adrenal axis may be responsible for the abortion.

The above observations provided evidence which involved the fetus in the aetiology of prolonged pregnancy although the data indi-

cating the specific involvement of the fetal pituitary–adrenal axis were less convincing. Liggins *et al.* (1967) established that, after electrocoagulation of the pituitary of an otherwise normal fetal lamb, pregnancy was prolonged indefinitely and was associated with hypoplasia of the adrenal cortices (Liggins and Kennedy, 1968). Parturition occurred at the expected time in multiple pregnancies if one fetus had an intact pituitary, or in single pregnancies if less than 70% of the pituitary tissue was removed. Prolonged pregnancy was also reported in two ewes after bilateral fetal adrenalectomy (Drost and Holm, 1968). Ablation of the fetal adrenal medullary tissue did not result in prolonged gestation, indicating the primary role of the adrenal cortex (Liggins, 1969a).

These experiments clearly established an essential role for the fetal pituitary in the initiation of parturition but did not determine whether the fetus played an active or passive role in the process. Liggins (1969b) showed that fetal infusion of synthetic $ACTH_{1-24}$, but not other pituitary hormones, caused premature delivery in 4–7 days. The infusion of glucocorticoid hormones, such as cortisol and dexamethasone, into the fetal lamb also induced premature labour. Infusion of these compounds at similar doses per unit weight into the mother were ineffective in influencing the length of gestation. Furthermore, the active principle appeared to reside in the glucocorticoid moiety because infusions of mineralocorticoids such as deoxycorticosterone were ineffective (Liggins, 1968, 1969b).

These experiments showed that an intact fetal pituitary–adrenal axis was essential for the initiation of parturition in sheep and that activation of this pathway could cause premature labour. Bassett and Thorburn (1969) provided evidence that activation of the fetal pituitary–adrenal axis preceded normal-term parturition. In the chronically catheterized sheep fetus, there is a gradual increase in plasma glucocorticoids beginning about 15 days before term, accelerating to a marked increase in the last 3–4 days, a finding consistent with the earlier observation of Comline and Silver (1961) that the adrenal glands of the fetal lamb grow markedly in the last 10 days or so of intrauterine life. However, these findings gave no insight into the trigger mechanism which activated the fetal pituitary–adrenal axis. (HPA; abbreviations used in this chapter are given in Table 10.1).

Table 10.1 Abbreviations used in chapter 10

$17\text{-}OHP_4$	17α-hydroxyprogesterone
$17\text{-}OHP_5$	17α-hydroxypregnolone
ACTH	adrenocorticotrophic hormone
AVP	arginine vasopressin
B	corticosterone
CBG	corticosteroid-binding globulin
CRF	corticotrophin-releasing factor
EP	receptor for PGE_2
F	cortisol
Gpp(NH)p	guanylylimidodiphosphate
GTP	guanine triphosphate
HETE	eicosatetranoic acid
HMW	high molecular weight
HPA	hypothalamo – pituitary – adrenal
HPD	hypothalamo – pituitary disconnected
HPETE	hydroperoxyeicosatetraenoic acid
IP	inositol phosphate
IRMA	immunoradiometric assay
βLPH	β-lipotrophin
ME	medium eminence
MSH	melanocyte-stimulating hormone
NDGA	nordihydroguaiaretic acid
P_4	progesterone
P_5	pregnenolone
PGE_2	prostaglandin E_2
POMC	proopiomelanocortin
PVN	paraventricular nucleus
RIA	radioimmunoassay
SON	supraoptic nucleus
TGF	transforming growth factor

10.2 PLASMA CORTISOL CONCENTRATIONS IN THE FETAL LAMB

The preparturient increase in fetal plasma glucocorticoids concentration first described

by Bassett and Thorburn (1969, 1973) has been reconfirmed many times (Comline *et al.*, 1970; Alexander *et al.*, 1973; Drost *et al.*, 1973; Strott *et al.*, 1974; Thomas *et al.*, 1976; Brown *et al.*, 1978; Magyar *et al.*, 1980a). Magyar *et al.* (1980a) showed that the fetal plasma cortisol concentrations increased significantly from day 11.8 ± 1.0 (SEM) before labour, and again during the last 3–4 days of uterine life, then decreased rapidly within the first week post partum. Cortisol concentrations in fetal plasma may, in fact, start to increase about 25 days before delivery (Norman *et al.*, 1985; Challis and Brooks, 1989).

Isotopic kinetic techniques showed that the cortisol present in the fetal circulation before 120 days of gestation is derived by transplacental transfer from the mother (Hennessy *et al.*, 1982), and it is only after this time that the fetal adrenal gland contributes. The increase in plasma cortisol concentrations may reflect an increase in the cortisol-binding capacity of fetal plasma (Fairclough and Liggins, 1975; Ballard *et al.*, 1982). Fetal infusion of ACTH at day 127 of gestation can stimulate an increase in the cortisol-binding capacity of fetal plasma (Challis *et al.*, 1984). The simultaneous administration to the fetus of metyrapone, an 11β-hydroxylase inhibitor, blocks the increase in cortisol binding capacity in the fetal circulation, suggesting that the increase in fetal plasma cortisol may be the stimulus for transcortin (CBG) production (Challis *et al.*, 1984).

10.3 ADRENOCORTICOTROPHIC HORMONE (ACTH)

The measurement of ACTH in ovine fetal plasma has been fraught with difficulties. In addition to $ACTH_{1-39}$ several large molecular weight precursors of ACTH are present in the fetal circulation (see Jones, 1983, for references). Most of the earlier radioimmunoassays (RIAs) for ACTH cross-reacted to some extent with these high molecular weight (HMW) forms and also small molecular weight species. This probably accounted for the higher resting values reported in earlier studies, i.e. 207 ± 151 pg/ml (Jones *et al.*, 1978a) and 366 ± 42 pg/ml (Rees *et al.*, 1975; Nathanielsz *et al.*, 1977). With the development of more specific antisera, the values measured were 69.6 ± 7.1 pg/ml (Wintour *et al.*, 1980), 20–30 pg/ml (Norman *et al.*, 1985) and 13.0 pg/ml (Pradier *et al.*, 1985). Less specific assays using antisera which cross-react with HMW ACTH peptides have considerable value if used in conjunction with chromatography to determine changes in the processing of the precursor hormone proopiomelanocortin (POMC) (Crosby *et al.*, 1988, 1989).

Using one of the less specific antisera, Jones and Roebuck (1980) and Jones (1983) showed that until 135–140 days of gestation, the HMW forms predominate in plasma, and that $ACTH_{1-39}$ represented only 25–30% of the total ACTH pool. From 140 days onwards the proportion of $ACTH_{1-39}$ relative to the HMW forms rose (Jones and Roebuck, 1980). The HMW forms of ACTH have a low steroidogenic potential (Gasson, 1979, 1980; Chatelain and Dupouy, 1980; Roebuck *et al.*, 1980; Durand *et al.*, 1984a; Brieu and Durand, 1987), and Jones (1983) argued that most previous studies on fetal plasma ACTH were misleading because the RIAs used measured both active and relatively inactive ACTH molecules. When measured after peptide separation by gel filtration and RIA, the concentration of $ACTH_{1-39}$ in fetal sheep plasma remained at low levels until day 135 before increasing markedly until term (Jones, 1983). Using preparative gel filtration of plasma extracts, preliminary data indicated that $ACTH_{1-39}$ increased in parallel with the major increase in plasma cortisol from day 140 onwards (Jones, 1983). However, measurements of 'total' immunoreactive ACTH concentrations failed to demonstrate significant changes before the prepartum increase in the fetal cortisol concentration (Rees *et al.*, 1975;

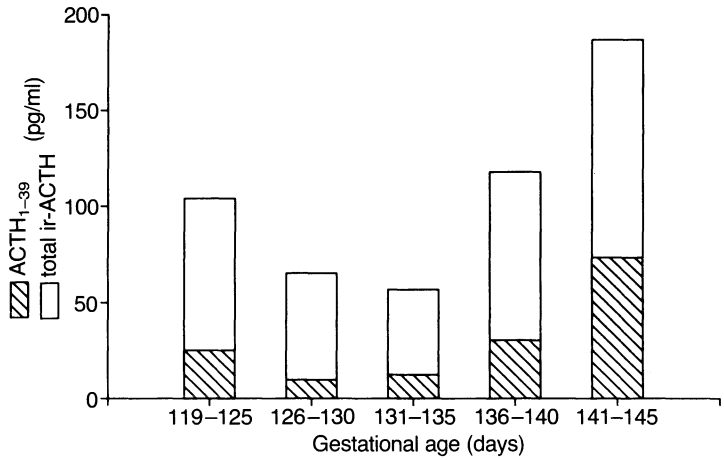

Figure 10.1 Fetal plasma concentrations of ACTH $_{1-39}$ and total immunoreactive ACTH in intact fetal lambs during late gestation. Samples were subjected to chromatography on Sephadex G50 fine and then quantitated by radioimmunoassay.

Jones *et al.*, 1977a; Wintour *et al.*, 1980; Rose *et al.*, 1982; Jones, 1983).

In contrast to the above findings, Norman *et al.* (1985), using a direct RIA which is reported to be more specific for $ACTH_{1-39}$, have shown a small progressive increase in fetal plasma ACTH during the last 30 days of pregnancy. The initial phase of the ACTH rise preceded or coincided with the increase in plasma cortisol, agreeing with the earlier data of Hennessy *et al.* (1982). Recent studies using an IRMA show a progressive increase in $ACTH_{1-39}$ concentrations during the last third of gestation (Deayton *et al.*, 1993)

Gel filtration chromatography (Sephadex G50) and subsequent RIA have indicated that $ACTH_{1-39}$ in fetal plasma increases over the last 20–25 days of gestation (Hollingworth *et al.*, 1990a), and that $ACTH_{1-39}$, calculated as a percentage of total immunoactivity, increases from ~15% at 126–130 days to ~40% at 141–145 days of gestation (Figure 10.1).

Recently, we have used a two-site IRMA (Crosby *et al.*, 1988) to measure directly the basal levels of the HMW ACTH precursor peptides (proopiomelanocortin [POMC, M_r 31K, K_{av} =0.08] and pro-ACTH [M_r22K]) and $ACTH_{1-39}$ as a function of gestational age. Under basal conditions, the concentration of the precursor peptides was high and did not change significantly during the last third of gestation (69±7 to 82.7±7 pmol/l at 110–114 and 140–142 days of gestation respectively; Carr *et al.*, 1992). However, basal $ACTH_{1-39}$ concentrations increased from 4.4±0.4 pmol/l (Carr *et al.*, 1992) at 110–114 days to 10.5±1.1 pmol/l at 140–142 days. The molar ratio of the HMW forms to $ACTH_{1-39}$ decreased from 15.7 at 110 days' to 7.9 at 140 days' gestation. These findings confirm and extend the earlier studies of Jones and Roebuck (1980) and Hollingworth *et al.* (1990a) and demonstrate that the bioactive $ACTH_{1-39}$ concentrations increase progressively during the last third of gestation while the concentration of the HMW species remains unchanged. The POMC and pro-ACTH peptides used in this IRMA were purified from peptides secreted by human small cell lung cancer cells (DMS–79; White *et al.*, 1987). POMC peptides in the culture medium were characterized by Sephadex G75 chromatography and specific immunoradiometric analysis.

The functions of the HMW ACTH peptides, which are present in high concen-

tration in fetal plasma, are still a matter of debate. It has been proposed that the HMW forms are weakly steroidogenic and possibly growth-promoting in low concentrations (Gasson, 1979; Chatelain and Dupony, 1980; Roebuck *et al.*, 1980; Durand *et al.*, 1984a). Some peptides derived from the N-terminal fraction of the POMC molecule also show biological activity in adrenal steroidogenesis (Pederson and Brownie, 1980; Al Dujaili *et al.*, 1981; Lis *et al.*, 1981). N-POMC-derived peptides (N-POMC-(1-61) amide), γ_2 melanocyte stimulating hormone (MSH) and γ_3-MSH potentiate the acute steroidogenic activity of $ACTH_{1-24}$ on ovine fetal adrenal cells (Durand *et al.*, 1984a). Other POMC-derived peptides, including β-LPH, also possess a trophic effect, these were shown to enhance the sensitivity of the fetal adrenal cells to the steroidogenic actions of $ACTH_{1-24}$ (Durand *et al.*, 1984a).

Fetal bilateral adrenalectomy markedly increased the proportion of $ACTH_{1-39}$ compared with intact controls, and $ACTH_{1-39}$ was present in substantial amounts (30% of total immunoactivity) from as early as 117 days of gestation.

In contrast, Jones and Roebuck (1980) have proposed that the HMW precursors of ACTH which are present in the fetal circulation may antagonize the stimulatory effect of ACTH on the adrenal earlier in gestation, and the preferential secretion of $ACTH_{1-39}$ late in gestation may explain the increase in fetal growth and cortisol secretion at that time, 1983). Durand *et al.* (1985a,b) stressed that, in the studies of Roebuck *et al.* (1980), a substantial reduction in ACTH-induced steroidogenesis was only obtained when the ratio of HMW forms of ACTH/$ACTH_{1-39}$ was about 10. This ratio was always <4 in the fetal pituitary (Silman *et al.*, 1979) and lower in fetal blood (Jones and Roebuck, 1980). However, it has recently been shown, using an IRMA, that the molar ratio of HMW species/$ACTH_{1-39}$ at days 110–114 clearly exceeded this figure, but by days 140–142, the ratio had decreased to 7.9 (Carr *et al.*, 1992). This decreasing ratio may explain the increase in fetal adrenal steroidogenesis as term approaches.

In contrast to earlier results, recent experiments provide strong evidence that POMC and pro-ACTH (used at concentrations found in fetal lamb plasma) inhibit $ACTH_{1-24}$ -induced secretion of cortisol from ovine fetal adrenal cells *in vitro* (Crosby *et al.*, 1993). By themselves, neither of the HMW peptides had any steroidogenic action on the adrenal cells. However, both independently inhibited $ACTH_{1-24}$-stimulated cortisol secretion from adrenal cells derived from fetal sheep between days 116 and 132 of gestation. In cells from fetuses greater than 140 days' gestation, pro-ACTH, but not POMC, consistently inhibited the action of $ACTH_{1-24}$, suggesting the effects of POMC vary as a function of gestational age. At physiological concentrations, these HMW peptides markedly lowered the maximum cortisol response of fetal adrenal cells to $ACTH_{1-24}$. These findings suggest that, at the concentrations of the HMW species found in fetal plasma (Carr *et al.*, 1992), the steroidogenic action of $ACTH_{1-39}$ (or $ACTH_{1-24}$) is severely blunted and that the fetal plasma cortisol concentrations required to induce parturition cannot be achieved until the concentrations of $ACTH_{1-39}$ present in the fetal circulation increase substantially. At the present time we lack detailed information on the plasma concentrations of the precursor peptides from day 140 until term. Clearly, this inhibitory action of the HMW species can be overridden by high concentrations of ACTH, since fetal infusion of $ACTH_{1-24}$ will initiate premature labour. In the days preceding parturition, the plasma $ACTH_{1-39}$ concentrations may have increased sufficiently to override the inhibitory action of the HMW species.

It has been argued that, after fetal hypophysectomy, the fetal adrenal gland should be more sensitive to ACTH due to the removal of the large molecular weight 'inhibi-

tory' peptides. Some peptides derived from the N-terminal fraction of the POMC molecule show biological activity in adrenal steroidogenesis (Pedersen and Brownie, 1980; Al Dujaili *et al.*, 1981; Lis *et al.*, 1981). N-POMC-derived peptides ($N\text{-}POMC_{1-61}$) amide, γ_2-melanocyte-stimulating hormone (MSH) and γ_3-MSH potentiate the acute steroidogenic activity of $ACTH_{1-24}$ on ovine fetal adrenal cells (Durand *et al.*, 1984a). Other POMC-derived peptides, including β-LPH, also possess a trophic effect and enhance the sensitivity of the fetal adrenal cells to the steroidogenic actions of $ACTH_{1-24}$ (Durand *et al.*, 1984a). It might be expected that the adrenal glands would be less responsive to $ACTH_{1-24}$ after hypophysectomy, which removes all these other peptides, and when $ACTH_{1-24}$ was infused into fetuses hypophysectomized 7–16 days earlier the fetal cortisol concentrations were substantially lower than those in intact fetuses (Kendall *et al.*, 1978b). These results suggest that, without the pituitary, the fetal adrenal is less responsive to ACTH and that HMW species may exert an important trophic action on the fetal adrenal and enhance its responsiveness to $ACTH_{1-24}$ or $ACTH_{1-39}$. Removal of pituitary hormones *in vivo* for 6 days (by fetal hypophysectomy) resulted in a decreased ability of cultured adrenal cells from these fetuses to produce cAMP and corticosteroids in response to $ACTH_{1-24}$ compared with cells from control fetuses (Durand *et al.*, 1985a), although Connors and Liggins (1980) saw no change in the responsiveness of fetal adrenals to ACTH within 24 h after hypophysectomy. The secretion of large molecular weight POMC species by the fetal pituitary may therefore: (i) assume a trophic role for the fetal adrenal, preparing it for the increased levels of $ACTH_{1-39}$ which will follow, and (ii) modulate the action of $ACTH_{1-39}$ released at the same time under stressful conditions and thus exert a protective role against the premature release of ACTH.

There may also be extrapituitary factors which inhibit fetal adrenal activity (Durand *et al.*, 1982a, 1985a,b). PGE_2 produced by the placenta may exert an important trophic action on the HPA (section 10.10.1). Recent studies have shown that, following fetal hypophysectomy at 125 days' gestation, a continuous infusion of very small amounts of $ACTH_{1-24}$ (115 pmol/h/kg) starting immediately after surgery, induced delivery at term (Jacobs *et al.*, 1993). Using an IRMA, the concentration of $ACTH_{1-24}$ in carotid artery plasma of hypophysectomized fetuses during the infusion was undetectable (less than 2.2 pg/ml) throughout the study, whereas the fetal plasma concentration of $ACTH_{1-39}$ in age-matched control fetuses ranged from a mean of approximately 35 pg/ml at day 135 to 160 pg/ml at term (day 147). In this study, only very low concentrations of bioactive ACTH were required to induce normal adrenal growth, a normal preparturient increase in fetal plasma cortisol concentrations and delivery at term. The authors (Jacobs *et al.*, 1993) concluded that in the absence of the pituitary, the fetal adrenal glands become more responsive to ACTH, presumably due to the removal of pituitary-derived inhibitory factors such as POMC and pro-ACTH. This study also showed that, in this preparation, the action of ACTH is permissive in that no increase in plasma ACTH concentrations was needed and, given very small amounts of ACTH, the adrenal gland itself can initiate parturition at normal term. Presumably, in normal pregnancies, the adrenal 'clock' is overridden by a central (hypothalamic?) 'clock' which determines the timing of the increase in bioactive $ACTH_{1-39}$ against an inhibitory background of HMW ACTH peptides. Clearly, this study focuses attention on the importance of the fetal adrenal glands in the timing of parturition. Another novel feature of these studies (Crosby *et al.*, 1993; Jacobs *et al.*, 1993) is they suggest that different products ($ACTH_{1-39}$ and POMC, pro-ACTH) of the same pro-hormone may act as

agonists and antagonists of their target organ, the fetal adrenal gland.

10.4 DEVELOPMENT OF FETAL ADRENAL FUNCTION

The increase in fetal plasma cortisol concentrations, starting about 10–12 days before parturition (Magyar *et al.*, 1980a), coincides with an enhanced responsiveness of the fetal adrenal to $ACTH_{1-24}$ (Liggins *et al.*, 1977). Before that time the immature fetal adrenal cortex responds poorly to short (1–2 h) infusions of $ACTH_{1-24}$ (10 μg/h) (Bassett and Thorburn, 1973; Liggins *et al.*, 1977; Brown *et al.*, 1978), yet a similar infusion into the mother caused a very rapid increase in maternal corticosteroid concentrations. The plasma cortisol response to $ACTH_{1-24}$ indicated that fetal adrenal sensitivity increased as a function of age late in gestation (Rose *et al.*, 1982). Although hypoxaemia raised the ACTH concentration in fetal plasma, the increase in ACTH was associated with a large and rapid increase in plasma corticosteroid concentrations only after day 139 (Jones *et al.*, 1977b). Similarly, the increase in plasma ACTH concentrations in response to haemorrhage (Rose *et al.*, 1978) and hypotension (Rose *et al.*, 1981) occurs without any significant corticosteroid response until late in gestation (0.89–0.98 of gestation). Although the bioactivity of the ACTH peptides released in these experiments is still uncertain (section 10.3), the pattern of responses of the fetal adrenal gland, as judged by the cortisol concentrations, was similar to that observed with $ACTH_{1-24}$, indicating that an increase in adrenal sensitivity late in gestation (during the last 10–12 days) corresponded to the increase in fetal plasma cortisol concentrations (Magyar *et al.*, 1980a). The increase in cortisol concentrations is an expression of the release of bioactive $ACTH_{1-39}$ from the fetal anterior pituitary gland.

The adrenal response to corticotrophin-releasing factor (CRF) occurs by 110–120 days' gestation, with a marked response at 125 days' gestation (Norman *et al.*, 1985; Pradier *et al.*, 1985). Norman *et al.* (1985) observed a significant increase in the plasma cortisol concentrations in normal fetuses as early as 125–130 days' gestation, i.e. some 25 days before delivery. The gestation length of sheep with chronically instrumented fetuses is often several days shorter than the mean gestation length of the flock and can vary between laboratories, sheep breeds and the number of experiments carried out on the fetus. Cortisol assays also vary between laboratories and it is easier to detect small changes in cortisol concentrations with more sensitive and specific assays. Nevertheless, the cortisol response to CRF in the above studies occurred earlier and was more marked than expected and raises the possibility that the pituitary (and or placental) factors released by CRF are more steroidogenic than $ACTH_{1-24}$. Another index of increased trophic drive to the fetal adrenal gland is its change in weight: the fetal adrenal gland grows in parallel to the growth of the fetus until day 130–135 when there is a rapid growth surge (Comline and Silver, 1961; Liggins, 1969a), indicating that significant amounts of $ACTH_{1-39}$ do not appear in the fetal circulation until this time.

10.5 FETAL MATURATION – *IN VITRO* STUDIES

In a perifusion system, the corticosteroid production of adrenal tissue from fetal lambs (100–145 days' gestation) in response to $ACTH_{1-24}$ increased gradually until 137 days and then increased markedly until term (145 days) (Bassett and Thorburn, 1973; Madill and Bassett, 1973). This increase paralleled the increases in adrenal weight and plasma corticosteroid concentration which occurred before birth (Madill and Bassett, 1973). It was suggested that *in vivo* the adrenal may well be responding at near-maximal rates to stimulation by endogenously produced ACTH dur-

ing the last 7–10 days of gestation, although this is clearly not so after birth (Madill and Bassett, 1973). These studies showed that, although the adrenals of younger fetuses can respond acutely to ACTH stimulation, it is the *in vivo* maturation of the ACTH-responsive system of the fetal adrenal which is rate limiting in the marked increase in corticosteroid concentrations during the last week before parturition. The studies of Madill and Bassett (1973) illustrate that the fetal adrenal depends on ACTH to maintain its steroidogenic capacity. The weight of the adrenals, the plasma cortisol concentration and the response of the adrenals to ACTH increase in parallel.

When $ACTH_{1-24}$ is infused over 3–4 days in amounts that result in supraphysiological concentrations in the plasma, fetal adrenal maturation is induced, but it is not known whether ACTH in physiological concentrations is responsible by itself for the normal preparturient increase in fetal adrenal responsiveness. An extrapituitary inhibitor of adrenal maturation (Durand *et al.*, 1982a, 1985a,b) and PGE_2, released from the placenta (section 10.10.1), has been suggested to play a role in fetal adrenal maturation.

Although the acute response of the fetal adrenal to ACTH is relatively weak before about 136–140 days' gestation, many studies have shown that prolonged infusion of $ACTH_{1-24}$ (4–10 μg/h) before that time can induce premature adrenal maturation, with high levels of cortisol in the fetal plasma at delivery (Liggins, 1968; Bassett and Thorburn, 1973; Strott *et al.*, 1974; Kendall *et al.*, 1977). The doses used are probably pharmacological and exceed the calculated production rate of $ACTH_{1-39}$ (40 ng/h) by a factor of 50–200 (Jones *et al.*, 1975; Nathanielsz *et al.*, 1977). When the dose of $ACTH_{1-24}$ was reduced to 0.25 μg/h, starting at day 129, two fetuses were delivered at 143 and 144 days' gestation, suggesting possible premature delivery (Cabalum *et al.*, 1982). Clearly this dose of $ACTH_{1-24}$ must have been close to or at the threshold: it would be of value to measure the plasma concentrations of ACTH and cortisol in hypophysectomized and control fetuses infused with 100–200 ng/h of $ACTH_{1-24}$ from 120 days' gestation. This amount of ACTH should provide sufficient trophic support for the fetal adrenal. If the hypophysectomized fetuses (with ACTH infusion) are delivered at normal term, it would suggest that the trigger for parturition may reside in the adrenal or the placental–adrenal axis.

Recently, these questions have been addressed experimentally. Fetuses hypophysectomized at 125 days' gestation and infused with 0.2 μg/h $ACTH_{1-24}$ delivered prematurely while those infused with 0.1 μg/h delivered at term (Jacobs *et al.*, 1993). These experiments demonstrate how exquisitely sensitive the fetal adrenal glands are to biologically-active ACTH in the absence of the pituitary.

Because of their earlier observations and those of others indicating that many peptide hormones are secreted in a pulsatile fashion, Lye *et al.* (1983) compared the effect of administering ACTH as pulses (66 ng/min given for 15 min every 2 h) with giving the same dose (990 ng per 2 h) as a continuous infusion. This dose of ACTH (~500 ng/h) is half the dose (1 μg/h) used by Cabalum *et al.* (1982) but only twice the apparent threshold (see above). Pulsatile administration of ACTH was continued until premature delivery occurred with a mean time interval of 99.1 h for singleton fetuses. Both the continuous and pulsatile modes of administration of $ACTH_{1-24}$ provoked a significant increase in the fetal plasma cortisol concentrations (Lye *et al.*, 1983). Unfortunately, plasma concentrations of ACTH were not measured. However, increasing the $ACTH_{1-24}$ dose from 250 ng/h (Cabalum *et al.*, 1982) to 500 ng/h (Lye *et al.*, 1983) was sufficient to induce premature parturition, suggesting that the system is very sensitive to a small change in ACTH concentrations.

10.6 BIOCHEMICAL CHANGES IN THE FETAL ADRENAL ASSOCIATED WITH MATURATION

The fetal adrenal responds *in vitro* to ACTH with maximum cortisol output per unit weight of gland early in pregnancy (days 50–60); the capacity is reduced during mid-pregnancy but returns again near term (Wintour *et al.*, 1975). It has been suggested that there is a suppression or inhibition of adrenal function around day 100 (mid-gestation) (Durand *et al.*, 1982a, 1985a,b) and the withdrawal of this inhibition may be responsible for the increased adrenal responsiveness to ACTH (adrenal maturation) that precedes parturition. A lack of circulating $ACTH_{1-39}$ (or the presence of HMW species) would also explain this so-called inhibition because the infusion of $ACTH_{1-24}$ can reverse it.

Administration of $ACTH_{1-24}$ to fetuses after day 100 of gestation causes premature maturation of fetal adrenal function (Challis *et al.*, 1982a; Durand *et al.*, 1982b, 1984b; Lye *et al.*, 1983; Cathiard *et al.*, 1985, Challis and Brooks, 1989). Specifically, the changes in the adenylate cyclase system and steroidogenic enzymes resemble those seen before normal-term parturition. Infusion of $ACTH_{1-24}$ (100 μg/day for 5 days) into 115-day ovine fetuses caused a marked increase in the ability of adrenal cells to produce both cAMP and corticosteroids, when stimulated by $ACTH_{1-24}$ or cholera toxin (Durand *et al.*, 1981a; Challis *et al.*, 1982b). The changes in the cell membrane included:

1. an increased activity of the regulatory and/or catalytic subunits of adenylate cyclase as demonstrated by a greater response of cyclase to both sodium fluoride and guanylylimidodiphosphate [Gpp(NH)p] compared with that of control fetuses;
2. the appearance of a more efficient 'coupling' between ACTH receptors and adenylate cyclase, because $ACTH_{1-24}$, which is unable to increase cyclase activity in membranes from control fetuses, stimulated this enzyme in membranes from $ACTH_{1-24}$-treated fetuses;
3. an increased number of ACTH receptors from 47 ± 4 to 106 pmol per μg of DNA (Durand *et al.*, 1981b).

10.7 ACTH RECEPTORS IN THE FETAL ADRENAL

Recent studies have been directed towards elucidating changes in the number of receptors for ACTH (Durand, 1979), in the activity of adrenal adenylate cyclase (Durand *et al.*, 1981a–c) and in activities of the enzymes operant in the cortisol biosynthetic pathway (Anderson *et al.*, 1970, 1972; Madill and Bassett, 1973). ACTH binding sites have been identified in cell membrane preparations of fetal sheep adrenal glands. Determination of the affinity of the binding sites by Scatchard analysis gives an apparent K_d of about 10^{-7} M, a lower binding affinity than normally associated with membrane receptors (Durand, 1979). However, the K_d of the receptor–hormone binding and the apparent ED_{50} of adenylate cyclase activation by ACTH ($2–5 \times 10^{-8}$ M) are reported to be well correlated (Durand *et al.*, 1985b). There is another small pool of high-affinity sites in adult adrenal membranes (K_d 10^{-12} M or 10^{-10} M) (Lefkowitz *et al.*, 1971; McIlhinney and Schulster, 1975). The hypothesis of a dual messenger function in ACTH action on adrenal steroidogenesis has received considerable attention (Li *et al.*, 1989; Gallo-Payet and Payet, 1989). ACTH is now known to stimulate steroidogenesis by at least two mechanisms. Both appear to involve specific cell membrane receptors, but only one class of receptor recruits the formation of cAMP in the signal transduction process. It has also been proposed that mobilization of intracellular calcium mediates steroidogenesis in response to a receptor species independent of adenylate cyclase (Yanagibashi, 1979; Kojima *et al.*, 1985; Rasmussen *et al.*, 1986). More-

over, low concentrations of ACTH can stimulate steroid secretion without detectable changes in intracellular cAMP, and can induce calcium influx as well as a rise in cytosolic calcium (for references see Gallo-Payet and Payet, 1989). Accordingly, Gallo-Payet and Payet (1989) have postulated that, at low concentration, ACTH binds preferentially to the high-affinity site of its receptor (type I), leading to calcium influx by depolarization of the membrane potential, and to steroid secretion predominantly through an inositol phosphate (IP_3)- and Ca^{2+}-stimulated pathway. At higher concentrations, ACTH also binds to a lower affinity site of its receptor (type II), largely stimulating cAMP production and further increasing steroid secretion. Li *et al.* (1989) have proposed that $ACTH_{1-10}$ and $ACTH_{11-24}$ promote adrenal steroidogenesis by different mechanisms. Using bovine adrenal cells they found that one class of receptor recognized $ACTH_{1-10}$, but not $ACTH_{11-24}$, and that it was linked to the cAMP messenger pathway. In contrast, $ACTH_{11-24}$ was linked to the IP_3 pathway. Presumably $ACTH_{1-24}$ works through both the type I (IP_3/Ca^{2+}) and type II (adenylate cyclase) pathways. It is therefore of considerable interest that $ACTH_{11-24}$ displaces ^{125}I-labelled $ACTH_{1-24}$ from its binding sites on ovine fetal adrenal preparations, whereas $ACTH_{1-10}$ does not (Durand *et al.*, 1985b). This would suggest that the type I receptor and its associated IP_3/Ca^{2+} pathway is present in fetal membranes (between 100 and 130 days' gestation), whereas the type II receptor and its associated cAMP pathway is not.

The number of $ACTH_{1-24}$ binding sites, expressed per μg of DNA, remains constant from day 124 to day 140, then increases dramatically (threefold) between day 140 and term (Durand *et al.*, 1985b). The close temporal relationship between the increase in adrenal adenylate cyclase responsiveness, the plasma corticosteroid concentrations and the number of adrenal ACTH receptors from day 140 supports the functional specificity of these binding sites and strongly suggests that the increase in their number plays an important role in the preparturient maturation of the fetal adrenal (Manchester and Challis, 1982; Durand *et al.*, 1985b). It also indicates that the preparturient increase in ACTH receptors is closely linked to adenylate cyclase activity of the receptors and suggests that the receptors are of type II. Adrenal cells between 100 and 130 days' gestation have high levels of ACTH receptors, but their response to ACTH, as judged by adenylate cyclase activity, is poor (Durand *et al.*, 1981a–c). At 124 days' gestation, $ACTH_{1-24}$ was not able to increase adenylate cyclase activity in crude membrane preparations from ovine fetuses. It is possible, therefore, that the ACTH receptors present in the fetal adrenal between 100 and 130 days are type I and are associated with the IP_3/Ca^{2+} pathway, and that the increase in receptors during the last 7–10 days is due to a marked increase in type II receptors which account for the increase in adenylate cyclase activity and steroidogenesis. The loss of sensitivity of the fetal adrenal in mid-gestation may be associated with the loss of type II receptors (due to low $ACTH_{1-39}$ concentrations), and the biochemical changes observed at this time may be equivalent to a functional hypophysectomy with a selective loss of type II receptors. This situation can be reversed by the infusion of $ACTH_{1-24}$ into young fetuses, in which the changes in cAMP and corticosteroid production closely resemble those that occur spontaneously at term (Durand *et al.*, 1981b) and with $ACTH_{1-24}$ infusion of hypophysectomized fetuses (Jones *et al.*, 1978b). It has been shown in adult hypophysectomized rabbits that ACTH alone can induce its own (presumably type II) receptors, and so the preparturient increase in ACTH receptors may be due to a direct effect of ACTH.

It is therefore possible that, with very low levels of ACTH in mid-gestation, the numbers of type II receptors are lost and post-receptor changes occur. At day 63, ACTH,

cholera toxin, Gpp(NH)p and forskolin all stimulated cAMP and cortisol output by ovine fetal adrenal cells (Manchester and Challis, 1982; Durand *et al.*, 1985b, 1987; Challis and Brooks, 1989). Responses to these agonists were lost at day 100 but reappeared near term (Durand *et al.*, 1981a; Manchester and Challis, 1982). Durand *et al.* (1981b) were unable to stimulate adenylate cyclase activity with ACTH using adrenal membranes from day 124 fetuses, although sodium fluoride and Gpp(NH)p were effective. By day 140, however, the ACTH effect had reappeared and was enhanced by Gpp(NH)p. Manchester and Challis (1982) concluded that their inability to stimulate steroid output in response to ACTH between days 100 and 130 could relate to the presence of a population of ACTH receptors that are not functionally linked to adenylate cyclase. However, the receptors may be linked to the IP/Ca^{2+} pathway. Although in these studies there was no steroidogenic response to ACTH, earlier *in vitro* studies (Glickman and Challis, 1980; Magyar *et al.*, 1980b) had shown a small response to ACTH, and Norman *et al.* (1985) and Pradier *et al.* (1985) found that CRF administration to fetuses between 115 and 130 days' gestation caused a small but significant increase in cortisol concentrations; this response may be mediated by the type I receptor.

It has been suggested that the block to adrenal responsiveness after day 124 is due to decreases in GTP availability or GTP binding (Durand *et al.*, 1981b), and that coupling through the G_s protein is probably a rate-limiting step in cAMP production (Durand *et al.*, 1985b). It assumed that appropriate (possibly type II) receptors are present before 140 days but the available data would be consistent with a lack of adenylate cyclase-coupled (type II) receptors. These receptors can be induced *in vivo* or *in vitro* by ACTH treatment. As the studies of Li *et al.* (1989) indicate that ACTH acts via both receptors simultaneously, the results with $ACTH_{1-24}$ suggest that, if only the type I receptor is present (e.g. between 100 and 130 days' gestation), the steroidogenic response, although present, would be greatly reduced. The appearance of the type II receptor (e.g. at 137–140 days) would greatly enhance the steroidogenic response to ACTH. If the development of adenylate cyclase activity in the fetal adrenal membranes is dependent on the presence of biologically active ACTH in the fetal circulation, it would suggest that $ACTH_{1-39}$ concentrations in fetal plasma must be low until about 137 days' gestation or inadequate to induce the adenylate-coupled (type II) receptors.

In summary, the increase in fetal cortisol concentrations occurs in two phases the first, starting 20–25 days before delivery, is small and gradual and the second, starting some 4–5 days before delivery, is rapid and marked. It is possible that $ACTH_{1-39}$ at low levels (or the HMW species of POMC at high concentrations) acts via the high-affinity type I receptors to produce low levels of steroidogenesis and low cortisol concentrations, and that with increasing $ACTH_{1-39}$ concentrations the type II receptors are induced and steroidogenesis and cortisol secretion increase markedly.

10.8 INHIBITION OF FETAL ADRENAL FUNCTION

Adrenal cells from 115 to 120-day ovine fetuses, when cultured for 6 days, underwent spontaneous maturation of their response to $ACTH_{1-24}$ (Durand *et al.*, 1981a, 1982a, 1985a,b). In cells maintained in ACTH-free media, basal cAMP production remained low and constant; an exponential increase in their cAMP response to a 2-h treatment of $ACTH_{1-24}$ was observed, and by day 6 the response was 25-fold higher than on day 1. When cells were exposed to $ACTH_{1-24}$ for 2 h per day from day 1 onwards, the development of the cAMP response was faster, but

the production of cAMP was only slightly greater than that of cells cultured in ACTH-free media (Durand *et al.*, 1982a). Durand *et al.* (1982a) therefore postulated the existence in the ovine fetus of factor(s) which inhibit the 'spontaneous' development *in vivo* of some component(s) of the $ACTH_{1-24}$-sensitive adenylate cyclase system. The action of the putative inhibitory factor(s) can be overcome by infusing fetal lambs with $ACTH_{1-24}$. In some cell systems, calcium can antagonize the actions of cAMP: calcium–calmodulin complex activates cAMP phosphodiesterase, the enzyme that catalyses the metabolism of cAMP to the inactive 5'-AMP. An increase in free cytosolic calcium ion can therefore decrease the levels of cAMP and cAMP-dependent protein kinase activity and change the activities of the enzymes that are substrates for this kinase (Mendelson, 1988). It is possible that an inhibitory factor might work via such a system and suppress cAMP levels. Oka *et al.* (1989) have shown that angiotensin II and transforming growth factor beta (TGF-β), both of which are known to act through IP_3/Ca^{2+} receptors, can block the stimulatory actions of ACTH on cortisol production in cultured bovine fetal adrenal cells. In ovine fetal adrenal cells angiotensin II and TGF-β inhibited the ACTH induction of cortisol production and $P450_{17\alpha}$ expression (Rainey *et al.*, 1991). The putative inhibitor(s) could be therefore acting via this IP_3/Ca^{2+} pathway. However, at low concentrations, ACTH binds to high-affinity sites (section 10.7), leading to calcium influx through voltage-dependent Ca^{2+} channels secondary to decreased potassium permeability, leading to steroid secretion by the IP_3/Ca^{2+} pathway (see Gallo-Payet and Payet, 1989). This receptor pathway may operate in the fetal adrenal despite the functional absence of the adenylate cyclase pathway. It is possible that at low concentrations, $ACTH_{1-39}$ binds to the high-affinity sites, producing low levels of cortisol and inhibiting the adenylate cyclase pathway. However, as $ACTH_{1-39}$ concentrations increase, adenylate receptors increase, thereby stimulating steroidogenesis.

Challis *et al.* (1984) have shown that trifluoperazine, a calmodulin antagonist, blocks both ACTH- and dibutyryl cAMP-stimulated cortisol output by term fetal adrenal cells, providing further evidence that the calmodulin system is involved in post-receptor events in the fetal adrenal. In addition, the calcium channel blockers nifedipine and verapamil inhibit steroidogenesis in bovine adrenal cells induced by $ACTH_{1-10}$, $ACTH_{11-24}$ or $ACTH_{1-24}$ (Li *et al.*, 1989), suggesting that calcium is required for release of steroid from adrenal cells regardless of the receptor/effector mechanism.

10.9 STEROIDOGENIC PATHWAYS

Madill and Bassett (1973) showed that cortisol (F) was the principal corticosteroid released by the fetal adrenal at term, the molar ratio of F to corticosterone (B) in the perfusion eluate increased from 1.2 for tissues from fetuses of 100–200 days' gestation, to 2.5 at 135 days. In older fetuses, the ratio varied between 1.5 and 12.5 with a mean of 5.3 (± 1.1) compared with 7.1 ± 0.3 in lambs and 10.5 ± 2.3 in adult sheep. Alexander *et al.* (1968) found a similar increase in the F/B ratio in adrenal venous plasma as the fetus neared term. Madill and Bassett (1973) considered the changes in the F/B ratio reflected an activation of 17α-hydroxylase by ACTH. Wintour *et al.* (1977) reported the inability of adrenal quarters from fetuses of 90–120 days' gestation to produce F in response to ACTH. Anderson *et al.* (1970) suggested that both 17α and 11β hydroxylating enzyme systems were relatively inactive in the adrenal cortex of the fetal lamb at 122 days' gestation and that these activities increased greatly just before term or after prolonged fetal infusion of ACTH (Anderson *et al.*, 1972).

In an attempt to elucidate the change in activities of enzymes involved in corticosteroid synthesis, Manchester and Challis (1982)

measured the formation of F and B in the presence of pregnenolone (P_5), 17α-hydroxypregnenolone (17α-OHP_5), progesterone (P_4) and 17α-hydroxyprogesterone (17α-OHP_4). In Day 50 tissue all four substrates were converted to F, and P_5 and P_4 were converted to B, showing the presence of 11β- and 21-hydroxylase activities as well as 5,3β-hydroxysteroid dehydrogenase. By Day 100 only 17α-hydroxysteroids were converted to F and the conversion of P_4 to 17α-OHP_4 was low. By day 130 and at term, both P_4 and 17α-OHP_4 were converted to F. It was concluded that there was a marked increase in 17α-hydroxylase activity during the later part of gestation and at term it was no longer rate limiting for cortisol production. The activity of 3β-hydroxysteroid dehydrogenase enzyme also increased during late gestation, but at term it remained, relatively, a rate-limiting enzyme (Manchester and Challis, 1982). Similar conclusions were reached by Durand *et al.* (1982b).

10.10 PROSTAGLANDIN E_2

Placental prostaglandin (PG) synthesis, as judged by the PG synthetic capacity of cotyledonary microsomes (Rice *et al.*, 1988) and isolated placental cells (Risbridger *et al.*, 1985), increases markedly from day 100 onwards. The ovine placenta secretes increasing amounts of PGE_2 into the fetal and maternal circulations (Fowden *et al.*, 1987), in parallel with the increase in fetal cortisol (Thorburn *et al.*, 1988; Thorburn and Rice, 1990). The increase in PGE_2 precedes that of ACTH or cortisol (S.A. Hollingworth, personal communication) and the placenta, by releasing PGE_2, may play an important role in the activation of the fetal HPA axis (Rice and Thorburn, 1988; Thorburn *et al.*, 1988, 1989, 1991; Thorburn and Rice, 1990).

10.10.1 CENTRAL ACTIONS OF PGE_2

The PGs have been implicated in the regulation of the activity of the HPA axis. PGE_2 stimulates ACTH release from the pituitary, and PGs of the E series may act at a suprapituitary site because their action is blocked by the administration of morphine or lesions in the median eminence (de Wied *et al.*, 1969; Peng *et al.*, 1970). Local administration of PGs of the E, F, A and B series stimulate ACTH secretion when injected into medial basal hypothalamus at doses (0.5–1 μg) that are without effect when injected into the lateral basal hypothalamus, the anterior pituitary or the tail vein (Hedge, 1977, for review). Local hypothalamic administration of indomethacin completely prevents compensatory adrenal hypertrophy as well as the ACTH secretion induced by some stresses (Thompson and Hedge, 1978), suggesting that local synthesis of PGs in the hypothalamus can influence the secretion of corticotrophins.

The infusion of PGE_2 into the abdominal aorta (Vilhardt and Hedqvist, 1970) or of PGE_1 intravenously (Berl and Schrier, 1973) causes the release of vasopressin (AVP) and is probably, at least in part, a centrally mediated effect (Vilhardt and Hedqvist, 1970; Andersson and Leksell, 1975; Yamamoto *et al.*, 1976). Further evidence of a direct action of PGE_2 on the hypothalamus was the finding that PGE_2 was also active in an explanted guinea pig hypothalamo-neuro hypophysial complex (Ishikawa *et al.*, 1981). Since PGs are formed in the hypothalamus (Ojeda *et al.*, 1978; Hayaishi, 1983), it has been proposed that PGs exert a stimulatory action on ACTH release by increasing secretion of the ACTH-releasing hormones, CRF and AVP (Hedge, 1977; Thompson and Hedge, 1978). It is possible that PGs produced in the hypothalamus may be carried in the portal circulation to act on the pituitary.

PGE_2 stimulates the hypothalamus to release ACTH but its action on the pituitary is thought to be inhibitory. Several *in vitro* studies have shown that PGE_2, but not $PGF_{2\alpha}$, PGD_2 or PGI_2, inhibits the release of ACTH/β-endorphin after stimulation of the anterior pituitary by AVP or CRF_{1-41} (Vale *et*

al., 1978; Vlaskovska *et al.*, 1984; Vlaskovska and Knepel, 1984). Specific PGE_2 binding sites exist in the anterior pituitary gland (Malet *et al.*, 1982) and PGE_2 is the major PGH synthase (cyclooxygenase) product produced by the gland (Ojeda *et al.*, 1978; Pilote *et al.*, 1982; Vlaskovska *et al.*, 1984). AVP and CRF stimulated the secretion of PGE_2 by the anterior pituitary *in vitro* (Vlaskovska *et al.*, 1984). Thus it has been proposed that PGE_2 is formed locally in the anterior pituitary following CRF and/or AVP binding to the gland and may act as a negative-feedback modulator of ACTH/β-endorphin release and that the effects of blockade of the PGH synthase may be secondary to the removal of a local negative-feedback signal (PGE_2) (Vlaskovska and Knepel, 1984).

When indomethacin or other PGH synthase inhibitors are administered systemically (Weidenfeld *et al.*, 1980, 1981; Thompson and Hedge, 1981) or directly into the hypothalamus (Thompson and Hedge, 1978) ACTH secretion is stimulated. The major site of action of systemically injected indomethacin is considered to be the adenohypophysis and the stimulation is probably secondary to the removal of the local inhibitory control of PGE_2 on pituitary ACTH release.

Vlaskovska and Knepel (1984) have proposed that lipoxygenase-derived arachidonic acid metabolites may exert a stimulatory action on ACTH release from the pituitary. In this study the major metabolite of arachidonic acid in the adenohypophysis was found to be 12-OH-5,8,10,14-eicosatetranoic acid (12-HETE), indicating the relative importance of the C_{-12} lipoxygenase pathway of arachidonic acid metabolism (Pilote *et al.*, 1982). Nordihydroguaiaretic acid (NDGA), which inhibits lipoxygenase activity in the adenohypophysis and reduces the formation of 12-HETE, inhibited the release of β-endorphin in response to stimulation by AVP or CRF, although 12-HETE had no effect on ACTH release (Vlaskovska and Knepel, 1984). The inhibitory action of PGE_2 may also be mediated by the lipoxygenase pathway since PGE_2 no longer inhibited AVP-induced β-endorphin release in the presence of NDGA (Vlaskovska and Knepel, 1984). The potent stimulatory effect of indomethacin on ACTH release may therefore be due to a block of PGH synthase activity, thereby removing the inhibitory action of PGE_2 on the lipoxygenase pathway, and by the preferential shunting of arachidonic acid into the lipoxygenase pathway with the formation of stimulatory metabolites. The administration of PGH synthase inhibitors [4-amino antipyrine (4-AAP) and indomethacin] dramatically increases ACTH concentrations in adrenalectomized fetuses, suggesting that similar mechanisms may be operative in the fetal lamb (Hollingworth *et al.*, 1990b). When PGE_2 (2 μg/min) is infused into fetal lambs from day 110 onwards, there is a pronounced increase in plasma ACTH values (Hollingworth *et al.*, 1990c; Thorburn, 1991; Thorburn *et al.*, 1991). Chromatographic analysis of the plasma on Sephadex G50 columns revealed that PGE_2 stimulated the release of high and low molecular weight precursors as well as $ACTH_{1-39}$ (Figure 10.2).

PGE_2 appears to act on ACTH release at the level of the hypothalamus, because ACTH release does not occur in response to PGE_2 in hypothalamic–pituitary disconnected (HPD) fetuses. When the PGE_2 infusion into the fetus was prolonged for ⩾24 h, fetal plasma ACTH values declined to basal levels after 12 h, although cortisol concentrations remained elevated during the infusion (Thorburn *et al.*, 1991). The changes in ACTH and cortisol concentrations were similar to those during prolonged fetal hypoxaemia caused by a restriction in placental blood flow (Challis *et al.*, 1989; Hooper *et al.*, 1990). The decrease in ACTH values probably resulted from the inhibitory feedback of cortisol, and the prolonged increase in cortisol was probably due to a direct action of PGE_2 on the fetal adrenal (Louis *et al.*, 1976).

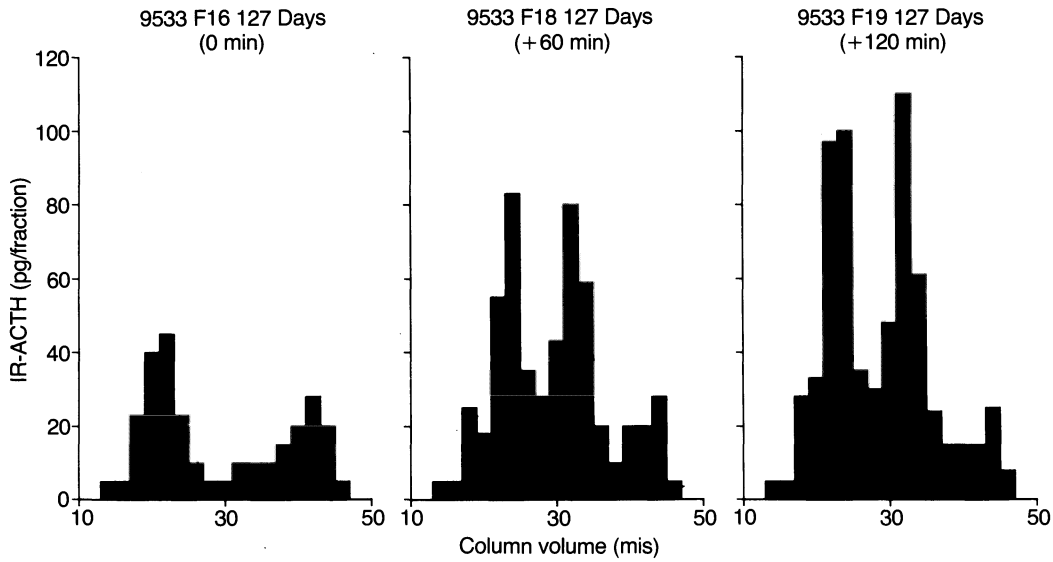

Figure 10.2 Elution profiles of immunoreactive (IR) ACTH in fetal plasma. Samples were collected at 0, 60 and 120 min after the infusion of prostaglandin E_2 (2 μg/min) into an intact fetus at 127 days' gestation. $ACTH_{1-39}$ elutes at 31 ml. Samples (1.0 ml) were subjected to gel filtration chromatography on Sephadex G50 fine using 1% formic acid (containing Polypep) as elution buffer at a flow rate of 10 ml/h.

10.10.2 PGE_2 ACTION ON THE FETAL ADRENAL

In adult animals exogenous PGEs stimulate adrenocortical cAMP production (Sarutz and Kaplan 1972; Honn and Chavin, 1977) and increase adrenal steroid production and release (Flack and Ramwell, 1972; Sarutz and Kaplan, 1972; Laychock and Rubin, 1975; Warner and Rubin, 1975; Ellis *et al.*, 1978). Prostacyclin is more potent than PGE_2 in stimulating steroidogenesis (Ellis *et al.*, 1978; Liggins *et al.*, 1982). The presence of PGs, particularly PGE_2, in adrenocortical tissue is well established. *In vitro* ACTH can induce adrenocortical PG synthesis (Laychock and Rubin, 1975) and indomethacin, which inhibits adrenal PG synthesis (Thompson and Hedge, 1981), can inhibit ACTH-stimulated glucocorticoid secretion (Honn and Chavin, 1977; Spät *et al.*, 1977). *In vitro* reduced PG synthesis inhibits corticosteroid secretion in response to ACTH but not dibutyryl cAMP (Gallant and Brownie, 1973) and indomethacin exerts a direct effect on the adrenal, decreasing responsiveness to acute elevations in ACTH (Thompson and Hedge, 1981). In the latter study, despite decreased responsiveness to ACTH, basal concentrations of corticosterone were increased by the indomethacin treatment, probably secondary to elevated plasma ACTH concentrations. Thompson and Hedge (1981) suggested that the site of action of PGs was at, or before, the activation of adenylate cyclase by ACTH. PGE_2 may therefore act to increase ACTH receptors or to improve the coupling of the receptor to the adenylate cyclase, possibly at the level of the G_s protein, or via the IP_3/Ca^{2+} receptor pathway.

By infusing PGE_2 and $PGF_{2\alpha}$ into fetal lambs on days 125–130 of pregnancy, Louis *et al.* (1976) examined the possibility that PGs might influence fetal adrenal production of corticosteroids. At this stage of gestation, the fetal adrenal responds poorly to short-term infusions of $ACTH_{1-24}$; PGE_2 provoked a

threefold increase in fetal plasma cortisol, whereas a similar amount of $PGF_{2\alpha}$ had no effect. The capacity of the placenta to synthesize PGs may therefore be associated with maturation of the fetal adrenal gland. There is a progressive increase in PGE_2 concentration in the fetal circulation (Fowden *et al.*, 1987), suggesting that the stimulus to fetal adrenal function may come from the placenta (Thorburn *et al.*, 1989). Liggins *et al.* (1982) confirmed the results of Louis *et al.* (1976) and showed that the effect of PGE_2 was not significantly different in intact and hypophysectomized fetuses, eliminating the possibility that pituitary peptides were involved. However, PGE_2 may release ACTH from the ovine placenta as it does from the human placenta (Petraglia *et al.*, 1987).

Specific PGE_2 receptors have been identified in the adrenal membranes of adult humans and sheep, and they stimulate adenylate cyclase activity (Dazord *et al.*, 1974). It is not known whether PGE_2 binding sites are present in ovine fetal membranes, but PGE_2 (10^{-5} M) did not stimulate adenylate cyclase in adrenal membranes of the fetal or newborn (3 days) lamb (Durand *et al.*, 1981b). PGE_2 presumably exerts its action on the fetal adrenal via membrane receptors linked to the adenylate cyclase system (Rice and Thorburn, 1988; Thorburn *et al.*, 1988; Thorburn and Rice, 1990; Thorburn, 1991). Coleman *et al.* (1985) have postulated that PGE_2 can act through three types of receptors, which they have designated, EP_1, acting via the IP^3/Ca^{2+} pathway (present in contractile tissues like smooth muscle); EP_2, via the adenylate cyclase pathway; and EP_3, also acting via the adenylate cyclase pathway but in an inhibitory mode. EP_1 receptors may therefore be present on the fetal adrenal between days 100 and 130 of gestation, and the infusion of PGE_2 may induce a steroidogenic response by stimulating the EP_1 receptors and activating the IP_3/Ca^{2+} pathway. These putative EP_1 receptors and the type I ACTH receptor may be linked to the same pathway. PGE_2, but not cAMP or LH, can stimulate P_4 synthesis in isolated ovine binucleate cells (Wango *et al.*, 1988), suggesting that PGE_2, may act in an autocrine/paracrine fashion to stimulate placental P_4 synthesis, probably by an IP_3/Ca^{2+} pathway. Further studies will be needed to determine whether the IP_3/Ca^{2+} pathway develops earlier than the adenylate cyclase pathway in the fetal adrenal.

10.11 THE DEVELOPMENT OF GLUCOCORTICOID FEEDBACK ON THE FETAL HPA AXIS

Perhaps the key element in the initiation of parturition in sheep is that cortisol must reach sufficiently high concentrations in fetal plasma and be maintained for long enough (36–48 h) to induce high 17α-hydroxylase activity in the placenta (Anderson *et al.*, 1975; France *et al.*, 1988; Mason *et al.*, 1989; Thorburn, 1991; Thorburn *et al.*, 1991). The increased activity of this enzyme causes an increase in the metabolism of P_5 away from P_4 to oestrogens, a profound increase in the oestrogen–progesterone ratio, a steep increase in PGF release, and thereby triggers parturition (Thorburn *et al.*, 1991). Analysis of hormone profiles (Thorburn *et al.*, 1989) of ewes entering term labour (Magyar *et al.*, 1980a; Elsner *et al.*, 1980; Nathanielsz *et al.*, 1982) showed that P_4 concentrations began to decrease rapidly 3.5 days (mean figure) before delivery and this coincided with fetal cortisol concentrations of about 30–40 ng/ml (Magyar *et al.*, 1980a). These levels are achieved only during the preparturient surge of cortisol (Thorburn *et al.*, 1989).

To achieve such high cortisol concentrations it is essential that high plasma $ACTH_{1-39}$ values are maintained during the preparturient cortisol surge. This raises the question of why, during the days preceding parturition, cortisol does not feedback on the hypothalamus and pituitary to inhibit the release of $ACTH_{1-39}$. Earlier in gestation (117–131 days' gestation), the fetal

hypothalamic–pituitary unit is very sensitive to cortisol (Wood, 1986) but, in the last few days of fetal life, the negative feedback sensitivity is apparently absent, allowing the preparturient rise in cortisol to be maintained (Wood, 1987, 1988). It has been suggested that the maintenance of ACTH involves some neural pathways which are not subject to feedback inhibition by cortisol (Wood, 1988) or that some other powerful stimulus to CRF release may override the negative-feedback effects of cortisol. Placental PGE_2, which is present in high concentration in the fetal circulation in the days preceding parturition, may provide such a stimulus (Thorburn, 1991).

The studies of Wintour *et al.* (1980) in adrenalectomized fetuses suggested that the hypothalamic drive to the pituitary increases from 120–125 days of gestation, leading to a progressive increase in ACTH and β-endorphin concentrations. This finding clearly demonstrated the presence of an hypothalamic drive to the pituitary causing the release of increasing amounts of ACTH into the fetal circulation. The full extent of the stimulus was only revealed when the inhibitory effect of cortisol was removed by adrenalectomy. In attempting to unravel the mechanisms involved in the initiation of parturition in sheep, it would seem essential to determine the nature of the stimulatory input into the hypothalamus.

After fetal adrenalectomy at 115 days' gestation, and hence removal of the inhibitory action of cortisol on the hypothalamus and pituitary, POMC mRNA levels in the fetal pituitary are significantly higher than in intact fetuses of the same gestational age (135 days) (McMillen *et al.*, 1990).

The high levels of pituitary POMC mRNA found in adrenalectomized fetuses suggested that, in addition to the stimulus to the hypothalamus from the central 'trigger', the hypothalamus and pituitary are released from the negative feedback effect of cortisol making them more responsive to any stimulatory inputs. The high plasma concentrations of PGE_2 found in adrenalectomized fetuses (Hollingworth *et al.*, 1990a) may provide a further stimulus for the release of CRH and AVP thus helping to maintain the high levels of ACTH found in these fetuses. To what extent the increase in plasma ACTH levels in adrenalectomized fetuses (Wintour *et al.*, 1980) is due to the progressive increase in fetal plasma concentrations of PGE_2, rather than stimulation from some central 'trigger' or from the removal of cortisol inhibition, is unknown. The cause of the increase in placental PGE_2 production is also unknown, although it has been suggested (Thorburn *et al.*, 1988; Thorburn, 1991) that it is related in some way to the rapid increase in fetal growth at this time.

Chromatographic analyses of plasma samples from adrenalectomized fetuses showed that $ACTH_{1-39}$ was present in substantial amounts much earlier in gestation (119 days was the earliest sample examined) than in plasma from control fetuses (Hollingworth *et al.*, 1990a; Thorburn *et al.*, 1991). The administration of cortisol to these adrenalectomized fetuses selectively reduced values of $ACTH_{1-39}$ (Hollingworth *et al.*, 1990b) but not those of high or low molecular weight precursors. The proposed model suggests that the $ACTH_{1-39}$ released from the CRF target cells resides in vesicles within those cells (Schwartz, 1990). Furthermore, the CRF responsive cells are the likely site for the release of pulses of $ACTH_{1-39}$ and a paracrine factor that acts to inhibit the secretion of ACTH (HMW forms) from other cells (Schwartz, 1990).

Parkes *et al.* (1988), using an IRMA to measure $ACTH_{1-39}$ specifically reported a parturient increase (fivefold) in $ACTH_{1-39}$ but found no evidence of a rise in $ACTH_{1-39}$ when the increase in fetal cortisol concentrations is expected. The increase in $ACTH_{1-39}$ concentrations may start about 126–130 days of gestation (Hollingworth *et al.*, 1990a) or far earlier (Norman *et al.*, 1985)

but adenylate cyclase activity in the fetal membrane and the major increase in fetal cortisol concentrations develop after 135–137 days of gestation.

A trophic drive to the HPA axis therefore appears to occur relatively early in gestation but is revealed only when the negative-feedback inhibition by cortisol is removed by fetal adrenalectomy. CRF is present in the hypothalamus quite early (115–120 days) but is not released until much later in response to cortisol.

If $ACTH_{1-39}$ is not released in significant amounts until late in gestation (e.g. $\geqslant$135 days' gestation), it is reasonable to ask what causes the initial increase in fetal cortisol levels. The present evidence suggests that HMW POMC species are present in the fetal circulation earlier than is $ACTH_{1-39}$ (Jones, 1983; Hollingworth *et al.*, 1990a; Thorburn *et al.*, 1991). Although they are considered to be only weakly steroidogenic, these peptides may be present in sufficient quantities to initiate a small increase in cortisol secretion from the fetal adrenal. PGE_2 secreted by the placenta may also play a key role (in concert with the HMW species) in stimulating cortisol secretion (Louis *et al.*, 1976; Liggins *et al.*, 1982). When placental PGE_2 release is stimulated by hypoxaemia secondary to restricting placental blood flow, cortisol concentrations are increased and maintained at high levels (Hooper *et al.*, 1990). Thus, together or individually, PGE_2 and the HMW species of POMC may initiate the increase in fetal cortisol levels, acting through a cAMP-independent pathway (section 10.7). This may be enhanced by a decrease in the plasma concentrations of the putative inhibitor proposed by Durand *et al.* (1982a). The gradual increase in fetal cortisol concentrations therefore plays an important part in initiating the maturation of key organ systems of the body (Liggins *et al.*, 1979; Thorburn, 1987) while delaying parturition, by inhibiting the release of $ACTH_{1-39}$, until the maturation process is complete.

Our recent results (Carr *et al.*, 1992), using an IRMA, show a progressive increase in $ACTH_{1-39}$ concentrations from early in the last third of gestation whereas the concentration of the HMW ACTH species remained unchanged, suggesting that the efficacy of the cortisol feedback decreases with time or the stimulus for the release of ACTH progressively increases or both.

Recent studies have clearly demonstrated the ability of cortisol to inhibit ACTH release in adrenalectomized fetuses (Hollingworth *et al.*, 1990b). The administration of cortisol to adrenalectomized fetuses, in amounts sufficient to achieve parturient levels of cortisol in fetal plasma, caused a dramatic decrease in $ACTH_{1-39}$ concentrations to very low levels. In normal fetuses at term, with the same cortisol concentrations, plasma $ACTH_{1-39}$ concentrations were found to be only modestly reduced (S.A. Hollingworth, personal communication, 1993). These results suggest that, in intact fetuses, some positive stimulus opposes the inhibitory action of cortisol on the hypothalamus. This positive stimulus must be independent of the 'trigger' which is present and active in both adrenalectomized and intact fetuses. Since fetal plasma PGE_2 concentrations are high at this time (Fowden *et al.*, 1987; Hollingworth, 1993) and PGE_2 is known to be a potent stimulator of ACTH release (Hollingworth, 1990a), it is possible that PGE_2, derived mainly from the placenta (Fowden, 1987), may be the stimulus that maintains the $ACTH_{1-39}$ concentrations high in the face of high circulating levels of cortisol in normal fetuses at term.

To summarize the above discussion, there appears to be a stimulatory drive to the fetal hypothalamus from a putative 'trigger' mechanism, the site and nature of which is unknown, although it is thought to reside in the central nervous system. This drive initially succeeds in producing only a small increase in fetal plasma $ACTH_{1-39}$ levels (Norman and Challis, 1987a; Carr *et al.*, 1992; Deayton *et al.*, 1993) and in initiating a small increase in fetal

plasma concentrations of cortisol starting about 120–125 days' gestation. This early activation of the HPA axis may be enhanced by the action of PGE_2 acting at the hypothalamus to stimulate the release of CRF and AVP, and thus ACTH and at the adrenal cortex to increase steroidogenesis. It is also possible that the 'trigger' may reside in the placenta and its action on the HPA axis is mediated by PGE_2. The activation of a placental trigger may be related to the growth of the fetus and the metabolic demands placed on the placenta (Thorburn, 1991; Thorburn *et al.*, 1988).

In the absence of adenylate cyclase (type 2) receptors in the fetal adrenal membranes before 137–140 days' gestation, $ACTH_{1-39}$ and PGE_2 may act via type 1 IP_3 receptors to initiate a small, but progressive increase in fetal cortisol concentrations. The increasing levels of cortisol in the fetal circulation exert a positive feedback action on the fetal adrenal cortex by increasing 17α-hydroxylase activity and enhancing the synthesis of further cortisol (see Challis and Brooks, 1989). The increasing cortisol levels may also influence the processing of POMC favouring the secretion of $ACTH_{1-39}$. In the light of recent data (S.R. Crosby, personal communication, 1993), the presence of high concentrations of HMW ACTH species before 140 days' gestation would reduce the responsiveness of the adrenal cortex to $ACTH_{1-39}$.

CRF is present in the fetal hypothalamus before 115–120 days' gestation, and can be released by the fetal infusion of PGE_2, but in the normal fetal sheep, it is not released in significant amounts until much later because of the inhibitory action of cortisol. The low concentrations of cortisol in fetal plasma between 120–140 days play an important role in preparing the fetus for postnatal life by initiating the maturation of key organ systems (Liggins *et al.*, 1979; Thorburn, 1987).

10.12 POSSIBLE HETEROGENEITY OF FETAL PITUITARY CORTICOTROPHS

The above proposal requires the differential regulation of the secretion of the various POMC species, favouring the secretion of the weakly steroidogenic POMC species initially and the more active $ACTH_{1-39}$ later. It was thought that the pituitary corticotrophs were a homogeneous population of cells that responded similarly to hypothalamic factors such as CRF and AVP. However, different cell populations appear to exhibit different secretory patterns in response to CRF, AVP or in the absence of a secretogogue (Schwartz and Vale, 1988; Schwartz, 1990; Schwartz *et al.*, 1991). Pradier *et al.* (1988) noted that in the adult sheep intermediate molecular weight forms of immunoreactive ACTH are secreted by the pituitary in response to AVP, whereas $ACTH_{1-39}$ is preferentially secreted in response to CRF. Thorburn *et al.* (1991) have suggested that the HMW species of POMC may be preferentially secreted in response to AVP by AVP target cells which could also secrete ACTH via a constitutive pathway (Schwartz *et al.*, 1991) and secrete a stimulatory paracrine factor which acts on adjacent corticotrophs (Schwartz, 1990). The putative stimulatory factor may be the lipoxygenase derivative (possibly 12-HPETE) mentioned above (section 10.10.1). This model could be used to explain changes in the fetal pituitary with increasing gestational age and in POMC peptide concentrations in the fetal circulation. The predominance of the HMW species of POMC in the fetal circulation before 135–139 days of gestation may be due to the earlier appearance of the AVP target cells in the fetal pituitary and, possibly, the secretion of AVP by the fetal hypothalamus during this time. This suggestion would be consistent with the findings of Norman and Challis (1987a,b) that the fetal pituitary is sensitive to AVP stimulation (as judged by an increase in plasma ACTH levels) between

days 100 and 130 of gestation but not at days 135–140.

Thorburn *et al.* (1991) have suggested that the late appearance of $ACTH_{1-39}$ in the fetal circulation may be due to the late appearance of CRF target cells or the suppression of CRF release by the low levels of cortisol in the fetal circulation. Fetal adrenalectomy experiments (Thorburn *et al.*, 1991) would favour the latter suggestion. The initial stimulatory drive from the hypothalamus to the fetal pituitary may therefore be AVP before subsequent release of CRF.

10.13 WHAT CONTROLS THE RELEASE OF $ACTH_{1-39}$?

The next critical step in the sequence of events leading to parturition in sheep is an increase in the concentrations of $ACTH_{1-39}$ in fetal plasma. There is some dispute about the timing of this step, but recent data indicate that a **significant** increase in $ACTH_{1-39}$ concentration does not occur before day 135 of gestation (Parkes *et al.*, 1988; Hollingworth *et al.*, 1990a; Deayton *et al.*, 1993) consistent with the timing of the rapid increase in ACTH receptors and adenylate cyclase activity in the fetal adrenal membranes, both of which might be expected since ACTH is known to increase its own adenylate cyclase receptors. These changes would explain the dramatic increase in fetal cortisol concentrations in the 4–5 days before delivery. The most obvious cause of this increase in $ACTH_{1-39}$ concentration is fetal plasma is an increase in the secretion of CRF by the hypothalamus. When feedback inhibition of the hypothalamus by cortisol is removed by fetal adrenalectomy, pituitary POMC mRNA levels increase markedly (McMillen *et al.*, 1990) and there is a marked increase in POMC peptides in the fetal circulation and the premature release of $ACTH_{1-39}$. If the stimulus for $ACTH_{1-39}$ secretion was coming simply from increased secretion of CRF, it might be expected that pituitary POMC mRNA levels would increase in the days before delivery, but McMillen *et al.* (1988) found reduced POMC mRNA levels after 140 days of gestation. However, when fetal pituitaries were removed from ewes in labour, Yang *et al.* (1991) found an increase in some ewes although there was considerable variability between pituitaries.

A potential difficulty in the interpretation of these results is that total anterior pituitary mRNA was measured; if only a subpopulation of the corticotrophs is responsible for secreting most of the circulating $ACTH_{1-39}$, these measurements may not reflect the change in POMC mRNA levels in these different cell populations. However, the decrease in the POMC mRNA levels observed by McMillen *et al.* (1988) is consistent with cortisol exerting a negative feedback (in the slow domain, Dallman *et al.*, 1987) at the pituitary level. Ozolins *et al.* (1990) have also demonstrated with HPD fetuses that cortisol can exert a negative feedback at the pituitary level. There are several possible reasons for the decrease in POMC mRNA levels in the pituitary before birth. Firstly, the secretion of CRF from the hypothalamus may actually be decreased rather than increased. Indeed, Brooks and Challis (1988) found that the CRF content of the fetal hypothalamus had decreased by day 140 to the low values observed at day 100, suggesting that high cortisol concentrations were exerting a negative-feedback effect on CRF gene expression, although the measurement of content must be interpreted with caution. The low levels of CRF may indeed be an expression of high turnover and low storage.

It seems likely that the fetal hypothalamus, and particularly the cells which secrete CRF, is subjected to powerful stimulatory influences which counteract the negative-feedback effects of cortisol and permit a continued secretion of CRF. It would seem that PGE_2 can provide a powerful stimulus for CRF and ACTH release in the fetal lamb (Thorburn, 1989; Thorburn *et al.*, 1991) and

high levels of PGE_2 are found in the fetal circulation in the days before parturition (Fowden *et al.*, 1987). PGs are also known to be synthesized locally in the hypothalamus of many species and may regulate the release of pituitary hormones (Hedge, 1977).

The second reason for the low POMC mRNA levels in the anterior pituitary after day 140 is the high fetal cortisol levels. Finally, the relative amount of HMW species of POMC secreted by the fetal pituitary decreases with increasing gestation (S.A. Hollingworth, personal communication) perhaps due to low levels of POMC mRNA in the putative AVP target cells rather than the CRF target cells. This suggestion would be consistent with the observation by Norman and Challis (1987a) that the fetal pituitary becomes less responsive to AVP by 135–140 days of gestation. Low levels of POMC mRNA in AVP target cells may be secondary to a decrease in the secretion of AVP by the fetal hypothalamus late in gestation or to an increased release of the inhibitor from CRF target cells.

Keeping all these reservations in mind, it is important to consider how the pituitary secretes increasing amounts of $ACTH_{1-39}$ despite decreasing amounts of POMC mRNA. There may be more efficient post-translational processing of the POMC mRNA (McMillen *et al.*, 1988) or the CRF target cells may assume a more important role in the days preceding delivery (Thorburn *et al.*, 1991) so that post-translational processing in these cells favours relatively more $ACTH_{1-39}$ and fully processed forms of POMC than HMW species (Schwartz, 1990). Although PGE_2 does not appear to have a direct stimulatory effect on the secretion of pituitary ACTH in the absence of CRF, since it does not increase ACTH secretion in HPD fetuses (S.A. Hollingworth, personal communication), PGE_2 may increase cAMP levels in the pituitary and therefore increase the efficiency of post-transcriptional events. Indeed, both CRF and PGF_2 can act via adenylate cyclase pathways and may act in concert to facilitate this process.

Whether these putative functional cell types correlate with the 'fetal' (AVP target) and 'adult' (CRF target) cell types (Perry *et al.*, 1985; Mulvogue *et al.*, 1986) needs to be determined. Fetal adrenalectomy delays the appearance of 'adult'-type cells, whereas cortisol infusion into the fetus hastens their appearance (Antolovich *et al.*, 1989). The present proposal suggests that various types of pituitary corticotrophs exist in the fetal pituitary during the last third of gestation. It is possible that the CRF target cells are relatively dormant before 135 days, but can be activated by the increased secretion of CRF after fetal adrenalectomy. The fact that the AVP-sensitive cells do not respond to a release of AVP after day 135 of gestation (Norman and Challis, 1987a) does not establish whether AVP target cells have disappeared or have become non-functional because of low mRNA levels resulting from a lack of stimulation by AVP in late gestation or the increased presence of paracrine inhibitors.

With reference to the more efficient post-translational processing of POMC in the near-term fetal pituitary, different processing pathways may occur in the different cell types. However, it is possible that all corticotrophs possess the same pathways and that the redirection of POMC processing occurs in all cells, leading to an increase in the synthesis of $ACTH_{1-39}$ in the face of normal or low levels of POMC mRNA, or that $ACTH_{1-39}$ is preferentially directed to a secretory rather than storage pathway. Several lines of evidence suggest that cortisol itself may influence post-translational processing by favouring the release of $ACTH_{1-39}$ over the HMW species (Thorburn *et al.*, 1991), perhaps by cortisol acting directly on the corticotroph to influence the translational process or by selectively inhibiting the AVP target cells.

In fetal sheep, the rise in plasma cortisol that precedes parturition (Bassett and Thorburn, 1969; Magyar *et al.*, 1980a) is associated

with an increase in the concentration of CBG in fetal plasma (Fairclough and Liggins, 1975; Ballard *et al.*, 1982; Challis *et al.*, 1985), particularly during the second half of gestation, resulting in a threefold increase in CBG capacity by 140 days of gestation (Ballard *et al.*, 1982). The expected rise in fetal CBG capacity did not occur in hydranencephalic, stalk sectioned or hypophysectomized fetuses. However, Fairclough and Liggins (1975) and Challis *et al.* (1985) found that cortisol stimulated the synthesis of its own binding protein. Ballard *et al.* (1982) reported that the concentration of unbound ('free') corticoids was 0.9 ng/ml (12% of total corticoids) at 115 days and did not increase until after 135 days, reaching a maximum level of 18.7 ng/ml (14.5% of total corticoids on the day before spontaneous term delivery), a 16- to 20-fold increase over values at 115–135 days. Fairclough and Liggins (1975) suggested that the early increase in CBG levels protects the fetus from increases in plasma corticoids that could initiate premature labour. Thus, despite apparently high total concentrations of cortisol in fetal plasma, the effective concentration of cortisol exerting a feedback action on the fetal hypothalamus and pituitary is much lower. Since cortisol is thought to induce CBG synthesis in the fetal liver, this mechanism would allow the adrenal to secrete high concentrations of cortisol while the cortisol itself induces its binding protein, thus lowering its 'free' concentration. This system would be particularly effective if the hypothalamus and pituitary were sensitive only to free cortisol whereas the placenta was also sensitive to bound form (i.e. total cortisol). The action of CBG is therefore to lower the efficiency of the negative-feedback system by maintaining lower free cortisol concentrations. The lower fetal cortisol (total) concentrations reported in some species may result from lower CBG levels.

10.14 FETAL HYPOTHALAMUS: ULTRASTRUCTURAL DEVELOPMENT

Specific antibodies to CRF and AVP have been used to locate CRF and AVP neurones in the paraventricular nucleus (PVN) and supraoptic nucleus (SON) of the hypothalamus of the adult sheep. CRF fibres derived from the neurones projected predominantly to the external lamina of the median eminence (ME), whereas AVP terminals were concentrated in the internal lamina (Levidiotis *et al.*, 1987). CRF neurones were first detected in the fetal PVN at 90 days of gestation, although no connections to the ME were apparent until 105 days. In contrast, AVP neurones were found from 42 days' gestation (earliest age examined); the cell bodies were mainly situated in the SON, but the fibres and terminals were present mainly in the external lamina of the ME and, and the electron microscope level, were closely associated with fenestrated portal vessels (Levidiotis *et al.*, 1987). At later stages there appeared to be redistribution of AVP fibres such that, by 132 days' gestation, AVP projections were more or less equally distributed between the laminae of the ME, whereas in the adult AVP fibres are directed mainly to the internal lamina, in which many are destined for the posterior pituitary. Consistent with the above findings, immunoreactive AVP concentrations in the hypothalamus increase progressively between day 63 and day 138, decrease on day 143 and rise again in post-partum animals (Brieu *et al.*, 1989). The ratio of immunoreactive AVP–CRF was about 5 at days 63 and 123 of gestation, but decreased to 1.2 by term (Brieu *et al.*, 1989). Challis and Brooks (1989) suggested that this ratio reflects the greater efficacy of AVP as a releaser of ACTH in younger fetuses and the decline in potency of AVP relative to CRF with advancing gestation. The early appearance of AVP relative to CRF is consistent with the proposal that AVP may be a significant (and perhaps the major) factor controlling

ACTH release in the ovine fetus before 105 days of gestation (Levidiotis *et al.*, 1987) and probably up to 125–130 days' gestation. It is clear that, despite considerable progress being made in the past few years, more work is needed to explore the many possibilities that have emerged (see review by Challis and Brooks, 1989, for further information on this topic).

10.15 THE 'TRIGGER' FOR PARTURITION

Although the suggestion (Liggins, 1969a) that the fetal hypothalamic–pituitary–adrenal axis played a primary role in the initiation of parturition in sheep has stood the test of time, the 'trigger' for parturition is still uncertain. A single trigger would seem unlikely, because such an important biological system should include a fail-safe mechanism. Some input to the hypothalamus that stimulates the secretion of CRF, leading to activation of the HPA axis, is favoured. The release of AVP appears to precede that of CRF. The placenta could also activate the HPA axis by secretion of PGE_2, although there is no evidence at the present time of placental PGE_2 being the 'trigger' for parturition. The merit of this proposal is that the placenta, being an interface between mother and fetus, responds to insults such as hypoxia, undernutrition and emboli by secreting more PGE_2 (Hooper *et al.*, 1990). The early release of PGE_2 may provide a mechanism for initiating premature labour when the fetus is compromised. Thorburn and Rice (1990) proposed that in normal pregnancies the growth pattern of the fetus may provide the trigger; when the fetus enters its rapid growth phase, PGE_2 secretion by the placenta increases, the HPA axis is activated and cortisol concentrations rise, initiating parturition. One advantage of linking the 'trigger' for parturition with fetal growth (and substrate supply) is that it ensures that the fetus does not outgrow its environment and that it is an appropriate size at term to pass through the birth canal. It provides, therefore, a link between size at birth, fetal maturity and the initiation of parturition.

Cutaneous temperature and pain receptors are active quite early in gestation in the fetal lamb, but the ascending spinothalamic tracts are not functional until around 100 days of gestation (J. Rawson and S.H. Rees, personal communication), and so information will not reach the brain until relatively late in gestation. It can be reasoned that, as the temperature-sensing pathways mature, the fetus becomes aware it is in a hot, humid environment with no means of regulating its temperature and so the 'stress' pathway (the HPA axis) is activated, resulting in its birth. This proposes a physiological mechanism by which the HPA axis might be activated to initiate parturition. This illustrates how the maturation of one physiological pathway may make continued intrauterine life untenable. There are probably many other examples, all of which are likely to activate the HPA axis.

10.16 SUMMARY

Given the evidence of HPA axis activation obtained to date, a possible scheme for the initiation of parturition emerges (Figure 10.3).

Early in the last third of gestation (100–120 days' gestation), the major ACTH species in the fetal circulation are high molecular weight and are probably derived mainly from the AVP target cells in the fetal pituitary. The secretion of HMW species is thought to be stimulated by AVP derived from the fetal hypothalamus. The stimulus for AVP release is either PGE_2, produced locally or in the placenta, or some other stimulatory input into the hypothalamus. The CRF target cells are thought to be relatively quiescent at that time, probably due to a lack of CRF since they can be readily activated to secrete $ACTH_{1-39}$ by adrenalectomizing the fetus and removing the inhibitory feedback effect of cortisol on

the release of CRF from the hypothalamus. The adrenalectomy results suggest that the very low levels of cortisol present before 125 days of gestation must be important for inhibiting CRF release **or** that some other adrenal product suppresses CRF release.

We propose that the major ACTH receptors present in the fetal adrenal before 135–140 days of gestation are type I (IP_3/Ca^{2+}). The HMW species and the $ACTH_{1-39}$ in low concentrations act via the type I receptors to stimulate the fetal adrenal to secrete low levels of cortisol. In some systems activation of IP_3 /Ca^{2+} (type I) receptors can inhibit the activity of the adenylate cyclase (type II) receptors. This may occur in the fetal adrenal and help delay the appearance of the type II receptors until 135 days. PGE_2 may, in concert with the ACTH peptides, stimulate the adrenal type I receptors.

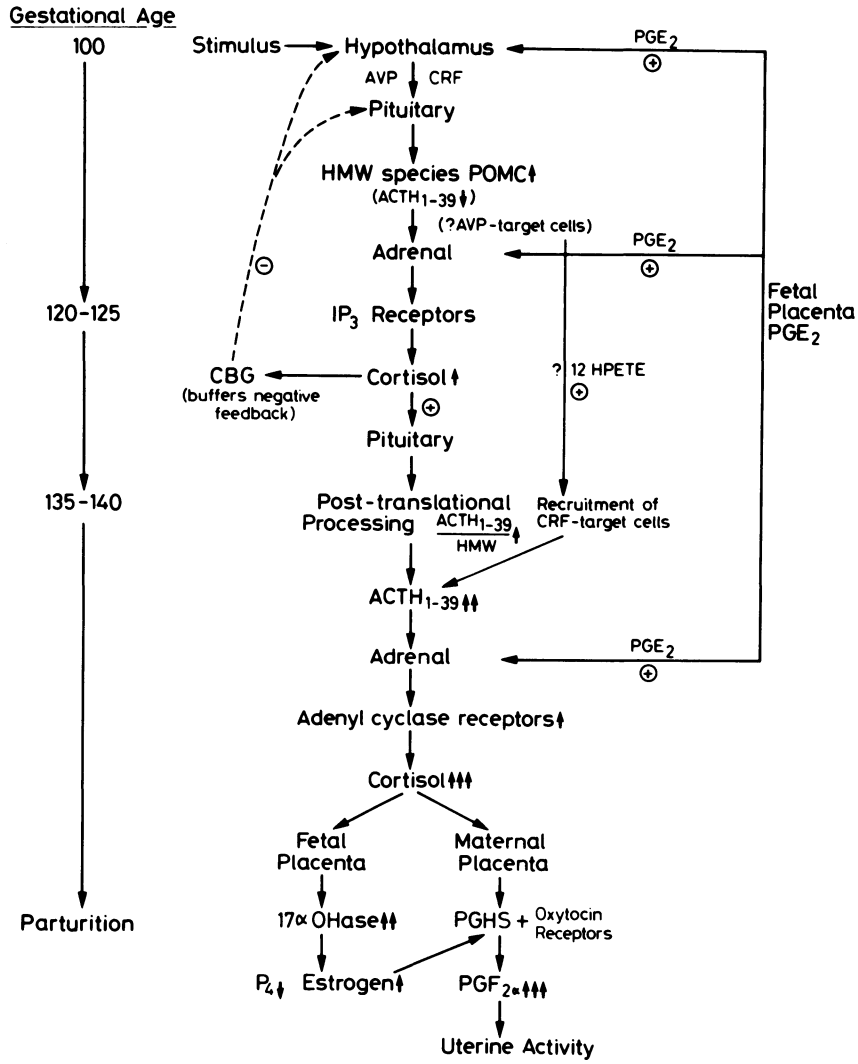

Figure 10.3 Diagrammatic representation of the pathways involved in the initiation of parturition in the sheep.

It is proposed that, with continued stimulation of the AVP target cells, a potent intercellular stimulator is produced which acts on the CRF target cells, rendering them more sensitive to CRF stimulation. Thus, about day 125, perhaps without any increased secretion of CRF, the CRF-responsive cells secrete increasing amounts of $ACTH_{1-39}$ and a substance which is thought to inhibit the activity of the AVP target cells. In this way, the major functional cell type in the fetal pituitary switches gradually from the AVP target cells to the CRF target cells. With the increasing secretion of $ACTH_{1-39}$ by the CRF target cells, increasing numbers of type II (adenylate cyclase) receptors appear in the fetal adrenal from day 135 onwards. The increase in type II receptors leads to a major increase in cortisol production by the fetal adrenal during the last 4–6 days before delivery.

The increasing levels of cortisol exert a negative feedback on the hypothalamus and pituitary. The cortisol inhibition of CRF is countered to a large extent by the stimulus of PGE_2. While the effect of cortisol on the CRF target cells is likely to inhibit transcription of the POMC gene, it may enhance post-transcriptional events leading to secretion of greater amounts of $ACTH_{1-39}$. The increasing levels of cortisol also augment 17α- hydroxylase activity in the fetal adrenal, enhancing the synthesis of further cortisol. Cortisol also stimulates the secretion of CBG from the fetal liver, lowering the concentration of free cortisol and reducing the negative-feedback effects of cortisol.

The progressive increase in the plasma concentrations of $ACTH_{1-39}$ results in a major increase in fetal plasma cortisol values over the last 4–6 days before delivery. The high levels of cortisol induce high levels of 17α-hydroxylase activity in the placenta and lead to a dramatic decrease in maternal P_4 concentrations and an increase in oestrogen concentrations. Finally, the change in the E–P_4 ratio stimulates the release of $PGF_{2\alpha}$ and the initiation of labour.

The foregoing is but one possible model for the initiation of parturition in the sheep. The fetal HPA axis is only the final common pathway leading to parturition, and the maturation of this pathway takes place in an orderly fashion over a relatively long time, at least the last third of gestation. In the fetus, as in the adult, the afferent information influencing the HPA axis can be derived from many sources and can act at several levels. It seems unlikely that a single 'trigger' for the initiation of parturition will be found.

ACKNOWLEDGEMENTS

The authors wish to thank Ms Jan Deayton for her assistance with collating the references, Ms Judi Herschell for typing the manuscript and Drs Jeffery Schwartz, Ross Young and Ross Jacobs for helpful discussions during the preparation of the manuscript.

11.1 INTRODUCTION

During lactation, the suckling offspring controls three major components of lactation: the production of milk within the mammary gland, the ejection of this milk to the offspring and, in many species, the suppression of ovarian activity or delay in implantation. Delaying a new pregnancy ensures sufficient time before the birth of the next offspring to permit adequate growth of the current offspring during lactation. This chapter will review endocrine changes in lactation and their relationship to fertility regulation post partum.

11.2 ENDOCRINE CHANGES ASSOCIATED WITH MILK PRODUCTION

The onset of milk secretion at parturition, lactogenesis, occurs in all mammals and appears to be related not to an increase in the secretion of lactogenic hormones but to a removal of an inhibition of their action at the level of the mammary gland (Forsyth, 1986). There is considerable species variation in prolactin concentrations during pregnancy, but in all species for which data are available prolactin shows a large periparturient increase. If prolactin is suppressed around parturition by the dopamine agonist, bromocriptine, the normal onset of lactogenesis is blocked in rats (Bohnet *et al.*, 1977), rabbits (Djiane and Durand, 1977), pigs (Taverne *et al.*, 1982), monkeys (Schallenberger *et al.*, 1981) and human (Cooke *et al.*, 1976; McNeilly, 1977; F. Peters *et al.*, 1986), confirming the essential role of prolactin. In contrast, suppression of prolactin at parturition in ruminants delays rather than prevents lactogenesis if milking is continued (Akers *et al.*, 1981; A.J. Davis *et al.*, 1983; Forsyth and Lee, 1993), although milk yield may be reduced by below average peripartum prolactin at a later stage of lactation in cows (Erb *et al.*, 1980), but not goats (Forsyth and Lee, 1993).

It appears, therefore, that in the majority of species, while prolactin is essential for the initiation of milk production at parturition, it is triggered by a withdrawal of progesterone (Kuhn, 1983) as a consequence of cessation of luteal function or that delivery of the placenta after term is a major triggering factor (see Cowie *et al.*, 1980; Forsyth, 1986). Jahn *et al.* (1989) show progesterone inhibition of casein synthesis *in vitro* in rabbit mammary explants by using physiological concentrations of prolactin and cortisol. Removal of prostaglandin $F_{2\alpha}$($PGF_{2\alpha}$), an active inhibitor of milk secretion, may also be involved. In late pregnant goats the mammary gland synthesizes $PGF_{2\alpha}$. Its secretion is switched from blood to milk 3–5 days prepartum (Maule Walker, 1984).

Once lactation is established, the continuation of milk production in all species is dependent on the pituitary gland (Cowie *et al.*, 1980). Experiments using hormone replacement in hypophysectomized lactating animals and *in vitro* organ culture of mammary tissue have shown a requirement for prolactin, growth hormone, insulin, thyroid hormones and glucocorticoids, the proportions and relative importance of which varies with species (Cowie *et al.*, 1980). In the following sections the change in secretion of these various hormones and their relative importance will be considered.

11.2.1 PROLACTIN

In all species so far studied, prolactin levels are raised during lactation (rat, Amenomori *et al.*, 1970; Terkel *et al.*, 1972; mice, Sinha *et al.*, 1974; Markoff *et al.*, 1981; rabbit, A.S. McNeilly and Friesen, 1978; Fuchs *et al.*, 1984; Californian ground squirrel, Thordason *et al.*, 1987; dog, Concannon *et al.*, 1978; blue fox, Mondain-Monval *et al.*, 1985; tammar wallaby, Hinds and Tyndale-Biscoe, 1982, 1985; and Bennett's wallaby, Curlewis *et al.*, 1986; bush-tailed possum, Hinds and Janssens, 1986; eastern quoll, Hinds and Merchant,

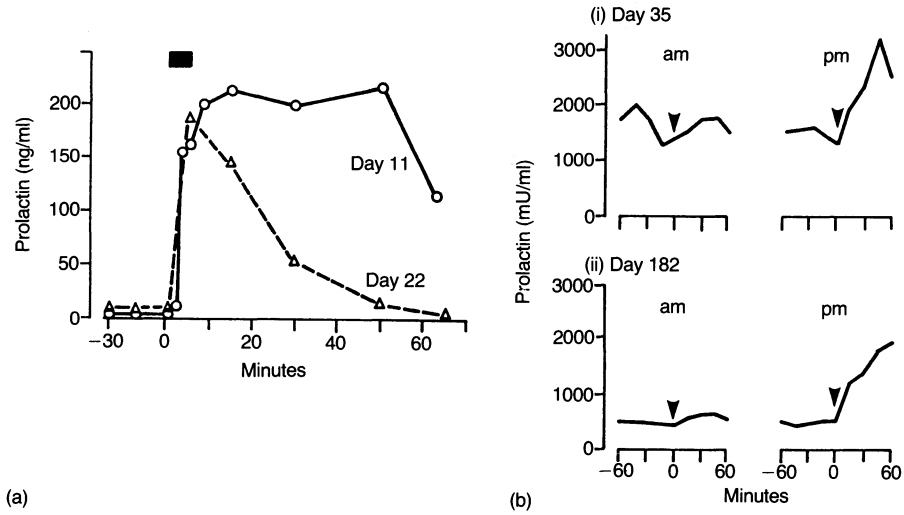

Figure 11.1 Effect of time post-partum on the suckling-induced release of prolactin in the rabbit (A) and human (B). The amount of milk taken and the duration of suckling was similar at the different stages of lactation but the amount of prolactin decreased. (From A.S. McNeilly and Friesen, 1978.)

1986; pig, Bevers *et al.*, 1978, 1981; van Landeghem and van de Wiel, 1978; Stevenson *et al.*, 1981; goat, Hart, 1974; sheep, Kann and Denamur, 1974; Lamming *et al.*, 1974; cow, Koprowski and Tucker, 1973a,b; red deer, Loudon *et al.*, 1983; mare, Worthy *et al.*, 1986; Weist and Thompson, 1987; elephant, A.S. McNeilly *et al.*, 1983a; rhesus monkey, Schallenberger *et al.*, 1981; marmoset monkey: A.S. McNeilly *et al.*, 1981; human, e.g. Delvoye *et al.*, 1978; Duchen and McNeilly, 1980; Howie *et al.*, 1980; A.S. McNeilly, 1980).

Prolactin is released in response to the suckling stimulus (Figures 11.1 to 11.3), and there is no evidence that prolactin levels increase in response to exteroceptive or other stimuli related to suckling or milking other than direct teat or nipple stimulation (Figures 11.2 and 11.3; rat, Voloschin and Tramezzani, 1984; Mattheij and Swarts, 1987; rabbit, A.S. McNeilly and Friesen, 1978; Fuchs *et al.*, 1984; goat, Hart and Linzell, 1977; human, Noel *et al.*, 1974; McNeilly *et al.*, 1983b).

In most eutherian species the prolactin response to suckling is greatest during early to mid-lactation and declines as lactation progresses (Figure 11.1; rat, Amenomori *et al.*, 1970; rabbit, A.S. McNeilly and Friesen, 1978; Fuchs *et al.*, 1984; sow, van Landegham and van der Wiel, 1978; sheep, J.R. McNeilly, 1972; goat, Hart, 1974; cow, Koprowski and Tucker, 1973a; Whisnant *et al.*, 1986a; human, Glasier *et al.*, 1984a; Johnston and Amico, 1986). However, the wide variation in suckling pattern and nursing behaviour between species results in a variable pattern of prolactin during lactation. In rabbits, which suckle only once per day for 2–3 min, prolactin increases immediately suckling begins and prolactin levels remain elevated for up to 4 h after the end of suckling (Figure 11.1; A.S. McNeilly and Friesen, 1978; Fuchs *et al.*, 1984). In the rat, sheep, cow, goat, rhesus monkey and human, prolactin also increases at the start of suckling but tends to decline at the end of the suckling period (Figures 11.2 and 11.3; Frantz *et al.*, 1972; Lamming *et al.*, 1974; Kann and Denamur, 1974; Noel *et al.*, 1974; Hart, 1975a; Frawley *et al.*, 1983; Glasier *et al.*, 1984a; Grosvenor *et al.*, 1986; Johnston and Amico, 1986), although this pattern may

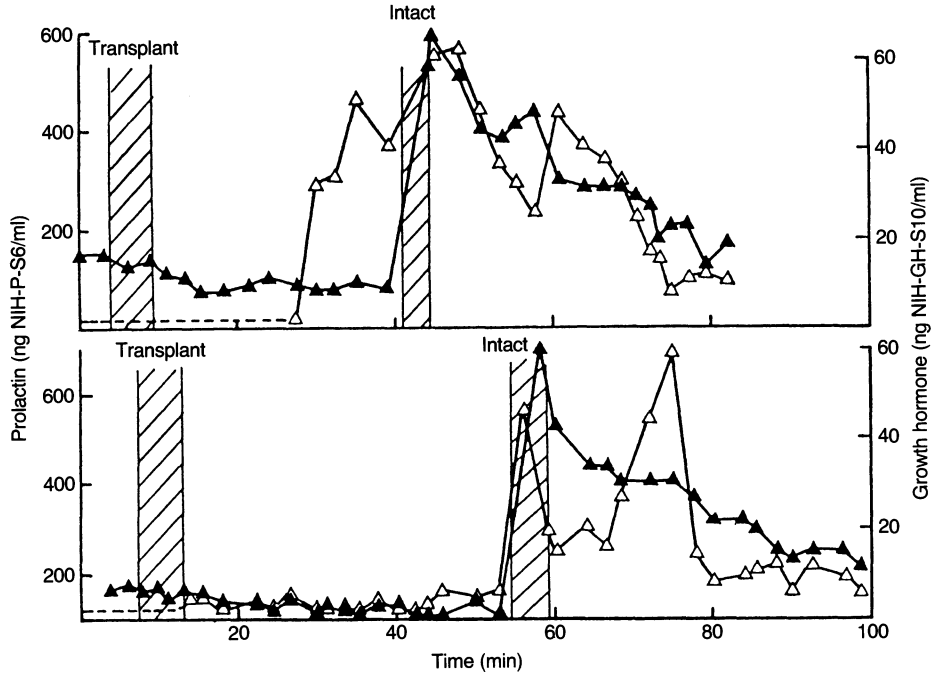

Figure 11.2 Changes in the plasma levels of prolactin (▲) and growth hormone (before, during and after milking (△) denervated, transplanted and intact innervated mammary glands in three goats. Note that prolactin concentrations increase only after milking of the innervated intact udder while, growth hormone release occurs after milking both the denervated and innervated udders. (From Hart and Linzell, 1977.)

vary within species throughout lactation (e.g. human, Hennart *et al.*, 1981; Glasier *et al.*, 1984a).

Studies of the mechanisms controlling the release of prolactin in response to the suckling stimulus have often utilized, as a model, the lactating rat deprived of all but one of its litter for a variable period before the pups are reattached. An immediate increase in prolactin is then seen at the start of suckling (e.g. Isherwood and Cross, 1980; Sirinathsinghji and Martini, 1984; Grosvenor *et al.*, 1986; Neill, 1986). However, this response is not normal in the rat, which spends up to 18 h per day nursing. Studies in which the changes in prolactin and suckling behaviour have been monitored throughout the day show considerable variation in suckling activity during each 24-h period and no precise relationship between suckling and prolactin levels (van der Schoot *et al.*, 1978; Sodersten and Eneroth, 1984; Nagy *et al.*, 1985, 1986a), a pattern also seen in the sow (Mattioli *et al.*, 1986). Indeed in the rat, maximum levels of prolactin could occur at times when mothers were away from the pups (Sodersten and Eneroth, 1984). In the rhesus monkey (Frawley *et al.*, 1983; Aso and Williams, 1985) and human (Tyson *et al.*, 1972; Noel *et al.*, 1974; Glasier *et al.*, 1984a) when breast feeds are infrequent with an interval of 4–5 h, a clear increase in prolactin is seen at each suckling period. However, when the frequency of feeds increases, the prolactin response to each feed diminishes but the overall basal level of prolactin is significantly increased (Delvoye *et al.*, 1977; Madden *et al.*, 1978; Stern *et al.*, 1986). Thus,

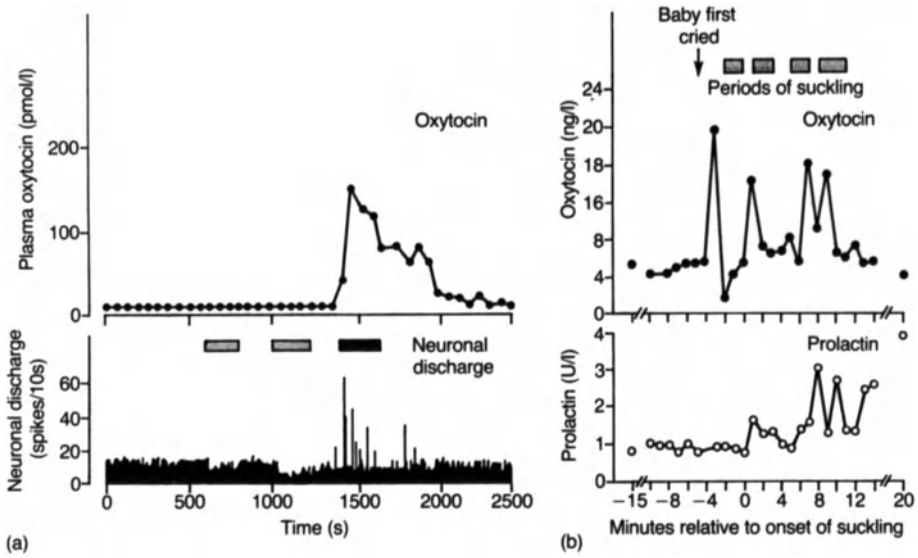

Figure 11.3 Changes in plasma levels of oxytocin in association with nursing in (A) a rabbit and (B) a human. In the rabbit oxytocin neurone activity is slow and irregular before nursing and plasma levels of oxytocin are undetectable. While the sight of the pups (▨) before nursing did not alter neuronal discharge or plasma oxytocin, the onset of nursing (■) was associated with an increase in the rate of firing of the oxytocin neurone followed by a sustained rise in plasma levels of oxytocin. In contrast, in the human, a large pulsatile release of oxytocin occurred when the baby cried before the onset of nursing. Thereafter, plasma levels of oxytocin increased in a pulsatile manner during the period of nursing. Plasma levels of prolactin only increased after the onset of suckling. (Redrawn from A.S. McNeilly *et al.*, 1983b, and Summerlee *et al.*, 1986.)

the frequency of suckling is associated with an overall increase in prolactin levels and a reduction in the amount of prolactin released at each suckling episode.

The strength of the suckling stimulus may also alter the amount of prolactin released at each suckling episode. More prolactin may be released in response to suckling of hungry pups in the rat (Grosvenor *et al.*, 1986; Jakubowski and Terkel, 1986a,b), and at milking if two teats rather than one are stimulated in the goat (Hart and Linzell, 1977). Basal levels of prolactin are greater in underfed red deer, whose calves suckle more frequently (Loudon *et al.*, 1983), but apparently not in the cow (Wheeler *et al.*, 1982), and are higher in malnourished humans throughout lactation (P.G. Lunn *et al.*, 1980; Hennart *et al.*, 1985) and in lactating marmoset monkeys suckling twins rather than single offspring (A.S. McNeilly *et al.*, 1981).

Plasma prolactin levels are only marginally elevated during the early stages of lactation when the young is very small in the bush-tailed possum (Hinds and Janssens, 1986), eastern quoll (Hinds and Merchant, 1986) and tammar (Hinds and Tyndale-Biscoe, 1982, 1985) and Bennett's wallaby (Curlewis *et al.*, 1986). When the joey begins its growth spurt in mid-lactation, prolactin levels increase dramatically, presumably in response to a greatly increased suckling activity and demand for milk in all these marsupials, although there may be some confounding effects of season (Tyndale-Biscoe and Hinds, 1984). Prolactin levels decline only when the joey leaves the pouch, returning to suckle only infrequently. In tammar wallabies, an

increase in prolactin receptors in the suckled gland in very early lactation probably enables this gland to respond selectively to low circulating prolactin (F. Stewart, 1984). The change in the pattern of prolactin in response to suckling or milking in goats, sheep and cattle is similarly confounded to some extent by the seasonal increase in prolactin which occurs in all three species with increasing day length (sheep, Walton *et al.*, 1977; goat, Hart, 1975b; cow, Peters and Tucker, 1978; Webb and Lamming, 1981). Since young ruminants are normally born in the springtime, this coincides with the time of the natural seasonal increase in prolactin. Nevertheless, prolactin levels in lactating ewes, whether in the breeding season (Clarke *et al.*, 1984) or anoestrus (Kann and Denamur, 1974; Lamming *et al.*, 1974), are greater than in non-lactating seasonally anoestrous ewes, and the prolactin response to suckling in both the sheep (J.R. McNeilly, 1972) and goat (Hart, 1975a) declines throughout lactation. The prolactin levels are similar in suckling and milked cows (Carruthers and Hafs, 1980; J.F. Smith *et al.*, 1981). In goats, milk yield increase resulting from more frequent milking is ultimately associated with an increase in prolactin receptors, an effect local to the more frequently milked gland within an animal (McKinnon *et al.*, 1988).

The control of prolactin secretion is complex and the mechanisms underlying the increased release of prolactin during suckling and throughout lactation remain poorly understood. The main control over prolactin is provided by tonic dopaminergic inhibition from the hypothalamus, with ovarian oestradiol providing both chronic and acute endocrine stimulation. A large number of prolactin secretagogues have been identified, but their physiological relevance remains uncertain. There is now evidence that prolactin secretion is subject also to paracrine control from the intermediate lobe and to controls operating within the anterior pituitary (Ben-Jonathan and Liu, 1992).

The primary prolactin-inhibiting factor is dopamine (Ben-Jonathan 1985). Tuberoinfundibular (TIDA) neurones terminate in the median eminence and release dopamine to reach the anterior pituitary via the long portal vessels. Tuberohypophysial (THDA) neurones project separately to the neural and the intermediate lobes of the posterior pituitary. They supply a lesser dopamine input to the anterior pituitary from the neural lobe via the short portal vessels. In the intermediate lobe, dopaminergic terminals synapse with glandular cells. Evidence in the rat suggests that the acute suckling stimulus causes a transient decline in dopamine levels in the hypophysial portal vessels (Plotsky and Neill, 1982) and the pituitary (Duker and Wuttke, 1985), allowing the prolactin in the pituitary to be transformed into a readily releasable form (Grosvenor *et al.*, 1986), which is then secreted into the circulation. A chronic reduction in the amount of dopamine released from TIDA neurones of the hypothalamus into the portal vessels may contribute to the maintenance of high prolactin levels throughout lactation, since hypothalamic dopamine turnover is reduced in lactation (Selmanoff and Wise, 1981; Demarest *et al.*, 1983) and the ability of prolactin to stimulate dopamine release from these neurones is also reduced (short-loop feedback, Demarest *et al.*, 1983).

In lactating rats, removal of the posterior pituitary elevates basal prolactin release, confirming an involvement of THDA neurones in tonic prolactin inhibition. However, suckling fails to increase prolactin in posterior lobectomized rats (Ben-Jonathan, 1985; Murai and Ben-Jonathan, 1987). Prolactin-releasing factor activity has now been identified in the posterior pituitaries of many species (fish, mouse, rat, hamster, rabbit, pigs, cows, sheep, monkeys and humans, Thomas *et al.*, 1989; Mori *et al.*, 1990; Averill *et al.*, 1991; Ben-Jonathan *et al.*, 1991; Ellerkmann *et al.*, 1991), but its exact nature remains to be determined. In the rat, the activity is localized

mainly in the intermediate lobe (Laudon *et al.*, 1990). Recently, Ellerkmann *et al.* (1992) have found in an *in vitro* model that *N*-acetylated α-melanocyte-stimulating hormone (and/or β-endorphin) from the intermediate lobe rapidly recruits anterior pituitary cells into the prolactin-secreting pool by the removal of a post-translational block to prolactin synthesis (Porter *et al.*, 1992).

In the model proposed by Ben-Jonathan *et al.* (1991), dopamine is suggested to exert tonic inhibition over the secretion of the posterior pituitary prolactin-releasing factor, as well as prolactin itself. Suckling acts to suppress dopamine and a large amplification of the prolactin secretory response results from removal of inhibition from lactotrophs plus increased release of and response to the releasing factor. In addition, and as first postulated by Benson and Folley (1956), oxytocin released from the neural lobe by suckling could also amplify prolactin release.

In several species the release of prolactin and, by implication, the changes in dopamine turnover appear to be mediated by a suckling-induced increase in opiate tone within the hypothalamus. Thus, blockade of opioid receptors with naloxone in the rat (Sirinathsinghji and Martini, 1984; Selmanoff and Gregerson, 1986), pig (Mattioli *et al.*, 1986), sheep (Gregg *et al.*, 1986; P.G. Knight *et al.*, 1986; Malven and Hudgens, 1987) and cow (Gregg *et al.*, 1986; Whisnant *et al.*, 1986a–c) results in a decrease in prolactin levels during lactation, while systemic administration of β-endorphin (Selmanoff and Gregerson, 1986) will increase prolactin. In the ewe, suckling causes a significant increase in the concentration of β-endorphin in the hypophysial portal vessels (Gordon *et al.*, 1987), although this may not be a specific effect. While naloxone apparently does not inhibit the prolactin response to breast stimulation in lactating humans (Lodico *et al.*, 1983; Cholst *et al.*, 1984; Tay *et al.*, 1993), there seems adequate evidence to imply that suckling causes the release of prolactin by a pathway at least involving an alteration in opioid tone within the hypothalamus.

The importance of prolactin for the maintenance of milk production in lactation varies, but it appears to be essential in most species other than ruminants. Thus, the specific suppression of prolactin with bromocriptine (Bohnet *et al.*, 1977; Madon *et al.*, 1986a) or prolactin antiserum (Nagai *et al.*, 1986) in the rat, and with bromocriptine in the mouse (C.H. Knight *et al.*, 1986) rabbit (Taylor and Peaker, 1975), Bennett's wallaby (Curlewis *et al.*, 1986), dog (Jochle *et al.*, 1987), pig (Fluckiger, 1978), rhesus monkey (Schallenberger *et al.*, 1981) and women (F. Peters *et al.*, 1986) results in a cessation of milk production. This effect can be reversed by administration of exogenous prolactin with the bromocriptine in rat (Bohnet *et al.*, 1977; Madon *et al.*, 1986a) and rabbit (Taylor and Peaker, 1975). Milk production is also absent in women with an isolated prolactin deficiency (Kauppila *et al.*, 1987a; A.S. McNeilly, 1985). In women, milk production can be enhanced by a drug-induced increase in circulating prolactin concentrations during lactation (Guzman *et al.*, 1979; Kauppila *et al.*, 1981; Aono *et al.*, 1982; Ylikorkala *et al.*, 1982; Hofmeyer *et al.*, 1985). In contrast, prolactin appears to have little importance in milk production in ruminants once lactation has been established. Suppression of prolactin has little or no effect on milk yield in the cow (Karg *et al.*, 1972; V.G. Smith *et al.*, 1974) and only marginally affects milk yield in the ewe (Hooley *et al.*, 1978; Gow *et al.*, 1983). Hart (1973) reported no effect of once-daily bromocriptine on milk yield in the goat, but given three times daily it reduced milk yield by 21% (C.H. Knight *et al.*, 1990). Studies of prolactin concentrations in plasma and whey show that, as circulating prolactin declines in goats, the ratio of prolactin and in whey to plasma increases, despite an absolute decline in whey prolactin concentrations. This may indicate increased efficiency of transfer across

the gland, perhaps contributing to the maintenance of substantial milk yields (Gabai *et al.*, 1992). The mammary gland may also synthesize prolactin. Transcription of the prolactin gene has been reported in milk secretory cells of the rat mammary gland (Steinmetz *et al.*, 1993), although the substantial suppression of milk yield by bromocriptine in this species (70–100% within 2 days dependent on the stage of lactation; Flint *et al.*, 1992) suggests the contribution of locally produced prolactin to sustaining milk yield must be limited. In ruminants there is no precise correlation between prolactin levels throughout lactation and milk yield (Hart *et al.*, 1979; Kazmer *et al.*, 1986). Exogenous prolactin given to high-yielding dairy cows either before or after peak yield fails to alter their lactation performance (K. Plant *et al.*, 1987). In goats, increasing post-milking prolactin concentrations by 100% by infusion produces a small effect on milk yield (Jacquemet and Prigge, 1991).

The major form of mature prolactin found in the pituitary of most species is a monomer of 199 amino acids, but prolactin shows a high degree of structural polymorphism, variants differing in biological activity (Sinha, 1992). Genetic variants may result from alternative splicing. Post-translationally modified forms also occur (cleaved, glycosylated, phosphorylated, deamidated, sulphated and polymeric). Binding proteins for prolactin have been described in the milk of rabbits, sheep, goats and humans (Postel-Vinay *et al.*, 1991). The physiological significance of prolactin variants in lactation is not known, but the rat mammary gland processes prolactin (Baldocchi *et al.*, 1992)

11.2.2 GROWTH HORMONE

In contrast to prolactin, relatively little is known about growth hormone and lactation in species other than ruminants, in part because suitable long-acting inhibitors of growth hormone have been unavailable until recently. A small increase in plasma levels of growth hormone may occur during suckling in the rat (Sar and Meites, 1969; Chen *et al.*, 1974), although levels remain relatively constant and independent of suckling throughout lactation (Nagy *et al.*, 1986a). However, immunoneutralization of rat growth hormone can reduce milk secretion (Madon *et al.*, 1986b; Flint *et al.*, 1992). The importance of growth hormone increases with stage of lactation and can be seen most clearly when prolactin is also suppressed. Suckling has no effect on growth hormone release in humans (Bryant and Greenwood, 1972) or dogs (Tsushima *et al.*, 1971) and a growth hormone-deficient human can breast feed successfully (Rimoin *et al.*, 1968). In the pig there is a slight rise in growth hormone levels in early lactation (Dehoff *et al.*, 1986).

In ruminants, growth hormone and not prolactin is of principal importance in galactopoiesis. An increase in plasma levels of growth hormone occurs in response to milking in the sheep (Martal, 1975), goat (Figure 11.2; Hart and Flux, 1973) and cow (Hart, 1983). Throughout lactation growth hormone levels are raised and are correlated positively with milk yield (Hart *et al.*, 1978, 1979; Hart, 1983; Barnes *et al.*, 1985; Kazmer *et al.*, 1985), are higher in high-yielding dairy cows than beef cows (Bines and Hart, 1977; Hart *et al.*, 1978, 1979) and are higher in dairy cows selected for high milk yield than in low-yielding dairy cows (Barnes *et al.*, 1985; Kazmer *et al.*, 1986). The increase in growth hormone appears to be an adaptation to the increase in metabolic load of lactation and the relative decrease in glucose. Food restriction of cows increases growth hormone (Athanasiou and Phillips, 1978; Katzmer *et al.*, 1985) and the high growth hormone levels in dairy cows are reduced to those of lactating beef cows when they are restricted fed to equalize the milk production (Hart, 1983). Since growth hormone is lipolytic and antilipogenic, these changes in growth hormone in

high-milk-producing ruminants occur in response to metabolic stimulants related to the production of milk (Bauman and Currie, 1980) rather than directly to the suckling stimulus. Indeed, in the goat, growth hormone continued to be released in response to the milking of a denervated udder while the prolactin response, which is mediated via teat stimulation alone was abolished (Figure 11.2; Hart and Linzell, 1977), and the changes in growth hormone only appear to occur in response to milk removal (Hart and Morant, 1980).

Growth hormone secretion is regulated by the hypothalamus through the inhibitory somatostatin and the stimulatory growth hormone-releasing hormone, both in turn regulated by biogenic amines or neuropeptides originating within the central nervous system (Baile *et al.*, 1986). In cows and sheep, elevation of endogenous growth hormone secretion with growth hormone-releasing hormone results in increased milk yield (Baille *et al.*, 1986; Hart *et al.*, 1985).

The importance of growth hormone in the control of milk production in the ruminant was first shown by Folley and Young (1938), and later in growth hormone replacement studies in hypophysectomized sheep and goats (Cowie, 1966, 1969; Cowie *et al.*, 1980), and is now being exploited commercially in cattle using recombinant DNA-derived bovine growth hormone (Bauman *et al.*, 1985; Eppard *et al.*, 1987; Flint, 1987; Tucker and Merkel, 1987). However, it is still unclear whether any actions of growth hormone on lactation are direct at the mammary gland or whether all are indirect, partitioning on nutrients for milk secretion away from body stores (homeorrhesis, Bauman and Currie, 1980). It has proved impossible to show binding of growth hormone to mammary microsomes by conventional methods (Akers, 1985), but two studies in cattle have shown messenger RNA for growth hormone receptors in the mammary gland: Glimm *et al.* (1990) used *in situ* hybridization, while Hauser *et al.* (1990) used solution hybridization–nuclear protection assays. Nevertheless, close arterial infusion of growth hormone into one mammary gland in sheep and goats did not affect milk yield until the dose was high enough to increase peripheral concentrations, when milk yield was increased in both mammary glands (McDowell *et al.*, 1987). By contrast, close arterial infusion of the growth hormone-dependent insulin-like growth factor I into one mammary gland of goats increased both blood flow and milk yield in the infused gland (Prosser *et al.*, 1990), an effect not seen when insulin-like growth factor I was given systemically: it presumably arrived at the gland complexed to insulin-like growth factor-binding proteins (S.R. Davis *et al.*, 1989). Flint *et al.* (1992) were unable to replace growth hormone by systemic insulin-like growth factors I or II, despite normalizing serum concentrations, in maintaining the milk yield of lactating rats in which growth hormone was immunoneutralized. The mammary gland contains type 1 and type 2 receptors for the insulin-like growth factors. In addition, messenger RNA for insulin-like growth factor I is present in mammary glands (L.J. Murphy *et al.*, 1987), largely in the stromal compartment (Hauser *et al.*, 1990). The possibility therefore exists of local action of locally produced insulin-like growth factors. Kleinberg *et al.* (1990) found in hypophysectomized, oestrogen-treated rats that mammary growth and the mammary gland content of messenger RNA for insulin like growth factor I are stimulated by local implants of growth hormone but not prolactin.

Thus, growth hormone plays an important role in lactation in ruminants. It may act coordinately at a number of sites, directly or via the insulin-like growth factors, to partition substrates to the mammary gland but also, possibly via local insulin-like growth factor production, to stimulate blood flow and/or to produce local metabolic effects. In other species, the role of growth hormone in lactation requires further investigation. The

studies of Flint *et al.* (1992) in rats indicate that it should not be neglected.

11.2.3 INSULIN

Lactation is generally agreed to be a hypoinsulinaemic state. Insulin levels tend to be lower in lactating than in non-lactating rats (Sutter-Dub *et al.*, 1974; A.M. Robinson *et al.*, 1978; Marynissen *et al.*, 1983; Jones *et al.*, 1984; Burnol *et al.*, 1986; Hubinont *et al.*, 1986; Mizoguchi and Imamichi, 1986) and cows (Hart *et al.*, 1978; Lomax *et al.*, 1979; Blum *et al.*, 1985; Denbow *et al.*, 1986; Gerloff *et al.*, 1986; Sutton *et al.*, 1986). Insulin also tends to be higher in low- than in high-yielding cows (Hart *et al.*, 1978, 1979; Bines and Hart, 1982), and in beef cows levels of insulin increase to normal at weaning (Rutter and Manns, 1987).

Lactation induces a state of negative energy balance in many species, especially in early lactation, resulting in a decrease in blood glucose. This, together with increased insulin clearance (Jones *et al.*, 1984), may lead to the lower insulin concentrations. In addition, in ruminants the pancreatic response to glucose and propionate infusion *in vivo* is diminished (Lomax *et al.*, 1979). Madon *et al.* (1988) found no difference in the insulin response to glucose *in vitro* in islets of Langerhans from virgin and lactating rats. However, Hubinont *et al.* (1986), comparing lactating with non-lactating rats at 14 days after delivery, found reduced insulin output in response to secretagogues in pancreatic tissue from lactating rats.

In addition to hypoinsulinaemia, tissue response to insulin is altered in lactation (Vernon, 1989). In both rats and ruminants insulin action on adipocytes is impaired in the lactating animal. The rat mammary gland is responsive to insulin, while the ruminant mammary gland appears to be refractory to the acute effects of insulin (Vernon, 1989), despite apparently similar requirements for insulin across species to maintain the synthesis of milk components *in vitro* (Vonderhaar and Ziska, 1989).

11.2.4 CORTICOSTEROIDS

Plasma levels of cortisol may (Koprowski and Tucker, 1973a,b; Dunlap *et al.*, 1981a,b; Ellincott *et al.*, 1981; Whisnant *et al.*, 1985, 1986a; Spicer *et al.*, 1986a) or may not (Carruthers and Hafs, 1980; G.L. Williams *et al.*, 1984; Faltys *et al.*, 1987) increase in response to suckling or milking in the cow. Overall, plasma levels of cortisol during lactation in the cow are similar to or only slightly higher than non-lactating cows throughout the day (Dunlap *et al.*, 1981b; Keech *et al.*, 1983; Faltys *et al.*, 1987). In both the cow (Keech *et al.*, 1983; Faltys *et al.*, 1987) and rat (Gala and Westphal, 1965) there is a slight decrease in the binding capacity of corticosteroid-binding protein, while in the rat there may also be a small increase in corticosterone levels, but only during the morning, in lactating versus non-lactating rats (Voogt *et al.*, 1969; Stern *et al.*, 1973). The adrenal response to stress does appear to be reduced in the lactating rat (Stern *et al.*, 1973), although a sustained release of corticosterone can occur in lactating rats following olfactory stimulation from hungry pups (Zarrow *et al.*, 1972). Alternatively, there is little effect of lactation on corticosteroids in the pig (Ash and Heap, 1975).

In most species, adrenalectomy inhibits lactation (Cowie, 1966; Cowie *et al.*, 1980). A requirement for adrenal corticoids for the synthesis of milk components is also shown by *in vitro* culture of mammary tissue with biphasic effects on α-lactalbumin (Cowie *et al.*, 1980; Vonderhaar and Ziska, 1989). The rabbit is an apparent exception since prolactin can maintain milk yield after hypophysectomy and adrenocorticotrophin has no additional effect (Cowie *et al.*, 1969). Nevertheless, the requirements of the mammary gland for corticoids to maintain milk production appear to be met without any major alterations in plasma concentrations. In rats,

in extended lactation (Flint *et al.*, 1984), corticosteroids may become limiting, although cortisol inhibits milk ejection. The effect on lactation may result in part from suppression of the anabolic activity of adipocytes.

The rat mammary gland contains both type I (mineralocorticoid) and type II (glucocorticoid) receptors, but stimulatory actions of glucocorticoids on milk protein synthesis are exerted solely through the latter (Quirk *et al.*, 1986). Another level of control in rats is the metabolism of glucocorticoids to inactive derivatives by 11β-hydroxysteroid dehydrogenase. The activity of the enzyme is reduced in lactation (Quirk *et al.*, 1990a,b)

11.2.5 THYROID HORMONES

The thyroid hormones, triiodothyronine (T3) and thyroxine (T4), increase in lactation after an initial decrease after parturition in the goat (Riis and Madsen, 1985), the cow (Hart *et al.*, 1978; Gerloff *et al.*, 1986; Khurana and Madan, 1986) and the buffalo (Khurana and Madan, 1986). The percentage of free T3 and T4 remained constant in the cow and was negatively correlated with the levels of non-esterified fatty acids and positively correlated with cholesterol (Hart *et al.*, 1978; Gerloff *et al.*, 1986), consistent with a thyroid hormone response to the negative energy balance of the lactating dairy cow. In humans, T3 levels were normal, but both free and bound T4 levels were lower and thyroid hormone binding globulin (TBG) was higher in lactating humans (Iwatani *et al.*, 1987). Basal T4 levels are reported to be low in agalactic mares (F.N. Thompson *et al.*, 1986), suggesting that a lack of T4 may adversely affect milk production.

The biologically active T3 is produced mainly in peripheral tissues, by 5′-monodeiodination of T4. Treatment of lactating dairy cows with recombinant derived bovine growth hormone produced a twofold increase in mammary tissue thyroxine-5′-monodeiodinase activity with no change in this activity in liver or kidney or in serum concentrations of T4 or T3 (Capuco *et al.*, 1989). In the mammary gland *in vitro* T3 selectively enhances α-lactalbumin synthesis in the mouse (Vondehaar and Ziska, 1989) and stimulates casein synthesis in rabbits (Houdebine *et al.*, 1978).

11.2.6 ADRENALINE AND NORADRENALINE

Very limited evidence suggests that there may be a transient increase in plasma levels of adrenaline and noradrenaline in response to suckling or milking in the rat (C. Clapp *et al.*, 1985), sheep (Barowicz, 1979; Ewy and Barowicz, 1981), goat (Kuanjshkekova, 1976). These catecholamines together with adenosine act through membrane receptors on adipocytes via a cascade controlling lipolysis (Vernon *et al.*, 1991). The transmission of signals by the adrenergic–adenosine signal transduction cascade is altered in lactation to produce lipid mobilization as an adaptation providing substrates to the mammary gland. The components of the cascade are under complex chronic endocrine control by growth hormone, insulin, glucocorticoids and possibly other hormones (thyroid hormones, sex steroids), which may vary both between species and with tissue depot within a species (Vernon, 1991). Direct actions on the mammary gland may also occur. The β-agonist cimaterol promotes lipolysis and protein synthesis in the mammary gland of lactating rats (Choi *et al.*, 1992).

11.2.7 RELAXIN

Relaxin is a homologue of insulin and plays an important role in pregnancy maintenance being produced by the corpus luteum and/or placenta (Kemp and Niall, 1984; Weiss, 1984). Although early studies suggested that suckling in the sow and ewe resulted in an increase in plasma levels of immunoreactive relaxin (Bryant and Chamley, 1976; Afele *et al.*, 1979; Whitely *et al.*, 1985) this has not

been confirmed. In the dog (Steinetz *et al.*, 1987), and in some studies the sow (Afele *et al.*, 1979; Whitely *et al.*, 1985), relaxin is detectable in plasma throughout lactation, but other studies find levels of relaxin to decline rapidly after parturition and remain undetectable throughout lactation in rats (Sherwood, 1980), pigs (Sherwood *et al.*, 1975, 1981; Kendall *et al.*, 1983), horses (D.R. Stewart and Stabenfeldt, 1981) and cats (D.R. Stewart and Stabenfeldt, 1985). However, in the guinea pig the lactating mammary gland is a source of relaxin detectable by immunocytochemistry and Northern analysis (Peaker *et al.*, 1989). Since circulating relaxin is low in the lactating rat, the inhibitory effects of relaxin on oxytocin release from the rat hypothalamus *in vivo* (Summerlee *et al.*, 1984; O'Byrne *et al.*, 1986) would appear to represent an effect of relaxin or similar compounds released within the hypothalamus rather than an effect of peripheral levels of relaxin.

11.2.8 CONCLUSIONS

Lactation results in changes in the serum concentrations of several hormones and these changes are in general most marked in early to mid-lactation. Most notably, prolactin and growth hormone concentrations are raised while insulin or thyroid hormones fall. With the possible exception of growth hormone, these hormones act via receptors on mammary cells to promote the synthesis of milk components, but their net effect is also to partition nutrients towards the mammary gland and away from storage depots such as fat (homeorrhetic control, Bauman and Currie, 1980). It is also increasingly evident that local controls operate within the mammary gland and other tissues to interact with the endocrine changes. Local controls include alterations in blood flow, in receptors, in intracellular signalling, in the metabolism of hormones or in the production of local effector molecules, both hormones and growth factors. Good data are available for relatively few species and already suggest species differences in the ways that hormonal control of lactation is exercised.

11.3 OXYTOCIN AND THE MILK EJECTION REFLEX

During lactation milk is secreted continuously but not necessarily at a constant rate into the alveoli of the mammary glands. The milk is made available to the suckling young by the action of oxytocin causing contraction of the myoepithelial cells surrounding the alveolus to expel the milk into the collecting ducts, cisterns and galactophores from which it can be withdrawn by the sucking young. This milk ejection reflex (MER) appears to be common to all mammals even though the pattern of nursing varies enormously between species. This variation is determined in part by the rate of milk production and the time taken for the mother to secure an adequate food supply.

The interval between nursing episodes ranges from alternate days in the tree shrew (R.D. Martin, 1966) to about once per day in the rabbit (Zarrow *et al.*, 1965) and 20 or more times in the laboratory rat (Lincoln *et al.*, 1973). The total duration of nursing (defined in terms of the time spent attached to the nipples) also varies from around 3 min per day in the rabbit to 18 h per day in the rat (Lincoln, 1983). Within species, the pattern of nursing also varies considerably, as illustrated during lactation in humans, in whom nursing intervals vary from every 20 min in the hunter-gatherer !Kung tribe of Botswana and Namibia to the 'westernized' pattern of suckling with 3- to 16-h intervals.

In spite of this great variation in suckling and nursing patterns, it is clear that the ejection of milk from the mammary gland occurs as a result of the release of oxytocin from the neurohypophysis (Figure 11.3). An increase in oxytocin measured directly in plasma by either bioassay or radioimmunoassay or by

recording increases in intramammary pressure, a response specific to oxytocin, has been demonstrated in the wallaby (Lincoln and Renfree, 1981a,b), rat (e.g. Lincoln *et al.*, 1973; Higuchi *et al.*, 1985; Grosvenor *et al.*, 1986; Samson *et al.*, 1986), guinea pig (I.C.A.F. Robinson *et al.*, 1981), rabbit (Bisset *et al.*, 1970; Summerlee *et al.*, 1986), dog (Eriksson *et al.*, 1987), pig (Folley and Knaggs, 1966; Forsling *et al.*, 1979; Ellendorf *et al.*, 1982), goat (Folley and Knaggs, 1966; A.S. McNeilly, 1972) sheep (Fuchs *et al.*, 1987), cow (Folley and Knaggs, 1966; Lawson and Graf, 1968; Cleverley and Folley, 1970; Forsling *et al.*, 1974; Gorewit, 1979; Schams *et al.*, 1984) and human (Cobo *et al.*, 1967; Coch *et al.*, 1968; Cobo, 1974; Weitzman *et al.*, 1980; Lucas *et al.*, 1980; A.S. McNeilly *et al.*, 1983b; Leake and Fisher, 1985; Amico and Finley, 1986; Johnston and Amico, 1986). Oxytocin levels also increase in the cerebrospinal fluid of the sheep brain during suckling (Kendrick *et al.*, 1986). There is no evidence for a concomitant release of vasopressin during MER in any species (Bisset *et al.*, 1970; Wakerley *et al.*, 1973; Bruhn *et al.*, 1981; Johnston and Amico, 1986; Meyer *et al.*, 1987).

The pattern of oxytocin release appears at first sight to be variable between species, but much of this variation appears to be due to measurement of oxytocin in blood samples collected too infrequently during the nursing period. Since the half-life of oxytocin in the circulation is about 1.5 min, sampling frequencies of more than 1 min would give a false pattern of release.

In studies in which sampling frequency is adequate, two patterns of oxytocin release are seen (Figure 11.3). In the rabbit (Fuchs *et al.*, 1984; Summerlee *et al.*, 1986; Figure 11.2a) and cow (Folley and Knaggs, 1966; Sibaja and Schmidt, 1975; Gorewit, 1979; Sagi *et al.*, 1980; Gorewit *et al.*, 1983; Mayer *et al.*, 1984; Schams *et al.*, 1984) the release of oxytocin appears to be sustained for most of the nursing period, although the amount released in the later stages of the milking period in the cow may decline (Gorewit, 1979; Schams *et al.*, 1984).

In contrast to this sustained release of oxytocin, in the rat (Higuchi *et al.*, 1985, 1986; Mayer *et al.*, 1986), goat (A.S. McNeilly, 1972), guinea pig (I.C.A.F. Robinson *et al.*, 1981), pig (Ellendorf *et al.*, 1982), sheep (Fuchs *et al.*, 1987) and human (Lucas *et al.*, 1980; A.S. McNeilly *et al.*, 1983b) oxytocin is released in a pulsatile manner during the period of nursing (Figure 11.3).

Recent studies in which recordings of the electrical activity of the oxytocin neurosecretory cells in the paraventricular nucleus of the hypothalamus in conjunction with measurement of oxytocin release suggest that, in the rat, a single milk ejection, which occurs over a 5- to 20-s period every 2–5 min during the nursing period is associated with a single coordinated burst of firing of the oxytocin neurosecretory cells (see Summerlee and Lincoln, 1981; Lincoln, 1983; Lincoln *et al.*, 1985). This leads to a single-bolus release of oxytocin from the posterior pituitary, resulting in a pulse of oxytocin in the plasma (Higuchi *et al.*, 1985, 1986; Meyer *et al.*, 1987). Since the next episode of coordinated firing of the oxytocin neurosecretory neurones in the rat does not occur for 2–5 min, and because of the short half-life of oxytocin in the circulation, plasma concentrations of oxytocin return to baseline before the next pulse release of oxytocin. However, in the rabbit during nursing the interval between bursts of coordinated oxytocin cell neurosecretory activity resulting in oxytocin release is less than 1 min (Paisley and Summerlee, 1984), and so each release of oxytocin will occur before plasma oxytocin levels have declined from the previous release of oxytocin (Figure 11.3; Summerlee *et al.*, 1986). It is probable, therefore, that the different patterns of oxytocin release seen during suckling are related to differences in the time intervals between the coordinated firing of the oxytocin neurosecretory cells in the paraventricular nucleus.

The amount of oxytocin released appears

to increase during early lactation to a peak around mid-lactation in the rat (Sutherland *et al.*, 1986), rabbit (Fuchs *et al.*, 1984; Summerlee *et al.*, 1986) and sheep (Fuchs *et al.*, 1987) and then decline, while in humans there does not appear to be any significant change throughout lactation (Lucas *et al.*, 1980; A.S. McNeilly *et al.*, 1983b; Johnston and Amico, 1986).

In the majority of studies, there is a large variation in the amount of oxytocin released and little or no relationship has been found between the amount released and the milk volume or flow of milk in the cow (Gorewit, 1979; Sagi *et al.*, 1980; Schams *et al.*, 1984), goat (A.S. McNeilly, 1972), sheep (Fuchs *et al.*, 1987) or human (Lucas *et al.*, 1980; A.S. McNeilly *et al.*, 1983b; Johnston and Amico, 1986). This suggests that milk ejection, i.e. the abrupt contraction of the myoepithelial cells, occurs once oxytocin concentrations have increased above a threshold (Schams *et al.*, 1984; Lincoln *et al.*, 1985). As a consequence, while an increase in intramammary pressure can be achieved by increasing the dose or amount of oxytocin given as bolus injections, thus forming the basis of the oxytocin bioassays (e.g. Tindal and Yokoyama, 1962; Bisset *et al.*, 1970; Lincoln *et al.*, 1973), oxytocin given as continuous infusions tend to produce wave-like contractions of the myoepithelial cells which are not synchronized between adjacent mammary glands (Lincoln *et al.*, 1985). Indeed, only by giving small bolus injections of oxytocin is it possible to reproduce the intramammary pressure changes seen during nursing in the wallaby (Lincoln and Renfree, 1981a,b), grey seal (Lincoln *et al.*, 1983) and human (Cobo *et al.*, 1967, 1968).

The sensitivity of the mammary gland to oxytocin may change during lactation. In the rat, the amount of milk released is greater on day 13 than day 8 of lactation, but this appears to be due to a decrease in mammary resistance (Lau and Henning, 1987) since the amount of oxytocin released appears to be similar (Sutherland *et al.*, 1986). In marsupials, on the other hand, there is a clear change in sensitivity of the mammary gland to oxytocin (Lincoln and Renfree, 1981a,b). In the agile wallaby, the mammary gland can be induced to contract in the early stages of lactation to injections or infusions of oxytocin which are ineffective at later stages of lactation. During early lactation, when the young joey is continuously attached to the nipple, only a very little oxytocin is required for milk ejection. As the joey grows so the sensitivity of the mammary gland to which it is attached declines. When the joey leaves the pouch, returning to suckle, suckling will release a large amount of oxytocin to eject milk from the older glands. This large release of oxytocin would have only a limited effect on the mammary gland to which a younger joey is simultaneously attached since the pressure response reaches a plateau at very low concentrations of oxytocin. Thus, by altering the sensitivity of the mammary gland to oxytocin, the wallaby has allowed the simultaneous suckling of a large and a small joey without necessarily altering the amount of oxytocin released in response to suckling (Lincoln and Renfree, 1981a,b; Lincoln, 1983).

The release of oxytocin in the rat occurs at regular intervals of 2–10 min, but only when the rat shows slow-wave sleep (Lincoln *et al.*, 1980), the suckling stimulus being sleep inducing in the rat (Lincoln, 1983). Milk ejections occur at regular intervals during this sleep phase provided the suckling stimulus is maintained, and rat pups remain attached to the nipples for up to 18 h per day (Lincoln *et al.*, 1973). In other species sleep is clearly not a prerequisite for milk ejection (Poulain *et al.*, 1981), although rabbits and guinea pigs do enter a 'trance-like' state during their periods of nursing (Lincoln, 1983).

In the rat (Lincoln, 1983) and guinea pig (I.C.A.F. Robinson and Jones, 1982), pups suckle vigorously after milk ejection has occurred and no oxytocin appears to be re-

leased in response to exteroceptive stimuli in these species. In the pig, oxytocin release and milk ejection may be initiated by either the mother calling the litter or the piglets squealing at the mother (Ellendorf *et al.*, 1982). The piglets often massage or butt the udder for 2–4 min before oxytocin release, and oxytocin release is associated with fast grunting in the sow before milk ejection when the piglets become quiet while suckling (Ellendorff *et al.*, 1982). It is possible therefore that oxytocin release may be induced occasionally before the onset of suckling. A similar release of oxytocin may occur before teat or nipple stimulation in cows, as a result of washing of the udder (Cleverley and Folley, 1970; Gorewit, 1979; Mayer *et al.*, 1984, 1986; Schams *et al.*, 1984) or in response to washing the udder and the sound and exteroceptive stimuli of the young goats (A.S. McNeilly, 1972) or ewes (Fuchs *et al.*, 1987) and in humans in response to preparations for nursing, in particular the cry of the baby (A.S. McNeilly *et al.*, 1983b). Indeed, spontaneous milk ejections may occur at regular intervals unrelated to suckling in humans during lactation (A.S. McNeilly and McNeilly, 1978). Oxytocin release and the milk ejection reflex may be inhibited by emotional or other forms of stress (Cross, 1955; Lincoln, 1983). This has been clearly demonstrated in the rabbit (Cross, 1955), pig (Ellendorff *et al.*, 1982), cow (Bruckmaier *et al.*, 1992) and human (I. Newton, 1961). In cattle, the injection of adrenaline at the time of milking reduced milk yield by restricting blood flow to the mammary gland without affecting oxytocin release (Gorewit and Aromando, 1985). Inhibitory effects of adrenaline are mediated by α-adrenergic receptors, while milk flow rates are increased by β-adrenergic agonists (Bruckmaier *et al.*, 1991).

It is clear that in all mammalian species studied milk ejection occurs in response to a suckling-induced or -related release of oxytocin from the posterior pituitary as a result of the coordinated firing of oxytocin neurosecretory cells in the paraventricular nucleus of the hypothalamus. In most species the pattern of oxytocin release is pulsatile, but when a sustained release does occur this is probably due to the interval between firing of the oxytocin neurones being shorter than the half-life of oxytocin in blood. In some species the release of oxytocin may occur before teat or nipple stimulation and can be inhibited by stress. It appears that in most, if not all species, oxytocin is required for milk ejection. Studies which failed to demonstrate a release of oxytocin even though milk yields were normal involved blood samples collected too infrequently. Where frequent samples are collected, the failure to demonstrate a release of oxytocin during nursing is always associated with a reduced or absent milk flow (Ellendorf *et al.*, 1982; Schams *et al.*, 1984).

11.4 OVARIAN ACTIVITY DURING LACTATION

During lactation the suckled offspring stimulates milk production and milk ejection but, in most mammalian species, the suckling stimulus also delays either the resumption of ovulation or, if ovulation takes place, delays the time of implantation. In this way the interbirth interval is extended, allowing the suckling young to grow to a point where natural weaning is occurring and a reduction or absence of milk will not adversely affect the health of the growing young. In many species (e.g. cow, monkey, human) suckling prevents ovulation, in others implantation is delayed after a post-partum ovulation (e.g. rat, marsupials), while in species such as the marmoset monkey and sheep there may be a very short delay before ovulations resume. In seasonal breeders, such as the sheep, births normally occur at the end of the natural breeding season and any lactational anoestrous period coincides with seasonal anoestrus. Thus, the impact of suckling on resumption of ovarian cyclicity is almost insignificant compared with some mainly

non-seasonal breeders such as the primate, in which extended periods up to 4 years of suckling-induced infertility may occur. A final consideration is that in some species, such as the rat and many marsupials, the young are born at a very immature state, perhaps equivalent to birth of human infant at 4–6 months of the 9-month gestation, and a delay before the next pregnancy occurs or becomes sufficiently established to have a detrimental effect on the concurrent lactation is essential. In view of these different strategies, it is not possible to review the changes in ovarian activity and gonadotrophin secretion as a whole, but it is necessary to discuss the strategies of individual species before drawing conclusions as to possible common pathways involved in the suckling-induced inhibition of ovarian activity.

11.4.1 RAT

Within 24–36 h of parturition, the exact timing depending on the time of parturition (Everett, 1961; J.R. Connor and Davis, 1980a,b), a post-partum oestrus and ovulation occurs in the rat whether the rat is or is not lactating. In the natural situation, it is probable that most conceptions occur at this time (Bennett and Vickery, 1970; Conaway, 1971), although more ejaculations are necessary for conception to occur (H.N. Davis and Connor, 1980). Although the lactating female is now also pregnant, implantation is delayed for 5–7 days compared with oestrous cycles in the non-lactating rat (Conaway, 1971), during which time the blastocyst is in a metabolically quiescent state (Gosden *et al.*, 1981). Parturition then occurs around day 28, a time when natural weaning is occurring (see A.S. McNeilly, 1987a). In the absence of mating or lactation the next oestrous occurs 5–6 days after parturition, while suckling delays oestrus and ovulation for up to 20 days with natural litter sizes (Rothchild, 1960, 1981; Maneckjee and Moudgal, 1975; van der Schoot *et al.*, 1978; Sodersten *et al.*, 1983), a delay which can be increased or decreased by increasing or decreasing the litter size (Rothchild, 1960; van der Schoot *et al.*, 1978). Suckling will only delay oestrus if the suckling stimulus is vigorous during the later stages of lactation, if for instance the pups are hungry (Rothchild, 1960; van der Schoot *et al.*, 1978; Lindblom *et al.*, 1985). Whether or not conception occurs at the post-partum oestrus in lactating rats, the corpora lutea formed are maintained throughout lactation, increasing in weight and progesterone production until mid-lactation, around day 10 (Rothchild, 1960; Grota and Eik-Nes, 1967; Tomogane *et al.*, 1969; Yoshinaga *et al.*, 1971; M.S. Smith and Neill, 1977; van der Schoot *et al.*, 1978; Gosden *et al.*, 1981; Taya and Greenwald, 1982; Taya and Sasamoto, 1987). The corpora lutea of pregnancy are also maintained, although with a much reduced activity (Taya and Greenwald, 1982). Both sets of corpora lutea are dependent on prolactin for the maintenance of progesterone secretion (Yoshinaga, 1974; Ford and Yoshinaga, 1975; M.S. Smith *et al.*, 1976; van der Schoot *et al.*, 1978; Taya and Greenwald, 1982) and, since the amount of prolactin available is related to the suckling intensity and hence litter size, the amount of progesterone secreted is indirectly related to litter size (Yoshinaga *et al.*, 1971; Coppings and McCann, 1979; Taya and Greenwald, 1982). Although corpora lutea are maintained throughout lactation, follicular development is suppressed. No large antral follicles are present and oestradiol levels are low during the first half of lactation (M.S. Smith and Neill, 1977; van der Schoot *et al.*, 1978; Gosden *et al.*, 1981; Taya and Greenwald, 1982; Uilenbroek *et al.*, 1982; Sodersten *et al.*, 1983; Taya and Sasamoto, 1987; Lux-Lantos *et al.*, 1990). No compensatory ovarian hypertrophy occurs after unilateral ovariectomy at this time (Mena *et al.*, 1974; van der Schoot and Greef, 1986a) and no ovulations will occur after treatment with an ovulatory dose of either LH or hCG (Taya and Greenwald,

1982; Taya and Sasamoto, 1987). Follicle growth resumes around day 10 of lactation, and plasma levels of inhibin (Taya *et al.*, 1989; Taya and Sasamoto, 1991; Yohkaichiya *et al.*, 1991) and oestradiol increase slightly at this time, allowing oestrogen-dependent implantation of the blastocysts to occur (Psychoyos, 1973; M.S. Smith and Neill, 1977; Taya and Greenwald, 1982; Taya and Sasamoto, 1987, 1991). Major follicle growth and the development of healthy antral follicles does not occur in rats with normal litter sizes until around days 17–18 (Taya and Greenwald, 1982; van der Schoot and Greef, 1986a,b; Taya and Sasamoto, 1987,1991). Although plasma oestradiol levels may not increase significantly, ovarian compensatory hypertrophy after unilateral ovariectomy will now occur in these later stages of lactation (Mena *et al.*, 1974; van der Schoot and Greef, 1986a,b).

11.4.2 PIG

Oestrus cyclicity in the pig is delayed for up to 6 weeks during lactation, and the delay is not necessarily dependent on the number of piglets suckling since lactational anoestrus can be maintained with as few as one or two piglets (Parvizi *et al.*, 1976; Kuravongkrit, 1984). However, the number of piglets and hence the suckling intensity can markedly affect the time from weaning to first oestrus and ovulation (Fahmy *et al.*, 1979), and this interval is also reduced with longer lactations, presumably because of a reduction in the suckling intensity of the older piglets (Self and Grummer, 1958; Moody and Speer, 1971; Cole *et al.*, 1975). A reduction in the suckling duration per day is achieved by removing the litter for up to 12 h (partial weaning) from the second to third week of lactation (D.M. Smith, 1961; Walker and England, 1978; L.H. Thompson *et al.*, 1981; Kirkwood *et al.*, 1983; Henderson and Hughes, 1984; Stevenson and Davis, 1984; E.A. Newton *et al.*, 1987) can result in the occurrence of oestrus during lactation, while split weaning, in which a portion of the litter is completely weaned, will increase the number of sows exhibiting early oestrus after weaning (Stevenson and Britt, 1981; Cox *et al.*, 1983; Henderson and Hughes, 1984; Stevenson and Davis, 1984).

Since first oestrus normally occurs between 12 and 20 days after parturition in the non-lactating sow, a proportion of the delay in resumption of oestrous cycles is due to recovery of the hypothalamo-pituitary axis from the suppressive effects of pregnancy (Elliot *et al.*, 1980). However, even in the absence of lactation, abnormal luteal function can occur for up to 6 weeks after parturition (Kuravongkrit *et al.*, 1983a,b). During lactational anoestrus no corpora lutea and only a small population of large follicles are present in the ovary (Lauderdale *et al.*, 1965; Palmer *et al.*, 1965a,b; Crighton and Lamming, 1969; Asch and Heap, 1975; Stevenson *et al.*, 1981; Cox and Britt, 1982a; Duggan *et al.*, 1982; Kuravongkrit *et al.*, 1982; Dyck, 1983; Edwards and Foxcroft, 1983; Foxcroft and Hunter, 1985; Shaw and Foxcroft, 1985; M.J. Martin *et al.*, 1986; De-Rensis *et al.*, 1991). There is a large population of small antral follicles in anoestrus and, with advancing lactation, the size of these follicles increases and the number undergoing atresia decreases (Palmer *et al.*, 1965b; Cox and Britt, 1982a; Kuravongkrit *et al.*, 1982; Foxcroft and Hunter, 1985) although no follicles of a size equivalent to a preovulatory follicle are usually seen (Palmer *et al.*, 1965b; Kuravongkrit *et al.*, 1982; Foxcroft and Hunter, 1985; Foxcroft *et al.*, 1987). After weaning there is a rapid increase in the number of medium and large follicles and a reduction in the number of small antral follicles with a concomitant increase in plasma levels of oestradiol (Palmer *et al.*, 1965a; Cox and Britt, 1982a; Dyck, 1983; Foxcroft *et al.*, 1987).

11.4.3 SHEEP

In natural conditions, lambing and sub-

sequent lactation occur in the spring at a time when day length is increasing, which coincides with the onset of seasonal anoestrus in most breeds of sheep. Thus, the effect of lactation on oestrous cyclicity is not clear. In suckled ewes which are either autumn lambing in which lambing occurs before the start of seasonal anoestrus, oestrous cycles resume within 3–5 weeks (Shevah *et al.*, 1975; Kann *et al.*, 1979). Lactation may (Shevah *et al.*, 1975; Kann *et al.*, 1979; Moss *et al.*, 1980; P.J. Wright *et al.*, 1980; Gregg *et al.*, 1986; Schirar *et al.*, 1989) or may not (Sharpe *et al.*, 1986; Malven and Hudgens, 1987) delay the resumption of oestrous cycles, but this variation may relate to differences between breeds of sheep and the latitude at which the studies were carried out. However, there is evidence of a reduction in fertility of lactating compared with non-lactating ewes following oestrus induction (Restall *et al.*, 1978; Rhind *et al.*, 1980).

11.4.4 COW

Both milking and suckling delay the onset of oestrous cyclicity after parturition in the cow (R.E. Short *et al.*, 1972; G.L. Williams, 1990), although suckling will cause a longer delay of up to 150 days (mean around 57 days) before first ovulation compared with 30–70 days (mean around 25 days) in milked cows (Wiltbank and Cook, 1958; Casida *et al.*, 1968; Oxenreider, 1968; R.E. Short *et al.*, 1972; Hurnick *et al.*, 1975; King *et al.*, 1976; Webb *et al.*, 1977; Bulman and Lamming, 1978; Schams *et al.*, 1978; Stevenson and Britt, 1979; Carruthers and Hafs, 1980; A.R. Peters and Lamming, 1984; Bryner *et al.*, 1990; M.G. Murphy *et al.*, 1990; Randel, 1990; Savio *et al.*, 1990a,b; Schemm *et al.*, 1990; Spicer *et al.*, 1990; G.L. Williams, 1990). In suckled cows the interval to first oestrus can be reduced if calves are removed temporarily or suckling is restricted (England *et al.*, 1973; Tribble *et al.*, 1973; J.S. Connor *et al.*, 1974; Randel *et al.*, 1976; Wetterman *et al.*, 1978; Carter *et al.*, 1980; Randel and Welker, 1981; Suzuki and Sato 1984; Fogwell *et al.*, 1986; I.A. Wright *et al.*, 1987). An increase in either milking frequency or the number of calves suckling may (H. Clapp, 1937; Wetterman *et al.*, 1978) or may not (Wetterman *et al.*, 1978; Lamming *et al.*, 1981; A.R. Peters *et al.*, 1981; Montgomery, 1982; A.R. Peters and Riley, 1982a) extend the interval to first oestrus.

The considerable variation in the delay to resumption of oestrus in both suckled and milked cows is related not only to suckling or milking patterns but is considerably influenced by environmental factors, of which photoperiod and nutrition are of major importance. Although not displaying seasonal anoestrus, non-lactating cows do show a seasonal change in ovarian follicular development (McNatty *et al.*, 1984). In parallel with this, the interval to oestrus is longer in suckled or milked cows calving in late autumn and winter than those calving in the spring or summer (Bulman and Lamming, 1978; Montgomery *et al.*, 1980; A.R. Peters and Riley, 1982b; P.J. Hansen and Hauser, 1983; P.J. Hansen, 1985). This effect can be replicated by artificial photoperiods (P.J. Hansen and Hauser, 1983, 1984) and is closely related to nutrition. Heavier and better nourished animals or those supplied with 24 supplementary dieting energy resume oestrous cyclicity earlier (Wiltbank *et al.*, 1964; Butler and Smith, 1989; Dunn *et al.*, 1969; A.R. Peters and Riley, 1982a; I.A. Wright *et al.*, 1987; Prado *et al.*, 1990; Randel, 1990), while oestrous cyclicity occurs later in poorly nourished cows (Lamming, 1966; Oxenreider and Wagner, 1971; Stevenson and Britt, 1979; I.A. Wright *et al.*, 1987) related to a reduction in body condition (I.A. Wright *et al.*, 1987; Randel, 1990).

Before first ovulation the final stages of follicular development are suppressed and plasma and milk levels of progesterone remain basal confirming the absence of ovulation (Labhetswar *et al.*, 1964; R.E. Short *et al.*, 1972; Webb *et al.*, 1977; Schams *et al.*, 1978; Lishman *et al.*, 1979; Rawlings *et al.*,

1980; Walters *et al.*, 1982; Bellin *et al.*, 1984; A.R. Peters and Lamming, 1984; Dufour and Roy, 1985; Moss *et al.*, 1985; Eduvie and Dawida, 1986; Garcia-Winder *et al.*, 1986, 1987; Jagger *et al.*, 1987; Bryner *et al.*, 1990; Perry *et al.*, 1991a,b). Plasma levels of oestradiol remain low and rise only with the development of large healthy follicles preceding the first preovulatory LH surge (Lishman *et al.*, 1979; Rawlings *et al.*, 1980; Walters *et al.*, 1982; Moss *et al.*, 1985; Jagger *et al.*, 1987; Garcia-Winder *et al.*, 1987; Spicer *et al.*, 1987a; Savio *et al.*, 1990a,b; Schemn *et al.*, 1990; Spicer *et al.*, 1990). Large healthy follicles have been observed in weaned cows by 7 days, in milked cows by 10 days and in suckled cows by 20 days post-partum (Oxenreider and Wagner, 1971; Hoffman *et al.*, 1973; Lishman *et al.*, 1979; Savio *et al.*, 1990a,b) with the percentage of non-atretic follicles in the ovary before first ovulation decreasing with time post-partum (Lishman *et al.*, 1979; Dufour and Roy, 1985). The corpus luteum of the first ovulation in both suckled and milked cows is usually short-lived (M.G. Murphy *et al.*, 1990; Savio *et al.*, 1990a; Perry *et al.*, 1991a).

11.4.5 NON-HUMAN PRIMATES

The majority of primates exhibit extended periods of suckling-induced ovarian inactivity, sometimes extending to 4 years in Old World great apes, monkeys and humans. In most species the resumption of ovarian activity has been assessed by monitoring interbirth intervals and the endocrine changes associated with the delay in resumption of ovulation are restricted to a very few species. Nevertheless, it is clear that lactation or suckling delays the resumption of ovulation in the great apes, such as the gorilla (Harcourt *et al.*, 1980) and chimpanzee (Douglas and Butler, 1970; Clegg and Weaver, 1972; Tutin, 1980), lesser Old World anthropoids such as the baboon (Rowell, 1974), various macaques (Kaufman, 1965; Fujiwara *et al.*, 1967; Vandenberg and Vessey, 1968; Drickamer, 1974; Weiss *et al.*, 1976a; Varley and Vessey, 1977; Simpson *et al.*, 1981; Wilson *et al.*, 1988; Gomendio, 1989; Nozaki *et al.*, 1990; Maeda *et al.*, 1991; Gordon *et al.*, 1992) and members of the genus *Cercopithecus* (Mallinson, 1971; Rowell, 1974) and the New World monkeys including the spider (Wolf *et al.*, 1975), howler (Carpenter, 1934) and squirrel monkeys (Travis and Holmes, 1974; Coe and Rosenblum, 1978), but not in the common marmoset (A.S. McNeilly *et al.*, 1981; S.F. Lunn and McNeilly, 1982) or cotton-top tamarins (Ziegler *et al.*, 1990). In the rhesus monkey, lactational infertility is associated with an absence of ovarian follicular development observed as the persistence of low plasma levels of oestradiol for up to 150 days post-partum (Weiss *et al.*, 1973; R.F. Williams and Hodgen, 1983; Gomendio, 1989; Gordon *et al.*, 1992), in contrast to the non-suckled monkey, in which normal follicular development and ovulation occurs by about 42 days post-partum with menses occurring 14 days later (R.F. Williams and Hodgen, 1983). In these non-suckled monkeys, the corpus luteum of pregnancy regresses soon after parturition with a resultant rapid decline in plasma levels of progesterone (Weiss *et al.*, 1973; Goodman and Hodgen, 1978; T.M. Plant *et al.*, 1980; Richardson *et al.*, 1985). In contrast, in suckled lactating mothers, the corpus luteum of pregnancy is maintained for the first 2–3 months post-partum as a result of the increased plasma levels of prolactin associated with lactation (T.M. Plant *et al.*, 1980; Schallenberger *et al.*, 1981; Richardson *et al.*, 1985) and, although plasma levels of progesterone do fall over the first few days post-partum, they are maintained above normal follicular phase levels for 2–3 months (Weiss *et al.*, 1973; T.M. Plant *et al.*, 1980; R.F. Williams and Hodgen, 1983). Luteolysis of this corpus luteum of pregnancy/lactation occurs if prolactin levels are suppressed either by weaning the infant (T.M. Plant *et*

al., 1980) or by treating the mother with bromocriptine (Schallenbelger *et al.*, 1981; Richardson *et al.*, 1985). In contrast to all primates studied so far, lactation in the common marmoset is not associated with any significant delay in the resumption of ovarian activity post-partum, even though the mothers normally have twins (A.S. McNeilly *et al.*, 1981; S.F. Lunn and McNeilly, 1982).

11.4.6 HUMANS

Breastfeeding and lactation in women can induce a period of ovarian inactivity and amenorrhoea for up to 4 years but, because of the immense variation in breastfeeding patterns, the duration of this interval is very variable and may be as little as 2–3 months even in a fully breastfeeding mother (Udesky, 1950; Perez *et al.*, 1972; R.V. Short, 1976; Delvoye *et al.*, 1978; A.S. McNeilly, 1979, 1987a; Kennedy *et al.*, 1989; Konner and Worthman, 1980; P.G. Lunn *et al.*, 1980; Andersen and Schioler, 1982; Howie and McNeilly, 1982; Brown *et al.*, 1985; Duchen and McNeilly, 1980; Gross and Eastman, 1985; Hennart *et al.*, 1981, 1985; P.G. Lunn, 1985; Rivero *et al.*, 1985, 1988; Wood *et al.*, 1985a,b; Stern *et al.*, 1986). During the period of lactational amenorrhoea, ovarian follicular development, whether monitored by changes in plasma levels of oestradiol or urinary excretion of oestrogen (Reyes *et al.*, 1972; Bonnar *et al.*, 1975; Rolland *et al.*, 1975; Andreassen and Tyson, 1976; Baird *et al.*, 1979; Duchen and McNeilly, 1980; A.S. McNeilly *et al.*, 1980, 1982a; Howie *et al.*, 1981, 1982; Howie and McNeilly, 1982; Glasier *et al.*, 1983; Gross and Eastman, 1983, 1985; Fraser *et al.*, 1989; Israngkura *et al.*, 1989; Gray *et al.*, 1990; Fink *et al.*, 1992), appears to be suppressed. Luteal function rarely resumes, although small short-term increases in oestrogen secretion lasting a few days (P.R. Lewis *et al.*, 1985; Rivero *et al.*, 1985, 1988; Shaaban *et al.*, 1990; R.V. Short *et al.*, 1991; Tay *et al.*, 1992) may occur but are usually not maintained (Howie and McNeilly, 1982; Gross and Eastman, 1985; A.S. McNeilly *et al.*, 1985; Flynn *et al.*, 1991). These increases in oestradiol are associated with the growth of follicles as visualized by ultrasound, and medium-sized non-steroidogenically active follicles are also observed (Flynn *et al.*, 1991). In non-breastfeeding women, an increase in plasma levels of oestradiol resulting from the development of a preovulatory follicle occurs within 15–30 days post partum and ovulation occurs within 30–50 days post-partum (Bonnar *et al.*, 1975; Baird *et al.*, 1979; A.S. McNeilly *et al.*, 1980; Howie and McNeilly, 1982; Howie *et al.*, 1982; Poindexter *et al.*, 1983; Gross and Eastman, 1985; Gray *et al.*, 1987).

Ovulation may occur in a proportion of humans during breastfeeding, and in some this may occur before menstruation and may result in a pregnancy (Howie and McNeilly, 1982; A.S. McNeilly *et al.*, 1983c; Gross and Eastman, 1985). In the majority, ovulation is followed by menstruation, and in 40–60% of menstrual cycles occurring while humans continue to breastfeed, the luteal phases of these menstrual cycles are associated with inadequate corpus luteum function (Delvoye *et al.*, 1980; Duchen and McNeilly, 1980; A.S. McNeilly *et al.*, 1980, 1982a,b, 1983c; Howie and McNeilly, 1982; Gross and Eastman, 1985; P.R. Lewis *et al.*, 1985; Gray *et al.*, 1990; Shaaban *et al.*, 1990), a situation similar to the resumption of menstrual cycles in a non-breastfeeding human post-partum (A.S. McNeilly *et al.*, 1980, 1982a, 1983c; Poindexter *et al.*, 1983; Gray *et al.*, 1987). Normal ovulatory menstrual cycles are more likely to occur later in lactation (A.S. McNeilly *et al.*, 1982a).

The duration of lactational amenorrhoea or infertility is directly related to the suckling activity of the infant (A.S. McNeilly, 1979, 1987a; A.S. McNeilly *et al.*, 1980, 1985; Howie and McNeilly, 1982; Thapa *et al.*, 1988; Kennedy and Visness, 1992), and this

accounts for the large variation in duration both within and between different societies. A reduction in breastfeeding, usually in terms of frequency but also in duration of each breast feed, can result in the resumption of ovarian activity even though breastfeeding continues (Rolland *et al.*, 1975; Delvoye *et al.*, 1978; Andersen and Schioler, 1982; Howie and McNeilly, 1982; Howie *et al.*, 1982; Brown *et al.*, 1985; Hennart *et al.*, 1985; Elias *et al.*, 1986; Gray *et al.*, 1990; Shaaban *et al.*, 1990; R.V. Short *et al.*, 1991). These changes in suckling pattern may occur as a result of factors influencing the baby, e.g. introduction of supplementary food (Howie *et al.*, 1982; Elias *et al.*, 1986) or the mother, in whom poor nutrition may extend the period of infertility (P.G. Lunn *et al.*, 1980; Hennart *et al.*, 1985). Suckling the baby at night may also prolong the duration of infertility (Howie and McNeilly, 1982; Wood *et al.*, 1985a,b; Elias *et al.*, 1986; Stern *et al.*, 1986) although in these circumstances suckling frequency and duration during the day also tend to be greater suggesting that it may not be an effect specific to night-time feeding (Stern *et al.*, 1986; A.S. McNeilly, 1987a).

11.5 GONADOTROPHINS

In most mammalian species for which adequate data are available, the changes in gonadotrophin secretion post-partum and during lactation are similar. Most of the variation between species appears to occur as a result of differences in the pattern of suckling, nursing or milking. The pituitary content of both LH and FSH is decreased in most species by the negative-feedback effects of the high levels of steroid hormones associated with pregnancy. After parturition, therefore, there is a finite time period during which pituitary synthesis of gonadotrophins returns to normal whether lactation occurs or not. The following sections will detail these changes in pituitary hormone content, plasma hormone concentrations and responses to ovariectomy and oestradiol.

11.5.1 FOLLICLE-STIMULATING HORMONE

The pituitary content of FSH increases to normal within a few days of parturition in the rat (M.S. Smith, 1982a, 1985; Taya and Greenwald, 1982), pig (Crighton and Lamming, 1969), sheep (Chamley *et al.*, 1976; Moss *et al.*, 1980; Crowder *et al.*, 1982; Clarke *et al.*, 1984) and cow (Labhsetwar *et al.*, 1964; Saiduddin *et al.*, 1968; Carruthers *et al.*, 1980; Cermak *et al.*, 1983; Moss *et al.*, 1985; Leung *et al.*, 1986). In the rhesus monkey, the pituitary content of FSH is decreased during early lactation but returns to normal by mid-lactation (Weiss *et al.*, 1976b). *In vitro*, pituitaries from lactating rats (M.S. Smith, 1982a, 1985) and cows (Leung *et al.*, 1986) release normal amounts of FSH in response to gonadotrophin-releasing hormone (GnRH). Plasma levels of FSH in most species return to those seen in normal non-lactating animals early in lactation (rat, M.S. Smith and Neill, 1977; M.S. Smith, 1978a,b; van der Schoot *et al.*, 1978; Taya and Sasamoto, 1980, 1987, 1990, 1991; Taya and Greenwald, 1982; pig, Stevenson *et al.*, 1981; Cox and Britt, 1982b; S. Edwards and Foxcroft, 1983; Shaw and Foxcroft, 1985; Foxcroft *et al.*, 1987; E.A. Newton *et al.*, 1987; sheep, Findlay and Cumming, 1976; Fitzgerald and Cunningham, 1981; Clarke *et al.*, 1984; Schirar *et al.*, 1990; cow, Dobson, 1978; Schams *et al.*, 1978; Webb *et al.*, 1980; Lamming *et al.*, 1981; Schallenberger and Petersen, 1982; G.L. Williams *et al.*, 1982, 1983; Leung *et al.*, 1986; Spicer *et al.*, 1986b, I.A. Wright *et al.*, 1987; Bryner *et al.*, 1990; human, Reyes *et al.*, 1972; Bonnar *et al.*, 1975; Rolland *et al.*, 1975; Keye and Jaffe, 1976; Baird *et al.*, 1979; A.S. McNeilly *et al.*, 1980; Howie and McNeilly, 1982; Glasier *et al.*, 1983; Tay *et al.*, 1992) or by mid-lactation in the rhesus monkey (T.M. Plant *et al.*, 1980; Gordon *et al.*, 1992). Injections of GnRH cause the release of nor-

mal amounts of FSH in the rat (M.S. Smith, 1982a, 1985), in the pig (Stevenson *et al.*, 1981; Cox and Britt, 1982a) and in humans (Jeppson *et al.*, 1974; Le Maire *et al.*, 1974; Andreassen and Tyson, 1976; Keye and Jaffe, 1976; Delvoye *et al.*, 1978; Tay *et al.*, 1993). In the cow, the FSH response to GnRH given either as a single bolus (Stevenson and Britt, 1980) or as small repeated injections (A.R. Peters *et al.*, 1985), while unaffected by suckling early in lactation (G.L. Williams *et al.*, 1982), declined with time post-partum in relation to the increase in ovarian follicular development and plasma levels of oestradiol (Jagger *et al.*, 1987).

Ovariectomy results in an increase in FSH, but the response depends on the stage of lactation and the suckling intensity. Thus, the FSH response to ovariectomy is reduced in early lactation in the rat (Taya and Sasamoto, 1991), pig (Stevenson *et al.*, 1981) and monkey (Weiss *et al.*, 1976a,b) but returns to normal by mid-lactation, while in the cow the post-ovariectomy FSH response is normal soon after parturition (Acosta *et al.*, 1983; Hinshelwood *et al.*, 1985). The FSH response to weaning depends on the degree of ovarian activity and the amount of steroid negative feedback. If follicular development is advanced and oestradiol levels are increased then there is no change in or even a decrease in FSH (pig, Foxcroft *et al.*, 1987; E.A. Newton *et al.*, 1987; cow, I.A. Wright *et al.*, 1987), while an increase in FSH may result if weaning occurs earlier in lactation when follicular development and hence steroid and inhibin feedback are suppressed (pig, Shaw and Foxcroft, 1985; E.A. Newton *et al.*, 1987). The positive-feedback response to an oestradiol challenge is reduced or absent during early and mid-lactation in both the monkey (Yamaji *et al.*, 1971; R.F. Williams *et al.*, 1979; T.M. Plant *et al.*, 1980; Schallenberger *et al.*, 1981; Ash *et al.*, 1984; Richardson *et al.*, 1985) and humans (Baird *et al.*, 1979; Glass *et al.*, 1981; Vermer and Rolland, 1982), and although absent at day 5 is normal by day 15–17 post-partum in the cow (A.R. Peters, 1984). In humans, oestradiol has a greater negative feedback effect on FSH (Baird *et al.*, 1979).

In summary, it appears that in most species both the pituitary content and plasma concentrations of FSH return to normal soon after parturition, suggesting that a lack of FSH is not involved in the suppression of ovarian activity post-partum. However, it must be remembered that in most species there is a lack of ovarian activity with consequent lack of the ovarian negative-feedback hormones oestradiol and inhibin. Therefore, it might be expected that plasma concentrations of FSH would be higher than normal.

11.5.2 LUTEINIZING HORMONE

Luteinizing hormone is normally released in pulses, each resulting from the release of a pulse of GnRH from the hypothalamus. It is thus appropriate to discuss changes in GnRH receptors in the pituitary in relation to changes in the pituitary content of LH and plasma levels of LH. As with FSH, the time course of changes in LH during lactation are similar between species when differences in suckling or milking intensity are taken into account. For clarity some of these changes will be described for each species and common features of all species then discussed.

(a) Rat

The pituitary content of LH, LHb and gonadotrophin α-subunit mRNA abundance is decreased during early lactation, increasing to that of a dioestrous female by mid-lactation (Ford and Melampy, 1973; M.S. Smith and Neill, 1977; M.S. Smith, 1978a,b; Steger and Peluso, 1978; Taya and Greenwald, 1982; Taya and Sasamoto, 1987; L.R. Lee *et al.*, 1989a,b; M.S. Smith and Lee, 1989). This reduced pituitary content of LH is accompanied by reduced hypothalamic GnRH content (Minaguchi and Meites, 1967; M.S.

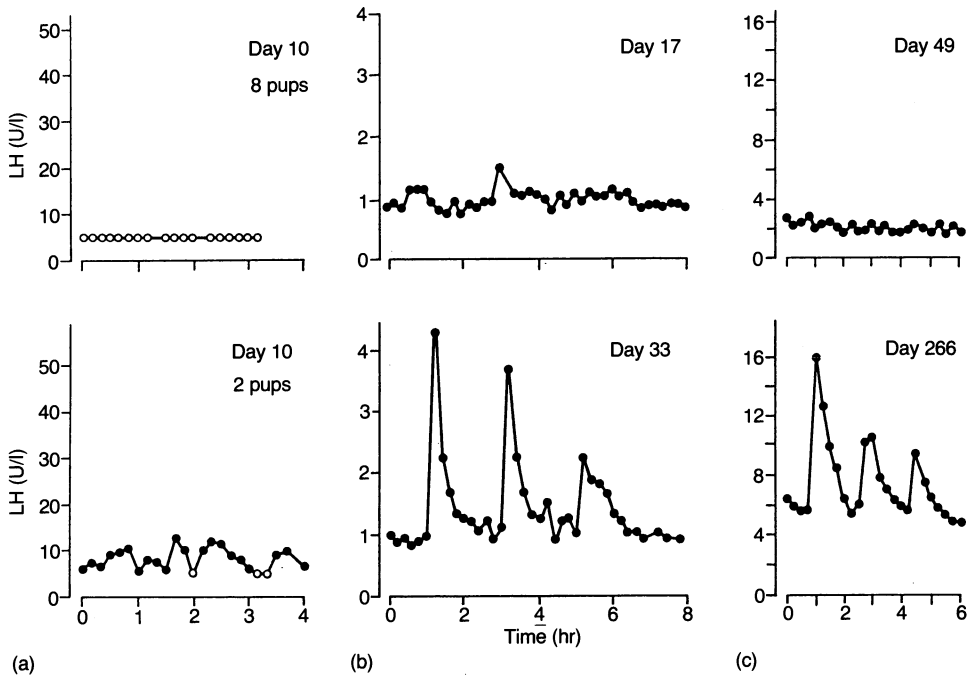

Figure 11.4 Changes in the pulsatile secretion of LH during lactation in the rat (A), cow (B) and human (C). Note that early in lactation in the cow and human, and in early to mid-lactation (day 10) in the rat suckled by a normal-size litter, the pulsatile secretion of LH is inhibited or absent. As lactation proceeds in the cow and human the pulsatile release of LH resumes and is associated with a return of ovarian follicular development. In the rat, a reduction in the suckling stimulus by reducing the number of pups from eight to two also results in an increase in the pulsatile secretion of LH. (Taken from Fox and Smith, 1984; Glasier *et al.*, 1984b; Riley *et al.*, 1981.)

Smith, 1978a) and there is a reduced or absent release of GnRH in response to the excitatory amino acid *N*-methyl aspartic acid (Pohl *et al.*, 1989). There is up to a 50% reduction in pituitary GnRH receptors (Clayton *et al.*, 1980; M.S. Smith, 1984), suggesting an absence of GnRH release from the hypothalamus, since GnRH in the rat is known to positively regulate its own receptors and GnRH receptor number reflects exposure of the pituitary to endogenous GnRH (Clayton *et al.*, 1982; Pieper *et al.*, 1982).

Basal plasma levels of LH are suppressed to around 25% of those in dioestrous (Figure 11.4; Ford and Melampy, 1973; Hammons *et al.*, 1973; Lu *et al.*, 1976a,b; M.S. Smith and Neill, 1977; M.S. Smith, 1978a,b, 1982b, 1985; van der Schoot *et al.*, 1978; Coppings and McCann, 1979; Taya and Greenwald, 1982; Uilenbroek *et al.*, 1982; Hansen *et al.*, 1983; Fox and Smith, 1984; Taya and Sasamoto, 1987, 1990, 1991; Lux-Lantos *et al.*, 1990) and increase in mid- to late lactation, around day 20, when plasma levels of progesterone decline and those of 20α-dihydroprogesterone increase (M.S. Smith and Neill, 1977; Taya and Greenwald, 1982).

These low basal levels of LH result from an absence of the normal pulsatile secretion of LH, at least on day 10 of lactation (Figure 11.4; Fox and Smith, 1984; L.R. Lee *et al.*, 1989a,b). Exogenous GnRH given as large bolus or small pulsatile injections releases LH from the pituitary both *in vitro* (M.S. Smith,

1982a, 1985) and *in vivo* (Lu *et al.*, 1976a,b; Hodson *et al.*, 1978; M.S. Smith, 1978a; Steger and Peluso, 1978; Fox and Smith, 1984; L.R. Lee *et al.*, 1989a,c) during lactation, but the amount of LH released is significantly reduced in comparison with dioestrus, and no potentiation of the LH response was seen in response to repeated injection of GnRH (Lu *et al.*, 1976a,b; Hodson *et al.*, 1978), as occurs normally during the oestrous cycle (Aiyer *et al.*, 1974). Longer treatment with pulsatile GnRH induces a rapid increase in GnRH receptors to normal (L.R. Lee *et al.*, 1989a,c), a response similar to the increase in LH pulse output, reflecting GnRH, and GnRH binding after weaning (L.R. Lee *et al.*, 1989a,b; M.S. Smith and Lee, 1989; Ciofi *et al.*, 1991). The increase in LH secretion was accompanied by an increase in LHβ and gonadotrophin α-subunit mRNA abundance (L.R. Lee *et al.*, 1989a,b) and could be reversed if suckling resumed (Maeda *et al.*, 1989).

In lactating female rats, the LH response to an oestradiol injection, which will induce the release of a preovulatory-type LH surge in the normal oestrous cycle (Legan *et al.*, 1975; Blake, 1977), is significantly reduced (M.S. Smith, 1978a; Coppings and McCann, 1979), the amount of LH released decreasing as litter size increases (Coppings and McCann, 1979). Similarly, the daily LH surges which can be induced in non-lactating rats when exposed to continuous oestradiol (Legan *et al.*, 1975) are abolished (Coppings and McCann, 1979) or dramatically reduced (Tsukamura *et al.*, 1988) during lactation. Plasma concentrations of progesterone are elevated during lactation due to the persistence of the corpus luteum of pregnancy and to the new corpora lutea occurring as a result of the post-partum ovulation. This progesterone, together with any follicular steroid production, may play a role in suppressing GnRH output, and this can be assessed by monitoring the changes in gonadotrophins after ovariectomy during lactation. When ovariectomy is performed in early lactation suckling can prevent the normal rise in serum and pituitary levels of LH and, to a lesser extent, FSH (M.S. Smith, 1978b, 1981), and the normal decrease in hypothalamic content of GnRH (Culler *et al.*, 1982a,b) and the post-ovariectomy suppression of LH and FSH can be enhanced if litter size is increased (Coppings and McCann, 1979). In contrast, when ovariectomy is performed in mid-lactation (days 10–15), suckling only reduced the increase in LH and FSH by 50% (M.S. Smith, 1981). The importance of the suckling stimulus in suppressing LH release was demonstrated in studies in which pups were separated from their mothers for 8–23 h (Isherwood and Cross, 1980; Sirinathsinghji and Martini, 1984). During the suckling period when the pups were reintroduced there was a dramatic increase in plasma levels of prolactin and rapid decrease in LH (Isherwood and Cross, 1980; Sirinathsinghji and Martini, 1984) but not FSH (Sirinathsinghji and Martini, 1984), the increase in LH associated with an increase in pulsatile LH/GnRH release (Maeda *et al.*, 1989). Although these results suggest that suckling will induce an acute decrease in LH secretion, suckling and nursing activity, in the rat is a more continuous activity with nursing periods lasting up to 18 h. The suckling activity of the pups declines throughout lactation with considerable variation during each 24 h period (van der Schoot *et al.*, 1978; Sodersten and Eneroth, 1984) and, although LH levels may be lower during a 24-h period in mothers suckling 10 rather than five pups (van der Schoot *et al.*, 1978), there is no precise relationship between suckling activity and LH release (van der Schoot *et al.*, 1978; Sodersten and Eneroth, 1984). This suggests that during lactation in the rat the effect of suckling on LH secretion is related more to a chronic alteration in secretion than a series of acute changes occurring every suckling episode. Nevertheless, in the rat, reduced basal levels of LH during lactation result from a suckling-

induced decrease in the hypothalamic content of and subsequent release of GnRH from the hypothalamus, which results in a reduced number of GnRH receptors in the pituitary and a decrease in both the synthesis and release of LH both basally and in response to both GnRH and oestradiol. A similar situation occurs in other species.

(b) Pig

During the first 3–4 weeks of lactation the pituitary content of LH (Crighton and Lamming, 1969; Cox and Britt, 1982b) and GnRH (Cox and Britt, 1982b) and basal plasma levels of LH remain low (Aherne *et al.*, 1976; Parvizi *et al.*, 1976; Dyck *et al.*, 1979; van der Wiel *et al.*, 1979; Cox and Britt, 1982b, Duggan *et al.*, 1982; Stevenson and Britt, 1979; Stevenson *et al.*, 1981; Edwards and Foxcroft, 1983; Foxcroft *et al.*, 1987; E.A. Newton *et al.*, 1987), and neither pituitary nor plasma levels of LH increase in response to ovariectomy at this stage (Crighton and Lamming, 1969; Stevenson *et al.*, 1981). The suppression of LH is associated with an absence or decrease in the pulsatile release of LH (Parvizi *et al.*, 1976; van der Wiel *et al.*, 1979; S. Edwards and Foxcroft, 1983; Shaw and Foxcroft, 1985; Foxcroft *et al.*, 1987; E.A. Newton *et al.*, 1987) and is directly related to litter size (Kuravongkrit, 1984).

From the third week of lactation onwards the pulsatile secretion of LH resumes, but initially at a lower frequency than normal (Shaw and Foxcroft, 1985; Foxcroft *et al.*, 1987; Barb *et al.*, 1991; Rojkittikhun *et al.*, 1991). Plasma levels of LH in intact (Elsaesser and Parvizi, 1980; Stevenson and Britt, 1980; Stevenson *et al.*, 1981; Kirkwood *et al.*, 1984a; Shaw and Foxcroft, 1985; Foxcroft *et al.*, 1987) and ovariectomized sows (Stevenson *et al.*, 1981) and the amount of LH released in response to GnRH also increases from the third week of lactation (Bevers *et al.*, 1981; Stevenson *et al.*, 1981; Rojansthien *et al.*, 1987). A positive-feedback response to exogenous oestradiol is also re-established by day 35 of lactation, having been absent on day 5 and greatly reduced on day 15 of lactation (Elsaesser and Parvizi, 1980; Ramirez *et al.*, 1985; Cox *et al.*, 1988; De-Rensis *et al.*, 1991), although oestradiol will induce oestrus behaviour throughout lactation (Cox *et al.*, 1988).

The LH response to weaning increases with time during lactation. In early lactation (day 10) the LH response to the natural post-weaning increase in oestradiol is poor (S. Edwards and Foxcroft, 1983; Kirkwood *et al.*, 1984a,b). In contrast, a significant increase in basal levels of LH due to an increase in LH pulse frequency but not amplitude occurs after weaning from day 2 onwards (Cox and Britt, 1982b; S. Edwards and Foxcroft, 1983; Shaw and Foxcroft, 1985; Foxcroft *et al.*, 1987; E.A. Newton *et al.*, 1987; Rojkittikhun *et al.*, 1991), and is related to a significant increase in both pituitary content of LH (Crighton and Lamming, 1969; Cox and Britt, 1982b) and hypothalamic content of GnRH (Cox and Britt, 1982b). The pattern of the pulsatile secretion of LH is very variable in the later part of lactation and, while sows exhibiting early oestrus after weaning tend to have increased pulsatile LH release before weaning (Shaw and Foxcroft, 1985), there does not appear to be any relationship between post-weaning LH pulsatility and time to oestrous onset (Foxcroft *et al.*, 1987).

(c) Sheep

In the ewe the hypothalamic content of GnRH (Moss *et al.*, 1980; Crowder *et al.*, 1982; Clarke *et al.*, 1984), pituitary content of LH (Chamley *et al.*, 1976; Jenkin *et al.*, 1977; Restall and Starr, 1977; Restall *et al.*, 1977; Moss *et al.*, 1980; Crowder *et al.*, 1982; Clarke *et al.*, 1984; Wise *et al.*, 1985) and plasma levels of LH (Jenkin *et al.*, 1977; Clarke *et al.*, 1984; Gregg *et al.*, 1986; Sharpe *et al.*, 1986;

G.S. Lewis and Bolt, 1987; Malven and Hudgens, 1987) return to normal within 14 days after parturition whether or not lactation occurs, as does the mRNA content for the gonadotrophin α and LHb subunits (Wise *et al.*, 1985), GnRH receptor (Crowder *et al.*, 1982) and oestrogen receptor (Wise *et al.*, 1986). Basal levels of LH increase in parallel with an increase in pulsatile LH secretion during lactation, although the rate of increase in LH pulse frequency slows as the number of lambs suckled increases (Schirar *et al.*, 1990; Wise, 1990). The increase in pulsatile release of LH is directly related to an increase in pulsatile release of GnRH measured in the hypophyseal portal vessels (Wise, 1990). In early lactation, when pituitary LH content is low, only 30–40% of GnRH pulses release LH compared with 70–80% later in lactation (Wise, 1990). However, the effect of lactation on the resumption of oestrous cycles varies considerably among breeds of sheep even though most parameters of LH secretion appear to return to normal early in lactation (see previous section). In lactating ewes lambing during the breeding season a paradoxical increase in both basal levels of LH (Restall and Starr, 1977) and the pulsatile secretion of LH occurred (P.J. Wright *et al.*, 1981a,b,c; Clarke *et al.*, 1984), the frequency of pulses being greater than during either the luteal phase or seasonal anoestrus. The LH response to GnRH returns to normal earlier in ewes lambing in the autumn (P.J. Wright *et al.*, 1980) than those lambing in the spring during the late breeding or early anoestrous season (Chamley *et al.*, 1974; Jenkin *et al.*, 1977) but, in spite of this normal response to GnRH, only around 50% of ewes show a normal positive-feedback response to oestradiol by 30 days post-partum (P.J. Wright *et al.*, 1980, 1981a,b). Chronic treatment of lactating ewes with low-dose oestradiol decreases the LH response to GnRH (Leakakos *et al.*, 1987) and causes a greater suppression of LH in lactating than non-lactating ovariectomized ewes. These results suggest that suckling can induce an increase in sensitivity to the negative-feedback effects of oestradiol, but the response varies considerably between different breeds of ewe.

(d) Cow

Both the pituitary content of LH (Labhetswar *et al.*, 1964; Saididdin *et al.*, 1968; Cermak *et al.*, 1983; Moss *et al.*, 1985; Leung *et al.*, 1986) and the plasma concentration of LH increase to normal levels by 30–50 days post-partum (Echternkamp and Hansel, 1973; Dickery *et al.*, 1975; Goodale *et al.*, 1978; Schams *et al.*, 1978; Rawlings *et al.*, 1980; Troxel *et al.*, 1980; Webb *et al.*, 1980; Kesler *et al.*, 1981; Fisher *et al.*, 1986; I.A. Wright *et al.*, 1987; M.G. Murphy *et al.*, 1990; Savio *et al.*, 1990a; Schemm *et al.*, 1990; Spicer *et al.*, 1990; Canfield and Butler, 1991; Lucy *et al.*, 1991). The increase in basal levels results from a resumption of the pulsatile release of LH (Stevenson and Britt, 1979; Carruthers and Hafs, 1980; Carruthers et al, 1980; Forrest *et al.*, 1980; Rahe *et al.*, 1980; Lamming *et al.*, 1981; A.R. Peters *et al.*, 1981; Ramirez-Godinez *et al.*, 1982; Walters *et al.*, 1982; Fisher *et al.*, 1986; G.L. Williams *et al.*, 1987; I.A. Wright *et al.*, 1987; M.G. Murphy *et al.*, 1990; Schemm *et al.*, 1990; Lucy *et al.*, 1991; Savio *et al.*, 1990a; Canfield and Butler, 1991) and occurs more rapidly in milked than suckled cows (A.R. Peters and Lamming, 1984). The LH response to GnRH both *in vivo* (Webb *et al.*, 1977; Schallenberger *et al.*, 1978, 1982; Fernandes *et al.*, 1978; Foster *et al.*, 1980; Jaeger *et al.*, 1987) and from the pituitary *in vitro* (Moss *et al.*, 1985; Leung *et al.*, 1986) also increases with time post-partum, although there is no change in either the affinity or number of GnRH receptors in the pituitary during lactation (Moss *et al.*, 1985; H.C. Leung *et al.*, 1986). Weaning does not affect GnRH release from the stalk median eminence *in vitro* (Connor *et al.*, 1990) and hypothalamic GnRH content is greater in suckled

than non-suckled ovariectomized cows (Zalesky *et al.*, 1990).

A major increase in the pulsatile secretion of LH occurs in the few days preceding first ovulation post-partum (Figure 11.4; Walters *et al.*, 1982; P.J. Hansen and Hauser, 1983; Garcia-Winder *et al.*, 1984; A.R. Peters and Lamming, 1984; Fisher *et al.*, 1986; M.G. Murphy *et al.*, 1990; Perry *et al.*, 1991a), and this increase in LH stimulates follicle development and an increase in plasma concentrations of oestradiol (Fisher *et al.*, 1986; M.G. Murphy *et al.*, 1990). Suckling delays this increase in LH pulsatility and weaning is associated with a rapid increase in LH pulse frequency without a change in pulse amplitude (Fogwell *et al.*, 1986; Faltys *et al.*, 1987; Rutter and Manns, 1987; I.A. Wright *et al.*, 1987). This increase can be prevented by maintaining cows in a state of hypoglycaemia or negative energy balance (Rutter and Manns, 1987; Canfield and Butler, 1991; Randel, 1990; Schrick *et al.*, 1990; G.L. Williams, 1990; Lucy *et al.*, 1991) and the increase in frequency is less in cows in poor body condition (I.A. Wright *et al.*, 1987) and can be stopped by reintroduction of the suckling calf (I.A. Wright *et al.*, 1987). Increasing dietary energy can reduce the time to first ovulation, apparently by increasing LH pulse amplitude but not frequency (Canfield and Butler, 1991; 1990; Lucy *et al.*, 1991).

Oestrogen-induced positive-feedback release of LH occurs in most suckled and milked cows by day 15 post-partum (Radford *et al.*, 1978; R.E. Short *et al.*, 1979; Schallenberger *et al.*, 1982; A.R. Peters, 1984), but the amount of LH is significantly reduced compared with non-lactating cows, suggesting a suckling-induced reduction of response. The LH response to ovariectomy on days 4–5 post-partum is delayed for 5–10 days in cows suckling one or two calves (Schallenberger *et al.*, 1982; Acosta *et al.*, 1983; Garcia-Winder *et al.*, 1984; Hinshelwood *et al.*, 1985), but both plasma levels and the pulse frequency of LH increase throughout the post-partum period until they are equivalent to non-suckled ovariectomized cows by 40–60 days post-partum (Garcia-Winder *et al.*, 1984). However, this escape from the inhibitory effects of suckling alone can be delayed by treatment with oestradiol (Acosta *et al.*, 1983; Hinshelwood *et al.*, 1985). Indeed, the post-partum interval in intact suckled cows can be shortened by treatment with an anti-oestrogen (Chang and Reeves, 1987), supporting the view that suckling in the cow causes an increase in sensitivity to the negative-feedback effects of oestradiol.

(e) Non-human primates

During lactation in the rhesus monkey, plasma levels of LH remain suppressed for the first 9 months post-partum and then increase to normal follicular plasma levels by 12 months (T.M. Plant *et al.*, 1980). Injection of GnRH in the first month or of oestradiol for the first 3–6 months post-partum fails to induce an increase in LH (Yamaji *et al.*, 1971; R.F. Williams *et al.*, 1979; T.M. Plant *et al.*, 1980; Schallenberger *et al.*, 1981; Ash *et al.*, 1984; Richardson *et al.*, 1985), in contrast to non-suckled monkeys, in which a normal response returns within the first month post-partum (T.M. Plant *et al.*, 1980). The positive-feedback effect of oestrogen on LH gradually increases after 6 months to reach normal by 10–11 months post-partum (Figure 11.5; T.M. Plant *et al.*, 1980; Schallenberger *et al.*, 1981).

The suppression of gonadotrophin secretion and positive-feedback effects of oestrogen can be induced in non-post-partum rhesus monkeys fostering neonates (T.M. Plant *et al.*, 1980), confirming that the effect of lactation is due to the suckling stimulus alone and not any events associated with pregnancy or parturition (Schallenberger *et al.*, 1981). Indeed, suckling delays the increase in both LH and FSH after ovariectomy in early lactation in cynomolgus monkeys (Gordon *et al.*, 1992).

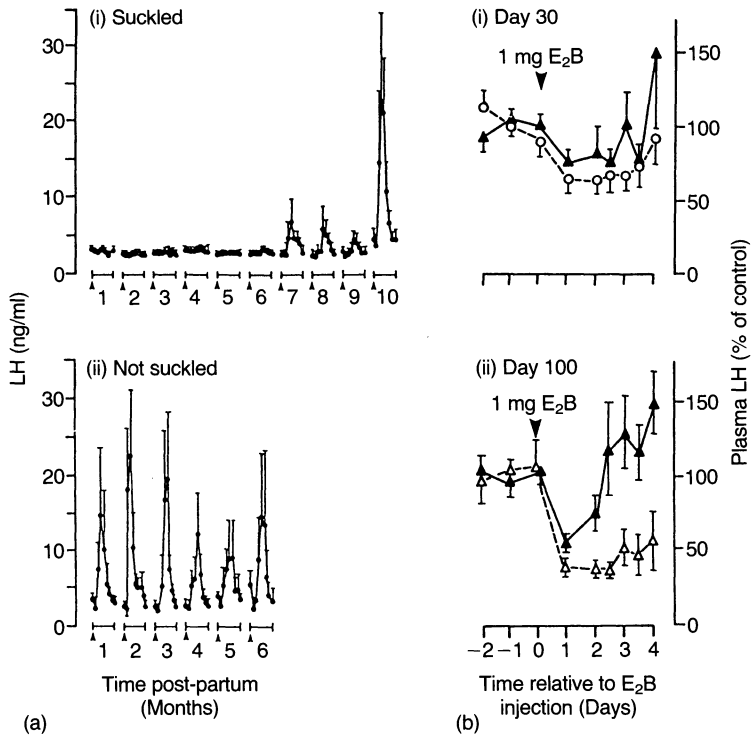

Figure 11.5 Changes in the positive- and negative- feedback effects of oestrogen on the secretion of LH with time post-partum in the rhesus monkey (A) and human (B). Note that in both suckled monkeys and humans the positive-feedback effect of oestrogen is inhibited by suckling while the negative-feedback effects of oestrogen are enhanced in humans. (From Baird *et al.*, 1979; T.M. Plant *et al.*, 1980.)

(g) Human

In non-breastfeeding humans, plasma levels of LH return to normal cycle levels within 20–25 days post-partum (Bonnar *et al.*, 1975; Rolland *et al.*, 1975; Baird *et al.*, 1979; A.S. McNeilly, 1979; Howie and McNeilly, 1982; Glasier *et al.*, 1983), while in breastfeeding humans, plasma levels increase to the lower limit of normal by day 20 and remain suppressed throughout most of the period of lactational amenorrhoea (Reyes *et al.*, 1972; Bonnar *et al.*, 1975; Rolland *et al.*, 1975; Keye and Jaffe, 1976; Delvoye *et al.*, 1978; Baird *et al.*, 1979; Duchen and McNeilly, 1980; A.S. McNeilly *et al.*, 1980; Glasier *et al.*, 1983, 1984b; Kremer *et al.*, 1991; Nunley *et al.*, 1991; Fink *et al.*, 1992; Tay *et al.*, 1992, 1993). These reduced plasma levels of LH are associated with either absent or low-frequency, low-amplitude pulses of LH (Figure 11.4; Madden *et al.*, 1978; Tyson *et al.*, 1978; Glasier *et al.*, 1984b, Gross and Eastman, 1985; Nunley *et al.*, 1991; Tay *et al.*, 1992, 1993) and a reduced LH response to large-bolus injections of exogenous GnRH (Jeppson *et al.*, 1974; Le Maire *et al.*, 1974; Andreassen and Tyson, 1976). Normal pulsatile release of LH can be induced by the injection of small boluses of GnRH (Glasier *et al.*, 1986), suggesting that there is a reduction in the total amount of LH in the pituitary but that the amount is still sufficient to allow the normal pulsatile release of LH if GnRH was secreted by the hypothalamus. During full breastfeeding, in which LH levels are suppressed, oestradiol

fails to induce a positive-feedback release of LH (Baird *et al.*, 1979; Glass *et al.*, 1981; Vermer and Rolland, 1982) and levels appear to be more suppressed than normal by oestradiol, suggesting a suckling-induced increase in sensitivity to the negative-feedback effects of oestradiol (Figure 11.5; Baird *et al.*, 1979). As breast feeding declines, plasma levels and the pulsatile secretion of LH increase, stimulating follicular oestrogen secretion and ovulation (Figure 11.4; Rolland *et al.*, 1975; P.G. Lunn *et al.*, 1980; A.S. McNeilly *et al.*, 1980; Glasier *et al.*, 1983, 1984b).

(g) Summary

The suckling or milking stimulus in all species for which there are adequate data results in a suppression of the normal pulsatile secretion of LH, with a consequent maintenance of plasma levels of LH which are lower than those in the normal oestrous or menstrual cycle. This reduction in LH is related, at least in some species, to a decrease in pituitary content of LH, a reduced GnRH receptor content and a decrease in the ability of both GnRH and oestradiol to induce a normal release of LH. These results suggest that suckling or milking suppresses the hypothalamic output of GnRH or disrupts the normal regular pattern of pulsatile release of GnRH from the hypothalamus. In contrast to LH, plasma levels of FSH usually return to normal early in post-partum lactating animals, suggesting that suckling or milking has only a minimal effect on FSH secretion. However, this is probably not the case, since both the FSH and LH response to ovariectomy is suppressed if oestradiol replacement is given, and enhanced sensitivity to the negative-feedback effects of oestradiol can be demonstrated for both FSH and LH.

11.6 INDUCTION OF OVARIAN ACTIVITY DURING LACTATION

If the lack of ovarian activity during lactation is due to the reduction in gonadotrophin secretion rather than any change in the sensitivity of the ovary to the available gonadotrophins, it should be possible to induce follicle growth and ovulation by increasing gonadotrophin secretion in the animal using appropriate GnRH stimulation or by giving exogenous gonadotrophins. In early lactation in the rat no follicles are present which are capable of ovulating in response to a single large injection of human chorionic gonadotrophin (hCG), but responsive follicles could be induced by pretreatment for 5 days with low doses of either hCG or LH (Taya and Greenwald, 1982; Taya and Sasamoto, 1987, 1988a, 1990). An increase in FSH alone occurring after immunoneutralization of GnRH in lactating rats does not affect follicle growth (Taya and Sasamoto, 1988b). In the pig, treatment with FSH or pregnant mare serum gonadotrophin (PMSG) alone or in combination with human chorionic gonadotrophin (hCG) fails to induce oestrus and ovulation early in lactation, but the percentage of sows showing oestrus and conceiving increases after the third week of lactation (Hausler *et al.*, 1980; Britt *et al.*, 1985). While continuous infusion of GnRH failed to induce oestrus (Britt *et al.*, 1985), the pulsatile administration of GnRH for 60 or more hours will induce oestrus in most sows from day 24 of lactation onwards (Cox and Britt, 1982b; Britt *et al.*, 1985) and the percentage responding decreases the earlier the treatment is started in lactation.

In both the sheep (P.J. Wright *et al.*, 1983, 1984; G.S. Lewis and Bolt, 1987) and cow (Rahe *et al.*, 1980; Riley *et al.*, 1981; A.R. Peters *et al.*, 1985; Vostermans and Walton, 1985; Spicer *et al.*, 1986a–d), ovulation can be induced by repeated injections of low doses of GnRH usually administered at a constant interval of 1–2 h, a frequency similar to that occurring in the normal follicular phase of the

cycle (Baird and McNeilly, 1981). However, the results of such treatments are variable, and while ovulation may be induced corpus luteum function is often inadequate (Garcia-Winder *et al.*, 1986; Spicer *et al.*, 1986b; Jagger *et al.*, 1987; V.G. Smith *et al.*, 1987; Braden *et al.*, 1989), a situation similar to that after treatment of lactating cows with single intramuscular injections of GnRH (Schams *et al.*, 1973; Britt *et al.*, 1974; Webb *et al.*, 1977; Kesler *et al.*, 1978, 1981; Zaied *et al.*, 1980; C.N. Lee *et al.*, 1983). In sheep, adequate luteal function after low-dose GnRH treatment occurs if the frequency of the pulsatile administration is progressively increased (3-hourly to hourly) and is further improved if ewes are pretreated with progesterone (P.J. Wright *et al.*, 1984), a situation similar to induction of ovulation in acyclic non-lactating anoestrous ewes (McLeod *et al.*, 1982; A.S. McNeilly *et al.*, 1982c; McNatty *et al.*, 1984). A similar improvement in luteal function occurs if milked or suckled cows are pretreated with progesterone before the start of GnRH treatment (Garcia-Winder *et al.*, 1986, 1987; Spicer *et al.*, 1986a,c; V.G. Smith *et al.*, 1987).

In humans, gonadotrophin stimulation immediately post-partum fails to stimulate oestrogen secretion (Zarate *et al.*, 1972; A.S. McNeilly *et al.*, 1980; Howie *et al.*, 1981), but thereafter either exogenous gonadotrophins (Nakano *et al.*, 1975; Andreassen and Tyson, 1976) or GnRH-induced increases in endogenous gonadotrophins (Zanartu *et al.*, 1974; Andreassen and Tyson, 1976; Glasier *et al.*, 1986) will stimulate follicular development, oestrogen secretion and ovulation, although as in the cow corpus luteum function may be inadequate (Glasier *et al.*, 1986).

These results show that the failure of ovarian follicular development during lactation is due principally to a lack of adequate gonadotrophin stimulation, mainly LH. Injections of a large bolus of hCG, LH or GnRH to induce a large release of endogenous LH, all of which expose the ovary to LH in amounts similar to the preovulatory LH surge, will only induce ovulation with the formation of an adequate corpus luteum if a follicle(s) is present in the ovary at a sufficiently advanced stage of development to respond adequately. Such follicles can be induced by treatment with pulsatile low-dose injections of GnRH at a frequency which mimics closely the normal increase in LH pulse frequency seen in the normal follicular phase of the oestrous or menstrual cycles. In the majority of cases this will result in ovulation and the formation of an adequate corpus luteum, and the percentage showing normal responses can be further improved by pretreatment with progesterone, although the mechanism remains unclear. The final question that remains is: how does suckling or milking suppress endogenous GnRH and hence LH secretion during lactation?

11.7 MECHANISMS OF SUCKLING/MILKING-INDUCED SUPPRESSION OF GnRH

11.7.1 PROLACTIN

Because of the close association between raised prolactin levels and the suppression of ovarian activity, it has been suggested that prolactin may play an important role in either or both the suppression of gonadotrophin secretion or inhibition of gonadotrophin action at the ovary (for discussion see A.S. McNeilly, 1979, 1984, 1985, 1987a,b, 1993; A.S. McNeilly *et al.*, 1982a). The importance of prolactin in normal ovarian function varies between species and appears to play a key role in the rat, but has less or no importance in other species (A.S. McNeilly, 1984). Thus, the role of prolactin in controlling ovarian activity will first be discussed in the rat.

The corpora lutea of lactation in the rat are dependent on prolactin, and treatment with CB154 to suppress prolactin in early and mid-lactation results in a rapid decline in plasma levels of progesterone (Tomogane *et al.*, 1969; Lu *et al.*, 1976b; Rothchild, 1981; S. Hansen *et*

al., 1983). While treatment in early lactation results in oestrus around 8–10 days later, treatment in mid-lactation (days 9–13) results in a rapid return of oestrus (Tomogane *et al.*, 1969; Lu *et al.*, 1976b; S. Hansen *et al.*, 1983). These results suggest that prolactin does play an active role in suppressing oestrus, probably indirectly via progesterone, but the different responses to CB154 appear to relate more directly to the extended delay of the LH response to CB154 in early rather than mid-lactation (Lu *et al.*, 1976b). A more clear-cut effect of prolactin *per se* on LH release is seen after ovariectomy. Suppression of prolactin with CB154 after ovariectomy in early lactation resulted in an increase in plasma levels of LH to 50% of those seen in non-lactating ovariectomized females, while FSH increased to normal castration levels (M.S. Smith, 1978b, 1981). Both LH and FSH increased to normal castration levels when prolactin was suppressed by CB154 after ovariectomy in mid-lactation (M.S. Smith, 1978b, 1981). Since the effects of CB154 could be overcome by concomitant treatment with prolactin (M.S. Smith, 1978b, 1981), this implies that prolactin *per se* was having a direct effect suppressing GnRH release after ovariectomy. Indeed, prolactin causes a reduction in GnRH receptors when administered in mid-lactation (M.S. Smith and Lee, 1989). Although such a situation may occur during lactation there does not appear to be a precise inverse relationship between prolactin and LH during any 24-h period in lactation in the rat, and maximum levels of prolactin may or may not coincide with alterations in LH (van der Schoot *et al*, 1978; Sodersten and Eneroth, 1984).

In a manner similar to lactation-induced delay in implantation in the rat, the blastocyst and corpus luteum resulting from ovulation and conception occurring at the postpartum oestrus immediately after parturition in the wallaby remains in a quiescent state maintained by the suckling joey (lactational diapause, Tyndale-Biscoe *et al.*, 1986). This lactational diapause can be terminated by removal of the suckling joey (Tyndale-Biscoe, 1984) or by hypophysectomy of the mother (Hearn, 1974), suggesting that secretion of a pituitary factor is responsible for the suppression of luteal function and the resultant embryonic diapause. Treatment of wallabies with CB154 which will suppress prolactin (Tyndale-Biscoe and Hinds, 1984; Curlewis *et al.*, 1986) results in reactivation of the corpus luteum, while treatment with prolactin will prevent reactivation (Tyndale-Biscoe and Hawkins, 1977). These results suggest that prolactin released by the suckling joey is the key hormone in preventing reactivation of the corpus luteum. If this is the case, the amounts of prolactin required must be extremely small or the corpus luteum very sensitive to prolactin since there appears to be little or no change in prolactin levels during the early stages of the diapause in the wallaby (Tyndale-Biscoe and Hinds, 1984; Hinds and Tyndale-Biscoe, 1985; Curlewis *et al.*, 1986) or other marsupials.

In the pig (Kraeling *et al.*, 1982; Bevers *et al.*, 1983; Mattioli and Seren, 1985) sheep (Louw *et al.*, 1976; Kann *et al.*, 1979; Fitzgerald and Cunningham, 1981; P.J. Wright *et al.*, 1981a) and cow (Cummins *et al.*, 1977; Clemente *et al.*, 1978; Schallenberger *et al.*, 1978; G.L. Williams and Ray, 1980; Montgomery, 1982) suppression of prolactin with CB154 during lactation had little or no effect on LH secretion or the onset of oestrus in lactation. In sows there is no correlation between prolactin levels throughout lactation and plasma levels of FSH or LH (Stevenson *et al.*, 1981; Foxcroft *et al.*, 1987), and the acute suckling stimulus has no effect on endogenous levels of LH or the LH response to GnRH (Stevenson *et al.*, 1981). Similarly, in the cow, while suckling delays oestrus for considerably longer than milking, plasma prolactin levels are similar in suckled and milked cows (Carruthers and Hafs, 1980; J.F. Smith *et al.*, 1981) and in cows suckling one or two calves (Wheeler *et al.*, 1982).

In the ewe, high levels of prolactin may directly reduce ovarian oestradiol (A.S. McNeilly and Baird, 1983) and progesterone (Rhind *et al.*, 1978) secretion and reduce the positive-feedback effect of oestradiol on LH release (Kann and Denamur, 1974; Kann and Martinet, 1975). While these effects may contribute to the reduced fertility of lactating ewes following the induction of oestrus (Restall *et al.*, 1978; Rhind *et al.*, 1980), it is more likely that this is due to an inadequacy of LH secretion induced by the suckling stimulus directly (J. Pelletier and Thimonier, 1973; Kann and Martinet, 1975; Kittock *et al.*, 1983). In the goat, maintenance of the seasonal photoperiodic increase in prolactin by continual exposure to artificially long day lengths in the autumn did not affect the normal time of onset of ovarian cyclicity (Hart, 1975b).

In red deer, a delay in the resumption of oestrous cycles after seasonal anoestrus in poorly nourished hinds was associated with increased plasma levels of prolactin (Loudon *et al.*, 1983). However, this increase in prolactin was related to a three to 10-fold increase in the frequency of suckling in the poorly nourished hinds suggesting that the prolactin changes were of secondary and minor importance. Thus, in ruminants there seems little evidence to support a major role of prolactin in suppressing gonadotrophin release during lactation.

Although injections of prolactin in bonnet monkeys may reduce the acute LH response to GnRH and extend the period of lactational infertility (Maneckjee and Moudgal, 1975; Maneckjee *et al.*, 1976), in the common marmoset, ovulatory cycles and conceptions occur soon after delivery even though mothers are usually suckled by twin offspring and have high plasma levels of prolactin associated with lactation (A.S. McNeilly *et al.*, 1981).

In the rhesus monkey, the increased plasma levels of prolactin during lactation maintain the corpus luteum of pregnancy and a low output of progesterone during the first 2–3 months of lactation (Dierschke *et al.*, 1973). However, lactational infertility lasting 9–12 months extends well beyond the time when corpus luteum function ceases and plasma levels of progesterone decline to normal follicular phase levels, suggesting that any indirect role of prolactin on the corpus luteum is of little importance in maintaining infertility. Indeed, in rhesus monkeys, both basal levels of LH and FSH and the positive-feedback effects of oestradiol continue to be inhibited by suckling when prolactin secretion is suppressed by treatment with CB154 throughout lactation (Schallenberger *et al.*, 1981).

In women, a close association between increased plasma levels of prolactin (hyperprolactinaemia) and the duration of infertility during lactation has supported the possibility that prolactin may be directly involved in lactational infertility in women (Delvoye *et al.*, 1978; Duchen and McNeilly, 1980; Andersen and Schioler, 1982; Gross and Eastman, 1983; Hennart *et al.*, 1985; Wood *et al.*, 1985a,b; Stern *et al.*, 1986; Fink *et al.*, 1992). Indeed, in some but not all studies, the increase in oestradiol associated with the resumption of ovarian follicular development is negatively correlated with the plasma level of prolactin (Delvoye *et al.*, 1978; P.G. Lunn *et al.*, 1980; Andersen and Schioler, 1982; Howie and McNeilly, 1982; Gross and Eastman, 1983; Hennart *et al.*, 1985; Wood *et al.*, 1985a,b). An increased release of prolactin in response to suckling throughout the day and night associated with prolonged lactational amenorrhoea has been reported (Diaz *et al.*, 1989, 1991), although this has not been confirmed (Tay *et al.*, 1992). However, the plasma level of prolactin in women is related to the amount of breastfeeding occurring throughout a 24-h period (Delvoye *et al.*, 1978; Konner and Worthman, 1980; Howie *et al.*, 1980; Howie and McNeilly, 1982; Gross and Eastman, 1983; Wood *et al.*, 1985a,b; Stern *et al.*, 1986; Unvas-Moberg *et al.*, 1990;

Tay *et al.*, 1992) and there is no acute effect of suckling on the release of LH or FSH (A.S. McNeilly *et al.*, 1980; Dawood *et al.*, 1981; Glasier *et al.*, 1984b).

Studies *in vitro* using cultured granulosa cells from human follicles or corpora lutea (McNatty *et al.*, 1974; W.L. Edwards *et al.*, 1982; A.S. McNeilly *et al.*, 1983b; Hunter, 1984; Alila *et al.*, 1987) suggest that prolactin may or may not have a direct inhibitory effect on steroid production (see A.S. McNeilly, 1980; A.S. McNeilly *et al.*, 1982b). Similarly, drug-induced hyperprolactinaemia during the follicular phase of the menstrual cycle may block normal follicular development (L'Hermite *et al.*, 1978, 1979; Kauppila *et al.*, 1984, 1987b; Payne *et al.*, 1985; Sowa *et al.*, 1986), while an increase in prolactin in the luteal phase appears to have little or no effect on corpus luteum function (Bennink, 1979; A.S. McNeilly, 1985). A direct effect of the drugs used to manipulate prolactin levels on the secretion of LH cannot be ruled out (A.S. McNeilly, 1987a, Payne *et al.*, 1985), and thus the role of prolactin, if any, in the suppression of gonadotrophin secretion in humans during lactational amenorrhoea must be viewed with caution. Any effect would appear to be minimal (A.S. McNeilly, 1987a,b, 1993).

Any direct effect of prolactin in suppressing GnRH output from the hypothalamus was suggested to be via the short-loop feedback effect of prolactin on dopamine, in which high levels of prolactin increased dopamine turnover in the hypothalamus, specifically in the tuberoinfundibular neurones, and this resulted in an increase in dopamine release into the hypophysial portal vessels and inhibition of further prolactin release. This short-loop feedback affecting prolactin release occurs in the rat, mouse, hamster, sheep and monkey (Hokfelt and Fuxe, 1972; Herbert and Martenz, 1983; Steger *et al.*, 1985; Bartke *et al.*, 1987; Curlewis and McNeilly, 1991). Although an increase in dopamine can inhibit the secretion of LH in some species (see A.S. McNeilly, 1987b), this is not necessarily the case (Steger *et al.*, 1985; Bartke *et al.*, 1987). In lactation in the rat not only is hypothalamic dopamine turnover decreased (Selmanoff and Wise, 1981; Demarest *et al.*, 1983) associated with an increase in neuropeptide-Y (Ciofi *et al.*, 1991) and VIP expression (Gozes and Shani, 1986), the ability of prolactin to increase dopamine turnover, the short-loop feedback, is severely attenuated (Demarest *et al.*, 1983; Moore, 1987). Blockade of dopamine action by a dopamine antagonist did not affect LH release in breast-feeding humans (Tay *et al.*, 1993). Thus, it seems unlikely that an alteration in dopamine turnover, at least related to changes in prolactin, is a principal mediator of the suckling-induced inhibition of GnRH (A.S. McNeilly, 1987b).

11.7.2 OPIOIDS

Suckling may increase hypothalamic opioid tone, and this could cause the suppression of GnRH output on the one hand and the suckling-induced increase or maintenance of elevated levels of prolactin. However, results in different species and in different experiments in the same species vary considerably. Administration of the opioid receptor blocker naloxone to lactating rats (Sirinathsinghji and Martini, 1984; Selmanoff and Gregerson, 1986; Wu *et al.*, 1992), sows (Armstrong *et al.*, 1986; Barb *et al.*, 1986; Mattioli *et al.*, 1986; Armstrong *et al.*, 1988; Kraeling and Barb, 1990), ewes (Gregg *et al.*, 1986; P.G. Knight *et al.*, 1986; Leakakos *et al.*, 1987; Malven and Hudgens, 1987) and cows (Whisnant *et al.*, 1986a–c) may result in an increase in LH secretion and, where measured, a decrease in prolactin. Although in sheep this effect may be seen in both suckled and non-suckled ewes post-partum (Leakakos *et al.*, 1987), suggesting that the response is more related to the after-effects of the high levels of progesterone during pregnancy, this is clearly not the case in sows or cows, in which the

response occurs in the presence of only minimal levels of ovarian steroids. However, in pigs (Armstrong *et al.*, 1990; Barb *et al.*, 1991), dairy cows (Canfield and Butler, 1991), rhesus monkeys (Gordon *et al.*, 1992) and humans (Kremer *et al.*, 1991; Tay *et al.*, 1993) naloxone or naltrexone treatment did not affect pulsatile LH release, and there was a minimal effect in suckled cows (Myers *et al.*, 1989; Rund *et al.*, 1989).

An increase in the release of β-endorphin into the hypophysial portal vessels in response to the suckling stimulus occurs. Although no changes in hypothalamic β-endorphin levels occur during lactation in rats (Dondi *et al.*, 1991), an increase in β-endorphin was observed in suckled cows (Connor *et al.*, 1990) and intracerebroventricular administration of β-endorphin increased prolactin secretion in the lactating rat (Taya and Sasamoto, 1989). Thus, it is possible that an alteration or increase in opioid tone within the hypothalamus may be involved in the suckling-induced maintenance of prolactin secretion and inhibition of GnRH/LH release, but the evidence at present is contradictory.

11.8 CONCLUSIONS

The suckling or milking stimulus and the metabolic changes related to milk production during lactation result in a major change in the endocrinology of the mother. In the majority of mammalian species, suckling or milking induces the release of prolactin, which is essential for milk production, with the exception of the ruminants. In this species growth hormone is of much greater importance than prolactin in maintaining milk production and growth hormone release occurs principally in response to the relative hypoglycaemia associated with the production of milk and little is released directly in response to teat or nipple stimulation. The secretion of the other metabolic hormones such as insulin, glucagon and the thyroid hormones is also modified to accommodate the metabolic load of lactation, greater changes occurring as the amount of milk produced increases, in particular in the dairy cow. While the changes in these metabolic hormones occur in response to the altered metabolism of the mother due to milk production, prolactin and oxytocin are released in response to nipple or teat stimulation. Oxytocin release in some species may become conditioned to stimuli occurring before direct stimulation, but such a conditioned release does not occur for prolactin.

In the majority of species, suckling directly inhibits the release of GnRH from the hypothalamus resulting, principally, in the inhibition of the pulsatile release of LH and the resultant inhibition of ovarian follicle growth or low steroid secretion by follicles that do grow under the influence of FSH. Plasma levels of FSH are usually normal throughout lactation. The ease of induction of ovulation during lactation suggests that there is no ovarian insensitivity to gonadotrophins during lactation and any role of prolactin in suppressing gonadotrophin secretion appears to be species dependent but very minimal. Although a suckling-induced increase in opioid tone within the hypothalamus may be involved in the maintenance of prolactin secretion, there is little evidence that opiates are involved in the suppression or disruption of the pulsatile pattern of release of GnRH during suckling. Indeed, while prolactin release must be maintained to allow continual milk production throughout lactation in most species, the influence of suckling on GnRH and hence gonadotrophin release is very variable. The exact pathways involved in directing the suckling stimulus to cause oxytocin release, prolactin release and modulation of GnRH release remain unresolved. It is clear that the suckling infant plays the only important role in controlling the endocrine changes during lactation. By varying its demand for milk it alters the metabolic–endocrine response for the required milk pro-

duction in the mother, it releases prolactin to allow this milk production and oxytocin to eject the milk and finally inhibits the release of gonadotrophins, thus preventing the resumption of ovarian activity, and hence fertility, pregnancy and the birth of the next infant, until it is ready and able to survive without total reliance on milk.

12.1 INTRODUCTION

Cohen and Massey (1984) have pointed out that in animal reproduction 'much more passes between the generations than simple information coded for by DNA'. In mammals, quite apart from factors such as 'cultural inheritance', the observation acquires tangible validity in the secretion of milk. It is sometimes overlooked that lactation is part of reproduction. Perhaps because, for over a century, increasing numbers of women have abandoned breastfeeding in favour of bottle feeding, lactation has come to be seen as an 'optional extra'. There are very serious grounds for questioning that perception, particularly under the social and environmental conditions in which the vast majority of human babies are reared. Indeed, artificial feeding is most appropriately compared with certain other technological innovations, like artificial insemination – invaluable on occasions, but hardly to be recommended for routine practice. In virtually all mammalian species (hystricomorphs, which are very precocious at birth, are a possible exception) lactation performs a crucial role in safeguarding the reproductive investment during the early stages of exterogestate life. Short's claim (1976) that 'Lactation is the central control of reproduction' has both figurative and physiological validity.

The point is perhaps emphasized by comparing the act of suckling with the only other aspect of mammalian reproductive behaviour involving passage of fluid between two individuals – copulation. In each case, neuroendocrine control is paramount, the fluid is expelled by muscular contraction, erectile tissues facilitate the fluid transfer and the act appears to satisfy a profound psychological impulse in both individuals. That the comparison is not mere analogy is emphasized by the commonality of several features to both processes, including the presence of certain nutritive and immunoreactive constituents in both fluids and the release of oxytocin from the adult pituitary gland in response to tactile stimulation.

In this volume, the subject of lactation is discussed in two chapters. Here we are concerned with the general significance of lactation and with the physiology and biochemistry of mammary function. Chapter 11 dealt with the endocrine system as it relates to lactation and, conversely, with the effects of suckling activity on maternal reproductive status.

Research on lactation is a growing field, which has been extensively reviewed in recent years in several publications, e.g. those edited by Larson and Smith (1974–78); Mepham (1983), Neville and Neifert (1983), Peaker *et al.* (1984) and Neville and Daniel (1987). The approach adopted here will necessarily be selective. Our aim is to identify the important principles of lactational function, and to do so discursively rather than merely documentarily.

12.2 THE EVOLUTION OF LACTATION

12.2.1 GENERAL

It is estimated that there are more than 4000 different extant species of mammal, but regrettably, as natural environments are progressively destroyed, the number is declining. Mammalia are classified into three superorders: the Ornithodelphia, Marsupialia and Eutheria. There are some important differences, as well as many similarities, between the lactational processes exhibited by species of the three superorders. However, space does not permit more than a generalized approach, and this inevitably means concentration on eutherians, which constitute over 95% of all mammalian species. Readers are referred to Griffiths (1983) for a review of lactation in monotremes (Ornithodelphia) and to Renfree (Chapter 7) for a review of marsupial lactation.

The single morphological feature by possession of which mammals are classified as

distinct from other vertebrates is the mammary gland. Since lactation is a crucial element of the mammalian reproductive strategy it seems important to examine evidence relating to the evolution of the gland and its secretion. This necessitates some consideration of the physiological implications of palaeontological findings.

Mammals are thought to have evolved from synapsid (mammal-like) reptiles during the Triassic period, approximately 200 million years ago (Kemp, 1982). Palaeontological evidence suggests that all early mammals were small (about the size of shrews), homoiothermic, nocturnal animals, which fed on insects and other invertebrates. The radiation of the mammals during the Cretaceous/Tertiary transition (70–150 million years ago) coincided with the extinction of dinosaurs and other larger reptiles, and it is probable that these divergent outcomes were related to the ability of mammals to withstand much more readily the pronounced climatic and vegetational changes occurring during this period (Pond, 1976). Juvenile reptiles are morphologically similar to adults but, because the young of large species are so much smaller than their parents, their diets differ markedly. Thus, breeding populations could only become established in habitats providing food suitable for all developmental stages. It seems that this constraint, exacerbated by the inability to cope with marked temperature fluctuations, proved an insuperable problem for dinosaur survival (Pond, 1976).

By contrast, for mammals, the habitat need only satisfy the nutrient requirements of the adult, since the neonatal diet, in the form of milk, is produced at the expense of the maternal diet and/or tissues. Parental feeding of juveniles is a widespread phenomenon, being practised by species as diverse as birds, fish and insects (Chadwick, 1977), but its particular nature in mammals may be seen to confer certain 'advantages' by comparison with alternative strategies (such a claim is not meant to imply 'causal teleology', as is discussed in section 12.2.5).

Thus, within limits, irrespective of the precise nature, mass and frequency of intake of the maternal diet, the neonate receives relatively constant supplies of milk of fairly uniform composition, because milk precursors may be mobilized from maternal body stores. This metabolic strategy has several consequences favourable to survival and reproduction.

1. Freed of responsibility for its own survival, the neonate may continue to grow and develop, in 'embryonic' fashion, to attain sexual maturity, a condition reached much earlier in mammals than in reptiles of equivalent body weight.
2. Lactation frees the mother from the necessity to carry young *in utero* for prolonged periods, a factor of considerable value to species in which there is reliance on speed to escape predators or on mobility to search for food.
3. Lactation effects a substantial economy in neonatal metabolism by allowing a delay in the appearance of teeth until the skull and jaws are almost fully developed: mammals exhibit diphyodonty (two sets of teeth) in contrast to the polyphyodonty which characterizes reptiles (Pond, 1976).
4. Finally, lactation would appear to exert a crucial role in the establishment of social organization, a factor of undoubted importance in species survival. The sustained physical proximity between adult and young, on which nursing depends, provides a psychological environment conducive to cooperativity and learning, which in our own species has resulted in all those achievements of art and culture which are valued so highly. As remarked elsewhere, 'perhaps not without justification we might perceive the human breast, innocently elaborating a seemingly bland fluid, to be the very font of human civilization' (Mepham, 1987a).

These distinctive features of the lactational process seem highly suited to a 'colonizing' strategy, i.e. the practice by which animals may reproduce rapidly in a highly changing environment. By analogy with weeds, mammals were able to establish themselves in habitats inhospitable to those species, like the large reptiles, with more fastidious ecological demands.

12.2.2 THE EMERGENCE OF MAMMARY FUNCTION

Most theories of the evolution of lactation have regarded it primarily in terms of mammary development. The theory of Darwin (1872), as modified by Long (1972), adopts the following scenario: (i) the development in therapsid reptiles of a vascularized incubation area ('brood patch') following the attainment of homeothermy; (ii) enhanced neonatal survival through utilization of the cutaneous secretion from the vascularized area; (iii) utilization of the secretion as food following chance ingestion by the neonate; (iv) improvements in suckling behaviour, transfer processes (e.g. teat elongation) and nutritional quality of the secretion.

Several suggestions have been made for the primary adaptive benefit of the protolacteal secretion (stage ii, above). For example, Bresslau (1920) proposed a role in heat transfer; Haldane (1965) suggested maintenance of water balance by prevention of desiccation; and Graves and Duvall (1983) invoked the theory that the ventral exudates possessed pheromonal properties which facilitated maternal–infant aggregation. One recent theory is particularly attractive in that it draws on the molecular evolution of a pivotal factor in mammary biosynthetic processes, α-lactalbumin, which is a component of the enzyme lactose synthetase (section 12.6.3). It was first proposed by Brew and colleagues (see Brew, 1970), and more recently confirmed by extensive analyses (e.g. Phillips *et al.*, 1987), that α-lactalbumin was most probably derived from lysozyme by a process of gene duplication. Hayssen and Blackburn (1985) interpreted such findings as indicating that the primary role of protolacteal secretion was that of protecting the eggs or young from bacterial, fungal or protozoal infection. It is interesting that while a lysozyme with bactericidal activity has been detected in both placental and monotreme (i.e. echidna) milks, the milk of echidna does not contain α-lactalbumin. The lysozyme of echidna milk does, however, show activity in the lactose synthetase system (Hopper and McKenzie, 1974). It thus appears that monotreme milk contains a protein which is a structural and functional intermediate of lysozyme and α-lactalbumin. Hayssen and Blackburn (1985) envisaged that duplication of the lysozyme genetic material may have occurred as early as 300 million years ago. Thereafter, as the duplicated material evolved, its product became involved in milk secretion in an intermediate form, possessing both nutritive and lysosomal activity, as in echidna milk. According to this theory, although the gene for lysozyme duplicated much earlier, the evolution of α-lactalbumin only occurred after the split between monotreme and placental species. In fact, lysozyme is only one of several microbial inhibitors in milk, including, for example, immunoglobulins, lactoferrin, peroxidase and xanthine oxidase, which suggests that the protective role of milk predated its nutritional function (Blackburn *et al.*, 1989). The protolacteal secretion might have provided important antimicrobial protection at the egg surface and/or, following ingestion, in the pharynx and digestive tract of the offspring.

This postulated link between bactericidal and nutritive functions of milk provides a rationale for the evolution of milk which seems appropriately parsimonious. But the question of the evolution of suckling is more problematical. The issue was clearly identified by Mivart in the following terms (cited by Darwin, 1872).

> Is it conceivable that the young of any animal was ever saved from destruction by accidentally sucking a drop of scarcely nutritious fluid from an accidentally hypertrophied cutaneous gland of its mother? And even if one was so, what chance was there of the perpetuation of such a variation?

Haldane (1965) addressed these questions and concluded that suckling behaviour was not accidental, but an aspect of infant behaviour developed prior to the emergence of the nutritive secretion. This reasoning, articulated with characteristic wit and erudition, rests on analogy with behaviour patterns of certain extant birds in hot, dry climates, e.g. lapwing and sand grouse. Such birds periodically wet their feathers by water immersion and then sit on their eggs, thus cooling them. Had this practice been adopted by therapsid reptiles in hot climates not only would hatching rates have improved, but the wet hair would also have provided the newly hatched young with a necessary water supply, a consideration of even greater importance had these species been ureotelic. Haldane envisaged that both habits, parental hair-wetting and hair-sucking by the young, became genetically determined so that when milk evolved the young were already equipped to exploit this novel source of water and nutrients.

Attractive as the theory may seem, it assumes that mammals evolved from hair-coated reptiles in hot climates, an assumption challenged by Long (1972) but supported by Kemp (1982). Recently, reviewing a wide range of evidence, Blackburn *et al.* (1989) have deduced that lactation probably arose in endothermic, oviparous ancestors, possessing hair (probably a pelage) and exhibiting a degree of maternal care. Behavioural and psychosexual aspects of suckling are discussed by Blass and Teicher (1980).

12.2.3 THE EVOLUTION OF LACTATIONAL METABOLIC CAPACITY

It was for long considered that the mammary gland evolved from eccrine sweat glands, but a range of evidence now suggests closer homology with epitrichial (apocrine and sebaceous) glands. However, since the two types of epitrichial glands have specializations which preclude their direct ancestry to the mammary gland, it has been suggested that the latter either arose from an evolutionary precursor of extant epitrichial glands or represents a neomorphic 'hybrid' assemblage of the two gland populations (Blackburn *et al.*, 1989).

According to this scenario the mammary gland acquired its specific nutritive role through amplification of the secretory activity of these premammalian cutaneous glands. But it is questionable whether such changes were of a qualitative nature. Thus, certain extant lepidosaur reptiles possess lipid-secreting glands, which, like mammary glands, are sensitive to endocrine influences, including that of prolactin (see Pond, 1984). If the appearance of the mammary gland were to mark the emergence of mammals, one might have to conclude that it represented merely a quantitative change in a pre-existing morphological structure. Indeed, Van Valen (1960) has argued the case for inclusion of therapsids in the class Mammalia.

There is, however, another aspect of lactation which merits attention, namely the implications for maternal metabolic activity. Kemp (1982) identified three major problems for land-dwelling animals, namely temperature variation; loss of body water, with attendant difficulties in maintaining osmotic and ionic balance; and gravitational problems due to the absence of buoyancy in air. Successful mastery of such problems in mammals has largely depended on endothermy, an efficient, but in energy terms, extravagant, means of achieving homeothermy. However, the problems faced by juveniles are poten-

tially more severe than for adults because not only is energy required for growth but their greater 'surface area–volume' ratio also renders them more subject to temperature variation and water loss. Thus any strategy for mammalian neonatal nutrition would seem to depend on a high rate of maternal nutrients and, particularly, energy provision in milk. The scale of energy transfer involved is indicated by Blaxter's (1961) calculation that for certain small mammals (which all mammals were throughout the Mesozoic era; Lillegraven, 1980) the energy content of the milk secreted in a single day is equal to that of the whole litter at birth. It seems clear that so abrupt and major a metabolic change could only be achieved by maternal acquisition of the capacity to accumulate and mobilize energy and nutrient supplies adequate to sustain milk formation: and it is for this reason that Pond (1983, 1984) has argued that the significant quantum change in mammalian evolution was metabolic rather than morphological.

In most mammalian species, fat (with an energy value per gram twice that of both protein and carbohydrate) is the main form of milk energy. Pond's analysis of adipose tissue in several species has revealed a relatively uniform interspecies distribution of adipocytes of similar size, which may signify that the organization of adipose tissue evolved principally in connection with its role in provisioning lactation (Pond, 1984). In any event, in many species lactation is attended by a profound reorientation of maternal metabolism such that nutrients are preferentially channelled to the mammary glands. This recasting of metabolic priorities, which has been termed 'homeorhesis' (see Bauman and Elliot, 1983), is largely regulated by endocrine factors. In high-yielding dairy cows, it is signified by a negative maternal energy balance for about 10 weeks post partum, with approximately 30% of milk energy being derived from mobilization of body fat over the first month (Bauman and Elliot, 1983).

This analysis suggests the following scenario, which is based largely on that of Blackburn *et al.* (1989).

1. Evolution of egg incubation behaviour in synapsid reptiles, following development of hair, endothermy and cutaneous glands;
2. evolution of a well-vascularized incubation patch on the ventral abdomen;
3. enhancement of egg survival by the antimicrobial action of cutaneous gland secretions of the incubation patch;
4. hypertrophy of these cutaneous glands, leading to their increased secretory activity, probably in response to stimulation by reproductive hormones;
5. gradual changes in the composition of the cutaneous glands' secretion to produce a more nutritious product, which first supplemented and subsequently replaced yolk nutrient provision;
6. concomitant increases in milk nutrient content and transfer efficiency to the young (e.g. suckling, milk ejection) and, following divergence of the ancestors of extant mammals, evolution of specializations, such as teats.

12.2.4 MAMMARY GLAND NUMBERS AND LITTER SIZE

An obvious limitation of lactational capacity of evolutionary significance is mammary gland number. It is common knowledge that the number of glands, and their distribution, is highly species variable (section 12.3). Aristotle (third century BC) was probably the first to record the claim that a species typical litter size is positively correlated with gland number, but in modern times the assertion has been questioned (e.g. Anderson and Sinha, 1972). The issue has recently been extensively examined for the class Rodentia by Gilbert (1986). Data from 266 species showed that mean litter size and gland number are significantly and positively correlated accord-

ing to a 'one-half rule', i.e. on average rodents have litter sizes equal to half their gland number. An apparent anomaly proved, on closer inspection, to add a new dimension to the analysis: arboreal squirrels, unlike terrestrial forms, appeared to underutilize their mammary capacity – until it was realized that the former were capable of gestating and nursing two litters simultaneously. However, a curious observation provides a salutary warning against too summary an analytical approach. Horseshoe bats (Rhinolophoidea) have two pairs of teats, but the pair located near the back legs, which are very large and jut out of the fur, serve no secretory role but merely act as 'dummies' – attachment points for the young that facilitate their transport by the mother during the first days after birth (Wickler, 1969). This strategy is also employed by certain marsupial and rodent species to transport the litter from the nest in times of danger (Blass and Teicher, 1980).

Given the association between gland number and litter size, it is pertinent to consider whether the former limits the latter or vice versa. Clearly, in a contemporary context, the mother can only nurse simultaneously a litter size which does not exceed gland number, and there is evidence that, despite 'neonatal rotation', infant mortality increases when this number is exceeded. Indeed, Gilbert's (1986) analysis showed that maximum litter size was almost identical to gland number. But this does not reveal the causal relationship on an evolutionary time-scale. However, while it is possible by selective breeding to substantially increase litter size in a few generations, attempts to breed for supernumery glands have had only limited success. Thus, it appears more likely that it is gland number which has determined litter size rather than the reverse.

12.2.5 WHY DON'T MALES LACTATE?

In concluding this brief survey of the evolution of lactation, it is appropriate to consider an apparent constraint on the adoption of this reproductive strategy. Pigeons and doves exhibit a form of parental care analogous to lactation in which parents of both sexes regurgitate so-called 'crop milk' and feed it to their newly hatched squabs. The fact that both parents produce crop milk raises the question of why this does not appear to have been reported for mammals. It is clearly a matter of general interest: Gould (1987), essayist and popularizer of biology, has revealed that no single item has aroused more curiosity among his correspondents than 'why men have nipples'.

Daly (1979) has argued that, given the long interval between conception and parturition, it is unsurprising that male parental investment of any kind should be slight. Generally, low paternity confidence, i.e. the probability that the male sired the offspring in question, would seem to be decisive. There are, however, some species in which stable pair bonding, with consequent high paternity confidence, is the rule. Daly's analysis of data for two such orders of mammals, the Canidae and the Hylobatidae, revealed that male parental investment was significant but took forms such as provisioning the mother with food and protecting the territory. In the case of canids, lactational capacity does not appear to limit neonatal survival; constraints are more probably imposed by the family's capacity to derive adequate food from the available hunting grounds in the most arduous season. Daly (1979) concluded that male lactation, while not posing insurmountable physiological problems, has probably been precluded because sexually dimorphic lactational physiology had already evolved substantially before any involvement of male parental investment occurred.

12.3 MORPHOLOGY OF THE MAMMARY GLAND

12.3.1 GENERAL

Notwithstanding the claim that lactation may have evolved primarily in consequence of changes in maternal metabolism, in present-day mammals the mammary gland assumes a paramount role as both the site of milk synthesis and secretion and the sensory organ on which regulation of the whole process largely depends. At least from the time of Galen (second century AD) to that of von Haller (eighteenth century), the glands were assigned the merely passive role of filters, separating off substances preformed in blood (see Mepham, 1986). By contrast, the modern conception is that in many respects the metabolic activity of lactating mammary glands surpasses that of most other organs of the body. The object of this section is to review briefly our current understanding of the morphological infrastructure which supports and channels this activity. Mammary development is not discussed here: readers are referred to reviews by Cowie *et al.* (1980), C.W. Daniel and Silberstein (1987) and Russo and Russo (1987).

Milk is produced by the mammary epithelium, a single-cell layer arranged in numerous spherical alveoli, into the hollow lumina of which the milk is secreted (Figure 12.1).

Surrounding each alveolus is a loose network of myoepithelial cells which, by contracting, expel milk from the alveolar lumina. Groups of alveoli assume a racemose configuration, with milk from neighbouring alveoli draining into common ductules and ducts of progressively larger diameter. Groups of alveoli form lobules, which are separated from neighbouring lobules by connective tissue septa. It is thus usual to categorize parenchymal tissues as either lobuloalveolar or ductal. The ducts terminate in storage spaces beneath the teat or nipple,

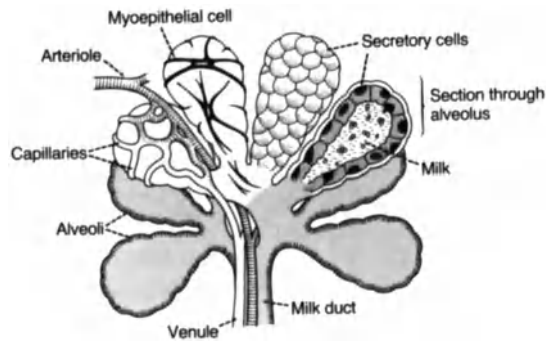

Figure 12.1 Diagrammatic representation of a cluster of mammary alveoli showing, from left to right: the outer vascular layer; within the latter, the myoepithelial cell layer; within the latter, the bases of the secretory cells; and finally, a transverse section through an alveolus.

from which milk is removed by the suckling young. The relative size of these spaces is highly species variable, e.g. in rats less than 10% of the milk may be contained therein prior to suckling, whereas for dairy animals the spaces (termed 'cisterns' or 'sinuses') may accommodate half the milk. Non-parenchymatous mammary tissues constitute the stroma, i.e. skin, blood and lymph vessels, nerves, connective and adipose tissues. Descriptions of the gross anatomy of mammary tissue of various species are referenced by Cowie and Tindal (1971) and G.H. Schmidt (1971).

Mammary gland number and disposition on the ventral body surface differ appreciably between species, e.g. two pectoral glands in humans and elephants; two inguinal glands in goats and guinea pigs; four inguinal glands in cows; and numerous glands, arranged in bilateral pairs along the abdominal surface, in rats, cats, dogs and pigs. Wherever situated, the glands share the blood, lymph and nerve supply of the contiguous skin area. Mammary arteries terminate in networks of capillaries surrounding each alveolus (Figure 12.1), but arteriovenous anastomoses and arteriovenular bridges are common in mammary tissue, particularly in the teats.

Mammary innervation is principally of two types: (i) sensory nerves originating from tactile receptors in the skin, the receptors, in the form of unmyelinated nerve endings being particularly prevalent in the teats (Cross and Findlay, 1969), and (ii) sympathetic motor nerves innervating contractile tissues of the blood vessels (which effect vasomotor control) and teat musculature. Contraction of the latter causes teat erection, thus facilitating its retention in the mouth of the suckling young. There is also electrophysiological and histochemical evidence for sparse innervation of a third type, namely of the large ducts: this might be involved both in detection of changes in intraductal pressure and, by reflex changes in smooth muscle tone, in altering ductal capacity (Linzell, 1974). Myoepithelial cells are not innervated. For more detailed discussion of mammary blood vessels and nerves the reader is referred to Linzell (1974).

12.3.2 ULTRASTRUCTURE

The functional unit of the mammary epithelium is the secretory cell. This performs the roles of absorbing materials, which have been delivered in arterial blood, from the interstitial fluid; synthesizing milk constituents; and transferring these synthesized products, together with certain others which have undergone no metabolic change, into the alveolar lumina.

The ultrastructure of the secretory cells, as revealed by electron microscopy, provides many clues as to how these processes occur (Figure 12.2).

The cells are generally roughly cuboidal,

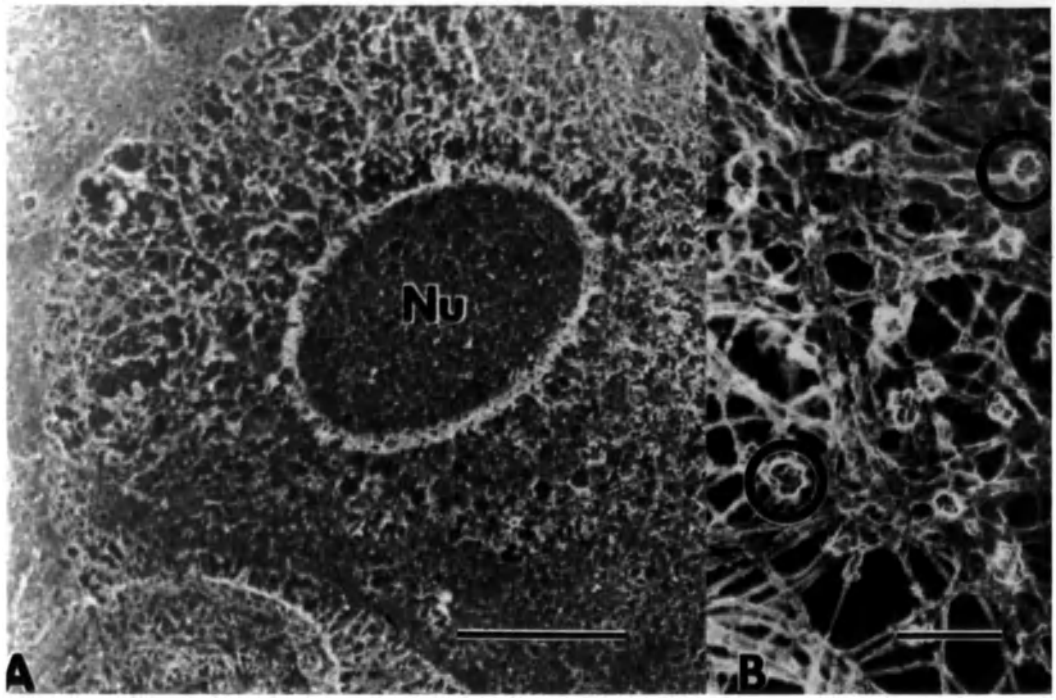

Figure 12.3 Platinum replicas of detergent-insoluble primary mouse mammary cell cytoskeletons. In A, at low magnification (scale bar 5 μm), the nuclear lamina (Nu) and cell borders are easily visualized. In B, at higher magnification (scale bar 0.2 μm), polyribosomes (circles) are attached to the filamentous cytoskeleton. Micrographs are printed as negatives (Reproduced from Aggeler *et al.*, 1988, with permission.)

but become flattened in the apicobasal axis when the alveoli are full of milk and, conversely, elongated just following milk ejection. The cytoarchitecture also shows a pronounced apicobasal polarity, i.e. the nucleus tends to be situated basally and much of the apical cytoplasm is crowded with Golgi and secretory vesicles, containing protein granules, and with fat globules. Rough endoplasmic reticulum is well developed and numerous mitochondria are scattered throughout the cytoplasm. The basal membrane is highly convoluted, with many infoldings and interdigitating processes, but by contrast the apical membrane bears only a diminutive 'hedge' of microvilli, interrupted in some sections by fat droplets in the process of 'pinching off' and secretory vesicles undergoing exocytosis (section 12.7). Despite the wide range of compositions in milks of different species, there appears to be considerable uniformity in mammary tissue at the ultrastructural level (Wooding, 1977).

The fibrillar infrastructure of all cells is composed of the cytoskeleton (Figure 12.3), a system involved in maintaining structural integrity, transport of materials within cells, cell motility and intercellular communication.

Three cytoskeletal systems have been described: microfilaments of actin (6 nm diameter); intermediate filaments of keratin (7–11 nm); and microtubules of tubulin (22 nm). In the mammary gland the constituent proteins of these systems may exist in either free or polymerized form, and lactation is associated with a marked shift in equilib-

rium towards a greater degree of tubulin polymerization, as well as with **net** tubulin synthesis. The cytoskeletal system appears crucial for milk synthesis and secretion, and it is hardly surprising that it has been shown to be influenced by several endocrine and other regulatory factors which affect milk secretion (see Loizzi, 1987). There are even suggestions that the cytoskeleton may participate in nuclear regulation of mRNA processing. To quote Bissell and Hall (1987), 'The cytoskeleton. . . . emerges as the structure most likely to integrate form into function'.

Cell junctions

Description of the properties of the secretory epithelium is, however, by no means encompassed by reference to intracellular features. Of crucial importance are the intercellular junctions which confer on the epithelium several important properties, namely mechanical strength, apicobasal polarity, coordination of physiological activity and restriction of solute leakage between cells (the paracellular route). The study of mammary cell contacts has recently provided several new insights, which are summarized briefly below.

With the introduction of electron microscopy, the junctional complex between neighbouring cells (referred to as the 'terminal bar') was seen to comprise three distinct junctions (Pitelka, 1985). Invariably, the most apical of these is the 'tight junction' (zonula occludens), a region where the outer leaflets of two cells appear to be intermittently fused (Figure 12.4).

The tight junctions form belts surrounding the apical poles of cells, so that each is sealed to its neighbours in a continuous, cellular mosaic. Below the tight junction is the intermediate junction (zonula adhaerentes) and, in many sections, beneath that are one or more desmosomes (maculae adhaerentes). In both intermediate junctions and desmosomes (Figure 12.4) a dense material is present under, and occupying the 20–30 nm space between, the two cell membranes: this intercellular 'glue' probably consists of membrane-associated glycoproteins. In addition to these three types of junction, gap junctions (maculae communicantes), 'spots' in which a 2–4 nm gap separates two apposed membranes, are scattered in apparently random fashion in tissue sections.

Research over the last 20 years has led to the ascription of specific functions to the different junctional types. Thus, tight junctions serve the roles of acting as a paracellular permeability barrier and as intramembrane barriers delimiting the apical and basal domains. Both intermediate junctions and desmosomes are adhesive, their locations serving to maintain epithelial structural integrity and to protect tight junctions from mechanical damage such as might occur when intra-alveolar pressure is raised. Desmosomes are particularly well developed in ductal tissue, where they connect ductal and epithelial tissues in like and unlike pairs, while hemidesmosomes appear to be sites of attachment of myoepithelial and epithelial cells to the basal lamina and fibrous stroma. Gap junctions act as leakproof intercellular communication channels, allowing the spread of ions, small molecules and electrical currents. They may thus provide an explanation for the synchronous secretory behaviour of cells in a single alveolus (Pitelka and Hamamoto, 1983), but paracrine secretions (section 12.8.4) crossing the apical membrane may also be involved.

The cell junctions are further characterized by the cytoskeletal elements of which they are composed. Actin filaments, continuous with a web beneath the apical membrane, attach to membranes of tight and intermediate junctions; and keratin filaments are inserted into, and looped through, the dense cytoplasm of belt and spot desmosomes. Gap junctions are composed of 7- to 8-nm-diameter protein particles (connexons),

which are arranged in roughly hexagonal fashion in linking two apposed cell membranes: each connexon is penetrated by a 2-nm-diameter central pore, which thus provides a continuous hydrophobic channel between the two cells (Pitelka and Hamamoto, 1983).

Insight into the nature of cell junctions has been obtained by use of the freeze–fracture technique, which involves freezing excised tissue in liquid nitrogen and then breaking it in two. The fracture tends to follow natural cleavage planes, thus exposing an inner protoplasmic (P) face of the leaflet and an outer exoplasmic (E) face. A metal replica for transmission electron microscopy may be prepared by deposition of a platinum–carbon film on the cleaved surface, followed by dissolution of the tissue. Use of this technique reveals the lines of fusion of two cell membranes as a network of ridges, about 8 nm in diameter, on the P face and as complementary grooves on the E face (e.g. Morgan and Wooding, 1982). The pattern is continuous where the fracture plane shifts from one membrane to the other, indicating that the ridges and grooves are closely parallel and probably make contact in the intercellular spaces. It is presumed that in living tissue the junction is consolidated by fusion of outer lipid leaflets of the junctions: the ridges themselves are thought to be proteinaceous (Pitelka, 1985).

Since tight junctions constitute the paracellular permeability barrier, much interest has centred on the ultrastructural changes they might undergo in conditions where leakage is believed to occur, e.g. prior to parturition,

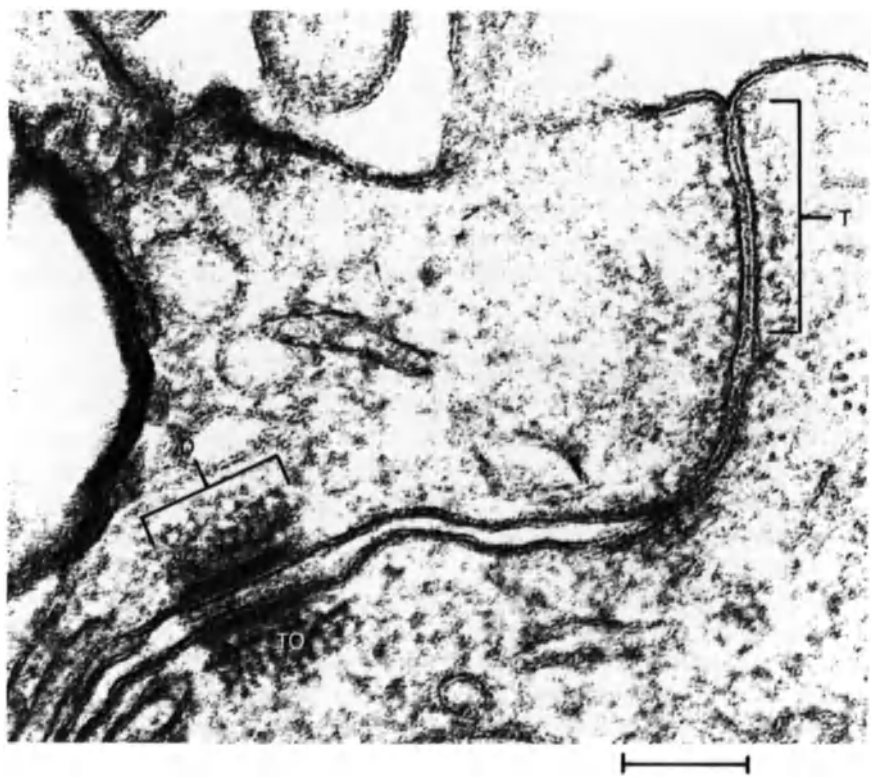

Figure 12.4 Electron micrograph of the apical regions of two secretory cells in ovine mammary tissue (scale bar 0.1 μm). T, tight junction; D, desmosome; TO, tonofilaments. (Courtesy of Dr F.B.P. Wooding.)

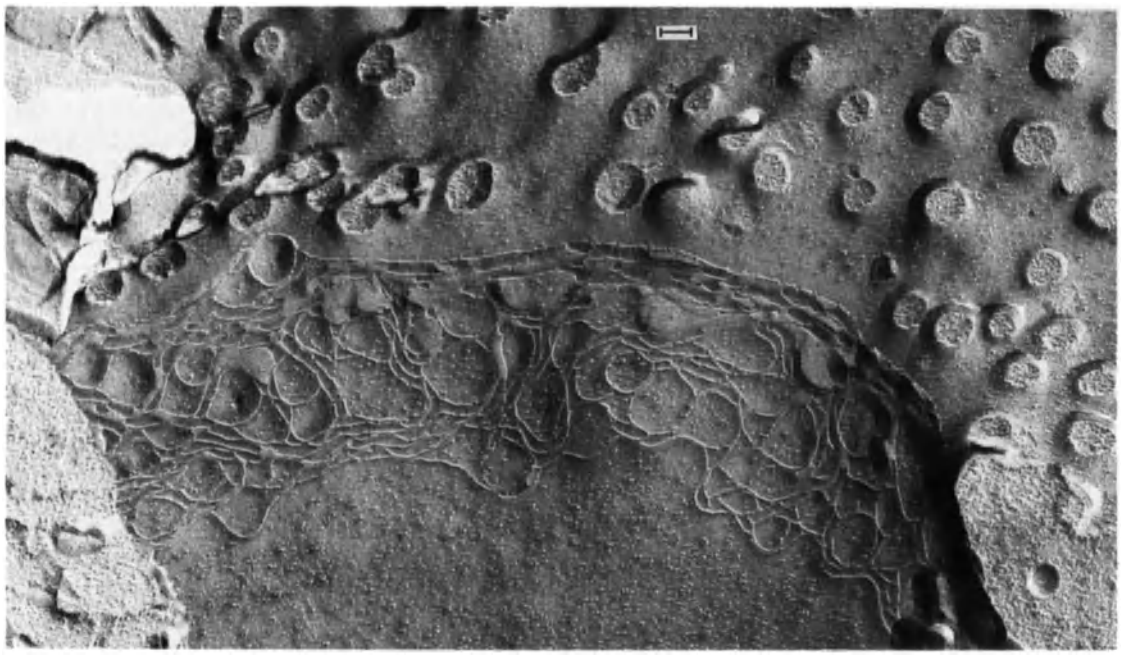

Figure 12.5 Freeze–fracture replica of part of a tight junction belt between two secretory cells in fully lactating (1 month post partum) ovine mammary tissue (scale bar 0.1 μm). (Reproduced from Morgan and Wooding, 1982, with permission.)

during the oestrous cycle and in late lactation. Freeze–fracture studies on mammary tissue from sheep (Morgan and Wooding, 1982) and mice (Pitelka and Taggart, 1983) have indicated that in such conditions the ridges become disordered and variously orientated, in contrast to the compact network, parallel to the apical border, which is characteristic of the normal lactating gland (Figure 12.5).

In rabbits, a species in which there is a pronounced paracellular leak in declining lactation, the junctional complexes become drastically attenuated a few days after attainment of peak milk yield, and it seems likely that ridge number varies inversely with degree of leakage, possibly in a logarithmic relationship (Pitelka, 1985).

The ridge pattern would appear to adapt readily to changes in cell shape in the course of the alveolar filling and emptying cycle. Thus, Pitelka and Taggart (1983), investigating the effects of mechanical tension in cells of a confluent epithelial monolayer plated on collagen gel, showed that undirectional stretching led to repositioning of the junctional ridges along lines of least resistance.

12.3.3 MYOEPITHELIAL CELLS

In many micrographs of mammary tissue it is possible to identify transverse sections of myoepithelial cells in close proximity to the basal surface of secretory cells (Figure 12.2). Their orientation, surrounding alveoli in a basketwork arrangement is, however, more readily appreciated in scanning electron micrographs (Figure 12.6).

In the rat gland, there appear to be about five cells per alveolus, each with 3–5 primary processes extending from the nuclear region, which branch to give 8–10 terminal processes per cell.

Ultrastructurally, myoepithelial cells are

similar to smooth muscle cells, the cytoplasm being replete with filamentous tracts and plasmalemmal caveoli: the tracts are composed of actin filaments and a loose network of intermediate filaments. Apart from myofilaments, the cells possess the usual organelles, but in poorly developed form, e.g. few mitochondria, a diminutive Golgi apparatus, free ribosomes and small cisternae of rough endoplasmic reticulum (Hollman, 1974).

Since myoepithelial cells contract in coordinated fashion in the milk ejection reflex, it is likely that some form of intercellular communication exists. There is general agreement that intra-alveolar cells do not form a

Figure 12.6 Scanning electron micrograph of mammary alveoli from a lactating rat, with most connective tissue removed by enzyme and acid treatment (magnification ×1000). V, small blood vessels; M, myoepithelial cells; S, secretory cells (Reproduced from Nagato *et al.*, 1980, with permission.)

syncytium, and it is surmised that gap junctions provide the route by which the spread of regulatory ions or molecules is effected (Pitelka and Hamamoto, 1983).

12.3.4 EXTRACELLULAR MATRIX

A recent area of research, which seems likely to prove extremely fruitful, is that concerned with the role of the extracellular matrix, the complex of acellular material by which cells are connected within tissues. In epithelial tissues this includes the basement membrane, which contains the basal lamina (derived from parenchymal cells) and a reticular lamina (derived from connective tissue cells), the two acting as a functional unit (see Bissell and Hall, 1987). In mammary tissue the basal lamina is an approximately 30-nm-thick, low-density layer, which forms a smooth blanket around the alveolar epithelium (including the myoepithelial cells) and is composed of a specific non-fibrillar collagen type IV, a glycoprotein (laminin) and other glycoproteins and glycosaminoglycans (see Pitelka and Hamamoto, 1983). Not only does the extracellular matrix influence the form of the epithelial cells and the development of the mammary epthelium as a whole, but it also interacts with the secretory cells during lactation, modulating their synthetic and secretory activity. Properties of the extracellular matrix have been investigated by using primary cell cultures in defined media on various substrata, from which it has been demonstrated that, for example, markedly different patterns of protein are secreted when cells are cultured on plastic, on attached collagen gels and on released collagen gels. In some cases proteins which are not normally present in milk are secreted, suggesting that alteration of the extracellular matrix may remove repressors or induce promoters. Many of these effects may be mediated by changes in cell morphology and cytoarchitecture (Bissell and Hall, 1987).

12.4 MILK COMPOSITION

12.4.1 GENERAL

Analyses of the compositions of milk of different species reveal the striking fact that, apart from superficial qualitative similarities, there is an enormous variation in the concentrations of specific constituents. There can be little doubt that evolutionary pressures have been paramount in shaping these compositional differences, but the notion that each milk is ideally suited to the 'needs' of the young (a notion which finds frequent expression, even in scientific literature) comes uncomfortably close to the causal teleology (aptly nicknamed Panglossism, with reference to Dr Pangloss in Voltaire's *Candide*), which has been so rightly deprecated by Medawar and Medawar (1984). How the infant develops is clearly, in some measure, a consequence of what sort of, and how much, nutrient it receives: its appetite is only one side of the equation. Moreover, a simplistic 'nutritional' rationale for milk composition might be misleading because milk contains not only recognized nutrients but also chemicals whose presence might best be described as 'adventitious'. A case in point is the regrettable appearance of polychlorinated biphenyls (PCBs), from pesticide use, in milk (Rogan, 1986). How many milk constituents fall into this category of useless and/or harmful components?

However, even allowing for the importance of evolutionary pressures in shaping milk composition, it is evident that factors such as physicochemical necessity and maternal metabolic capacity must constitute important constraints. Wilson (1975) discussed the latter aspect in terms of 'parent–offspring conflict', a theme provocatively espoused by Dugdale (1986), who claimed that human milk is unlikely to be optimal for infant development, as to secrete such a milk would jeopardize maternal survival. Latham (1986) would appear to have effectively countered

this claim since, even ignoring a whole range of attributes of lactation which benefit both mother and baby, the difference in maternal energy cost between 'optimal' and 'adequate' energy supply to the infant seems insignificant in humans. Moreover, from their extensive studies, Prentice and Whitehead (1987) concluded that 'human pregnancy and lactation are remarkably resilient to the effects of energy restriction'. Nevertheless, there must come a point when the costs to the mother of her parental investment outweigh the perceived benefits (however 'cost' and 'benefit' are defined) and this point may be reached earlier in species in which lactation imposes a proportionately greater strain on maternal metabolism, such as small laboratory animals, than it usually does in women.

12.4.2 GENERAL CHARACTERISTICS OF MILK

It would be inappropriate in a chapter of this nature to present a detailed survey of milk composition. Readers are referred for such information to Davies *et al.* (1983), Jenness (1985) and the books edited by Fox (1982, 1983, 1985). Rather, the object of this section is to survey briefly the important functional aspects of milk composition and the physiological 'strategies' which have resulted in the wide spectrum of milk compositions reported.

It is usual to discuss milk constituents according to major nutrient types, such as carbohydrates and proteins, and this approach is adopted below. From a functional viewpoint, however, it also seems appropriate to employ three categories, namely (i) nutritional (i.e. macronutrients), (ii) protective (immunological and other antimicrobial properties) and (iii) regulatory (i.e. including hormones, growth factors, enzymes, vitamins and trace elements). The categories are not absolute since some milk components perform several functions. The properties of the different milk constituents in relation to these three functions are discussed in turn.

One or two general points should be noted at the outset. Citations of data on milk composition are biased to cow's and human milk. This is because these milks have been examined more rigorously than others, because they are of greatest practical importance for most people and because they exemplify quite well the scale of interspecies variation. Most values quoted, for these and other milks, are for 'mature' milk, i.e. around peak lactation, but marked changes occur during the course of lactation. Two examples will illustrate this point: (i) in most species, protein concentrations are high, due to the presence of immunoglobins, in the period immediately following parturition, when the secretion is termed colostrum; (ii) in rabbits the lactose concentration falls 80% between days 20 and 30 of lactation (Cowie, 1969).

12.4.3 NUTRITIONAL PROPERTIES OF MILK

Lipids

Milk lipids are a chemically heterogeneous group of compounds, which are most usually referred to as 'milk fat', although the terms are not strictly synonymous. They are the most variable milk components, in both concentration and chemical composition, whether interspecies, intraspecies or within-animal differences are considered. Recorded values range from over 500 g/l in milk of some seals to trace amounts only in rhinoceros milk (see Table 12.1).

In all species, triacylglycerols (TGs) are predominant, but there is much variation depending on the relative preponderance of a wide range of fatty acids which become esterified with glycerol. For example, 437 different fatty acids have been isolated from cow's milk (Patton and Jensen, 1976). These include: normal straight-chain fatty acids of chain length 2:0 to 28:0, including all odd-carbon numbers; saturated branch-chain acids;

monoenoic acids 10:1 to 26:1 (including various isomers); dienoic acids of chain length 14, 16, 18, 20 and 24 (including various isomers); polyenoic acids; keto acids; and hydroxy acids (Jenness, 1974). In those species subjected to detailed study, 14 fatty acids predominate, but individual analyses may show appreciable differences depending on factors such as diet and stage of lactation. The distribution of fatty acids between the three positions of the triacyl-*sn*-glycerols is not random, an observation which appears to have physiological significance. For example, the high concentration of 16:0 in the *sn*-2 position of human milk fat renders it more digestible by the human infant than are other natural fats (Filer *et al.*, 1969).

Milk lipid is secreted in the form of spheri-

cal globules in which TG is surrounded by a milk fat globule membrane (MFGM) composed chiefly of phospholipid and protein complexes, but also incorporating cholesterol and several enzymes. In cow's milk the globules range from 0.1 to 20 μm in diameter: there appear to be species- and breed-specific distributions of globule size (see Davies *et al.*, 1983).

Proteins

Milk protein concentrations range from less than 10 g/l in primates to over 200 g/l in some lagomorphs (see Table 12.1). The two major groups of protein are caseins, which are mostly precipitated at acid pH (pH 4.6 for cow's milk) and by the action of the gastric enzyme chymosin (rennin), and milk serum (whey) proteins, which usually remain in solution at the pH of casein precipitation. Minor protein groups include enzymes and those in the MFGM.

Caseins are milk- and species-specific phosphoproteins, usually of molecular weights in excess of 20 000, in which virtually all the phosphate is combined with seryl residues as phosphomonoesters. A high concentration of prolyl residues distributed widely along the polypeptide chains gives caseins an open tertiary structure, susceptible to proteolytic digestion. Caseins are relatively hydrophobic proteins, which under the ionic conditions in milk associate in colloidal micelles of 100–300 nm diameter, composed of submicelles of 15–20 nm diameter (see Davies *et al.*, 1983).

Electrophoretic techniques indicate that casein is a complex and variable mixture of proteins. Thus, in cow's milk, α_s-, β- and κ-caseins have been described, but even such types contain different molecular forms, e.g. there are four genetic variants of α_{s1} and two of α_{s2}: the extent of phosphorylation is also subject to variation. In cow's milk, α_{s1}-, α_{s2}-, β- and κ-caseins are present in the micelle in roughly the ratio 3:1:3:1, but about 10% of the micelle consists of calcium and inorganic phosphorus, together with smaller amounts of citrate and magnesium. About 75% of milk calcium is combined directly with inorganic phosphate in micelles, the rest being bound directly to the caseins and to citrate (see D.G. Schmidt, 1982). An important 'design feature' of the casein micelle is its ability to maintain a high concentration of both protein and calcium phosphate in a dispersed form of low viscosity. This property, which is likely to be important in a fluid stored for long periods after secretion and expelled through fine-bore ducts, facilitates transfer of bone-forming minerals to the young. 'Kappa' caseins, which are glycoproteins, stabilize casein micelles, but lose this property when specifically cleaved by chymosin: the resulting curd seems to be important to effective digestion and nutrient absorption in the neonatal intestinal tract.

There is much dissimilarity between cow's and human milk with respect to casein content. Caseins constitute about 80% of cow's milk proteins, but only about 45% of those in human milk (Harzer and Haschke, 1989). Moreover, β-casein is the major casein of human milk, but α_{s1}-casein that of cow's milk. There are consequently substantial differences in the mineral contents, amino acid contents and types of curd formation in the two milks (see Hambraeus, 1982).

Serum proteins include both milk-specific (e.g. α-lactalbumin, β-lactoglobulin) and non-specific proteins (e.g. immunoglobulins and blood serum albumin). α-Lactalbumin has been detected in all milks which also contain lactose, but not in some (e.g. of the Californian sea lion) reported to be devoid of this disaccharide (see Jenness, 1974). Such differences are explicable in terms of the role of α-lactalbumin in lactose synthesis (section 12.6.3). β-Lactoglobulins are the most prevalent milk serum proteins in ruminant milks, but absent, or present at very low concentrations, in other milks (e.g. human). It has been speculated that β-lactoglobulin may

play regulatory roles in mammary phosphorus metabolism (Farrell and Thompson, 1971) and in vitamin A transport (Papiz *et al.*, 1986; Godovac-Zimmerman and Braunitzer, 1987).

Lactoferrin and transferrin are two milk proteins which bind iron. Transferrin, identical to the protein in blood, has been isolated from cow's and rabbit milk, and lactoferrin (which also occurs in secretions such as saliva and semen) from some (including human and ruminant milks) but not others (see Jenness, 1974). Relationships between the molecular structure and function of lactoferrin have been discussed by Baker *et al.* (1987). Ceruloplasmin, which binds copper, has been detected in human and cow's milk (see Jenness, 1979).

Non-protein nitrogenous compounds

Certain milks contain appreciable amounts of non-protein nitrogenous compounds, and it seems likely that some, at least, fulfil specific nutritional functions. For example, in human milk they constitute about 25% of the total nitrogen, whereas in cow's milk the figure is only about 6% (Hambraeus, 1982). Urea is generally a major component of this fraction, but in human milk taurine is present at high concentration, an observation which has been related to its possible roles in neonatal brain development (Huxtable and Lippincott, 1983), membrane protection, cell volume regulation and detoxification (Chesney, 1988).

Carbohydrates

The great majority of milks analysed contain lactose: reports of failure to detect it in some milks (e.g. of seals, sea lion and walrus) are countered by others which cite trace amounts (see Jenness, 1974). In the majority of species, its concentration is within the range 10–100 g/l (see Table 12.1), values for human milk being among the highest recorded (Jenness, 1986).

Lactose

Lactose is a disaccharide, comprising glucose and galactose linked $\beta 1 \rightarrow 4$, which is formed by the enzymic galactosylation of free glucose. Although lactose is the classical 'milk' sugar, the trisaccharide sialyllactose is a prominent sugar in the milk of rats and mice (Kuhn, 1972), and a predominant one in the milk of monotremes (see Davies *et al.*, 1983; Amano *et al.*, 1985). In human milk and cow's colostrum small amounts of lactose are modified by the addition of further sugars to form trioses, tetraoses, pentaoses, etc. The particular sugar structures so formed in human milk correspond to those on erythrocyte surfaces that define particular blood groups, since the same sets of biosynthetic enzymes are involved. Human milk contains 10–25 g/l of oligosaccharides other than lactose: cow's milk contains only 1–2 g/l.

Lactose is hydrolysed by lactase (β-galactosidase) in the neonatal intestinal brush border, and the monosaccharides released are absorbed across the gut wall into the portal blood. Galactose is converted to glucose so that it can supplement glucose as a source of metabolizable energy.

Milk salts

These exist in milk as (i) diffusible salts, i.e. low molecular weight ions and complexes, and (ii) non-diffusible salts, i.e. bound to protein. In cow's milk, the most prevalent cations are K^+, Na^+, Ca^{2+} and Mg^{2+}; the most common anions, Cl^-, inorganic phosphates and proteins. Measured as 'ash' (see Table 12.1), the mixture of incombustible mineral oxides remaining after the milk incineration, they are present in different milks within the range 2–20 g/l (Jenness, 1986). The principal ions of the non-diffusible phase are Ca^{2+}, Mg^{2+}, inorganic phosphate and citrate,

which are almost entirely associated with casein micelles. K^+, Na^+ and Cl^- are, by contrast, almost exclusively diffusible. Appreciable species differences exist in both total salt concentrations and partitioning between the diffusible and colloidal phases. For example, concentrations of the following in human milk are expressed as a percentage of their concentration in cow's milk: K, 39%; Na, 26%; Ca, 27%; P, 12%; Fe, 33%; Cu, 285%.

12.4.4 PROTECTIVE PROPERTIES OF MILK

The attainment of independent existence by the neonate is by no means as consummate as the act of parturition might appear to signify. Not only is there continuing dependence on milk nutrients, but there is also heavy reliance on parental protection from predators, parasites, bacteria and viruses. At birth, the mammalian immune system remains underdeveloped. Whereas in most species the cell-mediated (T-cell) system develops early in fetal life, it is largely ineffective because it is unchallenged in a uterine environment which admits few infectious agents. On the other hand, the humoral immune system develops later, often after birth, so that the onus for neonatal protection in the period immediately post partum continues to rest with the mother (Solari and Kraehenbuhl, 1987).

Ehrlich, in 1902, was reputedly the first to propose the transfer of passive immunity to offspring via milk (see Reiter, 1985a), but only very recently has it become appreciated how wide is the range of protective mechanisms involved. These may be summarized as: (i) selective secretion of antibodies derived from maternal blood plasma; (ii) antibody production in the mammary gland in response to local antigenic stimulation, with subsequent secretion in milk; (iii) transfer in milk of immunocompetent and phagocytic cells; (iv) secretion of non-immunoglobulin protective proteins; (v) secretion of antimicrobial lipids; and (vi) secretion of nitrogen-containing and other saccharides, which constitute the 'bifidus factor' promoting resistance to neonatal intestinal infections. Each protective mechanism is discussed briefly below. Typically, the secretion of colostrum, in which the activity of protective mechanisms is much higher than in mature milk, lasts for a relatively short time post partum. However, low levels of antibody persist throughout lactation and increase at involution, when they presumably provide resistance to mammary infections in conditions of milk stasis (Lascelles and Lee, 1978).

Passive transfer of immunity

In some species (e.g. primates, rabbits) all IgG immunoglobins are transferred to the fetus across the placental membranes, so that the neonate acquires plasma concentrations of IgGs equal to those of its mother. In other species (e.g. ungulates) all maternal IgGs are transferred in colostrum during the first few hours post partum, whereas in yet others (e.g. rodents, cats, dogs) they are acquired both *in utero* and via colostrum (see Butler, 1974). As a generalization, IgG is at highest concentration in species in which colostrum is the exclusive route, IgA in other species. Colostrum possesses several features which protect immunoglobins from denaturation and digestion in the neonatal gut, e.g. high buffering capacity, the presence of a trypsin inhibitor and, for IgG1, considerable resistance to proteolytic digestion. In ruminants, absorption of Igs into blood is limited to a period of 24–36 h post partum when the gut wall remains permeable, but there is much interspecies variation e.g. this period is 16–20 days in rodents (Butler, 1974).

Despite the short period during which Ig absorption occurs, the resistance it provides to various viral and bacterial pathogens is crucial. The protection afforded against the potent gut bacterium *Escherichia coli* suggests

that absorption across the gut wall is not always essential (Roy and Smith, 1987).

Local production of antibodies

Failure to penetrate the gut wall is, indeed, a characteristic of secretory IgA (sIgA), the principal Ig of human and rat colostrum and milk. IgAs may either be derived from maternal plasma or produced locally by plasma cells adjacent to mammary epithelial cells (Figure 12.2). In the latter case there is evidence that they are produced in response to antigenic stimuli arising during the act of suckling (Lascelles and Lee, 1978). Whether of systemic or local origin, IgA is modified by addition of a secretory component, produced by the epithelial cells, and secreted as sIgA (Solari and Kraehenbuhl, 1987).

Transfer in milk of immunocompetent and phagocytic cells

The presence of cells in milk and colostrum has long been recognized. The colostral 'bodies of Donné', described in the 1840s, and thought by some to be detached epithelial cells whose subsequent lysis was important in milk secretion (see Mepham, 1986), are now known to be macrophages replete with lipid vacuoles (Head and Beer, 1978). About 90% of cells in human milk are monocytes or macrophages, which possess the usual property of phagocytosing micro-organisms: in colostrum and milk they also produce complement components (C3 and C4), lysozyme and lactoferrin.

The remaining cells are mostly lymphocytes, of which, in human colostrum, about half are T cells and about one-third B cells: the surface immunoglobulin on many of the latter is IgA (Head and Beer, 1978). In rats and mice, T cells, reactive to transplantation alloantigens, can adoptively immunize the neonate; and such observations, together with demonstrations of the *in vitro* reactivity of milk-borne T and B cells, provide strong evidence that maternal lymphocytes reactive to micro-organisms become incorporated into neonatal tissues, where they provide short-term protection.

Secretion of non-immunoglobulin protective proteins

The antimicrobial properties of lysozyme, lactoferrin, transferrin and lactoperoxidase in milk have been stressed by Reiter (1985a,b). Lactoferrin, for example, inhibits growth of coliform bacteria by chelating iron, which is necessary for their growth. The high concentration of lactoferrin in human milk means that the infant may ingest 3 g/day in early lactation.

Apart from their specific activities, several instances of synergy have been described. For example, the protoplasts produced in the lytic activity of lysozyme on *Micrococcus luteus* are strongly agglutinated by lactoferrin; and sIgA enhances the antimicrobial activity of lactoperoxidase against *Streptococcos mutans* (see Reiter, 1985a).

Secretion of antimicrobial lipids

In recent years there has been growing evidence that milk lipids may perform a protective role. It has long been known that certain fatty acids possess antibacterial activity, e.g. 12:0, 16:1 and 18:2, but benefits only seem realizable for the suckling young when there is a sufficiently high activity of milk lipase to supplement the low intestinal activity of this enzyme. Unlike cow's milk, human (and gorilla) milk contains a bile salt-stimulated lipase (Hernell and Blackberg, 1985) which, activated in the neonatal intestine, releases fatty acids and monoacylglycerols able to effect antimicrobial action (Kabara, 1980). Host resistance applies not only to bacteria, but also to yeasts, fungi and viruses.

Secretion of bifidus factor

György (1953) was the first to describe a factor in human milk (with activity exceeding

that of cow's milk by up to 100-fold) which promotes the growth of *Lactobacillus bifidus* in the neonatal intestine. On hydrolysis the factor yielded *N*-acetyl glucosamine, fucose and galactose. Bifidobacteria metabolize milk saccharides to lactic and other acids, the resulting low pH inhibiting growth of many enteropathic bacteria. Thus, one week post partum, 95% of the culturable bacteria in the fecal smear of breast-fed infants are *L. bifidus* flora (Vorherr, 1978).

12.4.5 REGULATORY PROPERTIES OF MILK

Limitations of a classification based on functional attributes of milk constituents are, perhaps, here most evident. Components in this class include somewhat heterogeneous groups, best characterized as having important roles which are not usually defined as nutritional or protective, and which are mostly present at low concentrations. The majority of analyses have been performed on cow's and human milks.

Hormones and growth factors

Milks of several species contain factors which stimulate both growth of gastrointestinal tissues *in vivo* and replication of cells cultured *in vitro* (Koldovsky, 1989). For example, several hormones which have growth promoting action in the neonate have been detected in human milk, including insulin, thyroxine, cortisol and luteinizing hormone-releasing hormone (LHRH) (Morriss, 1985). It is possible that some of the growth effects may be additional, or subsequent, to the roles of hormones, e.g. stimulation of neonatal gonadotrophin release in the case of LHRH. But, in addition, several distinct growth factors have been described. In human milk, the following have been reported: human milk growth factors (HMGF) I, II and III; mammary-derived growth factor; transforming growth factors (Morriss, 1985); and IGF1 (Corps *et al.*, 1988). Several lines of evidence suggest that HMGF III, a 6000 Da molecular weight peptide which accounts for 75–90% of growth factor activity in the milk, is probably a form of epidermal growth factor (EGF) (Shing *et al.*, 1985; and see Dembinski and Shiu, 1987). In addition to its nutritional and protective function (section 12.6.3), lactoferrin may also have a role as a mitogenic agent for enterocytes of the suckling young (Nichols *et al.*, 1987).

Recent reports have established the presence of opioids in human and cow's milk, in both cases derived from β-casein. These oligopeptide casomorphines may influence gastrointestinal motility in the suckling young (H. Daniel *et al.*, 1990), and since they are absorbed into the blood they may also have important effects on neonatal metabolism and behaviour via the central nervous system (Teschemacher, 1987).

Enzymes

Approximately 60 enzymes have been detected in both cow's milk (Kitchen, 1985) and human milk (Hamosh *et al.*, 1985; Renner *et al.*, 1989). Their prevalence varies widely from one species to another. In many cases their presence may simply reflect the shedding of cell fragments into the milk, such as is amply demonstrated by the 'signets' or 'cytoplasmic crescents' associated with milk fat globules (section 12.7.5). Some such fragments may reflect cell damage, whereas others may be an inevitable accompaniment of secretory mechanisms. However, it is possible that some of the enzymes are actively secreted and benefit the young and/or the mother: lactoperoxidase, lysozyme and lipase may be of this sort.

Trace elements

Twenty two minerals are believed to be essential in the human diet. All have been detected in either cow's or human milks,

mostly in both (Flynn and Power, 1985). Certain minerals, e.g. calcium, phosphorus, sodium and potassium, have been discussed above, but the majority are 'trace elements', which are usually present in cow's and human milks at concentrations less than 1 mg/l (although that of zinc often exceeds 3 mg/l).

For most elements there is no simple relationship between maternal dietary intake and milk content. Trace elements may pass readily into milk, or be concentrated in, or largely excluded from, milk. They are rarely free in milk, but bound to a variety of ligands, a fact which has repercussions for their bioavailability in the neonate. For example, in cow's milk, most zinc and manganese is bound to casein, whereas copper is bound equally to casein and low molecular weight (<1000 Da) compounds. In human milk, binding patterns are quite different, e.g. most manganese and copper is bound to whey proteins, while zinc is bound to milk fat and low molecular weight compounds (Lonnerdal, 1985). For many elements, suitably sensitive methods have only become available in the last decade. This has led, for example, to a reduction of an order of magnitude in the accepted values for chromium and manganese in human milk (Casey *et al.*, 1985).

Vitamins

All the vitamins have been detected in milk, but, as for trace elements, only recently have sufficiently sensitive methods been available to permit reliable assays. Several analyses have been reported for cow's (see Cremin and Power, 1985) and human (see Jensen and Neville, 1985) milks. Certain vitamins are bound to specific proteins in milk (e.g. B_{12} and folate). Since vitamins are derived from the maternal diet, their milk concentrations vary accordingly. However, there is some evidence that vitamin C is synthesized in mammary cells in both cows and humans (see Cremin and Power, 1985).

12.4.6 INTERSPECIES DIFFERENCES IN MILK COMPOSITION

Several attempts have been made to rationalize the wide differences in milk composition evident in different species, e.g. Blaxter (1961), Davies *et al.* (1983), Oftedal (1984) and Jenness (1986). Essentially, two types of factor may be said to be involved: biological (i.e. higher level organizational), stemming from ecological, behavioural, developmental and metabolic differences; and physicochemical, relating to constraints imposed by factors such as solubility, electrical neutrality and osmotic equilibrium. Doubtless the two types of factor interact in complex ways.

Biological factors

A fruitful approach to the analysis of mammalian reproductive strategies as a whole is that introduced by McArthur and Wilson (1967), and developed by Pianka (1970), in which species are classed as exhibiting *K*- or *r*-selection strategies. *K*-selecting species produce few young, at an advanced developmental stage (precocial) – a strategy favouring stable environmental conditions. By contrast *r*-selection, for which there is close competition between species, produces large numbers of immature (altricial) young, so that the total population is kept close to the carrying capacity of the environment. Such criteria define extremes; many species exhibit intermediate characteristics. The classification has been shown to be applicable to milk composition. For example, *K*-species (e.g. primates, ungulates) secrete milk of lower protein content than *r*-species (e.g. rodents), a difference readily explicable by their different growth rates (R.D. Martin, 1984). The observation that the low protein content and prevalence of whey proteins, which characterize human milk, are associated with slow body growth and increased longevity led Bounous *et al.* (1988) to propose that human milk serves to extend the time available for the mental processes of learning.

In this accomplishment, by contrast with physical capacities, humans are supreme among animal species.

A consideration of clear importance is energy transfer, i.e. the capacity of the mother to furnish energy-yielding nutrients and that of the offspring to utilize energy in relation to their genetic potential. Several analyses (e.g. Oftedal, 1984; R.D. Martin, 1984) show that energy output in milk at peak lactation is correlated with maternal weight in a manner akin to Kleiber's law, i.e. $E_o = k\ W_m^{0.75}$ where E_o is energy output (kJ/day) and W_m is maternal mass (kg). Reproductive strategy was also found to be an important factor, since milk energy output in *r*-species was more than twice that of *K*-species of the same maternal body mass (Oftedal, 1984). A similar relationship exists for milk energy output and neonatal mass. The bioenergetics of lactation in marsupial and placental mammals have been discussed by Nicoll and Thompson (1987).

The habitats of some species would appear to exert overriding influence on milk composition because they encompass certain environmental extremes, e.g. those of Arctic and aquatic mammals. These species secrete milk with very high fat content, e.g. for polar bears 331 g/kg; and for grey seals 532 g/kg (Jenness, 1974). Such high concentrations may be related both to the rapid deposition of subcutaneous fat in the suckling young, which provides an insulating layer reducing heat loss, and to the high energy value of fat, which serves to maintain body temperature in conditions of external cold. An alternative explanation, which probably also applies to some desert species, is that high fat content represents a means of conserving water. But the low water intake of desert mammals may be surpassed by that of phocid seals, which abstain from eating and drinking during the several weeks of lactation, so that all water for milk secretion and other purposes must come from maternal body stores, chiefly in the form of fat (Bonner, 1984).

In one sense, milk composition is an abstraction; what is more crucial for the neonate is **intake** per day, a quantity which depends on suckling frequency, duration and volume consumed, as well as composition. Extreme variations in suckling frequency have been reported, e.g. at about 20 min intervals in mice, hourly in pigs, once daily in rabbits, once every 2 days in tree shrews, and once a week in the northern fur seal (Cross, 1977). Despite the importance of other factors, there appears to be an inverse relationship between suckling frequency and the concentration of milk constituents (R.D. Martin, 1984). Caution is, however, required in interpreting data from feral animals, both because the extent of supplementary feeding is unknown and because it is difficult to ensure that milk collection procedures have not altered the nature of the sample analysed.

Physiochemical factors

Whatever the biological pressures involved in shaping milk composition, ultimately physicochemical constraints must determine the limits of plasticity. It is an almost invariable observation that milk is isosmotic with blood plasma (Peaker, 1983) (milk of the elephant seal is an apparent exception; Peaker and Goode, 1978). This is advantageous in energy terms because secretion of either hyperosmotic or hypo-osmotic fluid would involve energy expenditure. Lactose is usually the major osmole in milk, though not in all species, the balance being due largely to the diffusible salts (Linzell and Peaker, 1971). However, lactose concentrations may vary quite widely, both during an individual lactation and between species (Cowie, 1969; Jenness, 1974; Chalk and Bailey, 1979). Therefore, lactose, or indeed any free sugar, has not been essential for the evolution of milk in general; and it seems possible that milk sugar evolved as a metabolically disposable alternative to salt, in species in which a

hot climate obliged the young to drink large amounts of milk for the sake of its water.

Although lactose is often the major determinant of milk water, under conditions where lactose secretion is reduced (e.g. during starvation) the relative proportions of diffusible salts in milk increase. In general, during established lactation there is an inverse relationship between the milk concentration of lactose and those of Na^+ and K^+ (Peaker, 1983). In contrast, under conditions when the paracellular route is operating (e.g. as a result of alveolar distension when milk is not removed) the milk concentrations of Na^+ and Cl^- increase and those of K^+ and lactose decrease, as equilibration with extracellular fluid (ECF) occurs: thus the normal inverse correlation between lactose and K^+ becomes positive (Peaker, 1983). Clearly, the relative concentrations of anions and cations in milk are governed by the requirement for electrical neutrality. In most eutherian species the milk concentrations of fat and protein depend largely on their rates of secretion relative to that of lactose and, hence, of water. Thus, in a study of many species, both fat and protein concentrations were shown to be negatively correlated with lactose concentration, whereas there was a positive correlation between fat and protein concentrations (R.D. Martin, 1984).

Analyses of milks of 37 species (Davies *et al.*, 1983) show a marked positive correlation between calcium and phosphorus concentrations, suggesting the prevalence of colloidal calcium phosphate. Moreover, total calcium and phosphorus contents in 33 milks were positively correlated with protein concentration, indicating an essentially constant stoichiometry for the calcium phosphate–casein complex (Jenness, 1979).

It is apparent that milk composition in different species is subject to multifactorial determination, with inputs arising from the environment, mother and offspring interacting in a complex and changing manner. The realization of these inputs in terms of milk composition is likely to be unique for each species, and constitutes a 'code' for neonatal development which bears comparison with the genetic code inherited at birth.

12.5 PROVISIONING THE MAMMARY GLANDS

12.5.1 GENERAL

It has been noted that the energy supply to the neonate in the form of milk often far exceeds that which is provided *in utero*: typically, parturition signals a marked and rapid increase in the provision of nutrients to the young as the route of transfer is switched from the placenta to the mammary glands. An important element of the maternal capacity to meet this new demand is the implementation of profound and concerted changes in whole-body metabolism. These changes may be categorized as: (i) enhancement of the entry rate (flux) of nutrients into body metabolic pools; (ii) diminution of nutrient utilization by tissues non-essential to lactation; (iii) augmentation of nutrient partitioning to the mammary glands and metabolically related organs, by means of cardiovascular changes; and (iv) stimulation of mammary substrate uptake by means of membrane-located carrier systems. The homeorhetic control of this repartitioning process is largely effected by the endocrine system (see Chapter 11), but other humoral and neural factors are also involved.

Most studies of the metabolic changes accompanying lactation have been performed on dairy species, for obvious commercial reasons. But often they are also suitable species from the experimental viewpoint, because of their large size, docile nature and ability to yield milk in response to abnormal milking stimuli (i.e. hand or machine milking). The unfortunate aspect of this bias is that ruminant metabolic activity exhibits distinctive features in consequence of the participation of rumen microbes in the digestion

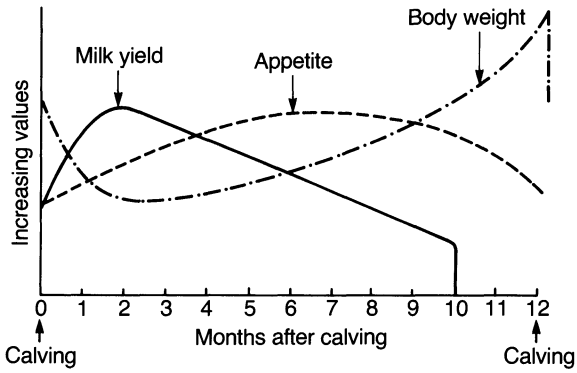

Figure 12.7 Changes in milk yield, body weight and appetite of dairy cows during lactation.

process, so that results from studies on dairy animals are not readily transposable to other species, for example non-ruminant herbivores, omnivores and carnivores.

One of the most notable features of body metabolism in dairy ruminants is the condition of negative energy balance, which in cows may persist for several weeks post partum. During this period the output of energy in milk exceeds that in food intake, and body weight is lost as tissue stores are mobilized (Figure 12.7).

Thus, studies on high-yielding cows showed that for the first 2 weeks of lactation 70% of milk fat was derived from adipose tissue stores, the mean figure for the first 12 weeks of lactation being about 40%. Such changes were achieved by reduced lipogenesis and increased lipolysis in adipocytes, together with increased lipid uptake by mammary cells (Bauman and Elliott, 1983; Vernon and Flint, 1984). Much less is known about repartitioning of protein metabolism at the onset of lactation, but muscle protein appears likely to serve a storage role analogous to adipose tissue. Bauman and Elliott (1983) estimated that in high-yielding cows muscle proteolysis might furnish 300 g/day of amino acids.

Ruminants differ most markedly from other species in respect of carbohydrate metabolism: because of rumen microcrobial activity, carbohydrates are largely fermented to the fatty acids acetate, butyrate and propionate, so that little glucose is absorbed into the blood from the gastrointestinal tract. Blood glucose concentrations in ruminants (largely derived from propionate by hepatic gluconeogenesis) are typically much lower than those in non-ruminants, whereas those of acetate are higher (e.g. see G.H. Smith *et al.*, 1983). Mammary glucose uptake is essential for milk secretion, so that lactation places additional demands on glucose supply. In goats, glucose flux at peak lactation is about double that in non-lactating animals (Annison and Linzell, 1964), a change which is due to a combination of reduced glucose uptake by adipocytes, reduced oxidation, increased gluconeogenesis and, probably, increased hepatic glycogenolysis and intestinal absorption (see Bauman and Elliott, 1983; Vernon and Flint, 1984). Calcium and phosphorus requirements in milk are met both by increased intake and absorption and by skeletal depletion (Bauman and Elliott, 1983).

Nutrient fluxes during lactation are thus markedly influenced by increased appetite. Hunger and satiety signals are generated in the CNS by pathways which, at the hypothalamic level, are believed to involve peptides of the cholecystokinin and opioid families (Baile and Della-Fera, 1988). Peripherally, signals may arise from physical (e.g. rumen distention) or chemical (e.g. ruminal concentrations of acetate and propionate) stimuli (Baile and Forbes, 1974). In dairy cows, in which food intake is the primary limitation on milk production, consumption during lactation may be four times maintenance requirements (Baile and Della-Fera, 1988).

Cardiovascular changes which result in an enhanced supply of substrates to the mammary glands are an important element of the partitioning of nutrients in lactating animals. Hanwell and Linzell (1972), working with rats, showed that not only was the onset of

lactation attended by a greatly increased cardiac output but there were also marked changes in its fractional distribution, such that mammary glands, liver and intestinal tract received larger proportions of the cardiac output, whereas skin received a smaller proportion. In some tissues, e.g. liver, both the flow rate per unit weight of tissue and the organ weight increased, whereas for others, e.g. skin, despite reductions in both weight and the fraction of cardiac output received, the increased cardiac output meant that flow rates per unit weight of tissue were maintained. Such comprehensive studies have not been carried out on dairy ruminants, but data reported for goats (A.J. Davis *et al.*, 1979) show a marked increase in mammary blood flow (MBF) in the periparturient period: MBF more than doubled between 7 and 9 days prepartum and 2 days post partum, with the largest component of the change occurring over the 2 days preceding parturition. During established lactation in cows and goats the mammary glands receive about 16% of the cardiac output (S.R. Davis and Collier, 1985).

The most extensive studies on MBF during established lactation were carried out on goats by Linzell and colleagues (see Linzell, 1974). The apparently labile nature of MBF, and its sensitivity to even minor stress, have led to an appreciable variation in reported values. Moreover, the several methods of measurement used do not give identical results (e.g. see Reynolds *et al.*, 1968). But for routine and repetitive MBF measurement in dairy ruminants Linzell's continuous thermodilution method (Linzell, 1966; Fleet and Mepham, 1983) has proved convenient and reliable when used in animals with surgically exteriorized mammary vein loops. More recently, blood flow probes utilizing the Doppler shift principle have been used to monitor mammary blood flow (MBF) (Fleet *et al.*, 1992). From extensive studies on goats it was concluded that, in full lactation, approximately 500 volumes of blood perfuse the mammary glands for each volume of milk secreted, a figure which also applies to cows (e.g. Peeters *et al.*, 1979). This ratio is, however, only an approximate index, and estimates of MBF derived from milk yield (MY) measurements are probably only accurate to within ± 30%. In late lactation, the MBF/MY ratio increases to over 1000 and, obviously, to infinity in dry animals.

The physiological factors which determine MBF *in vivo* remain a matter of uncertainty. There has been no shortage of reports of changes in MBF in response to various stimuli, e.g. adrenaline, vasopressin, 5-hydroxytryptamine, some prostaglandins and carbon dioxide are all mammary vasoconstrictors; while acetylcholine, histamine, adenosine and bradykinin are vasodilators (Linzell, 1974). The milking procedure and administration of exogenous oxytocin have also been reported to increase MBF in dairy animals, e.g. by 60% in cows (S.R. Davis and Collier, 1985). But definition of factors of physiological, rather than pharmacological, significance has been hampered by the possibility of atypical responses in anaesthetized animals in which MBF is depressed, and by anomalous results in isolated perfused gland experiments. For example, *in vivo* mammary ischaemia and bradykinin both induce reactive hyperaemia, whereas in perfused glands MBF is reduced (Linzell, 1974).

12.5.2 SUBSTRATE UPTAKE BY THE MAMMARY GLAND

The lactating ruminant mammary gland has proved to be a very useful organ system in which to study the quantitative relationships between substrate uptake and product output. The long-standing recognition of this utility is illustrated by the claim (Florkin and Stotz, 1977) that Cary's (1920) studies on lactating cows provided the first quantitative evidence for the importance of amino acids in protein synthesis in any biological system. In essence, this facility arises from a unique

combination of the attributes of (i) large gland size, (ii) favourable anatomical features (e.g. accessibility of the secretory product and of the gland's venous drainage), (iii) high secretory rate and (iv) absence of turnover of the secretory product in the duct system. This has meant that techniques such as determination of substrate arteriovenous (AV) concentration differences, isolated gland perfusion, and intra-arterial infusion can be performed much more easily for mammary glands than for other organs (e.g. see Fleet and Mepham, 1983; Mepham, 1987a).

The use of AV difference determinations combined with MBF measurements and techniques such as isotope dilution (see Fleet and Mepham, 1983; Mepham, 1993) has led to definition of the magnitude of substrate uptake by ruminant mammary glands in relation both to the output of milk constituents and to the metabolic economy of the whole animal. For example, it was shown by Annison and Linzell (1964) that in goats at peak lactation over 85% of the glucose flux was absorbed by the udder and that the glucose uptake largely accounted for lactose output, for a substantial proportion of glycerol of milk TG and, following oxidation, for about 40% of the total carbon dioxide produced by the glands. Whereas glucose is also the major precursor of lactose in non-ruminants (e.g. in pigs; see Linzell et al., 1969), the source of milk TGs exhibits much interspecies variability. In cows and goats, acetate, as well as being a major energy source for the mammary gland, is the principal precursor of those fatty acids of chain length up to C_{16} which are synthesized via the malonyl CoA pathway. By contrast, in certain non-ruminants glucose is the major source of these fatty acids, whereas non-ruminant herbivores utilize carbon from both acetate and glucose in mammary lipogenesis (section 12.4.3). A minor role is also played in ruminants by 3-hydroxybutyrate. However, the source of milk TG fatty acids of chain length C_{18} and above, and of a proportion of C_{16}, is quite different. In both ruminants and non-ruminant species these fatty acids are derived directly from blood, either from the plasma free fatty acid pool or from plasma lipoproteins following lipolysis within the lumina of mammary capillaries (section 12.4.3).

Historically, the blood precursors of milk proteins have been a matter of much uncertainty (see Mepham, 1986), and even now there appear to be grounds for some modification of views held widely since the 1950s. Isotopic tracer and AV difference studies in both whole animals and isolated organs suggested that plasma free amino acids were the principal, if not sole, precursors of milk-specific proteins, although in the case of non-essential amino acids there was evidence for intramammary synthesis, using nitrogen of certain amino acids (particularly that of arginine and ornithine) absorbed by the glands in excess of their output in milk (e.g. see Barry, 1961; Mepham, 1982). Subsequently, however, a minor contribution of amino acids from erythrocyte glutathione was suggested (Baumrucker, 1985), and quite recently it has been proposed that plasma oligopeptides might also contribute to the intracellular pool from which milk proteins are synthesized (Jois *et al.*, 1984). In so far as the latter proposal is based on AV determinations of amino acids in plasma samples before and after deproteinization, it depends on the assumption of complete deproteinization, which needs to be fully substantiated. A further dimension to the problem of identifying milk protein precursors is added by the claim that there is substantial intracellular degradation of protein prior to secretion (Mayer *et al.*, 1980; Oddy *et al.*, 1988). Despite the possible contribution of other sources, it remains likely that plasma free amino acids are usually the principal precursors of mammary-synthesized milk proteins: in some cases over 70% of an amino acid perfusing the gland is extracted from the blood plasma (see Mepham, 1982).

12.5.3 TRANSPORT OF SUBSTRATES INTO MAMMARY CELLS

The availability of substrates for milk synthesis depends not only on their rates of supply in blood perfusing the glands but also on their passage across at least two barriers, either or both of which might limit the transfer process, i.e. the capillary endothelium and the basolateral membrane of the secretory cell. For some substrates, additional barriers might be involved, namely erythrocyte membranes and intracellular membranes. Passage into interstitial fluid is governed both by capillary permeability and by the concentration gradient across the capillary wall, with molecules such as glucose largely diffusing through water-filled pores and lipid-soluble molecules also penetrating the endothelial membranes.

Transport of glucose across basolateral membranes of secretory cells has been studied almost exclusively in laboratory rodents, using non-metabolized analogues, such as 3-O-methyl glucose and 2-deoxyglucose, to circumvent problems associated with the rapid metabolism of glucose itself. Such studies suggest that glucose is transported into mammary cells by a system of the type which has been best characterized for mammalian erythrocytes, i.e. a process of facilitated diffusion. In rats, the activity of this putative transporter appears to be rate limiting for mammary glucose utilization (Threadgold *et al.*, 1982). The ability of the cells to absorb glucose is modulated by the animal's nutritional and hormonal status (Threadgold and Kuhn, 1984; Page and Kuhn, 1986), but the extent to which common mechanisms are involved in both is unresolved. Changes in glucose-transporting capability during mammary ontological development of murine cells, cultured *in vitro*, showed an 18-fold increase in V_{max} between mid-pregnant and mid-lactational developmental stages, suggesting an increase in numbers of transporters but not their affinity characteristics (Prosser and Topper, 1986).

Recently, Madon *et al.* (1990), using a wide range of techniques (such as photoaffinity labelling and polyclonal antibodies raised against previously characterized transporters), have proposed that the glucose transporter on the rat mammary cell plasma membrane is analogous to the rat brain glucose transporter, which has been designated 'GLUT 1'. This 55-kDa glycoprotein has been extensively studied, and competing models have been proposed to account for its mode of action (Silverman, 1991).

Threadgold and Kuhn (1979) reported that mammary cells cannot synthesize glucose because they lack glucose-6-phosphatase activity. Hence, glucose required for lactose synthesis (and other purposes) is derived from blood. Threadgold *et al.* (1982) suggested that cellular uptake was the rate-limiting step in overall glucose metabolism, and hence, because lactose is the major osmole of milk, of milk secretion as a whole. Certainly, when isolated perfused glands were deprived of glucose milk secretion was inhibited, whereas restoration of its supply re-established secretion (see Mepham, 1993).

Attention has only quite recently been turned to amino acid transport systems in mammary cells, and current progress is fairly limited. The notion that glutathione might participate in amino acid transport via the γ-glutamyl cycle (Baumrucker and Pocius, 1978) seems to have been invalidated by the discovery that γ-GTPase in mammary cells is oriented towards the extracellular surface, thus confining the role of glutathione to provision of glutamic acid, cysteine and glycine (Baumrucker, 1985).

The most promising approach to characterizing mammary amino acid transport systems appears to be that which seeks to extend the paradigm formulated by Christensen and colleagues (see, for example, Christensen, 1984), in which amino acids are divided into groups sharing affinities for distinct carrier

systems. For example, A, L and ASC systems have been described for neutral amino acids in many tissues and many species, as have separate anionic and cationic (e.g. Y^+) amino acid transporters. Systems are characterized by properties such as: amino acid specificity; sodium dependence or independence; and concentrative or exchange capability. The complexity of any description of amino acid transport is apparent when one considers the shared and/or overlapping affinities of different amino acids for specific transporters, interaction between different substrates such that transport might be either stimulated or depressed, and the potential modulation of transporter activity by factors such as turnover or endocrine influences (see Mepham, 1988).

Studies employing slices of bovine mammary tissue (Baumrucker, 1985) and diced murine mammary tissue (Neville *et al.*, 1980) suggested the presence in either or both of A, L, ASC and Y^+ carrier systems. However, a disadvantage of such preparations is that the normal spatial relations of the vascular, interstitial, intracellular and luminal compartments are disrupted, so that errors which might derive from extensive cell damage are compounded with others due to loss of basoapical orientation. Use of the isolated perfused guinea pig mammary gland preparation (S.R. Davis and Mepham, 1974) is thought to avoid such problems, and when used in conjunction with the 'paired tracer' technique of Yudilevich *et al.* (1979) permits measurement of both entry and efflux of amino acids. Evidence has been presented, using this technique, for the presence in guinea pig mammary glands at peak lactation of A, L, ASC and Y^+ systems, but A system activity was assessed as very low (Mepham *et al.*, 1984). Studies on transport in mammary tissue of glucose and amino acids are reviewed more extensively by Mepham (1988).

It was noted above that fatty acids of chain length C_{16}, C_{18} and longer are derived from serum lipoproteins. AV difference studies on cows and goats (see Annison, 1983) showed that TG from only the chylomicron and low-density (d=1.005–1.019) lipoprotein fractions are absorbed by mammary tissue. The uptake process is dependent on prior lipolysis of the TG, effected by lipoprotein lipase, an enzyme which is bound to the mammary capillary endothelium. The microscopical studies of Schoefl and French (1968), on tissue from laboratory rodents, showed that chylomicrons become embedded in mammary capillary endothelium, giving it a scalloped appearance. Earlier *in vitro* studies showed that lipoprotein lipase becomes strongly absorbed on to chylomicrons (D.S. Robinson *et al.*, 1955).

In lactating ruminants (but not in some laboratory rodents, see Hawke and Taylor, 1983) free fatty acids (FFAs) normally show no **net** AV differences across the mammary gland, but despite this their uptake is suggested by a fall in specific radioactivity when isotopically labelled FFAs perfuse the gland (see Annison, 1983). The apparent contradiction of these results is explained by postulating that FFA uptake is masked by simultaneous release into the mammary venous blood of fatty acids derived from TG lipolysis. Probably the most convincing evidence for lipolysis of TG in the mammary gland is the virtually identical pattern of incorporation of [^{3}H]glycerol and ^{14}C-labelled fatty acids into milk fat in experiments on goats in which isotopes were infused either as free [^{3}H]glycerol and [^{14}C]palmitate, or as [^{3}H]glycerol tri-[^{14}C]palmitate (C.E. West *et al.*, 1972). Lipolysis is not always complete and monoacylglycerols as well as FFA may be produced. The processes by which the latter traverse the capillary endothelium and basal membrane of the secretory cell are matters of uncertainty.

12.6 METABOLIC ACTIVITY OF MAMMARY CELLS

12.6.1 BIOSYNTHESIS OF MILK PROTEIN

Reference has been made above to the major classes of milk proteins. Before discussing their biosynthesis, recently reviewed in detail by Mepham *et al.* (1992), we need to consider briefly the impact which has been made by application of modern molecular biology and fractionation techniques and automated peptide sequencing methods.

Currently, there is emphasis on the application of DNA sequencing procedures to cDNA prepared from mRNA coding for the proteins and to isolated genes. With the aid of these techniques attention has also widened to include caseins and whey proteins of the cow (Brew *et al.*, 1970; Brew, 1972; Ribadeau-Dumas *et al.*, 1972; Grosclaude *et al.*, 1973; Brignon *et al.*, 1977), sheep (Jollès *et al.*, 1974; Richardson and Mercier, 1979), goat (MacGillivray *et al.*, 1979; Préaux *et al.*, 1979), deer (McDougall and Stewart, 1976), horse (Visser *et al.*, 1982), rabbit (Hopp and Woods, 1979; Dayal *et al.*, 1982), guinea pig (Hall *et al.*, 1984a, 1984b), rat (Brown *et al.*, 1977; Hirose *et al.*, 1981; Blackburn *et al.*, 1982; Hobbs and Rosen, 1982; Qasba and Safaya, 1984), mouse (Kinkade *et al.*, 1976; Hennighausen *et al.*, 1982a,b), human (Findlay and Brew, 1972; Metz-Boutigue *et al.*, 1984) and other species. References to β-lactoglobulin biosynthesis in various species may be found in Godovac-Zimmerman and Braunitzer (1987). By and large, all these milk proteins are relatively small and stable, and frequently exhibit variant forms. Unusual proteins which have also been found in certain milks include a variably phosphorylated 'whey acidic protein' in rats, mice and rabbits (R.M. Mckenzie and Larson, 1978; Hennighausen *et al.*, 1982a), a temperature-sensitive protein named 'galactothermin' in humans (Schade and Reinhart, 1970) and a distinctive whey protein appearing later in lactation in the tammar (Nicholas *et al.*, 1987).

The casein genes

The calcium-binding, micelle-forming properties of the caseins can now be related both to their molecular characteristics and to their organization within the genome. Several casein genes, or fragments of them, from rat, cow and guinea pig genomes, have been inserted into phages or plasmids, obtained as pure clones, and finally sequenced. Their construction resembles that of many other eukaryotic genes in having large non-coding nucleotide sequences (introns) intervening between stretches of coding sequence (exons) (Yu-Lee and Rosen, 1983; Jones *et al.*, 1985). From the analysis of these, and flanking, sequences it seems likely that an ancestral casein gene arose by the recruitment of four unrelated exons. These are a highly conserved non-coding 5′ exon of unknown function, an exon coding for the signal peptide that ensures secretion, a small exon coding for a phosphorylation site and an exon coding for hydrophobic amino acids. This evolutionary stage must have been followed by intragene duplication, especially to give multiple phosphorylation sites, and by intergene duplication to give the gene cluster that genetic analyses have recently identified (Matyukov and Urnyshev, 1980; Mercier and Gaye, 1983). Later on, separate mutations, deletions or insertions will have ensured that each gene acquired a characteristic individual sequence (Hobbs and Rosen, 1982; Rosen, 1987). Such an evolutionary scheme readily accounts for the three related calcium-binding bovine caseins (the highly phosphorylated α_{s1}- and α_{s2}-caseins, and the less phosphorylated β-casein) and for the homologous α-, γ- and β-caseins of rats and rabbits. It also accommodates the larger number of caseins identified, and located on chromosome 9, in the mouse (Gupta *et al.*, 1982) and the two caseins in humans. All these are of

the $\alpha_s$type. An unrelated gene is that coding for the κ-casein of bovine and ovine milk which, although it may carry a single phosphate residue, is differently constructed and does not bind calcium.

Expression of casein genes

Following the transcription of complex eukaryotic genes into correspondingly large RNA within the nucleus, the intron transcripts become excised. The remaining transcripts are simultaneously spliced together to form a mRNA with a continuous sequence of nucleotide codons corresponding to the protein to be translated; flanking sequences of the mRNA that do not become translated are believed to influence the stability and translatability of the rest. In the case of rat α- and β-casein genes, such splicing results in the linking of a single phosphorylatable sequence –Ser–Ser–Glu–, encoded by the 3′ end of exon IV, to a glutamate residue, encoded by the 5′ end of exon V. This creates the sequence –Ser–Ser–Glu–Glu – in which both serines satisfy the phosphorylation signal –Ser–X–glu– (X being any amino acid). In this way splicing converts a weak single phosphorylation site in a strong double one (Rosen, 1987).

The availability of cell-free translation systems, in which added mRNA can direct the synthesis of new, immunochemically detectable protein, and the availability also of [^{32}P]cDNA synthesized by reverse transcription of mRNA *in vitro*, has provided assays for mRNA species coding for individual casein or α-lactalbumin molecules (Rosen *et al.*, 1980). In tissue from intact rats, mice, rabbits and guinea pigs such mRNA is present throughout pregnancy and may even be detected in the virgin animal. Levels rise during pregnancy in the rat and mouse, and rise even more sharply with the onset of lactation (Nakhasi and Qasba, 1979; Hobbs *et al.*, 1982; Vonderhaar and Nakhasi, 1986). In the guinea pig α-lactalbumin mRNA clearly preceded casein mRNA in its appearance (Burditt *et al.*, 1981). Evidently, mRNA concentration is likely to be one important factor determining the rate of protein synthesis. This is supported by the finding that prolactin, cortisol and insulin, which jointly induce the greatest mammary differentiation and synthetic activity *in vivo* and *in vitro*, also maximally enhance tissue or tissue explant levels of casein- and α-lactalbumin mRNA. In the same way, progesterone, which inhibits the onset of milk protein synthesis *in vivo* and *in vitro*, also inhibits casein mRNA formation (Topper, 1970; Houdebine, 1976; Teyssot and Houdebine, 1981; Kulski *et al.*, 1983b). Prolactin, which probably plays the central role in this lactogenic complex of hormones, achieves its effect through a two- or three-pronged action. Its binding to receptors at the cell surface both enhances the rate of casein gene transcription and somehow stabilizes the resulting mRNA, whose turnover half-life within the cell increases from a few hours to several days (Guyette *et al.*, 1979; Teyssot and Houdebine, 1980; Kulski *et al.*, 1983a). In rabbits, prolactin has additionally been shown to stimulate the formation of ribosomal 28S RNA, although it confers no extra stabilization (Teyssot and Houdebine, 1980). This third prong of action may account for the increased numbers of ribosomes at lactogenesis.

The transcription of eukaryotic genes is promoted by the initial attachment of the large enzyme RNA polymerase immediately upstream (that is, on the 5′ side) of the transcription start codon ATG (A=adenine, T=thymine, G=guanine). The effectiveness of such a 'promoter' region in initiating transcription by the polymerase stems from its particular sequence of nucleotides. For many eukaryotic genes a TATA-like sequence is commonly found within promoter regions, and is believed to favour the binding of RNA polymerase. But other sequences may also influence transcription of the adjacent gene. Therefore, it may be presumed that the

strong expression of the major milk protein genes is likely to reflect a favourable constellation of nucleotides in their promoter regions. Comparative analysis of nucleotide sequences in the non-coding 5′ flanking region of three rat and bovine casein genes reveals them to be highly conserved, and to have an unusual TTTAAAT version of the TAT sequence (Yu-Lee *et al.*, 1986). At the same time, since the transcription of casein and α-lactalbumin genes is much accelerated by prolactin (or placental lactogen in late pregnancy) the promoters are likely also to be under the influence of an activating or inhibiting transcription factor controlled by this hormone. The details of prolactin action remain obscure, as do those of the positive influence on casein mRNA exerted by insulin.

Actions of steroid hormones

Cortisol and progesterone, respectively, reinforce and inhibit the transcriptional effects of prolactin on casein and α-lactalbumin genes, and have similar effects on the induction of lipogenic enzymes (Houdebine, 1976; Mayer, 1978; Rosen *et al.*, 1980; Teyssot and Houdebine, 1981; Kulski *et al.*, 1983a). Studies of the steroid hormone control of a variety of eukaryotic cells have recently focused upon short nucleotide sequences that bind steroid hormone–receptor complexes and enhance (or retard) the activity of nearby promoters. No single hormone is associated with any one unique sequence of nucleotides; rather, there appears to be a 'consensus' sequence that is able to bind a variety of steroid hormone–receptor complexes. The glucocorticoid-stimulated mouse mammary tumour virus, which has been much studied, has several such sequences upstream of the transcription start site as well as within the coding sequence itself. The 'enhancer' regions, or 'hormone response elements', appear to function at a distance (*trans* action) by enhancing the relevant promoter. A search for such sequences in the rat and bovine casein or α-lactalbumin genomes has revealed several, both in the 5′ flanking region and within the gene coding regions. They exhibit marked homology with glucocorticoid or progesterone receptor binding sequences associated with metallothionein, uteroglobin and lysozyme genes in other mammalian or avian tissues (Qasba and Safaya, 1984; Yu-Lee *et al.*, 1986). At the time of writing it seems possible that different steroid hormones may bind, through their receptors, to a common set of response elements, variously forming productive, partially productive or even inhibitory complexes (Ahe *et al.*, 1985). This situation appears to have arisen because steroid hormone receptors are all members of a multigene family, which also includes receptors for thyroid hormone and retinol (Chambon *et al.*, 1984; Gehring, 1987).

The scheme is attractive because one can readily envisage a mechanism by which two separate genes might evolve different sensitivities towards a common controlling hormone, for example the different sensitivities of α-lactalbumin and casein to cortisol (Nagamatsu and Oka, 1983). It also offers a plausible mechanism by which thyroid hormone can sensitize mouse mammary tissue to prolactin (Bhattacharjee and Vonderhaar, 1984).

Translation and processing

The time course of [^{3}H]leucine incorporation into protein has been followed in the rat mammary gland both *in vivo* and *in vitro* (Heald and Saacke, 1972). In both cases the protein product appeared initially in the ergastoplasm (rough endoplasmic reticulum), after about 30 min in the Golgi region, and from 30 to 60 min as an accumulation in the alveolar lumen. Such a pattern is explained by the initial translation of mRNA at the rough endoplasmic reticulum, and its passage through the stacked cisternae of the

Golgi apparatus, and its eventual concentration within the condensing vacuoles or elements of the *trans*-Golgi network. From these then arise the mature secretory vesicles which leave the cell by exocytosis at the apical membrane. Post-translational proteolysis, phosphorylation, glycosylation and complexing with calcium take place at specific points on this route (for review, see Mercier and Gaye, 1983).

The actual translation of mRNA at the ribosome has been little studied in the mammary gland, although the usual co-factors are required. The profile of aminoacyl tRNA precursors has been claimed to adjust, during lactation, to match the amino acid profile of milk protein (Garel, 1974). Therefore, little is known about possible controls at the translational step. However, in several reports the rates of synthesis of different milk proteins do not closely reflect the relative pool sizes of their mRNAs, so that some further element of control seems a distinct possibility (Burditt *et al.*, 1981; Geursen and Grigor, 1987). The translation of mRNA isolated from rat mammary gland or from polysomes of ovine udder, in a cell-free system from wheat germ, followed by the immunoprecipitation of individual milk proteins, was shown to reveal in each case an N-terminal 'signal' peptide extension. The amino acid sequences of several such radioactively labelled peptides have been determined by Edman degradation, and more recently from the sequence of the cloned cDNA (Lingappa *et al.*, 1978; Hobbs and Rosen, 1982; Mercier and Gaye, 1983). In ovine α_{s1}-, α_{s2}- and β-caseins these 15-residue sequences are highly conserved, with an N-terminal Met–Lys-$(X)_5$–Cys-$(X)_6$–ala– joining on to the rest of the molecule. Closely homologous to these are the signal sequences for rat α-, γ – and β-caseins and for mouse ε-casein. A positively charged residue separated by a stretch of hydrophobic residues from a connecting alanine is typical of many signal peptides in eukaryotic secretory proteins. The ovine κ-casein 21-residue peptide and the 18-residue β-lactoglobulin signal peptide are similar, though not homologous. However, the signal peptide of ovine α-lactalbumin lacks both a basic amino acid residue and a cysteine. Since the original discovery of a 'signal' peptide extension on the IgG light chain newly formed in a cell-free system (Milstein *et al.*, 1972), it has been established that possession of such a signal ensures the transport of newly synthesized proteins into the lumen of the endoplasmic reticulum. Several components of this transport machinery have been identified, but its actual mechanism and the reason for its wide tolerance of amino acid sequence remain unclear (Alberts *et al.*, 1983).

The translation of milk protein does not necessarily ensure its eventual secretion. Low rates of secretion, as in late pregnancy or during starvation, may partly reflect enhanced rates of degradation within the cell (Bienkowski, 1983; Hasan *et al.*, 1982). Caseins would appear to be good candidates for the class of proteins, rich in proline, glutamate, serine and threonine, claimed by the PEST hypothesis to be susceptible to rapid turnover (Rogers *et al.*, 1986).

Post-translational modifications

The immediate post-translational events in the formation and secretion of milk proteins must be inferred from studies of quite different secretory proteins such as those of the exo- and endocrine pancreas, salivary gland and even of viral coat proteins. Nevertheless, the secretions of other tissues, especially exocrine secretions, may be quite good models for the mammary gland. For example, phosphorylated salivary proteins have been characterized which, with their high proline content, appear not unlike casein (Wong and Bennick, 1980).

Therefore, guided by such studies, we can probably assume that a specific peptidase within the endoplasmic reticulum lumen cleaves the signal peptides of secreted milk

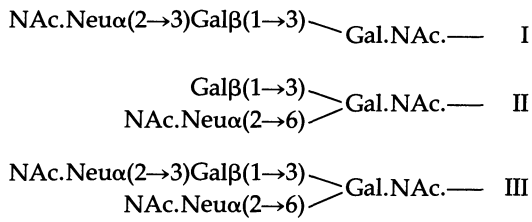
proteins. The remaining familiar milk proteins then pass through the stacked cisternae of the Golgi dictyosome to a still poorly defined *trans*-Golgi network of swollen tubules and condensing vacuoles, where the casein visibly assembles into micelles. The maturation of these vacuoles into more electron-dense secretory vesicles then precedes their actual secretion by exocytosis (Hollman, 1959). Secretion itself is described in section 12.7. In following this route out of the cell, some of the milk proteins acquire the phosphate or oligosaccharide residues that they are found to carry in milk. However, the extent of such post-translational modification is curiously variable, giving rise to the phenomenon of 'microheterogeneity' in the population of secreted molecules (Montreuil, 1980).

Studies of the phosphorylation of dephosphocasein by mammary preparations *in vitro* have shown the presence of an ATP-dependent, cyclic AMP-independent casein kinase embedded in the Golgi membrane and facing in towards the lumen. Phosphorylation requires Mg^{2+}, and is enhanced by Ca^{2+} and calmodulin (Bingham and Farrell, 1974; D.W. West and Clegg, 1983, 1984; Brooks and Landt, 1984). A casein kinase of guinea pig mammary Golgi membranes, which has been purified to homogeneity, appears to be tissue specific and phosphorylates only serine residues in the sequence –Ser–X–Glu–. Therefore, at least one further kinase must exist, to account for the phosphothreonine residues found in α_{s1}-casein variants (Pascall *et al.*, 1981; Moore *et al.*, 1985). In intact Golgi-derived vesicles casein phosphorylation is decreased by attractyloside or carboxyattractyloside, inhibitors of the mitochondrial adenine nucleotide transporter, and is enhanced by the nucleotide carrier alamethicin (D.W. West and Clegg, 1984). Direct transport of ATP into the lumen of Golgi membrane-derived vesicles from rat mammary gland has been described with possible exchange for 5'-AMP (Capasso *et al.*, 1989). Similar preparations also exhibit Mg^{2+}- or Ca^{2+}-dependent ADPase activity (Farrell *et al.*, 1992). These findings allow one to formulate a possible adenine nucleotide cycle in which cytosolic ATP entering the Golgi phosphorylates casein and generates ADP followed by AMP. The latter then passes back to the cytosol and mitochondria for rephosphorylation to ATP (Farrell *et al.*, 1992). This cycle has analogies with a uridine nucleotide cycle proposed to support lactose synthesis (see below), and emphasizes the essential cooperation of different subcellular compartments in the fashioning and secretion of milk products.

It may be noted, in parentheses, that the casein kinase activity frequently reported for other tissues, and even for the cytosol of mammary tissue, is not due to a true casein kinase, but rather to other protein kinases for which casein is merely a convenient substrate. The activity of mammary casein kinase (s) produces, in the cow, an α_{s1}-casein carrying typically eight phosphoserine residues, an α_{s2}-casein with up to 13 phosphoserines and a β-casein with usually five phosphoserines. Bovine κ-casein is sometimes referred to as non-phosphorylated, but in fact well exhibits the microheterogeneity referred to above by carrying one, two or three phosphate residues and varying amounts of carbohydrate per polypeptide chain (Vreeman *et al.*, 1986). Takeuchi *et al.* (1984) have proposed that phosphorylation and micelle formation of κ-casein precedes glycosylation, consistent with evidence for mainly surface glycosylation of the micelle (Slattery, 1978; Horisberger and Vonlanthen, 1980). Phosphorylation of the whey acidic protein appears not to have been studied. However, this is an unrelated protein of 14 kDa size and rich in cysteine residues which form disulphide links within the molecule.

The only commonly glycosylated milk proteins are κ-casein and lactoferrin, although the rat is unusual in that its α-lactalbumin is glycosylated (Brown *et al.*, 1977). Bovine κ-

casein carries three types of oligosaccharide in O-glycosidic linkage with serine or threonine:

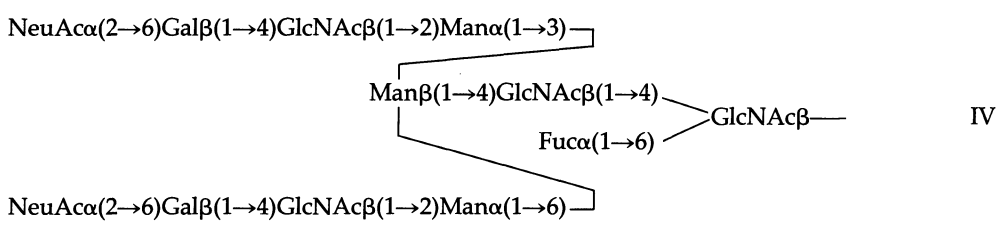


where I and II appear as uncompleted forms of the complete structure III (Van Halbeek *et al.*, 1980). The κ-casein of bovine colostrum carries more carbohydrate, in chains of greater complexity. The oligosaccharide chains of κ-casein from ovine colostrum also have the Gal-β(1→3)-Gal-NAc structure above, but carry Gal-β(1→4)-Glc-NAc-β(1→6) and Gal-β(1→3)-Gal-β(1→4)-Glc-NAc-β(1→6) attached to some of the Gal-NAc residues (Soulier *et al.*, 1980). The exact structure is not critical, but the presence of NAc-Neu residues (sialic acid residues) is. Such *O*-glycosyl chains are assembled by sequential glycosyl transfer from UDP-*N*-acetylgalactosamine, UDP-*N*-acetylglucosamine, UDP-galactose and CMP-*N*-acetylneuraminic acid in the Golgi apparatus. Since galactose may be attached in both 1→3 and 1→4 linkage, and *N*-acetyl-neuraminic acid in 2→3 and 2→6 linkage, it is evident that a family of glycosyltransferases, each with different sugar or positional specificity, must be employed. Since only the β14 galactosyltransferase and the α(2→3) and α(2→6) *N*-acetylneuraminyl (or sialyl) transferases have been studied in any detail in the mammary gland, their description will be deferred to the section on milk sugars, the synthesis of which they also catalyse.

In lactoferrin, by contrast, the oligosaccharide side chains are attached in *N*-glycosidic linkage with asparagine residues. Human lactoferrin has two glycosylation sites, from which five different oligosaccharide chains have been isolated. One of these has the structure shown in Equation IV with two others being variants of this (Spik *et al.*, 1982). This structure is characteristic of *N*-linked oligosaccharides, in which the Man_3-Glc-Nac_2 moiety is assembled in the endoplasmic reticulum and where the remaining *N*-acetylglucosamine, galactose, *N*-acetylneuraminic acid and fucose residues are attached in the Golgi apparatus (see Alberts *et al.*, 1983). As with the *O*-glycosyl chains, the particular structure formed reflects the family of glycosyltransferases, each with its particular specificity, that is present in the appropriate cell location.

12.6.2 ASSEMBLY OF THE CASEIN MICELLE

The major caseins of cow milk, α_{s1} and β, are strongly acidic and hence hydrophilic in their N-terminal regions, while being mainly neutral and hydrophobic in their C-terminal regions. The acidity arises particularly from the clustering of glutamate and serine phosphate residues. Under suitable ionic conditions these caseins assemble spontaneously into soap-like micelles (referred to henceforth as submicelles), the hydrophobic core of which is made up of the C-terminal regions of the polypeptide chains. The negatively charged outer regions ensure a strong mutual repulsion between nearby submicelles, which



therefore do not coalesce and flocculate unless excess of a strongly phosphate-binding cation such as Ca^{2+} is added. The less abundant α_{s2}-casein is not constructed in quite the same way. Serine phosphate groups are concentrated mainly, though not entirely, in the N-terminal moiety; the C-terminal region, while carrying a fair number of hydrophobic aromatic residues, also carries a distinct overall positive charge. Therefore, its arrangement within a submicelle is not yet fully evident. Like the α_{s1}- and β-caseins, κ-casein is highly amphopathic, but this time it is the N-terminal region that is very hydrophobic. It may be cleaved off by the action of the stomach enzyme chymosin (rennin) at a particular –Phe–Met– bond, forming the very insoluble 'para-K-casein'. The remaining moiety is the highly water-soluble 'caseinoglycopeptide', so called because it carries not only the phosphate residues but also the sialic acid-containing oligosaccharide chains.

Thus, it may be readily envisaged that κ-casein packs into the submicelle with its N-terminal region inward and its C-terminal region directed outwards, the branched oligosaccharide chains protruding into the surrounding medium. However, there is another particular feature of κ-casein, not shared by the α_{s1}- or β-caseins, that may be critical for the sharing out of κ-casein molecules among the different submicelles. This is the presence of two cysteine residues (three in the sheep), each of which forms a disulphide link with a cysteine of another κ-casein molecule, yielding a molecular population containing trimers, tetramers, pentamers, etc., up to greater than decamers (Talbot and Waugh, 1970). These disulphide links are probably due to the action of a sulphydryl oxidase in the endoplasmic reticulum, or else to a disulphide exchange enzyme employing oxidized glutathione made available by the sulphydryl oxidase (Kiermeier and Petz, 1967; Ferrier *et al.*, 1973; Janolino and Swaisgood, 1975).

The anticipated consequence of such linking is that each casein submicelle will acquire a larger or smaller cohort of κ-casein molecules confined, through their linking, to one sector of the spherical submicelle. Some submicelles will acquire no κ-caseins. Such mixed micelles, which form a family rather than a uniform population, may be those 15 to 20-nm-diameter particles that can be seen under the electron microscope, and that make up the subunits of the casein micelle proper, which is really a 'super-micelle'.

It is well established that the association of submicelles with each other requires millimolar concentrations of calcium and phosphate ions. From the histochemical localization of calcium this may occur mainly in the large vacuoles lying on the *trans* side of the Golgi stack, but might also include the peripheral regions of the *trans* cisternae (Wooding and Morgan, 1978). The growth of complete micelles is apparently self-limiting, particles not exceeding about 300 nm in diameter; this feature evidently underlies their remarkable stability, since particles of greater size would soon settle out. It is possible to devise a model according to which the size limitation arises from the construction of submicelles with differently sized cohorts of κ-casein. The accessibility of κ-casein in the micelle to lectins, to antibodies and to chymosin suggests its location predominantly in the outer shell of submicelles. Accepting the view that submicelles are held together by microcrystalline calcium phosphate bridges connecting the serine phosphates of the casein molecules, one can readily envisage a micelle assembly in which the central submicelles are poor in κ-casein and the outer ones are those in which abundance of κ-casein with its protruding oligosaccharide chains effectively prevents further submicelle accretion.

For further details on the ideas about casein micelle structure, the reader is referred to papers by Farrell (1973), Slattery and Evard (1973), Slattery (1978, 1979) and D.G. Schmidt (1980). According to Holt and Dalgleish (1986) the protrusion of κ-casein

from the surface even gives the micelle a hairy appearance. Whatever the structure that the casein micelle will eventually be found to possess, there is clearly a strong design feature that enables it to hold high concentrations of protein, calcium and phosphorus in a stable and mobile physical form in the milk. Equally clearly, this design stems from the detailed amino acid sequences of the proteins involved, and the structures of the genes from which they derive.

12.6.3 STRUCTURE OF LACTOFERRIN

The sequencing and recent X-ray crystallographic analysis of lactoferrin has related structure with function for another milk protein. The 80-kDa protein is folded into two lobes, reflecting a twofold internal sequence homology, each of which contains an iron binding site. The molecular structure is such that two tyrosine residues, one histidine and one aspartate are brought together from linearly distant parts of the polypeptide chain to create each, highly anionic and deeply buried, metal ion binding site. A carbonate ion is concomitantly bound to a nearby arginine residue, but there is no evident participation of the carbohydrate moiety of the protein (Baker *et al.*, 1987).

12.6.4 BIOSYNTHESIS OF MILK SUGARS

In addition to lactose and sialyllactose, which are prominent in rat and mouse milk, some milks contain lactose modified by the addition of other sugars to form trioses, tetraoses, pentaoses, etc. However, in this section we shall confine our attention to lactose and sialyllactose.

Rates of lactose formation

There are several ways in which the rate of mammary lactose (or sialyllactose) synthesis may be measured. In large domestic animals it can be calculated from the daily milk yield and the lactose concentration of milk. With the aid of a specially designed milking machine this has also been done for the guinea pig (Henderson *et al.*, 1983). In small animals, however, the milk yield is more usually gauged from the weight gain of the young (Brody and Nisbet, 1938) or from the increase in mammary tissue weight after a period of non-suckling (Hanwell and Linzell, 1972). A radiochemical method for determining rates of lactose synthesis *in vivo* employs the fact that plasma glucose is the sole precursor, at least in the rat, and measures the amount of [^{14}C]lactose formed over 30 min from plasma [^{14}C]glucose of known specific radioactivity (Carrick and Kuhn, 1978). These methods give similar results, but the shorter measurement time of the radiochemical method is more useful in following rapid changes in rate. Rates of lactose synthesis *in vitro* may sometimes reflect the enzymic capacity of the tissue quite well, but are wholly unreliable in reflecting its state of activation.

These several methods have delineated the quite different patterns of lactose synthesis during lactation in rats (Brody and Nisbet, 1938; Wilde and Kuhn, 1979), rabbits (Cowie, 1969), guinea pigs (Nelson *et al.*, 1951), goats (Fleet *et al.*, 1975) and cows (Rook and Campling, 1965). All species show a sharp rise in rate at, or before, parturition, but differ greatly in the time at which the rate peaks and later declines. Detailed studies of rats and mice have suggested that changes in tissue levels of lactose synthetase are responsible for these gross changes, and that enzymes earlier on the biosynthetic pathway are not limiting (Kuhn and Lowenstein, 1967; Kuhn, 1968; L. McKenzie *et al.*, 1971; Kuhn and White, 1977). In particular, the timing of lactose appearance around parturition is due to the withdrawal of progesterone (Kuhn, 1977), following which prolactin or placental lactogen stimulate the expression of the gene coding for the α-lactalbumin component of lactose synthetase (Turkington and Hill, 1968; Delouis, 1975, Nakhasi and Qasba, 1979). That this scheme holds true also for the

human is indicated by the timing of changes in progesterone and lactose (Kulski *et al.*, 1977) and by an extra leakage of α-lactalbumin into the bloodstream at lactogenesis (R.H. Martin *et al.*, 1980, 1981). The galactosyltransferase component of lactose synthetase is also induced at this time in the rat, albeit less dramatically, whereas its induction in the mouse seems to occur somewhat earlier (Palmiter, 1969; Turkington, 1971; L. McKenzie *et al.*, 1971).

In recent years these *in vivo* techniques have also revealed major short-term changes in rates of lactose synthesis according to nutritional status. In rats and mice withdrawal of food for 16 h completely shuts off lactose synthesis, which however restarts within 15 min of refeeding and climbs to 80% of the fed value by about 5 h (Bussmann *et al.*, 1984; Kuhn and Fisher, 1989). Partial restoration can also be achieved by the administration of glucose, maltose or sucrose into the stomach, but not by that of starch, fat or protein. In goats lactose synthesis also declines with starvation over 2 days, and is soon restored on refeeding (Faulkner *et al.*, 1981).

By contrast, lactose synthesis in the human breast is much less closely geared to maternal nutrition (Prentice *et al.*, 1986; Neville *et al.*, 1990), and this may be more typical of large animals with long breeding cycles and few young. The speedily reversible nature of the control of lactose synthesis in rodents that the above measurements imply is emphasized by findings with acini or slices of tissue *in vitro*. Surprisingly, the rates observed in preparations from 16 h-starved rats are indistinguishable from those in preparations from fed rats, the *in vivo* restraint having been lost during tissue preparation (Wilde and Kuhn, 1979; T. Page and N.J. Kuhn, unpublished work). Short-term control also manifests itself *in vivo* as a diurnal variation of lactose synthesis as well as of its sensitivity to nutritional change, both of which may in fact be consequences of diurnal variation in food intake (Carrick and Kuhn, 1978). In rats on a restricted food intake, the daily meal is rapidly followed by a burst of lactose synthesis that subsides to negligible rates during the rest of the day (Wilde and Kuhn, 1979).

Thus, the appearance of α-lactalbumin is probably mainly responsible for the initiation of lactose synthesis around parturition, and the tissue level of galactosyltransferase probably sets an upper limit to rates during established lactation. Actual rates during this period, however, are nutritionally controlled through short-term factors that may include insulin but really remain to be properly identified or established. Recent work has strengthened the long-suspected inhibition of milk formation by the accumulation of milk within the gland. More frequent milking of goats enhances production rates in a manner suggestive of the removal of some inhibitor (Henderson *et al.*, 1983). Isolated fractions of goat milk serum, of 10–30 kDa, inhibited both lactose and casein synthesis by rabbit mammary tissue *in vitro* or *in vivo* (Wilde *et al.*, 1987).

The lactose synthetase enzyme complex

The study of the purified enzyme complex 'lactose synthetase' is central to the study of just how lactose is formed and how this is controlled in the short-term. Early work with particulate fractions of mammary tissue from lactating guinea pigs, and then with partly purified enzyme from bovine milk, established the reaction:

$$\text{UDP-galactose} + \text{glucose} \rightarrow \text{lactose} + \text{UDP}$$

(Watkins and Hassid, 1962; Babad and Hassid, 1966). Later studies showed that the enzyme was specific for β-D-glucose, or for a very few analogues such as 5-thioglucose or 6-deoxyglucose (Kuhn *et al.*, 1980). UDP-galactose can only very poorly be replaced by UDP-4′-deoxyglucose or UDP-arabinose (Berliner and Robinson, 1982), and its utiliz-

ation is competitively inhibited by UDP or UDP-glucose. The effective irreversibility of the reaction can be ascribed to a large free energy change – unfortunately not yet determined – which at least in principle would allow the accumulation of high concentrations of lactose at its site of synthesis in the cell. In the course of purifying lactose synthetase from bovine milk, where it occurs in small but useful amounts, Ebner and his colleagues discovered two separate component proteins (Brodbeck and Ebner, 1966). One of these is the enzyme galactosyltransferase (EC 2.4.1.22), which by itself transfers galactose residues from UDP-galactose to non-reducing terminal *N*-acetylglucosamine residues of glycoproteins (Brew *et al.*, 1968). The product is a β1→4-galactoside that itself is often further modified by sialylation or fucosylation to form the finished glycoprotein. In cell-free preparations it is often convenient to use free *N*-acetylglucosamine as a galactosyl acceptor, but this is not strictly physiological. Galactosyltransferase occurs in many tissues, albeit at much lower concentrations than in the lactating mammary gland. The other protein turned out, unexpectedly, to be the long-known whey protein α-lactalbumin (Brodbeck *et al.*, 1967). The two proteins combine reversibly, in 1:1 stoichiometry, to create a 'lactose synthetase' that readily transfers galactose onto glucose. The enzymic activity remains the property of the transferase, which at the same time loses much of its ability to react with free *N*-acetylglucosamine. Combination with α-lactalbumin does not, however, impair galactosyl transfer onto glycoprotein acceptors, or indeed onto such analogues of *N*-acetylglucosamine as *N*-hexanoyl- and *N*-octanoylglucosamine. In the cell, therefore, it acts upon both glucose and glycoprotein substrates. In terms of reaction kinetics, the association with α-lactalbumin serves to lower the apparent Michaelis constant $K_{m\text{-glucose}}$ from about 1 M to 5 mM (Fitzgerald *et al.*, 1970; Klee and Klee, 1970), which begins to approach the physiological range (Page and Kuhn, 1987). This striking effect of α-lactalbumin has led to its designation as a 'specifier' or 'modifier' protein. In fact, it is better regarded as an allosteric ligand that, perhaps because of its unusually large size, exerts an unusually large effect.

α-Lactalbumin does not, in itself, participate in the mechanism of galactosyl transfer. The galactosyltransferases of different species readily interact with the α-lactalbumins of other species, even when these are phylogenetically distant enough not to cross-react with each other's antibodies (Ebner and Brodbeck, 1968). Great interest has been aroused by the finding of strong homology of α-lactalbumin with mammalian and avian egg-white lysozyme, with respect to both amino acid sequence and chain-folding structure (Brew, 1970; S.G. Smith *et al.*, 1987). The two proteins are believed to derive from a common ancestral precursor. Nevertheless, lysozyme cannot generally replace α-lactalbumin in lactose synthetase, nor does α-lactalbumin possess lysozyme activity.

For more detailed reviews on the enzymology and other aspects of lactose synthetase, readers are referred to Brew (1970), Ebner and Schanbacher (1974) and Brew and Hill (1975). Inositol is significantly, albeit slowly, galactosylated by lactose synthetase, giving the substance known as galactinol (White *et al.*, 1982). Both inositol and galactinol occur in small amounts in milk, but it is unclear whether they serve any function (Naccarato *et al.*, 1975). However, they are more significant constituents of semen, and it is of some interest that rat epididymis contains an α-lactalbumin-like protein that stimulates galactosyltransferase to use inositol as well as glucose (Qasba *et al.*, 1983).

Cation binding by lactose synthetase

Many glycosyltransferases are stimulated by millimolar concentrations of bivalent metal

cations such as Ca^{2+}, Co^{2+}, Mg^{2+} and Ni^{2+}, and especially by Mn^{2+} (see Navaratnam *et al.*, 1986). In the case of lactose synthetase, which has been investigated in greatest detail, an unexpectedly complex interaction with cations implicates both the galactosyltransferase and the α-lactalbumin components. α-Lactalbumin binds both Ca^{2+} and Zn^{2+}, one each at separate sites on the molecule (Murakami *et al.*, 1982; Murakami and Berliner, 1983). X-ray crystallography has defined the Ca^{2+} site as an 'elbow' of the polypeptide chain such that multiple coordination of oxygen atoms to Ca^{2+} lend it an association constant $K_{ass} = 10^{-6}$–10^{-8} M, depending upon the ionic strength of the medium (Mitani *et al.*, 1986; Stuart *et al.*, 1986). Binding of Zn^{2+}, also extremely tight, displaces the Ca^{2+}. It has been reported that the Ca^{2+} form of α-lactalbumin elicits a greater lactose synthetase activity than does the Ca^{2+}-free form (Musci and Berliner, 1985). However, lactose synthetase within permeabilized membrane vesicles, formed by the pinching off of Golgi membrane during the homogenization of mammary gland, does not show such a Ca^{2+} effect. At present, the physiological roles of Ca^{2+} and Zn^{2+} binding remain obscure. Although α-lactalbumin binds Ca^{2+} with the same avidity as does calmodulin or troponin C, its binding site is distinct and apparently not homologous.

By contrast with α-lactalbumin, the binding of metal ions by galactosyltransferase is clearly associated with activation. Kinetic studies of the purified enzyme have resolved two distinct types of Mn^{2+} binding site (Powell and Brew, 1976; O'Keefe *et al.*, 1980; Navaratnam *et al.*, 1988). Site 1 is half-saturated by about 10–30 μM Mn^{2+} in soluble forms of the enzyme, and is essential for activity. It may act as an electron sink in the drawing of electrons away from the bond to be broken, and towards the pyrophosphate grouping of UDP-galactose. Occupation of site 2 by Mn^{2+} gives a several fold further enhancement of activity (V_{max}) as well as affording thermal stability to the enzyme. However, *in vitro* this requires millimolar concentrations of Mn^{2+}, which are probably not physiological.

The question arises as to what are the natural activators of these two sites. Zn^{2+} and Co^{2+} ions can activate site 1, but do so less well than Mn^{2+}. Within intact vesicles arising from the Golgi membrane, permeabilized with the ionophore A23187, site 1 of lactose synthetase requires only 0.1–0.2 μM free Mn^{2+} for half-maximal activation. Yet in ruptured vesicles, or on solubilization, the enzyme requires 50–100 times as much. The interpretation of this remains uncertain (Kuhn *et al.*, 1991). At site 2 a quite different spectrum of cations can activate. Mn^{2+} can be replaced by Ca^{2+}, Mg^{2+}, Sr^{2+} or Ba^{2+}, and in fact Ca^{2+} has been envisaged as the natural occupant in view of its abundance in milk (Powell and Brew, 1976). However Ca^{2+} is not necessarily concentrated in the Golgi lumen, although Golgi-enriched vesicle fractions do accumulate it in an ATP-dependent marker (Neville and Watters, 1983).

The picture regarding site 2 is complicated by the finding that organic cations such as spermidine, lysyllysine or members of the series $^{+}NH_3$–$(CH_2)_n$–NH_3^{+} can also activate. Similar activation can be achieved with basic (cationic) proteins such as histone, clupeine, ribonuclease, melittin, etc. Mammary tissue and milk can be shown to contain basic proteins that activate at a concentration of only about 10 μg/ml, although these have not yet been characterized. Clupeine has been observed to enhance binding of glucose at the active site (Navaratnam *et al.*, 1986; Leong *et al.*, 1990).

Although these cation effects point to the presence of some regulatory system, it is too early to say how far they may mediate the short-term nutritional control of lactose synthesis described above. However, the activation of sialyltransferase, in the synthesis of

sialyllactose, by basic proteins implies that this form of control is not unique to lactose synthetase (Leong *et al.*, 1987, 1990).

Subcellular location of lactose synthetase

The Golgi location of lactose synthetase was first established by electron microscopy of mammary membrane fractions highly enriched in the enzyme (Keenan *et al.*, 1970). Subsequently, galactosyltransferase has been shown by immunofluorescence techniques to lie in the *trans*-most two or three cisternae of the Golgi stack, in HeLa cells and in hepatoma cells (Roth and Berger, 1982; Slot and Geuze, 1983). The enzyme is anchored, at least partly in dimeric form, in the Golgi membrane, with the active site directed towards the lumen (Brew, 1970; Kuhn and White, 1975a). Detergent is required to solubilize it, at which point it becomes extremely labile unless stabilized with detergent, phospholipid, Mn^{2+}, site 2 activators or serum albumin.

The properties of the enzyme have recently been reviewed (Ram and Munjal, 1986). The significance of this Golgi cisternal compartmentation lies in the fact that secretory (glyco)proteins, and (glyco)proteins destined for the cell membrane, pass through the Golgi lumen and acquire many of their glycosyl residues there. Indeed, self-glycosylation results in galactosyltransferase also being a glycoprotein (Trayer and Hill, 1971). α-Lactalbumin, which in the rat is also glycosylated (Brown *et al.*, 1977), is presumed also to pass through the lumina of successive Golgi cisternae, interacting reversibly with the galactosyltransferase and thus creating the lactose synthetase complex.

The important question now concerns the nature and concentrations of organic cations and bivalent metal ions in this Golgi compartment. Present evidence suggests that at low concentrations Mn^{2+} does not readily cross the Golgi membrane. Histochemical studies tend to locate high concentrations of free Ca^{2+} in the vacuoles distal to the *trans*-cisternae, although possibly including the outer rims of the latter (Wooding and Morgan, 1978). The high Ca^{2+} and Mn^{2+} affinities of α-lactalbumin and galactosyltransferase, on the other hand, seem to imply luminal concentrations of such ions in the range 10^{-6}–10^{-7} M.

Substrate access to the Golgi lumen

Enzyme compartmentation raises questions of substrate access. The access of cystolic glucose and UDP-galactose to the Golgi lumen has been studied in pinched-off membrane vesicles that retain internal α-lactalbumin. Both substrates readily penetrate the membrane to reach the lactose synthetase, but the product lactose does not diffuse out again. It can be released, however, when the vesicles are osmotically ruptured following exposure to high concentrations of penetrating solutes. With this as a monitoring device, one can show that the membrane specifically associated with lactose synthesis admits not only glucose but a wide range of sugars or sugar alcohols. Low temperatures are required to study this rapid penetration of polyols, which include D- and L-sugars and inositol, but not polyols of molecular weight greater than 200–300 Da (White *et al.*, 1980, 1981). Such low structural specificity, lack of saturability, and also absence of competitive inhibition, are consistent with the properties of a water-filled pore of about 1 nm diameter (White *et al.*, 1984). The passage of inositol is of interest, in view of its galactosylation and secretion into milk.

The probable equilibration of cytosolic and Golgi lumen glucose pools, together with the Golgi origin of the aqueous phase of milk, has given rise to the possibility that milk glucose concentrations may afford a direct guide to intracellular glucose concentrations (Kuhn and White, 1975b). This is of interest in so far as the latter might be a regulatory feature of lactose synthesis. A number of

studies following up this suggestion have supported the equivalence between milk glucose and intracellular glucose (see Faulkner and Peaker, 1987). However, whereas rates of lactose synthesis appear to correlate well with milk glucose concentrations in some cases, e.g. goats (Faulkner and Peaker, 1987) and humans (Neville *et al.*, 1986, 1990), they do not correlate in other cases, e.g. rat (Page and Kuhn, 1987; Grigor *et al.*, 1989). Nevertheless, there remains the interesting possibility that, with care in the interpretation, the minor components of milk may form a useful and readily accessible index of intracellular substances in the mammary gland.

The few studies carried out on the mechanism of UDP-galactose penetration of the Golgi membrane from mammary tissue have shown a specificity that includes UDP-galactose and UMP, but excludes UDP-glucose, UDP-glucuronate and UDP. The significance of this, which clearly implies a carrier-mediated transport, lies in the presence of a nucleoside diphosphatase (thiamine pyrophosphatase) in the Golgi apparatus. Through the action of this enzyme the UDP originating from the lactose synthetase reaction becomes hydrolysed to UMP, which is then transported back into the cytosol. There it is converted via UDP, UTP and UDP-glucose back to UDP-galactose which re-enters the Golgi lumen. Figure 12.8 depicts the way in which this organized system of coupled enzymes and transporters is envisaged within the Golgi cisterna, linked with the supporting reactions of the cytosol.

There is, in effect, a cycle of uridine nucleo-

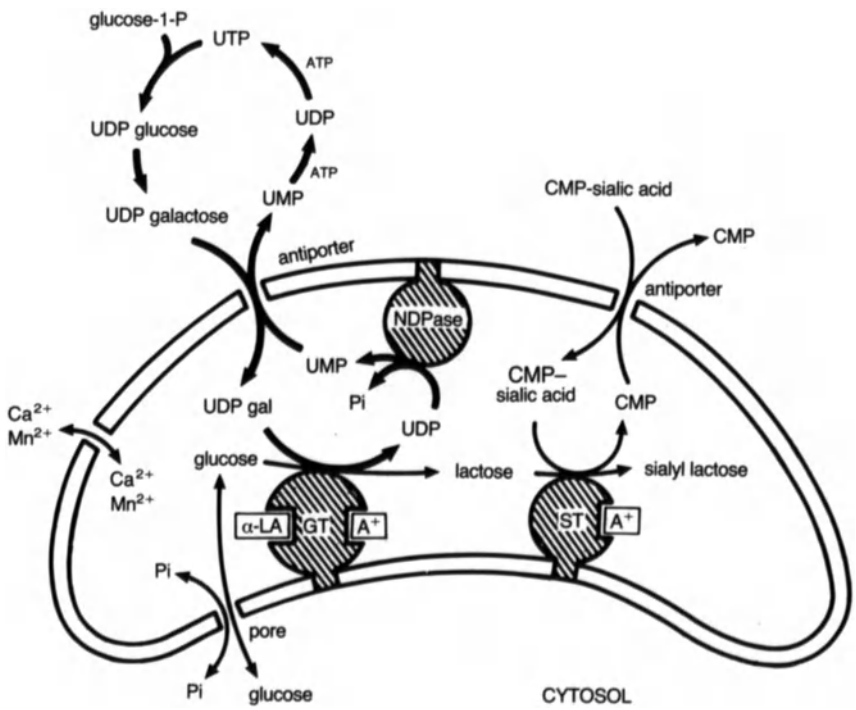


Figure 12.8 Current view of a *trans*-Golgi cisterna, showing coupled enzyme systems and membrane transporters, linking Golgi luminal and cytosolic processes. GT, galactosyltransferase; ST, sialyltransferase; NDPase, nucleoside diphosphatase; α-LA, α-lactalbumin; A^+, cationic activator. The uridine nucleotide cycle is shown with bold arrows.

tide molecules carrying galactose residues into the Golgi lumen on their backs (Kuhn and White, 1977).

The role of nucleoside diphosphatase, long regarded as a histochemical marker for Golgi apparatus in secretory tissues, is quite interesting. Its location, together with the membrane impermeability towards UDP, ensures the destruction of luminal UDP, which would otherwise powerfully inhibit lactose synthetase as a competitive analogue of UDP-galactose, while preserving cytosolic UDP. Hydrolysis of UDP costs the cell an extra 'high-energy' bond per lactose synthesized. Subsequent experiments with liver Golgi membranes have confirmed this scheme (Brandan and Fleischer, 1982; Barthelson and Roth, 1985) and have extended it to the transport of other sugar nucleotides as well as the sulphate donor 3'-phosphoadenosyl-5'-phosphosulphate (Perez and Hirschberg, 1986; Hirschberg and Snider, 1987). By analogy, it appears that a single carrier in the membrane may, as a symporter, mediate both the entry of UDP-galactose and the exit of UMP. This might justify regarding the nucleoside diphosphatase as a sort of pump that supplies a gradient of UMP, which drives the uptake of UDP-galactose. Possibly this is the chief justification for the hydrolysis of UDP, rather than the relief from inhibition of lactose synthetase.

The origins of other milk sugars

The oligosaccharides that appear in the milk of humans, rats and mice, and in the colostrum of cows and sheep, form a fascinating family. Even more so are those characterized in such abundance in the milk of marsupials such as the tammar wallaby (*Macropus eugenii*) and grey kangaroo (*Macropus giganteus*), in which galactosyl-β(1→3) galactosyl-β(1→4) glucose is prominent (Messer *et al.*, 1980), and in the milk of monotremes such as echidna (*Tachyglossus aculeatus*) or platypus (*Ornithorhynchus anatinus*), in which sialyl- and fucosyllactoses are particularly found (Messer, 1974; Kamerling *et al.*, 1982; Messer *et al.*, 1983), as well as a wide variety of oligosaccharides (Amano *et al.*, 1985). However, only a little enzymology has been done. These trisaccharides, and the higher oligosaccharides that also occur, are probably all formed by extension of lactose.

An α(2→6)sialyltransferase has been purified from bovine colostrum in both 56-kDa and 43-kDa sizes (Paulson *et al.*, 1977). The latter may be a degraded form of the former. However, the best sialyl acceptors for this enzyme are β-galactosides of *N*-acetylglucosamine or its derivatives, so that its function probably lies rather in the synthesis of glycoproteins.

Rat mammary tissue contains particulate sialyltransferase activity, which exhibits a K_m towards lactose of about 1 mM and yields mainly α(2→3)sialyllactose with a little α(2→6)sialyllactose (Carlson *et al.*, 1973; Leong, 1988; Leong *et al.*, 1990). A detailed study has been made of the way in which this enzyme, acting within tightly sealed vesicles of Golgi membrane origin, can be fed with lactose by lactose synthetase (Leong *et al.*, 1990). The two enzymes constitute a coupled enzyme system within the same Golgi compartment, in which free lactose liberated by the one becomes the substrate for the other. This is depicted in Figure 12.8.

The K_m value given above is of interest, as it may indicate the likely concentration of lactose within the normal Golgi cisternal lumen. Were it correct, it would imply that the concentration of lactose to milk values occurs only subsequent to the Golgi stack, possibly in the condensing or secretory vesicles.

An interesting feature of the detergent-solubilized sialyltransferase is its marked activation by the basic proteins histone and clupeine (Leong, 1988; Leong *et al.*, 1990). This is reminiscent of the behaviour of galactosyltransferase, and may point to a common regulating mechanism.

12.6.5 BIOSYNTHESIS OF MILK FAT

No biochemical aspect of mammary function has attracted so much attention over the last 30 years as the problem of milk fat synthesis. The complexities arise from the variety of the constituent fatty acids, their different origins within the body and our ignorance of the intracellular signalling mechanisms that mediate hormonal control of their synthesis and esterification. Yet much of the metabolic activity of the gland is directed towards making this energy-rich milk solid, so that the process has a disproportionate influence upon mammary activity as a whole. Reviews on this subject include those by S. Smith and Abraham (1975), Patton and Jensen (1976), Mayer (1978), Dils (1983), Munday and Hardie (1987) and Clegg (1988).

There is an enormous variety of fatty acid types encountered in milk fat, and the finding that, although the milk of a given species may have a 'characteristic' fatty acid profile, nevertheless it can be markedly influenced by the amount and the nature of fat in the diet. We owe this detailed knowledge to the exploitation of the high resolving power of gas–liquid chromatography, which has been extended even to the separation of intact triacylglycerols according to their carbon number, and hence their fatty acid complement. As far as the origins of milk fat are concerned, an important achievement of early workers in the field was to establish that the complex lipids of plasma are not taken up directly into the mammary gland. Rather, they are hydrolysed extracellularly, and the subsequently absorbed fatty acids and glycerol are then assembled anew into complex lipids within the cell (Kinsella, 1968; Easter *et al.*, 1971). It is now also clear that the short- and medium-chain fatty acids, and some of the $C_{16:0}$ fatty acids, are synthesized *de novo* within the secretory epithelial cells of the mammary gland. The remaining fatty acids are drawn from the triacylglycerol of plasma lipoproteins, and it is through their provision that the influence of dietary lipids is exerted. So far as is known, all these fatty acids enter a common pool of fatty acyl coenzyme A (CoA) within the cell, and the esterifying enzymes draw upon this pool with an element of specificity for their chain length or degree of unsaturation.

Esterification of fatty acids

Esterification is the only significant fate of long- and medium-chain fatty acids in the mammary gland, as oxidation appears to be a very minor process. The great majority of the fatty acids are assembled by enzymes of the rough endoplasmic reticulum to form the triacylglycerol of the milk fat globule (Stein and Stein, 1967). However, a not insignificant proportion go to replenish the phospholipids – particularly phosphatidylcholine, phosphatidylethanolamine and sphingomyelin in the cow – that are lost from the apical membrane when this gives rise to the milk fat globule membrane in the course of secretion (Patton and Jensen, 1976). It is the task of the enzymologist not only to document the metabolic pathways by which these complex lipids are formed, but also to account for the preferential attachment of particular fatty acids at particular positions of the glycerol moiety. The insoluble or the detergent-like nature of all these enzyme substrates has greatly hampered the application of traditional enzyme kinetics. Indeed, there is good evidence that long-chain fatty acids and their coenzyme A derivatives are largely attached to particular binding proteins (Keuper *et al.*, 1985; Morgensen *et al.*, 1987), so that the concentrations of their 'free' forms are probably around micromolar values.

sn-Glycerol 3-phosphate is the primary acyl acceptor for fatty acids, being formed partly by the NADH-dependent reduction of dihydroxyacetone phosphate that arises from glycolysis, and partly from the ATP-dependent phosphorylation of free glycerol that arises from the hydrolysis of the plasma triacylgly-

cerol supplying the fatty acids (see S. Cooper and Grigor, 1980; Dils, 1983). It is tempting to draw parallels with intestinal mucosa, where the dietary triacylglycerol is similarly disassembled, absorbed and reassembled. But, unlike in that situation, 2-monoacylglycerol is unlikely to be an important acyl acceptor in the mammary gland.

The phosphatidate formed by two successive acyl group transfers can then react with cytidine diphosphate choline (or cytidine diphosphate ethanolamine) to form phosphatidylcholine (or phosphatidylethanolamine). These are transported to the membranes of the cell by a mechanism that is not well understood. Alternatively, the phosphatidate undergoes enzymic hydrolysis to *sn*-1,2-diacylglycerol, the further esterification of which yields the triacylglycerol of milk. The non-random positioning of different fatty acids is intriguing (Breach *et al.*, 1973). Short- and medium-chain ones are found exclusively on the 3-hydroxyl, which typically also carries unusually long or unsaturated fatty acids.

In the milk fat of ruminants, other than sheep and goats, and of man and whales, palmitate occurs particularly at the 2-hydroxyl. This circumstance does not arise in carcass fat (except pig lard), in which the 2-position usually acquires unsaturated fatty acids. Although the fatty acid specificities of the three enzymes that acylate these hydroxyl groups have not been exhaustively examined, there are signs that the complement of fatty acids is mainly determined by the specificities of the two enzymes acylating positions 1 and 2 of glycerol phosphate (Breach and Dils, 1975; Kinsella, 1976; Marshall and Knudsen, 1977, 1979; S. Cooper and Grigor, 1980). The concentration of shorter chain or of unusual fatty acids at position 3 appears to owe more to fatty acid exclusion from positions 1 and 2 than to their positive selection by the diacylglycerol-specific acyltransferase (Marshall and Knudsen, 1979).

A feature of triacylglycerol synthesis that remains poorly researched in mammalian tissues is the manner in which the product is directed to that compartment of the cell where it is either stored (e.g. the cytosol in adipose tissue) or from where it is secreted (the Golgi apparatus in liver and intestine; the cytosol in mammary tissue). A good autoradiography study of newly formed [^{14}C]triacylglycerol, in cells of lactating-mouse mammary gland, clearly specified the rough endoplasmic reticulum as the site of synthesis (Stein and Stein, 1967). In another electron microscopic study, not actually in mammary gland, the fat droplet was ingeniously envisaged as growing within the lumen of the endoplasmic reticulum, gradually forcing apart the opposite membranes, which eventually come to form barely detectable strands overlying the surface of the fat droplet that now lies, essentially, within the cytosol (for references see Zaczek and Keenan, 1990).

Plasma origin of fatty acids

Milk fatty acids originating from the plasma are drawn from the chylomicrons and very low-density lipoproteins (VLDLs) that perfuse the mammary gland (Barry *et al.*, 1963; Schoefl and French, 1968; Bishop *et al.*, 1969; C.E. West *et al.*, 1972), and whose triacylglycerol is hydrolysed to monoacylglycerol and free fatty acid by lipoprotein lipase (Scow *et al.*, 1972). Lactating mammary tissue is immensely well endowed with this unusual enzyme, whose prolactin-dependent induction at lactogenesis is a major factor in the redirection of fatty acids (nutrient partitioning) away from adipose tissue and to the mammary gland (McBride and Korn, 1963; D.S. Robinson, 1963; Zinder *et al.*, 1974; Mendelson *et al.*, 1977). Extrapolating from studies on adipose tissue, we may presume that mammary lipoprotein lipase is synthesized within the epithelial cells and then

transported to an extracellular site on the luminal walls of the blood capillaries, where it binds and 'digests' passing chylomicrons and VLDL (see electron micrographs by Schoefl and French, 1968). After further hydrolysis of the immediate product monoacylglycerol, at an extracellular site not fully identified, all the fatty acids are absorbed into the cells, activated to their CoA thioesters, and re-esterified into milk fat. There is some evidence that monoacylglycerol may partly be absorbed and directly esterified in the mammary gland of pigs (Bickerstaffe and Annison, 1971a), but this seems not to be the usual pathway (Hansen *et al.*, 1986).

In general it seems that the fatty acids taken up from the plasma are utilized unchanged for milk fat synthesis. However, in the mammary glands of the cow, goat and sow a stearoyl CoA desaturase has been identified; the enzyme is located in the microsome fraction of tissue homogenates, and employs NADH (and presumably oxygen) to convert stearoyl CoA into oleoyl CoA. This ensures that the milk fat is not overendowed with saturated fatty acid arising by the biohydrogenation of unsaturated dietary fatty acids in the rumen (Bickerstaffe and Annison, 1971b; Kinsella, 1972; Davies *et al.*, 1983).

Biosynthetic origin of fatty acids within the mammary gland

The *de novo* synthesis of fatty acids is essentially a reductive condensation of acetyl and malonyl residues provided as their 'activated' thioesters. So great is the contribution of this process to mammary metabolism that it causes the respiratory quotient (ratio of carbon dioxide formed per oxygen molecule consumed) of the tissue to rise as high as 1.6. An early study with rat mammary slices nicely documented the shift of respiratory quotient, from below 1.0 to about 1.6, that accompanies the transition from pregnancy to full lactation (Folley and French, 1949). The formation of short- or medium-chain fatty acids is one of several unique metabolic features displayed by the mammary tissue of many species. Biosynthetic studies have well documented the retention of this feature by slices or explants of rat, rabbit, mouse and goat mammary gland incubated with [^{14}C]glucose or with [^{14}C]acetate *in vitro* (Wang *et al.*, 1971; Strong and Dils, 1972; S. Smith and Abraham, 1975; Grunnet and Knudsen, 1979). Therefore, it came as a surprise when the fatty acid synthetase, which was eventually purified, proved to generate mainly long-chain fatty acids and even to be indistinguishable from the synthetase of liver. In fact, the chain length of the product is markedly influenced by the ratio of the acetyl CoA and malonyl CoA substrates presented to the enzyme, a high ratio favouring the starting of new chains at the expense of finishing the old. Growing acyl chains, covalently attached to the 4-phosphopantetheine prosthetic group of the synthetase, are finally released by hydrolysis of the thioester by a thioesterase component (thioesterase I) of the enzyme complex.

A novel finding in rat and rabbit mammary gland, as opposed to non-mammary tissues, was a second, soluble, thioesterase of markedly shorter chain-length specificity. The action of this thioesterase II forestalls that of thioesterase I, so that a shorter-chain fatty acid is the product in the intact cell (Knudsen, 1979; Dils, 1983). The thioesterase II of rat mammary gland has been well characterized with respect to its amino acid sequence (Naggart *et al.*, 1987) and its induction during pregnancy (S. Smith and Ryan, 1979). It is interesting to note that the two non-protein milk substances that are unique to milk, namely medium-chain fatty acids and lactose, both require unique proteins for their synthesis, namely thioesterase II and α-lactalbumin.

However, the termination of fatty acid chains is also favoured by the presence of suitable fatty acid acceptors, although the

identity of those that operate within the mammary cell is not entirely clear. Nevertheless, these fatty acids, together with those arising from the plasma, are activated to their coenzyme A thioesters by an ATP-dependent fatty acyl CoA synthetase. In ruminant udder, where a weak medium-chain thioesterase II also appears to exist, the dominant process is a direct acyl transfer from the synthetase to coenzyme A, with conservation of the high-energy thioester bond (Grunnet and Knudsen, 1983; Mikkelsen *et al.*, 1985). This, too, is enhanced by the presence of suitable acyl CoA acceptors, possibly accounted for by a specific acyl CoA-binding protein such as has been purified from liver (Morgensen *et al.*, 1987)

Precursors for fatty acid synthesis

Complexity also surrounds the source of acetyl CoA and malonyl CoA precursors for fatty acid synthesis, and the origin of NADPH used as reducing agent. In most non-ruminants the acetyl CoA arises in the cytosol of the mammary epithelial cell from the action of ATP-citrate lyase upon citrate; this in turn originates from the mitochondria following its formation from pyruvate, which itself arises from carbohydrate, alanine or lactate. In ruminants or non-ruminant herbivores, however, the deficiency of ATP-citrate lyase spares the use of carbohydrate, and acetyl CoA arises instead from free acetate taken up from the plasma (S. Smith and Abraham, 1975). When the properties of mammary fatty acid synthetases are studied, it is found that butyryl CoA is as acceptable as acetyl CoA in initiating growth of the fatty acyl chain (Nandedkar and Kumar, 1969; Lin and Kumar, 1971). It is therefore of interest that ruminant mammary tissue is able to utilize acetoacetate and 3-hydroxybutyrate, which reach the plasma from the rumen, and to reduce these to butyryl CoA (Palmquist, 1969). These two ketone bodies can therefore serve as precursors of both the butyryl residues and the terminal four carbon atoms of long-chain residues of milk fat. In these ways it is seen that fatty acids can be fashioned out of a wide variety of precursors drawn from the plasma, and it is evident that the relative importance of each varies according to species and to nutritional state.

Reducing equivalents, in the form of NADPH, are generally believed to originate largely from the pentose phosphate cycle. Indeed, it was partly through the investigation of NADPH generation in the mammary gland of the lactating rat that the cycle and its role in lipogenesis generally was recognized (Abraham *et al.*, 1954; Glock and McLean, 1954). Mammary tissue is especially rich in the coenzyme NADP(H) and in the oxidative and non-oxidative enzymes of the cycle (McLean, 1958a,b; Gumaa *et al.*, 1971). In mammary preparations *in vitro*, the addition of glucose greatly enhances the incorporation of [^{14}C]acetate into fatty acid (Hirsch *et al.*, 1954). This is believed to reflect the provision of NADPH by the first two enzymes of the cycle, glucose-6-phosphate dehydrogenase and 6-phosphogluconate dehydrogenase. Consistent with their proposed role is their marked induction during the onset and course of lactation (McLean, 1958a). However, some NADPH almost certainly arises from the oxidation of malate in the rat. Interestingly, the formation of NADPH in sheep udder does not inevitably require the presence of glucose and the operation of the pentose phosphate cycle. Greenbaum and his colleagues have shown that acetate itself can be the source of reducing power, and have proposed a plausible metabolic pathway by which NADPH is ultimately generated through the action of a cytosolic isocitrate dehydrogenase, which is quite active in this tissue (Gumaa *et al.*, 1973). The challenge of estimating just what proportion of NADPH arises by way of the pentose phosphate cycle has been met, both *in vivo* and *in vitro*, by experiments in which the fates of differently ^{14}C-labelled glucose are monitored; the in-

terpretation is complex (Wood *et al.*, 1965; Katz and Wals, 1972; Chaiyabutr *et al.*, 1980).

This is not the place to describe the fascinating structure of the very high molecular weight fatty acid synthetase that enables it to be loaded with acetyl (or butyryl) and malonyl residues, to condense them reductively into saturated fatty acids, and finally to transfer the latter onto water or coenzyme A. Suffice it to remark that this 'polyfunctional protein' appears to have evolved from separate component enzymes by a process of fusion at the gene level (Hardie *et al.*, 1986). Important though these reactions may be in chemical terms, it is the preceding enzyme acetyl CoA carboxylase that catalyses the major rate-limiting and hormonally regulated step of lipogenesis. This enzyme is subject to both long-term inductive control (as, indeed, is also the fatty acid synthetase), and to short-term allosteric and phosphorylative control by agents and mechanisms as yet incompletely understood.

Several species exhibit a rise in acetyl CoA carboxylase activity during late pregnancy and early lactation, and immunotitration of the enzyme in rat mammary tissue has shown this to closely match the increase in actual amount of enzyme protein (Mackall and Lane, 1976). Studies with explants of rat, mouse and rabbit mammary tissue *in vitro* have shown that such induction can be mimicked by the addition of prolactin, insulin and (except in rabbit) cortisol. In particular, prolactin not only enhances the synthesis of new enzyme, but also retards its destruction (Mayer, 1978). Such studies on explant culture, together with studies on intact animals, give a picture of a constellation of lipogenic enzymes (pyruvate dehydrogenase, ATP-citrate lyase, acetyl CoA carboxylase, fatty acid synthetase, malic enzyme) being induced at the end of pregnancy by the withdrawal of progesterone and the presence of suitable levels of 'lactogenic' hormones prolactin, cortisol and insulin. However, whereas this appears to be sufficient for the induction of fatty acid synthetase, the induction of ATP-citrate lyase and acetyl CoA carboxylase, and of the lipogenic pathway as a whole, requires that the mother be suckled by the newborn. Therefore, there appears to be some overriding factor still to be identified (Martyn and Hansen, 1980, 1981).

Nutritionally induced changes in fatty acid synthesis

Rates of mammary fatty acid synthesis can be followed in the intact, anaesthetized, laboratory animal by the incorporation of ^3H_2O, which measures the synthesis from acetyl CoA arising from any source, and of [^{14}C]-glucose, which measures synthesis from glucose-derived acetyl CoA. In the fed animal, glucose provides about 60% of the carbon atoms (A.M. Robinson *et al.*, 1978; Williamson *et al.*, 1983; Bussmann *et al.*, 1984; Kuhn and Fisher, 1989). [^{14}C]acetate has been a useful precursor for some studies *in vitro*, but is not suitable for assessing either absolute or physiological rates. The *in vivo* techniques have revealed an extraordinarily close link with the maternal nutritional status. The rates decline within hours of food withdrawal in the rat (within 1 h in the mouse), and cease altogether by about 15 h. On refeeding, lipogenesis restarts within a few minutes, reaches 'fed' values by about 2 h, and overshoots by 5 h. These changes, too, are considerably faster in the mouse. Streptozotocin, an inhibitor of insulin secretion, blocks the return of lipogenic activity. Such large and rapid fluctuations, in a process that probably consumes about half the available body glucose, are clearly essential to ensure the survival of the mother in times of food shortage. In a similar manner, natural diurnal fluctuations in food intake (about a threefold decline between early morning and midday in rats) are accompanied by similar fluctuations in mammary lipogenesis (also about threefold, but with some delay). This must underlie much of the marked diurnal variation in

maternal metabolic rate, judged by heat output, that so closely follows the changing food intake (Brody *et al.*, 1938; Munday and Williamson, 1983). A rise in the fat content of the diet also leads to a decline in mammary lipogenesis without, however, alteration of the chain-length profile of the newly synthesized fatty acids (Grigor and Warren, 1980; Agius and Williamson, 1980).

The very striking nature of these physiological responses raises the question of their mode of control (Williamson, 1990). Plasma insulin is evidently closely involved, and some authors believe that a suitably sensitive response of the mammary gland to the two- or threefold changes in plasma insulin that have been documented might account for the control (A.M. Robinson *et al.*, 1978; Girard *et al.*, 1987). However, the possibility remains that some other hormone plays a role, although this is not glucagon, for which there are no receptors, and probably not adrenaline. The suggestion has been made that a gut hormone may influence mammary sensitivity to insulin (Williamson *et al.*, 1983). Presumably, such a hormone would be released by the presence of digestible carbohydrate in the intestine, since this appears to be the critical nutritional feature (Bussmann *et al.*, 1984; Mercer and Williamson, 1987).

Within the cell, in response to the nutritional signal, short-term control of lipogenesis is probably exerted more or less simultaneously at multiple points, namely glucose transport, phosphofructokinase, pyruvate dehydrogenase and especially acetyl CoA carboxylase. These all represent critical control points on what is really one long pathway for the conversion of glucose into fatty acid. It appears to be a general principle of pathway control that several different points are under coordinate control.

Recently, much attention has been given to the way in which the activity of acetyl CoA carboxylase is regulated. It undergoes activation in the presence of citrate, associated with polymerization into long threads (Ahmad *et al.*, 1978), and inactivation by long-chain acyl CoA, associated with depolymerization. Inasmuch as citrate is a precursor of acetyl CoA in the cytosol, these effects may represent feedforward activation and feedback inhibition. However, caution is due, as it is not yet evident that changes in the concentrations of these allosteric effectors are in fact employed by the cell to bring about alterations in enzyme activity. Therefore, the present focus of attention is upon the inactivation of the enzyme by ATP-dependent phosphorylation, and its reactivation by phosphatase-catalysed dephosphorylation. In rats starved for 24 h, rapidly isolated acetyl CoA carboxylase has been found to carry more phosphate, and to exhibit a lower V_{max} and decreased affinity for citrate. These changes were reversed after 2½ h of refeeding. Both cyclic AMP-dependent and 5′-AMP-dependent protein kinases are known to be able to phosphorylate the acetyl CoA carboxylase of mammary gland with accompanying inactivation. The latter is itself controlled by phosphorylation and dephosphorylation (Munday and Hardie, 1987; Ottey *et al.*, 1989) and is identical with β-hydroxy-β-methylglutaryl CoA reductase kinase (Carling *et al.*, 1989). Yet, striking though these changes are, it is not clear that they account for the reduced rate of lipogenesis over short periods of food withdrawal or in the streptozotocin-treated rat (Munday and Hardie, 1986). It may be that this is achieved rather through rapidly acting allosteric agents (Haystead and Hardie, 1986). There are many puzzles still remaining in the area of regulation of fatty acid synthesis, and the next few years will almost certainly bring forth surprises.

12.6.6 CONTROL OF METABOLIC FLOW

Metabolic balance studies, especially those employing radiochemical tracers, have given a fairly clear picture of how nutrients entering the gland are shared between different

pathways, even if this information as yet pertains to only a few species. About 90% of all long-chain fatty acids become esterified to triacylglycerol and the remainder to phospholipid (Stein and Stein, 1967). Amino acids are used primarily for the synthesis of milk protein, but certain types are converted into others in order to make up for a shortfall. A very interesting case is that of ornithine and arginine, which are used partly to generate extra proline required for synthesis of the caseins. The incidental consequence is that the mammary gland is the only organ other than the liver to produce substantial amounts of urea (Mepham and Linzell, 1967). Arginase appears in the rat mammary gland relatively late in lactation, when we may presume that supplies of proline become limiting (Folley and Greenbaum, 1947; Yip and Knox, 1972).

With glucose, and in ruminants acetate also, multiple fates are most evident and the question of metabolic steering arises. The flux of glucose carbon along the glycolytic pathway provides glycerol phosphate for milk fat formation, and pyruvate for both oxidation to yield ATP and acetyl CoA for lipogenesis. Glucose is also used for the synthesis of lactose, and in the pentose phosphate cycle to generate NADPH for lipogenesis. The other product of this cycle, glyceraldehyde phosphate, re-enters the glycolytic pathway in the case of the rat. In the ruminant, however, in which appreciable levels of the gluconeogenic enzyme fructose bisphosphatase occur, it is probably recycled to hexose phosphate in order to conserve carbohydrate (Crabtree *et al.*, 1981). In those species where sialyllactose is a significant milk sugar, glucose also provides the *N*-acetylglucosamine from which the sialyl moiety is synthesized. The different fates of glucose, together with pertinent original references, have been summarized (Kuhn, 1978). Similar metabolic decisions are taken in the case of acetate, which is also employed both as a lipogenic precursor and as a source of ATP. In ruminants, acetate largely supplants glucose as a source of fatty acids and ATP, leaving it to supply only lactose, glycerol phosphate and the pentose phosphate cycle. Glycolysis is therefore a relatively insignificant pathway. By contrast, in the rat, the importance of glucose as a fatty acid and ATP precursor, together with the lower concentration of lactose in the milk, combine to make glycolysis a highly significant route of metabolism, followed in importance by the pentose phosphate cycle.

Flux control by supply and demand

The proportions of glucose or acetate that are selected for oxidation to give ATP are relatively easily explained. Studies of energy metabolism in tissues generally make it quite clear that ATP is rarely limiting and that energy is supplied according to demand. In the lactating mammary gland, therefore, the major ATP-consuming processes of protein and fat synthesis (lactose synthesis is less important) stimulate the ATP-generating reactions of oxidative phosphorylation through their provision of ADP. The constancy of ATP/ADP ratios in mammary tissue before and after lactogenesis is an indication of the tight coupling and ample capacity of such respiratory control. Elaborate mechanisms exist to ensure adenine nucleotide homeostasis (Atkinson, 1977). A further demand on energy must arise from ion pumping across the plasma membrane, and perhaps also across the apical and secretory vesicle membranes, but these have not yet been assessed. Nevertheless, the pronounced increase in mammary oxygen consumption that is associated with the onset of lactation gives some idea of the extra energy demands made by the synthetic processes of the gland (Folley and French, 1949; A.J. Davis *et al.*, 1979).

A further good example of supply and demand is that of NADPH provision by the pentose phosphate cycle for the purpose of fatty acid synthesis. It has long been accepted

for lipogenic tissues generally that the cycle is essentially driven by the demands of lipogenesis and not, as previously held, the other way round. Glucose-6-phosphate dehydrogenase, the first and rate-limiting enzyme of the cycle, is inhibited by the high prevailing NADPH/NADP ratio of the cytosol. Utilization of NADPH by the reductive steps of fatty acid synthesis acts to relieve this inhibition and facilitate further operation of the cycle. The two processes form a tightly coupled system. The actual mechanism by which this inhibition by NADPH is achieved is complex, however, and has stimulated recent debate.

Internal metabolic homeostasis

At any given level of metabolic activity, a web of cooperative and allosteric interactions operates to coordinate different parts of the metabolic machinery in such a manner as to establish a homeostatic system of great efficacy. Thus, the inhibition of acetyl CoA carboxylase by long-chain acyl CoA ensures that lipogenesis does not exceed the capacity for esterification. The elevated levels of malonyl CoA that characterize active lipogenesis inhibit acyl CoA–carnitine acyltransferase, the rate-limiting enzyme on the pathway of fatty acid oxidation. Conversion of mitochondrial acetyl CoA into citrate relieves an inhibition of pyruvate dehydrogenase, whereas the withdrawal of cytosolic citrate for use as a lipogenic precursor relieves an inhibition of the key glycolytic enzyme phosphofructokinase. The activation of this enzyme, to replenish the precursors of citrate, in turn depletes levels of glucose 6-phosphate and thereby relieves an inhibition of hexokinase. With the exception of pyruvate dehydrogenase control by acetyl CoA, all these feedback inhibitions are mediated by the rapidly reversible binding of a metabolite to an allosteric site on the target enzyme.

It is presumed that excessive accumulation or depletion of metabolic intermediates is avoided by virtue of the binding strength, and the effect of binding upon enzyme activity, that each allosteric site has evolved. Understanding of this sort of homeostatic system, based upon a view of rapid equilibration of free with enzyme-bound metabolites, is fairly well advanced at a qualitative level. The quantitative reconstruction of such systems, however, is still at an early stage (Crabtree and Newsholme, 1987; Kacser and Porteous, 1987; Fell, 1992). It is not clear how far this viewpoint is compatible with the rather different one of metabolites being channelled, in some cases, directly from one enzyme to an adjacent one (Srivastava and Bernhard, 1986). In either case, however, there is second-by-second control.

Long-term inductive control

At the other time extreme, those changes in mammary activity that operate over several hours or even days are probably largely due to changes in amounts of enzymes. Numerous studies have shown that the total assayable amounts of such critical enzymes as lipoprotein lipase, phosphofructokinase, pyruvate dehydrogenase, acetyl CoA carboxylase, glucose-6-phosphate dehydrogenase and lactose synthetase increase during lactation with a pattern closely matching the increase in milk solid production (R.L. Baldwin and Yang, 1974; Kuhn, 1983). In a few cases, changes in enzyme activity have been related to changes in immunologically titratable protein or in actual rates of synthesis of enzyme protein (Mackall and Lane, 1976; Lobato *et al.*, 1986). Some enzymes that are expected to make less contribution to metabolic control, although equal contribution to catalytic activity, also show striking variations. Into this category fall 6-phosphogluconate dehydrogenase, malic enzyme and nucleoside diphosphokinase. Other enzymes change less markedly, for example fatty acid synthetase, phosphoglucomutase or ATP-citrate lyase.

A comparative study of milk composition in different species reveals what must be widely varying rates of biosynthetic pathways. For example, the lactose–fat ratio can vary enormously between species (Jenness, 1974; Bussmann *et al.*, 1984). Almost certainly these gross differences reflect different relative amounts of pathway enzymes, but curiously no one appears to have undertaken the cross-species survey that would be required to establish this.

Reversible short-term control

Profound changes in rates of milk solid synthesis can be observed within a few minutes of administering insulin, or of refeeding starved rats or mice. In well-fed lactating mice the removal of food for as little as 1 h reduces lipogenesis to less than half of that in continuously fed mice. It is not known how the rapid changes mediating this nutritional sensitivity are effected.

For many years it seemed likely that changed amounts of the second messenger cyclic AMP would account for these effects. Several authors were able to report changes in its tissue content with different stages of lactation, or else changes in rates of metabolism following exposure of tissue preparations to cyclic AMP or to its dibutyryl derivative. A role for cyclic AMP seemed all the more likely as the control of acetyl CoA carboxylase through reversible phosphorylation was uncovered (McNeillie *et al.*, 1981). In particular, this enzyme could be phosphorylated by added cyclic AMP-dependent protein kinase, with accompanying loss of activity. The control of lipogenesis by such a mechanism is well established in adipose tissue. However, tissue responses to added cyclic AMP have not been very striking, and much of the cyclic AMP of whole tissue may in fact be extracellular and due to milk. These problems have been reviewed by Clegg (1988). Further, although changes in the phosphorylation state of acetyl CoA carboxylase undoubtedly do occur, and make an important contribution to lipogenic control, other protein kinases can phosphorylate it in the absence of cyclic AMP (Munday and Hardie, 1984, 1986; Ottey *et al.*, 1989; Carling *et al.*, 1989).

The difficulty in accepting cyclic AMP as a second messenger that mediates acute nutritional effects has been pinpointed by recent experiments with acini of rat mammary tissue. Agents known to activate adenylate cyclase produced little elevation of cellular cyclic AMP concentration unless an inhibitor of its breakdown was also added (Clegg and Mullaney, 1985). Further, even when levels of cyclic AMP were experimentally raised, there was no inhibition of lipogenesis and no phosphorylation of acetyl CoA carboxylase (Clegg *et al.*, 1987). Activation of cyclic AMP-dependent kinase was not matched by change in activity of acetyl CoA carboxylase (Clegg, 1988; Clegg and Ottey, 1990).

Insulin is the only hormone that has repeatedly been shown to exert large and rapid effects upon mammary function *in vivo*. Within minutes it enhances glucose uptake and lipogenesis, and activates the mitochondrial enzyme pyruvate dehydrogenase and the cytosolic acetyl CoA carboxylase. The compartmentation of pyruvate dehydrogenase makes it unlikely to be activated directly by cyclic AMP. It is unfortunate that, in attempts to study the action of insulin *in vitro*, it has been found necessary to use concentrations that exceed physiological values by 1000- to 10 000-fold to achieve even quite minor stimulations. It must then be a matter of some doubt whether this is useful. For the most part, tissue preparations of mammary tissue taken out of the body have been remarkably unresponsive to insulin in the short term.

Increasingly, these disappointments in attempts to unravel the nature of the acute control of mammary metabolism suggest one of two possibilities. One is that mammary tissue is an especially delicately poised sys-

tem, the disturbance of which *in vitro* renders it insensitive to insulin or cyclic AMP. In favour of this is the fact that rates of carbohydrate utilization *in vitro* no longer distinguish between the fed or starved status of the donor animal, whereas *in vivo* such rates differ by up to 10-fold. The other possibility is that control of metabolism is really due to a web of different intracellular signals, of which cyclic AMP is only one, and perhaps in the mammary gland is not an important one. Recent research in the area of intracellular signals mediating hormone action increasingly seems to support this idea, and nowhere more so than in the actions of insulin, which may not only utilize novel signal substances but in some actions no simple second messenger at all (Haystead and Hardie, 1986; Saltiel and Cuatrecasas, 1986).

It is notable that the role of cyclic AMP in the hormonal control of carbohydrate and fatty acid metabolism is best established in liver and adipose tissue, where the anabolic action of insulin is balanced by the catabolic actions of other hormones such as glucagon, adrenaline and cortisol. In lactating mammary gland, however, there is no good evidence that any such hormone balance exists, and it may be that the anabolic action of insulin is counterbalanced only by a negative feedback from accumulating milk. It therefore seems important that attention should be given to other ways of mediating hormonal influence. Prolactin has recently been reported to raise concentrations of inositol 1,4,5-trisphosphate in mouse mammary explants (Etindi and Rillema, 1988). This substance is now widely accepted as the major intracellular signal for the release of internal stores of Ca^{2+}, an ion that has in turn long been associated with the activation of secretory tissues. Thus the problem of the acute control of mammary metabolism may become solved as the scope of investigation widens beyond that of cyclic AMP.

12.7 SECRETORY PROCESSES

12.7.1 GENERAL

When, in the nineteenth century, mammary tissue was first ascribed an active role in elaborating milk, microscopists vied with each other in proposing mechanisms for the secretory activity of the epithelial cells. Virchow's notion that milk resulted from complete cellular degeneration (holocrine secretion) was supplanted by Heidenhain's view that only the cell apex was lost (apocrine secretion). The later claim that there is no cytoplasmic loss (merocrine secretion) found firmer support in electron microscopical studies in the 1960s (see Mepham, 1986). Latterly, however, the question has become more complex because no single process appears capable of accounting for secretion of all the different milk constituents.

Major advances in understanding secretion (here defined as the passage of milk constituents from the mammary epithelium to the alveolar lumina) were achieved in the 1960s, a point well made by comparing Linzell's (1959) review and that he wrote with Peaker (Linzell and Peaker, 1971). The progress made is largely attributable to the use of a wide range of investigative techniques, such a autoradiography, histochemistry, isotopic tracers and electrical potential difference (PD) measurements, as well as to refinements in electron microscopy (EM).

It is useful in describing milk secretion to identify five routes by which different milk constituents enter the alveolar lumina, i.e. four transcellular modes, namely the Golgi route, fat secretion, monovalent ion secretion and serum protein secretion; and the paracellular pathway. For several reasons, both biochemical and physicochemical, there are likely to be interactions between the separate modes, but the classification provides a convenient framework for discussion.

12.7.2 THE GOLGI ROUTE

Post-translational modification of mammary-synthesized milk proteins occurs in vesicular elements of the Golgi apparatus. Subsequently, the proteins, frequently in micellar form, are packaged into secretory vesicles, formed at the *trans* face of the Golgi apparatus, which then move towards the apical pole of the cell by a process thought to involve cytoskeletal elements (see Loizzi, 1987). The synthesis of lactose in Golgi vesicles is considered to be responsible for the swelling of secretory vesicles through osmotic entry of water, but formation of larger vesicles seems also to be partly due to the fusion of smaller 'precursor vesicles' (Mather and Keenan, 1983).

Release of the vesicular contents into the alveolar lumina is achieved by exocytosis. The vesicles have a distinctive coat on their cytoplasmic face which, from electron micrography, appears to react with appropriate receptors on the cytoplasmic face of the apical membrane to produce an area of fusion – a 'pre-exocytotic attachment plaque' (Figure 12.9).

Presumably, this area of fusion becomes eliminated in the process of exocytosis but, probably because the process is very rapid, it has not been possible to discern intermediate stages by EM.

Nevertheless, the secretory vesicle coat material does become incorporated, if only transiently, into the apical plasmalemma (Franke *et al.*, 1976). Calcium, phosphorus and citrate are transported into Golgi vesicles from the cytoplasm and become associated with the contained casein micelles. It thus appears that lactose, milk-specific proteins, calcium, phosphorus and citrate are all secreted by a common path – the 'Golgi complex–secretory vesicle' route. This postulate finds support in the observation that in frequently milked goats receiving intravenous infusions of radioactively labelled milk precursors maximum specific radioactivities for all the above milk constituents occurred 2–3 hours later (Linzell *et al.*, 1976). Since lactose is the major osmole in milk, the route is also likely to be an important avenue for water transfer, but there is uncertainty as to whether osmotic equilibrium is complete prior to exocytosis. Peaker's earlier calculations (1977, 1978) suggested that lactose concentrations in Golgi vesicles were 3–4 times those in milk; later (1983), taking account of possible inaccuracies due to disruption of the mammary epithelium, he considered it safer to conclude that 'the contents of the Golgi vesicles could be at somewhat higher concentration than milk'; in either case, osmotic equilibrium would be completed by water diffusion across the apical membrane.

12.7.3 MONOVALENT ION SECRETION

In experiments in which isotopically labelled sodium, potassium and chlorine were infused intravascularly in frequently milked goats (Linzell *et al.*, 1976), maximum specific radioactivities in milk were achieved within 1 h, suggesting that the transfer process involved differs from the Golgi route described above.

The most widely accepted theory for monovalent ion secretion is that proposed by Linzell and Peaker (1971). It is based largely on PD determinations, tracer studies and measurements of concentrations of ions in ECF, intracellular fluid (ICF) and milk. In the transcellular process (i.e. involving passage across both basolateral and apical membranes of the cell), K^+ and Na^+ are distributed between ICF and milk in accordance with the PD across the apical membrane. The concentrations of Na^+ and K^+ are lower in milk than in the ICF but the ratio between them, 1:3 for most species, is similar in both fluids. Since Golgi-derived secretory vesicles appear to become incorporated into the apical membrane, it is postulated that K^+ and Na^+ are transferred into their lumina by the same process.

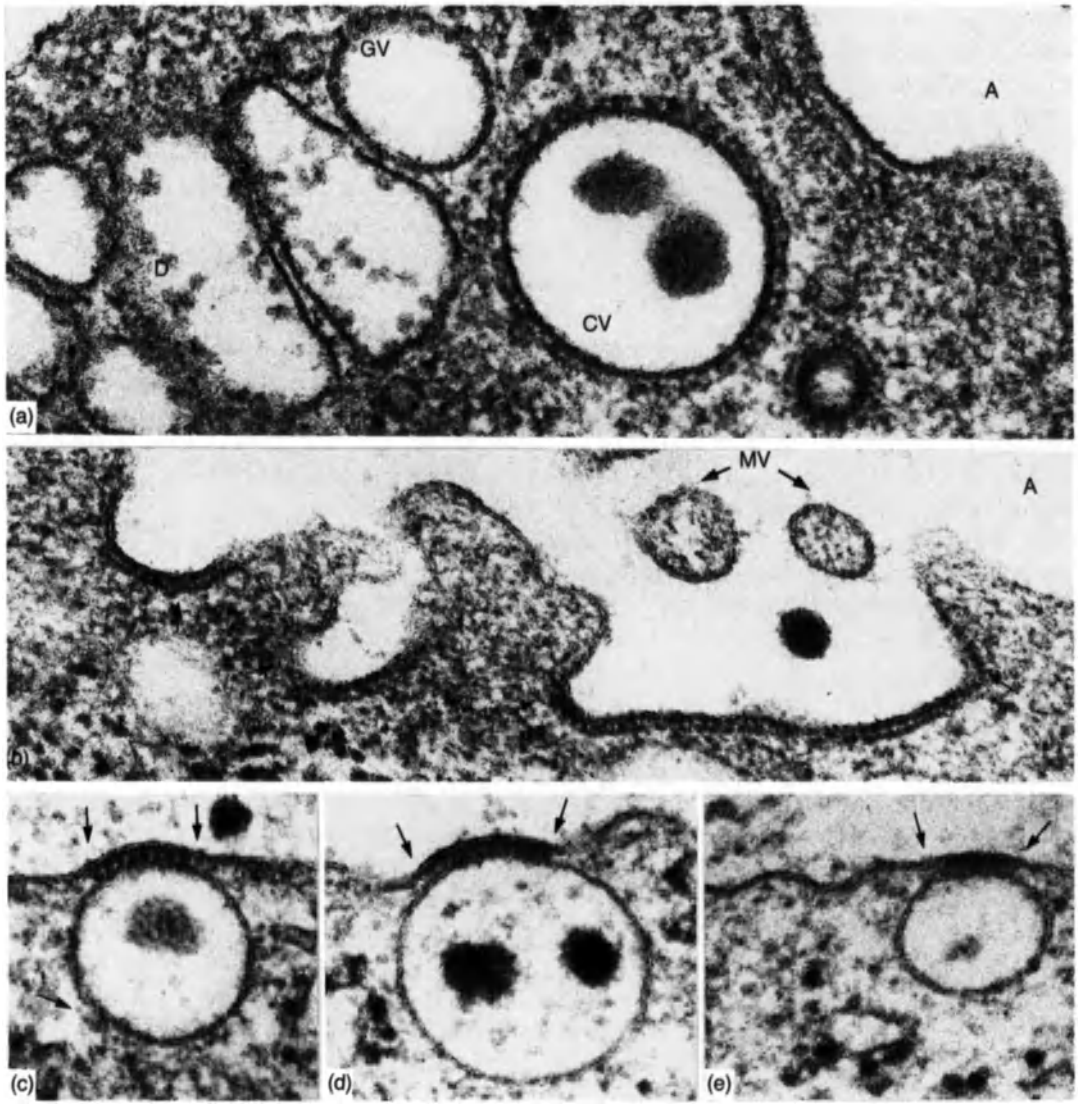

Figure 12.9 Electron micrographs of the apical region of secretory cells in lactating mammary tissue of a rat showing processes involved in the secretion of casein micelles. (a) The major types of vesicle are identified; GV, Golgi apparatus-associated vesicles with a smooth surface; CV, coated vesicles containing casein; arrow, smaller vesicles also coated on the cytoplasmic face. A = alveolar lumen (magnification ×97 750). (b–d) Pre-exocytotic attachment plaques forming between secretory vesicles and apical plasma membrane (short arrows): coated material is still present on some vesicles (long arrow in b) (magnifications: b ×85 000; c ×89 250; d ×93 500). (e) Integration of coat material of secretory vesicle membrane into apical plasma membrane (arrows); microvilli (MV) appear in cross-section (magnification ×95 000). (Reproduced from Franke *et al.*, 1976, with permission.)

The ICF concentrations of these ions are determined by a Na^+-K^+-activated ATPase, which histochemical studies indicate is confined to the basolateral surfaces of the cell (see Peaker, 1978).

The secretion of Cl^- does not, however, fit so readily into this scheme. Since both the electrical and chemical gradients would drive Cl^- from the cell into milk, it has been proposed that its low concentration in milk may be explained by reabsorption across the apical membrane, although other explanations might apply (Peaker, 1983). Thus, according to this hypothesis, milk concentrations of K^+ and Na^+ are maintained at low levels by the apical PD. Peaker's (1983) studies suggest that the PD is water-flow induced, in consequence of osmotic equilibration following lactose synthesis within the Golgi vesicles. Confirmatory evidence is provided by the decreased apical PD, with associated increases in milk K^+ and Na^+ concentrations, which resulted when isolated perfused goat mammary glands were deprived of a glucose supply (Peaker, 1977).

However, not all results obtained are consistent with the above scheme. For example, the studies of Berga and Neville (1985) on mouse mammary tissue suggest that the K^+/Na^+ ratios in intracellular fluid and milk are not the same. These authors postulated the existence of an active transfer system for Na^+ and/or K^+ at the apical membrane.

12.7.4 PARACELLULAR ROUTE

Whatever the precise nature of the transcellular route, a complicating factor in any definition of monovalent ion transfer to milk is the extent to which passage may occur **between** cells (the paracellular route). Most commonly, paracellular transfer is associated with the prepartum and involuting gland, but it may also occur in conditions in which the mammary epithelium is stretched (e.g. when the alveoli are distended with milk) or when the effectiveness of tight junctions is otherwise impaired (e.g. in mastitis). In such circumstances milk concentrations of Na^+ and Cl^- rise and those of K^+ and lactose fall, i.e. the gradients established by transcellular processes are partially offset by diffusion between the ECF and milk via leaky tight junctions (section 12.8.4). Depending on the degree of leakage, large molecules may also be involved, e.g. in late pregnancy α-lactalbumin may be detected in blood.

12.7.5 SECRETION OF MILK FAT

Autoradiographic studies showed that, within minutes of their intravenous injection, radioactively labelled fatty acids became associated with fat droplets in the mammary secretory cells (Stein and Stein, 1967). EM evidence suggests that TG molecules can be rapidly transferred, in the form of 'lipovesicles', to existing globules as they migrate from their sites of synthesis in endoplasmic reticulum towards the apical membrane (see Mather, 1987). In contrast, the appearance of isotopically labelled fat in secreted milk was only reached a maximum 5–7 h after the intravenous injection of fat precursors into goats (Linzell *et al.*, 1976). This is a much longer delay than for monovalent ions, lactose and proteins, and is indicative of a distinct secretory process.

It is presumed that, as for Golgi-derived secretory vesicles, cytoskeletal elements are important in intracellular migration of fat droplets, but it is transfer across the apical membrane which has attracted most attention, and indeed debate. According to the theory first proposed by Bargmann and Knoop (1959), as fat droplets reach the cytosolic face of the apical membrane they become enveloped by the latter, which eventually completely surrounds the 'pinched-off' fat globules present in the alveolar lumina (Figure 12.10).

Wooding (1977), on the other hand, claimed that fat droplet secretion depends on secretory vesicles, which by encircling the fat

droplets prior to their own fusion with the apical membrane effect fat secretion by a process which is, at least partly, exocytotic. Wooding denied the efficacy of 'pinching off' as an active secretory process, although admitting that milk fat globule membrane (MFGM) may acquire contributions from both secretory vesicles and apical sources.

Whether or not both apical and secretory vesicle membranes are involved, the nature of the attractive forces between them and the lipid droplets, which accomplish secretion of the latter from the cell, is a matter of considerable interest. As the cytosolic droplets come into contact with these membranes, a uniform dense layer of proteinaceous material (10–50 nm thick) is formed between the two surfaces so that in the MFGM of the secreted globule it is possible to identify four layers, namely, from the core outwards: (i) an

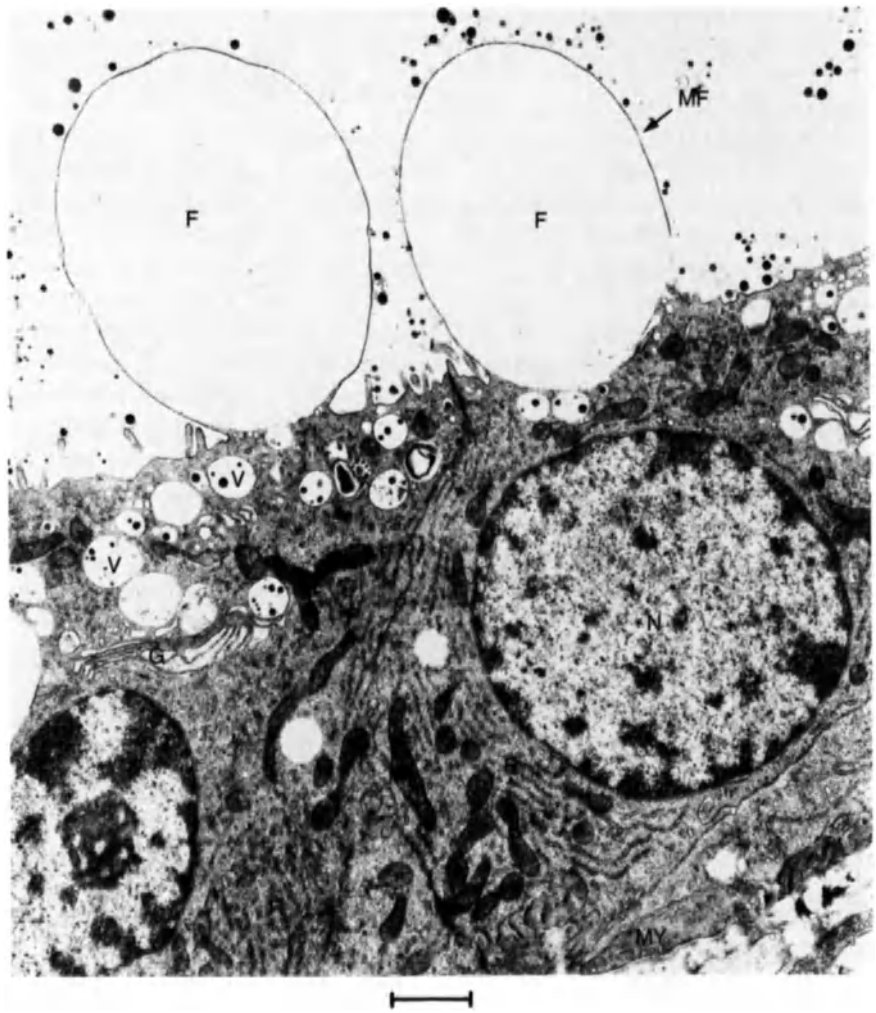

Figure 12.10 Electron micrograph showing secretion of fat droplets by two secretory cells in ovine mammary tissue (scale bar 1.0 μm). F, fat droplets; MF, milk fat globule membrane; V, secretory vesicle containing protein granules; N, nucleus; G, Golgi apparatus; R, rough endoplasmic reticulum, M, mitochondria; MY, myoepithelial cells. (Courtesy of Dr F.B.P. Wooding.)

amorphous layer of material derived from lipovesicles (<1 nm); (ii) the protein coat (10–50 nm); (iii) the lipid bilayer (10 nm); and (iv) the glycocalyx (<1 nm), a complex of glycosaminoglycans and oligosaccharide chains (Mather, 1987). The proteins of the second layer include butyrophilin and xanthine oxidase. The former is a mammary cell-specific glycoprotein which appears specifically located in the apical plasmalemma, the latter an enzyme distributed widely throughout the cell. The origin of elements of MFGM is thus diverse, and attempts at closer definition are complicated still further by EM evidence that intramembranous particles are cleared from the lipid bilayer during the process of secretion (Mather and Keenan, 1983).

Usually, globules of fat in alveolar lumina are simply surrounded by MFGM, although membrane material may subsequently be shed by a process of vesiculation (Wooding, 1977). In some cases, however (e.g. about 5% of fat globules in goat's milk), the globules have attached crescents of cytoplasm, often containing secretory vesicles and endoplasmic reticulum. It is surmised that these so-called 'signets' result from premature secretion caused by the mechanical stresses to which some cells may be exposed during milk ejection (Linzell and Peaker, 1971).

12.7.6 SECRETION OF IMMUNOGLOBINS

Ig molecules may either be derived from maternal plasma (e.g. IgG) or synthesized locally in the mammary gland by plasma cells in the lamina propria. In both cases secretion appears largely to involve transcellular passage following endocytosis. IgG1, though present in bovine plasma at roughly equivalent concentrations to IgG2, is highly concentrated in colostrum and milk. It is believed that IgG1 molecules bind, via their Fc domains, to specific receptors on the basolateral membranes of secretory cells and, following endocytosis, traverse the cytoplasm within vesicles (Lascelles, 1977).

The membrane receptors for polymeric Ig (e.g. IgA and IgM) transfer have been studied quite extensively. Following synthesis in the secretory cell, the receptor (a glycoprotein) is sorted to the basolateral membrane, where it binds to its polymeric Ig ligand. The receptor–ligand complex is then endocytosed and the endoplasmic vesicle shuttled to the apical membrane. Secretion of the complex, e.g. sIgA, involves exocytosis, but also cleavage of the receptor 'membrane anchoring domain' (Solari and Kraehenbuhl, 1987).

12.7.7 MEMBRANE FLOW

It is apparent that several of the secretory processes discussed involve either loss of membrane material from the cell (as in fat secretion) or transfer of membrane material from one cell organelle to another. Such observations imply that there is a continuous flow of membrane through the cells with selective additions and deletions of specific molecules occurring as membrane traverses the route: endoplasmic reticulum → *cis* Golgi vesicles → *trans* Golgi vesicles → secretory vesicles → apical membrane → MFGM. Moreover, it is likely that not only does membrane material flow, but that it is also recycled, since calculations for bovine mammary tissue indicate that the **net** gain of apical membrane from secretory vesicle fusion greatly exceeds the loss in MFGM. Reviews of research in this field are provided by Mather and Keenan (1983) and Mather (1987).

12.8 CONTROL OF MILK SECRETION

12.8.1 GENERAL

The factors modulating the rates of secretion of the various components of milk are clearly of paramount importance in terms of its adequacy in meeting neonatal nutritional requirements. For most, if not all, biological activity, two types of factor may be ident-

ified, often euphoniously categorized as 'nature' and 'nurture'. In the present context these might be expressed as 'genetic potential' and 'maternal nutrition', or more generally as 'endogenous' and 'exogenous' factors. Milk secretion is governed by the interaction of factors of these two types.

Earlier sections of this chapter have discussed numerous control points in the causal chain from food intake to milk output, including the metabolic priorities of the whole body, the substrate supply to the glands, carrier-mediated substrate access to the cell interiors and the subsequent synthetic processes involved in elaborating milk constituents. Chapter 11 deals with the predominant role of the endocrine system in controlling these processes. The object of this section is to summarize non-endocrine control factors operating at the level of the mammary epithelium which have not so far received attention.

One or two points are of wide applicability. Within a given species, genetic and environmental factors, together with limitations imposed by physicochemical determinants, act as significant constraints to fluctuations in milk composition. By and large, if milk secretion is proceeding, its composition will be fairly characteristic of the species concerned, at that particular lactational stage. This implies that the ultimate control of milk secretion may be subject to a single, or few, pivotal factor/s.

A second, rather self-evident, point is that secretory rate depends on the product of an intensity factor (the activity of the cells) and an extensity factor (their total number). The former is often gauged by the parenchymal RNA/DNA ratio, the latter by the total parenchymal DNA (i.e. DNA_t) (see Knight, 1984). Since secretory activity is reflected in the degree of differentiation of the cells, increases in the intensity and extensity factors correlate with cellular hypertrophy and hyperplasia respectively. Thus, increased milk output might be attributable to hypertrophy, hyperplasia or both processes together; decreased milk output to reduced cellular activity and/or reduced cell numbers, with necrotic cells not being replaced.

12.8.2 AUTOCRINE REGULATION

A unifying theme in these considerations is the concept of autocrine regulation. It has long been known that frequent milking of dairy animals leads to increased yields. For example, thrice-daily milking of cows (Archer, 1983) and goats (Henderson *et al.*, 1985) increased yields about 20% and 30%, respectively, above those obtained on the normal twice-daily routine. That this is not due to enhanced secretion of galactopoietic hormones is indicated by the fact that frequent unilateral milking (one gland only) of goats (Henderson *et al.*, 1983) and cows (Hillerton *et al.*, 1990) produces an increased yield only in that gland. While excessive physical distension of alveoli can reduce milk secretion, relief of that condition in frequently milked glands was not the explanation of the increased yields because it was achieved even when the milk removed was immediately replaced by an equal volume of isosmotic sucrose solution (Henderson and Peaker, 1984). Such observations led to the formulation of the hypothesis that enhanced yields in these experiments were due to more frequent removal of a locally active inhibitor present in the milk (Wilde and Peaker, 1990). Its inhibitory action has been demonstrated with mammary explants from mid-pregnant rabbits (Wilde *et al.*, 1987). In this bioassay system, progressive purification of the active agent was signalled by increasingly sensitive inhibition of lactose and casein synthesis. The inhibitor has been characterized as a heat-labile constituent of the serum protein fraction of milk, with a molecular weight of 10 000–30 000 daltons. It appears to act by negative feedback across the apical membranes of the mammary epithelium, and the dose dependence of the response indicates

that inhibition is determined by the concentration of the substance in the alveolar lumina (Knight *et al.*, 1988).

Whilst definitive identification of the putative autocrine regulator is lacking, there seems little doubt as to its importance in exercising fine control over the energetically expensive demands of milk secretion, such that supply is closely tailored to 'need'. This is perhaps best illustrated in species where a fixed 'teat order' prevails, e.g. pigs. A consideration which merits more attention than it has so far received is the necessity for an **increase** in inhibitory action with time if the galactopoietic effect of frequent milking is to be explained in terms of this autocrine regulator: the mere presence of the inhibitor in milk at constant concentration would not produce the observed results. Two types of factor can be identified (not mutually exclusive) which might transform a constant into an incremental inhibition: (i) a progressive increase in the intraluminal activity of the agent and (ii) a progressive increase in the sensitivity of the mammary epithelium to the agent. Conditions leading to (i) might include progressive increases in the rate of inhibitor secretion or activation following secretion (e.g. by proteolytic processing) and decreases in the extent of deactivation; conditions promoting (ii) might depend on changes in surface receptors or on conformational changes as cells are stretched due to alveolar filling.

12.8.3 MAMMARY CELL PROLIFERATION

A feature of the autocrine mechanism described is its acute nature. Frequent milking leads to a galactopoietic response within hours and on its discontinuation control yields are rapidly restored. When, however, frequent milking is continued for longer periods several response phases are identifiable (Wilde *et al.*, 1987). Within 10 days of the onset of frequent milking in goats the activity of two key lipogenic enzymes, acetyl CoA carboxylase and fatty acid synthetase, and of galactosyltransferase had significantly increased. But after 13 weeks of unilateral frequent milking, the activities of these enzymes did not differ between the thrice- and twice-milked glands despite the maintained elevation of milk yields in the former. Remarkably, RNA and DNA contents of the glands did not differ, implying that increased yields in the thrice-milked glands were achieved by greater efficiency of secretion from a stable cellular capacity.

In other experiments, 37 weeks after the onset of unilateral frequent milking, when yields in thrice-milked glands were 47% higher than controls, both parenchymal DNA_t and RNA/DNA ratios were significantly increased by frequent milking, whereas the activities of several enzymes were unchanged (Wilde *et al.*, 1987). These results suggest that frequent milking induces a series of distinct response phases: initially, acute autocrine mechanisms predominate, being succeeded by a hypertrophic phase and finally by a hyperplasic phase. Studies with [^{3}H]thymidine indicated that the latter was associated with increased cellular proliferation, but decreased cellular involution may also have been involved.

12.8.4 LOCAL FACTORS AT LACTOGENESIS

Evidence for a relationship between milk removal, cellular differentiation and secretory activity has also been reported for dairy ruminants during the periparturient period. For example, ultrastructural studies of mammary tissue from cows unilaterally milked prepartum showed markedly greater secretory cell Golgi development in milked than in non-milked glands (Akers and Heald, 1978), suggesting that the prepartum secretion is inhibitory to cellular differentiation. On the other hand, Linzell and Peaker's (1974) study of compositional changes in secreted ions of prepartum milked goats led them to propose that the secretions contained a factor which delayed the onset of lacto-

genesis by maintaining a paracellular leakage through the mammary epithelium. Removal of this factor thus led to 'tightening' of cell junctions and establishment of normal milk secretion. The studies on goats of Maule Walker and Peaker (1980) suggested that this local lactogenic inhibitor might be prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$), which is synthesized by the secretory cells. Just before parturition, the normal output of $PGF_{2\alpha}$ into mammary venous blood declines rapidly, whereas its concentration in mammary secretions increases. This implies a redirection of the excretory route for $PGF_{2\alpha}$ from one involving the basal membrane of the cell to that involving the apical membrane. Moreover, at this time the cells develop the capacity to metabolize $PGF_{2\alpha}$ to 13,14 dihydro-15, keto-$PGF_{2\alpha}$ ($DHKPGF_{2\alpha}$), releasing them from the inhibitory action of $PGF_{2\alpha}$ itself. Removal of excess $PGF_{2\alpha}$ in the milk by the neonate sustains this disinhibitory process (Maule Walker, 1984).

There thus appear to be at least two distinct autocrine factors which affect milk secretion at different lactational stages. Others have been proposed; for example, Gonzalez and Verly (1976) isolated a 2000 to 3000-Da compound from mammary tissue, which specifically and reversibly inhibited mammary DNA synthesis. Latterly there has been growing evidence for the involvement of peptide growth factors in control of mammary function, and it has been speculated that some may operate by an autocrine and/or paracrine process (see Dembinski and Shiu, 1987). There seems little doubt that unravelling the interaction between these putative local regulators and the wide array of systemic hormones which modulate mammary function will present formidable problems.

12.8.5 CELL NUMBERS

An important element of the gland's secretory activity may thus depend on its ability to increase or maintain secretory cell numbers during lactation. It has long been recognized that in rats and mice mammary cell proliferation continues post partum, contributing to the increasing milk yield in early lactation. But the realization that mammogenesis and lactation are not mutually exclusive processes in ruminants is relatively recent (Knight, 1984): in at least one dairy species, the goat, a significant increase in mammary DNA_t occurs in the first 3 weeks post partum (Anderson *et al.*, 1981). The natural changes in mammary development during lactation can be exaggerated by frequent milking (as described above) or by hemimastectomy, when compensatory hypertrophy of the remaining gland occurs (e.g. in goats; Knight, 1987). Few studies have been performed to evaluate the relative importance for secretion rate of changes in RNA/DNA ratio and DNA_t in the declining phase of lactation, but in rats reduction in RNA/DNA ratio seems more important (Knight *et al.*, 1984), whereas in goats falling yield is attributable to reduced DNA_t (Knight *et al.*, 1988).

12.8.6 INTERCELLULAR COORDINATION OF SECRETION

Since secretory rate is the resultant of the combined activities of individual cells, it is important to take account of controls which might operate at the supracellular level. The best-established factors are, of course, oxytocin and other humoral agents which stimulate myoepithelial cell contraction (Chapter 11), but the possibility of other mechanisms merits consideration.

Leaving aside pathological states, it is apparent that there is considerable cytological heterogeneity within even fully lactating glands. Thus, highly differentiated and largely undifferentiated cells can coexist in the same gland (Saake and Heald, 1974). On the other hand, within individual alveoli a high degree of secretory synchrony is usually apparent, both using histological techniques and in autoradiographic studies of the transit times of labelled milk precursors through

cells (Heald and Saake, 1972). There are, however, differences in transit times between equally differentiated alveoli both *in vivo* and *in vitro*. It is possible that local differences in intraalveolar pressure are responsible, via the postulated autocrine factor, but it is also conceivable that small molecules or ions (e.g. Ca^{2+}, Baumrucker, 1978) elicit pulsatile discharge of milk components (i.e. 'stimulus–secretion coupling'). If such secretory cycles were sufficiently rapid and temporally overlapping in different regions of the gland the outcome would produce the observed, fairly stable, secretory rate. The coordination evident between cells in a single alveolus is probably effected by agents permeating gap junctions (section 12.3.2).

12.9 TRENDS AND SIGNIFICANCE OF RESEARCH ON LACTATION

We conclude this chapter with a short survey of current trends in research on lactation, together with an assessment of the importance of present and future developments.

Lactation, directly or indirectly, plays a fundamental but largely unrecognized role in human welfare. In nutritional terms, breast milk provides totally for the requirements of younger infants, while animal milk does so significantly for many millions of adults. Lactation in non-dairy animals may also be vital in the rearing of livestock used for meat, and for countless other purposes, such as transport and draught power. In economic terms, milk is a major commodity, a fact which stems from the highly diverse nature of dairy products, e.g. butter, cheese, yoghurt, kumiss. For the vast majority of women, worldwide, lactation is the principal regulator of fertility, whereas breast cancer is one of the commonest causes of morbidity and mortality in the West. It is thus not surprising that most research on lactation is perceived as having foreseeable practical applications. But in addition, mammary tissue has proved to be very suitable material for those pursuing questions of much wider applicability; for example, fundamental studies on biochemical control processes are facilitated by the high metabolic activity of lactating tissue and its exquisite sensitivity to many hormones.

Historically, the medical context took precedence over that of dairying. If we regard von Haller's *Elementa Physiologiae Corporis Humani* (1778) as marking the beginning of modern physiology, for almost a hundred years virtually all scientific treatises which dealt with lactation were concerned primarily with its manifestation in women, e.g. the works of Young (1761) and A.P. Cooper (1840). Scientific interest in milk production in animals only developed with the industrialization of dairying in the latter half of the nineteenth century, leading to the publication of such important books as those by Furstenburg (1868) and Fleischmann (1896), and from then until only very recently the dairying context was dominant in lactational physiology. Recently, in the West, this situation has changed: as a result of milk production outstripping demand there has been a marked, if short-sighted, reduction in investment in dairy research.

Research of significance to human lactation has three principal goals: (i) definition of the physiological roles and control of breastfeeding to allow for prevention and/or correction of dysfunctions; (ii) definition of the composition of breast milk to permit formulation of acceptable substitutes; (iii) elucidation of factors instrumental in the diagnosis, causation, amelioration and cure of breast cancer. There is a sense in which the first two objectives are in conflict; and it is somewhat paradoxical that the commercial motivation to manufacture artificial milk (based on cow's milk) has only served to establish how different the compositions of human and cow's milk are, and how superior breast milk is to any contrived substitute. At a trivial level, attempts to mimic breast milk are reminiscent of Aesop's fable of the tortoise and the hare:

every 'improved' formula is rendered obsolete by deeper understanding of the nature of milk. The more serious aspect is the grave consequences of misapplication of this Western technology in developing countries, and, indeed, in the poorer sections of developed countries (e.g. Mepham, 1989a). Human lactation is discussed in recent books by Jelliffe and Jelliffe (1978), Neville and Neifert (1983), Jensen and Neville (1985), Schaub (1985), Hamosh and Goldman (1986) and Goldman *et al.*, (1987) and in two WHO reports (1981,1985).

Much research on mammary tissue is focused on the third objective above, i.e. tackling the problem of breast cancer, which in Britain and the USA is a common cause of morbidity and mortality in women. Most approaches build on the apparent hormone dependence of the disease (Angeli *et al.*, 1986), although fundamental cytological studies are also of undoubted importance. A link with breastfeeding is indicated by the claim that the incidence of premenopausal breast cancer is inversely related to earlier breastfeeding duration (McTiernan and Thomas, 1986).

Studies on the physiology and biochemistry of lactation form but a small segment of the field of dairy research, which encompasses chemical, microbial and engineering technology as well as agronomic, management and economic aspects of dairy husbandry. In the past, the benefits of physiological research seem to have related most directly to feeding systems for dairy animals and indirectly to procedures adopted in breeding, housing, milking and veterinary treatment. Attempts to manipulate milk yields by endocrine intervention, through mammogenic and galactopoietic responses, have been made for at least 50 years, but it is only recently that the prospect has appeared commercially viable. Large-scale production of bovine growth hormone (or somatotrophin, bST) by genetic engineering techniques, which it is proposed to administer regularly to cows by subcutaneous injection, has been claimed as 'the herald of a new technological era' (D.R. Baldwin, 1987). Critics focus on the undesirable social consequences of introducing a treatment which markedly increases milk yield in countries already producing a surplus (Mix, 1987) and on potential problems for animal welfare (Kronfeld, 1987). Whatever the merit of milk yield-enhancing technology in developed countries, there can be little doubt that appropriate research directed to increasing milk yields in poorer countries holds the promise of substantial development in both nutritional and economic terms (Mepham, 1987b). The problems encountered and strategies for their solution are discussed in the conference proceedings edited by A.J. Smith (1985). For other reviews on the physiology of lactation in dairy animals see the books edited by Larson (1985), Gravert (1987) and Garnsworthy (1988).

Genetic engineering also presents the prospect of exerting control over milk yield and composition in ways not even imagined only a few years ago. For example, growth hormone genes have been injected in porcine ova just following fertilization to produce transgenic animals. Were this technique to be applied successfully to dairy animals, it is possible to envisage a rapid and permanent improvement in productivity in developing countries (Hodges, 1986). However, such optimism could prove unfounded if improvements are not also made in animal nutrition, which is usually the major constraint to increasing milk yields in developing countries (Mepham, 1991).

Appropriate manipulation of other genes could, in theory, be used to effect compositional modification. For example, production of a low-fat milk would be found more acceptable by many in Western countries in which there is concern over the alleged association between ischaemic heart disease and saturated fat intake (Committee on Medical Aspects of Food Policy, 1984), and a

lactose-free milk would be a boon to many millions for whom consumption of raw milk is limited by the condition of lactose malabsorption (Paige and Davis, 1985). A striking demonstration of the capabilities of genetic engineering is the production by lactating transgenic sheep of pharmaceuticals for use in human medicine (Clark *et al.*, 1989). The potential for control by immunological means is suggested by results indicating the importance of autocrine control of milk secretion: isolation of the factor involved, and the raising of an antibody to it, might enable the suppression or stimulation of yields, respectively, according to requirements. Some of the wider issues presented by biotechnological advances in dairying are discussed by Mepham (1989b,c, 1991, 1992).

Another important development of recent years is the study of the energetics of lactation in the context of parental investment. Until they are weaned, young mammals receive all, or almost all, their energy requirements for maintenance and growth from maternal milk. Consequently, litter growth represents a meaningful index of maternal investment. The significance of the post-natal growth phase in mammals lies in the fact that a large proportion of the energy requirements for reproduction in females is associated with lactation (e.g. 75–80% in ungulates). Species survival is thus ultimately dependent on effective partitioning of energy between mother and infants, and elucidation of the means by which this is achieved in different species promises to provide valuable new insights into the evolutionary adaptation of reproductive processes to environmental conditions. The reader is referred to the volume edited by Loudon and Racey (1987) for discussion of these important questions.

uterus *170*, *171*
Ultrasonography for monitoring pregnancy 568
Urodele embryonic membranes 298
Urogenital sinus differentiation *610*, 611–12
Uteroferrin 308
Uteroglobin 102–3, 179, 883
Uterus
activity
and oestrogens 871
oxytocin 871–2
and prostaglandins 891
cell death 175–6
cell differentiation 168–73
glands 171–2
hormonal control 173–5
luminal epithelium 168–71
stroma 172–3, *173*
cell proliferation 164–5, *164*
hormonal control 165–7
intracellular mechanisms 167–8
closure 163–70, *170*, *171*, 288
decidual cell reaction 186–202
eicosanoid production, human 875–7
epithelium

glandular, hormonal control 174
response to blastocyst 184–6
lumen 168–71, *169*
epithelium, hormonal control 174
marsupial 710–15
morphology 162–4, 164
myometrium, sensitivity to prostaglandins 927–8
preparation for implantation, oestrous cycle 162–4
quiescence, maintenance by progesterone 869
sensitivity 180
in marsupials in diapause 700
stroma, hormonal control 174–5
trauma 189, 196–9

Vagina development 611
Vasopressin 809, 839, 1049
corticotroph responses 1023, 1025, 1029
release by prostaglandins 1017, 1021, 1027
stimulation of β-endorphin 1017
in tammar pituitary 727
Viviparity
evolution of 425–8
functional requirements 425
Virus-like particles in embryos 105

Wallaby, agile (*Macropus agilis*) (marsupial)
asynchromous lactation 743, *747*
mammary gland sensitivity 1050
Wallaby, Bennett's (*Macropus*) (marsupial)
prolactin in lactation 1038, 1041, 1043
Wallaby, swamp (*Wallabia bicolor*) (marsupial) 679
Wallaby, tammar (*Macropus eugenii*) (marsupial)
adrenal development 727–8, *728*, 735
annual cycle *682*
blastocyst in diapause *689*, *690*
corpus luteum
function 706–10, *707*, *708*, *709*
histology *681*
early cleavage *687*
embryo
development *724*
growth *695*
endometrial histology *681*
hormones
after corpus luteum excision *708*, *709*
concentrations in pregnancy, parturition and post-partum oestrus *684*, *702*, *734*, *735*
control of diapause *705*
intramammary pressure *749*, 1049, 1050
lactation
diapause 1067
intramammary pressure *749*, 1049, 1050
milk composition *744*
milk sugar 1145
myometrial activity in parturition 729, 731, *731*
oestrous cycle–pregnancy relationships *682*
organogenesis **730**
oxytocin 1049, 1050
parturition, control of *738*
pituitary development 725
preattachment phase *719*
placenta
steroid metabolism *718*
ultrastructure *717*
post-natal maturation **740**
pouch young *739*
pregnancy hormones **712**
progesterone
and endometrial weight *713*
after hypophysectomy *697*
prolactin *742*, 1038, 1041, 1042
and LH receptors in luteal tissue *698*
protein incorporation in diapausing blastocyst *701*
response
to oxytocin *697*
to prolactin *697*
to reserpine *697*
sexual differentiation 725–6
steroid hormone interactions in pregnancy *719*
Whale, first gasp 825
Wolffian duct 607, *608*

Yolk sac 236–8, *237*, *242*, 270–1
absorption 270–1
placenta
bilaminar 270
in cartilaginous fish 293–4
completely inverted 271
incomplete/partly inverted 270–1
trilaminar 270
placentation 270–1

Zygote, definition 94
Zona pellucida
formation 16–17
hatching 181–2

AUTHOR INDEX

Numbers in roman refer to authors cited in the text; those in **bold** refer to citations in the reference lists.
Given an index of this size the editor apologizes for any omissions.
