During a normal 24-h day the body's essential cellular and organ functions remain homeostatic despite intermittent nutrient intake and changing metabolic demand. A highly sophisticated and integrated system provides the metabolic adaptation for these normal changes in substrate provision and utilization. A basic knowledge of the normal metabolic responses in the feeding–fasting cycle is pivotal to the understanding of the changes that occur during periods of prolonged fasting and starvation. In this review of the biochemical aspects of the metabolic responses to fasting and starvation, the term 'fasting' is defined as the total absence of nutrient intake, whereas 'starvation' is defined as a prolonged period of inadequate food intake. During a period of prolonged fasting, the body undergoes a sequence of changes that include the initial depletion of fuel stores and metabolic adaptation. However, if fasting continues, metabolic decompensation will occur, finally resulting in death. The extent and rate of progression through these steps depend on the amount of fuel stores at initiation of the fast, the severity and duration of nutritional deprivation, and the presence or absence of a significant catabolic stress, such as injury, sepsis, or cancer (**Table 1**).

The Feeding–Fasting Cycle

Energy Requirements

Energy is essential for many important body functions, including the maintenance of cellular integrity and function, new tissue synthesis, thermoregulation, and

Table 1 Metabolic features and laboratory parameters of starvation and fasting

	Uncomplicated protein energy malnutrition (Marasmus)	*Hypoalbuminemic malnutrition (Kwashiorkor)*	*Stressed malnutrition (mixed)*
Etiology	Decreased energy intake	Decreased protein intake associated with catabolic stress	Decreased energy and protein intakes associated with catabolic stress
Metabolic adaptation			
Weight loss	Slow (months to years)	Intermediate (weeks to months)	Rapid (weeks)
Resting energy expenditure	Decreased	Decreased or increased	Increased
Nitrogen loss	Minimal	Increased	Increased
Water, sodium	Initial loss	Retention	Retention
Hormonal	Early small increase in catecholamines, glucagon, cortisol, growth hormone; then slow decrease	Increase in catecholamines, glucagon, cortisol, growth hormone	Increase in catecholamines, glucagon, cortisol, growth hormone
	Decrease in insulin, leptin	Decrease in insulin, leptin	Decrease in insulin, leptin
Laboratory parameters			
Albumin	Normal–slowly decreased	Decreased	Decreased
Transferrin	Normal–slowly decreased	Decreased	Decreased
Total lymphocyte count	Normal–slowly decreased	Decreased	Decreased
Skin hypersensitivity	Decreased	Decreased	Decreased

physical activity. The energy requirements of an individual vary with age, sex, body composition, physical activity, and stress. In the normal adult at basal state, approximately 75% of energy requirements reflect the energy needs of major organs (brain, ~20%; skeletal muscle, 18–22%; abdominal muscles, ~25%; and heart, ~11%). However, during normal daily activity the total energy requirement and the proportion of energy needed by different tissues may vary considerably. For example, with exercise the energy requirement of skeletal muscles increases, and during a meal the abdominal organs require more energy for the process of digestion and absorption. Children require additional energy for growth.

Energy Production

The body derives energy from the metabolism of carbohydrate, fat, and protein provided exogenously in the fed state and endogenously in the postabsorptive state. A mixture of metabolic fuels, including glucose, triacylglycerols, ketone bodies, nonesterified fatty acids, alcohol, and amino acids, are present in the circulation. The proportion of these energy substrates in the blood at any one time depends on the fed or fasting state of the individual, the extent of fuel stores, and recent or current metabolic demand. In a normal, nonobese, 70-kg adult there are approximately 500 MJ (120 000 kcal) contained in adipose tissue, 100 MJ (24 000 kcal) stored in muscle and visceral proteins, and 4.2 MJ (1000 kcal) stored as liver and muscle glycogen. During a normal day, half of the total energy requirement is met by carbohydrate metabolism. At this rate, glycogen stores would be exhausted after 1 or 2 days of fasting. However, glycogen stores are maintained for a longer period due to the production of glucose from gluconeogenesis (**Figure 1**).

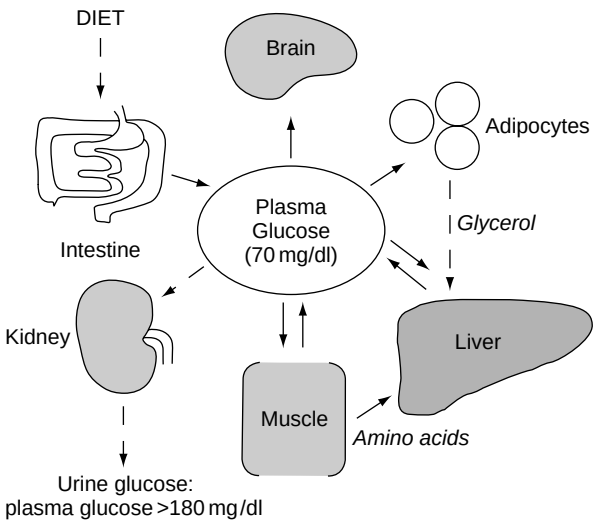

Figure 1 The metabolism of energy substrates to maintain glucose homeostasis.

Carbohydrate metabolism Glucose plays a key role in body metabolism. It is the preferred metabolic fuel for many tissues and is an essential fuel for the retina, red blood cells, the renal medulla, and the brain under normal conditions. In the fed state, glucose is derived from the digestion and absorption of carbohydrates provided in the meal. To produce energy from glucose, three metabolic pathways are involved (**Figure 2**). Glucose is first oxidized to form pyruvate via the glycolytic pathway. Pyruvate then enters the Krebs cycle and is completely oxidized to form NADH + H, $FADH_2$, and carbon dioxide. The NADH + H transports hydrogen to the respiratory chain, where it is used to reduce oxygen to water. The net yield of energy from the metabolism of 1 molecule of glucose is 38 molecules of ATP.

Because of the strict glucose requirements of the brain, the circulating blood glucose pool is tightly controlled at approximately 16 g. Three important mechanisms are responsible for this regulation:

1. Insulin enhances glucose uptake into muscle and fat and stimulates glycogen synthesis. It also inhibits lipolysis, glycogenolysis, and gluconeogenesis. High insulin levels will decrease blood glucose levels. Conversely, low insulin levels will cause a rise in blood glucose by decreased inhibition of glycogenolysis and reduced peripheral uptake of glucose.
2. Glucagon increases liver glycogen breakdown, gluconeogenesis, and ketogenesis from fatty acids. It also stimulates lipolysis from adipocytes in extrahepatic tissue. The net result of glucagon activity is an increase in blood glucose concentration that helps to maintain blood glucose levels despite the effect of insulin.
3. Neuroendocrine responses to glucose deprivation in the brain act to rapidly increase glucose release from liver glycogen.

The fed state is characterized by increased blood concentrations of glucose, amino acids, and fat. Insulin secretion is stimulated while glucagon levels remain unchanged or are decreased. As a result, there is increased glucose uptake into tissues and enhanced glycogen, protein, and triacylglycerol synthesis. Glucagon balances this effect by stimulating glycogen breakdown to maintain blood glucose levels. By this mechanism, blood glucose levels are controlled during periods of surplus carbohydrate ingestion and excess glucose is stored as glycogen or fat.

Glycogen is a complex hydrated polymer of glucose arranged in a highly branched, spherical form. It allows

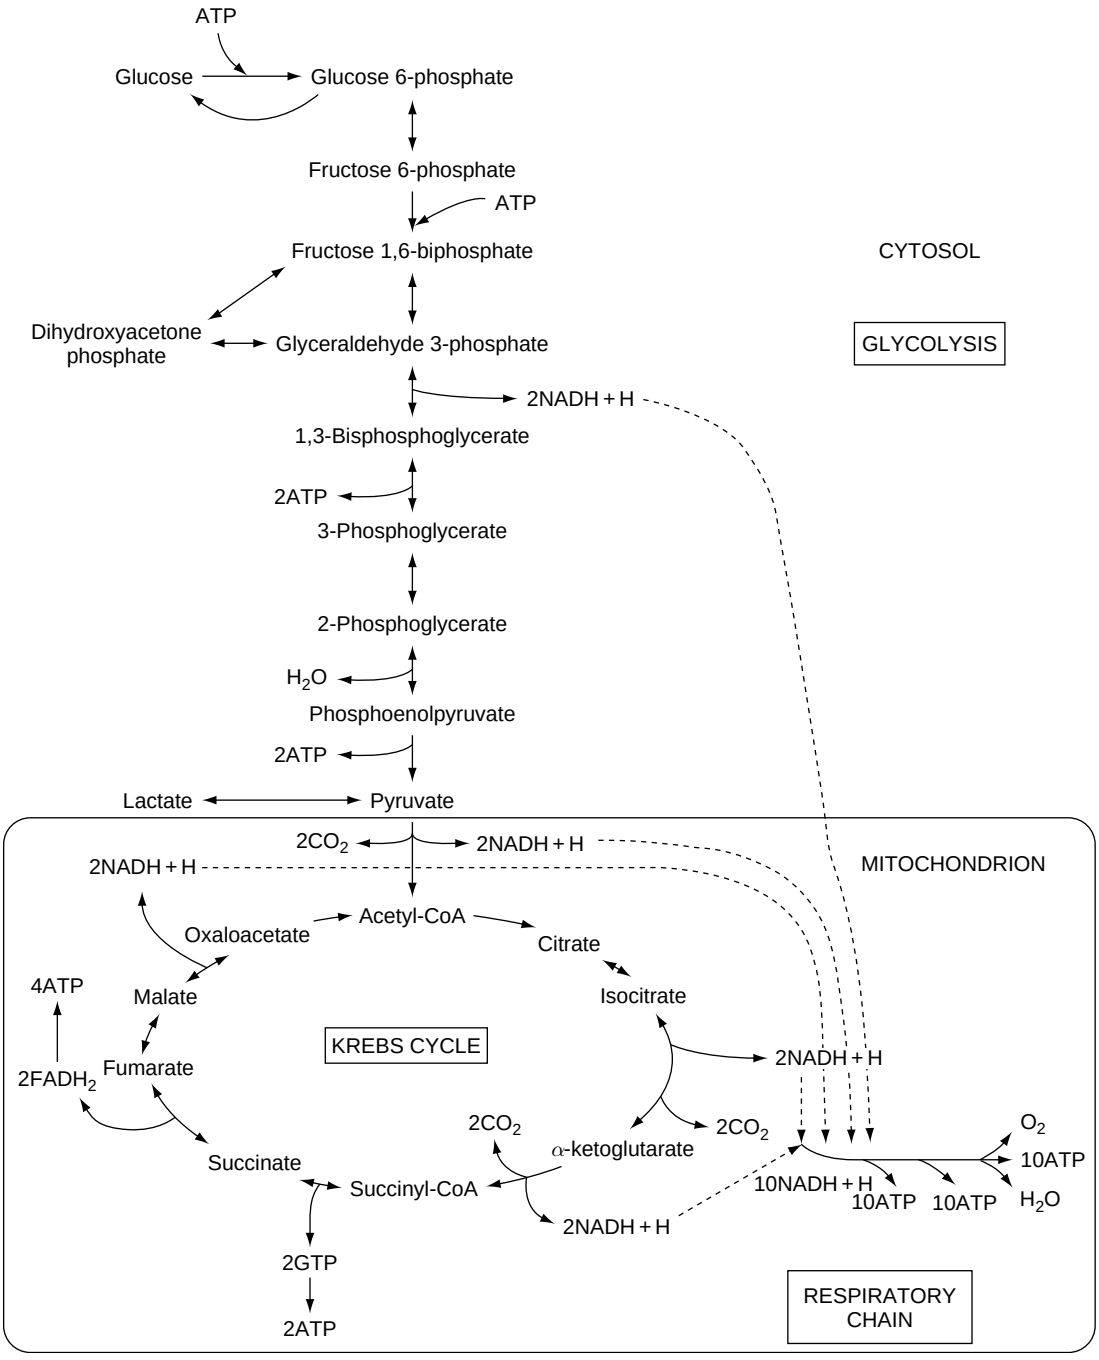

Figure 2 The production of energy from glucose via the glycolytic pathway, the Krebs cycle, and the respiratory chain.

glucose to be stored in large amounts without causing osmotic shifts. The terminal glucose molecules within this branching structure are accessible to the enzymes mediating glycogen breakdown to allow the rapid release of glucose in times of stress. The glycogen molecule expands in size after a carbohydrate-rich meal to approximately 40 nm in diameter and shrinks to 10 nm in diameter or less between meals. An adult male receiving a normal carbohydrate-containing diet has approximately 70 g of liver glycogen and 200 g of muscle glycogen. Glycogen is broken down by the enzyme phosphorylase. Glucose-6-phosphatase continues the breakdown of glycogen to glucose in the liver. Muscle glycogen is metabolized by anaerobic glycolysis to form pyruvate and lactate. Lactate is then transported to the liver, where it acts as a precursor for gluconeogenesis. This is called the Cori cycle (**Figure 3**). The Cori cycle contributes to approximately 40% of the normal plasma

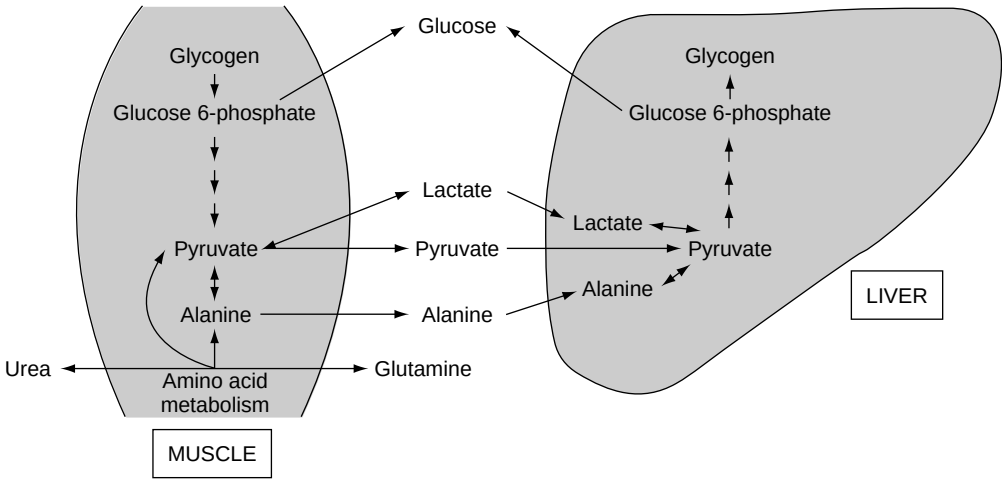

Figure 3 The metabolism of muscle glycogen and protein to form glucose involving the Cori cycle (lactate to glucose) and the glucose–alanine cycle.

glucose turnover. It has the advantage of providing energy (net 3 molecules of ATP) without the loss of glucose molecules. The energy required for the resynthesis of glucose in the liver is derived from fatty acid oxidation. The total body glycogen stores can meet the needs of the brain for approximately 3 days. After this period, alternative sources of metabolic fuel must be found.

Protein metabolism Body nitrogen resides in two main compartments. Approximately half of the body's nitrogen is contained in extracellular tissues such as collagen. The nitrogen present within these tissues is relatively fixed and does not change significantly with starvation. The nitrogen turnover within this compartment can be assessed by the measurement of hydroxyproline excretion. The remaining nitrogen is present in the lean muscle mass, comprising skeletal and visceral muscle. The proteins within these tissues are constantly being broken down and resynthesized at a rate of 3–3.5 g/kg/day in a young adult. Measurement of urinary 3-methylhistidine excretion and creatinine excretion can be used to estimate the fractional catabolic rate of skeletal muscle.

Protein synthesis and degradation involves several independent metabolic systems. The autophagic–lysosomal pathway facilitates most of the proteolysis occurring in the body. Another pathway, the proteasome–ubiquitin system, plays a central role in the degradation of specific proteins. For example, the proteasome is involved in the rapid regulation of many rate-limiting enzymes. The proteasome also mediates the loss of skeletal muscle protein in starvation and wasting disorders. The 26S proteasome consists of a proteolytic core complex, the 20S proteasome, and two 19S regulatory complexes. Substrates are conjugated with multiubiquitin chains before degradation. The autophagic–lysosomal system is regulated by plasma amino acid levels, whereas no such feedback mechanism has been demonstrated for the ubiquitin–proteasome pathway. The fatty acid, eicopentenoic acid, has been shown to downregulate ubiquitin-dependent proteolysis in mice after acute starvation. Furthermore, experimental data in starved rats suggest that ubiquitin–proteasome-dependent muscle proteolysis is ameliorated in response to insulin release and refeeding. The exact mechanisms involved in the regulation of ubiquitin–proteasome-dependent proteolysis are not completely understood.

Both autophagic–lysosomal and ubiquitin–proteasome pathways generate amino acids as their final product. Glutamine is the most abundant amino acid in humans. It is an important energy substrate for monocytes and the gut. Depletion of glutamine during starvation or chronic illness has been shown to inhibit the ubiquitin–proteasome proteolytic pathway and may contribute to impaired immune function of monocytes during starvation or critical illness.

In the fed state, amino acids digested and absorbed in excess of the body's immediate requirements for incorporation into proteins or other molecules are either oxidized for energy or metabolized to glycogen or fat. Protein provides approximately $17\,kJ\,g^{-1}$ ($4\,kcal\,g^{-1}$) of energy when metabolized as an energy source.

Prolonged fasting results in depletion of liver and muscle glycogen stores. In this clinical setting the conversion of amino acids to glucose contributes to the glucose requirements of the brain. The transition to metabolism of amino acids as an energy source is

mediated by an alteration in the balance of insulin and glucagon. The breakdown of tissue protein to provide glucose results in a sustained loss of body nitrogen of approximately 12 g per day. Experimentally, this loss of body nitrogen can be prevented by the administration of glucose. As a result of muscle protein breakdown, amino acids, predominantly alanine and glutamine, are released into the circulation. However, the amount of alanine released exceeds the alanine content of the muscle protein. This is because approximately one-third of the alanine released from muscle originates directly from the muscle protein, whereas the remaining two-thirds is derived from pyruvate. Pyruvate is formed by the metabolism of muscle glycogen or by the transamination of other amino acids contained within the muscle protein. Alanine is then transported to the liver, where it is rapidly taken up and converted to glucose: This is known as the glucose–alanine cycle (**Figure 3**). Despite the increased release of alanine from muscle, plasma alanine levels decline in early fasting. This results from the rapid uptake and conversion of alanine by the liver.

Fat metabolism Fat is an efficient store of energy providing approximately $38\,kJ\,g^{-1}$ ($9\,kcal\,g^{-1}$). Fat is predominantly stored as triacylglycerols within adipocytes. The amount of fat stores may vary substantially among individuals. In the fed state, insulin stimulates triacylglycerol synthesis. During fasting, triacylglycerol is converted to fatty acids and glycerol (**Figure 4**). Within days, glycerol and palmitate release increases by two or three times fed levels. This release is regulated by hormone-sensitive lipase. Due to the absence of glycerol kinase in white adipose tissue, glycerol cannot be completely metabolized within the adipocytes and is transported to the liver, where it is converted to glucose by gluconeogenesis. The fatty acids are either released from the adipocytes to be oxidized by the liver or other tissues or may be reesterified with glycerol 3-phosphate and reenter the cycle to form triacylglycerol (**Figure 4**). The energy cost of reesterification of fatty acids in starvation may account for 2 or 3% of the resting energy expenditure.

Oxidation of long-chain fatty acids (LCFAs) requires the mitochondrial carnitine system for transport into the mitochondrial matrix. This transport system consists of several enzymes, including the malonyl-coenzyme A (CoA)-sensitive carnitine palmitoyltransferase I (CPT-I), carnitine:acylcarnitine translocase, and CPT-II. CPT-I is regulated at

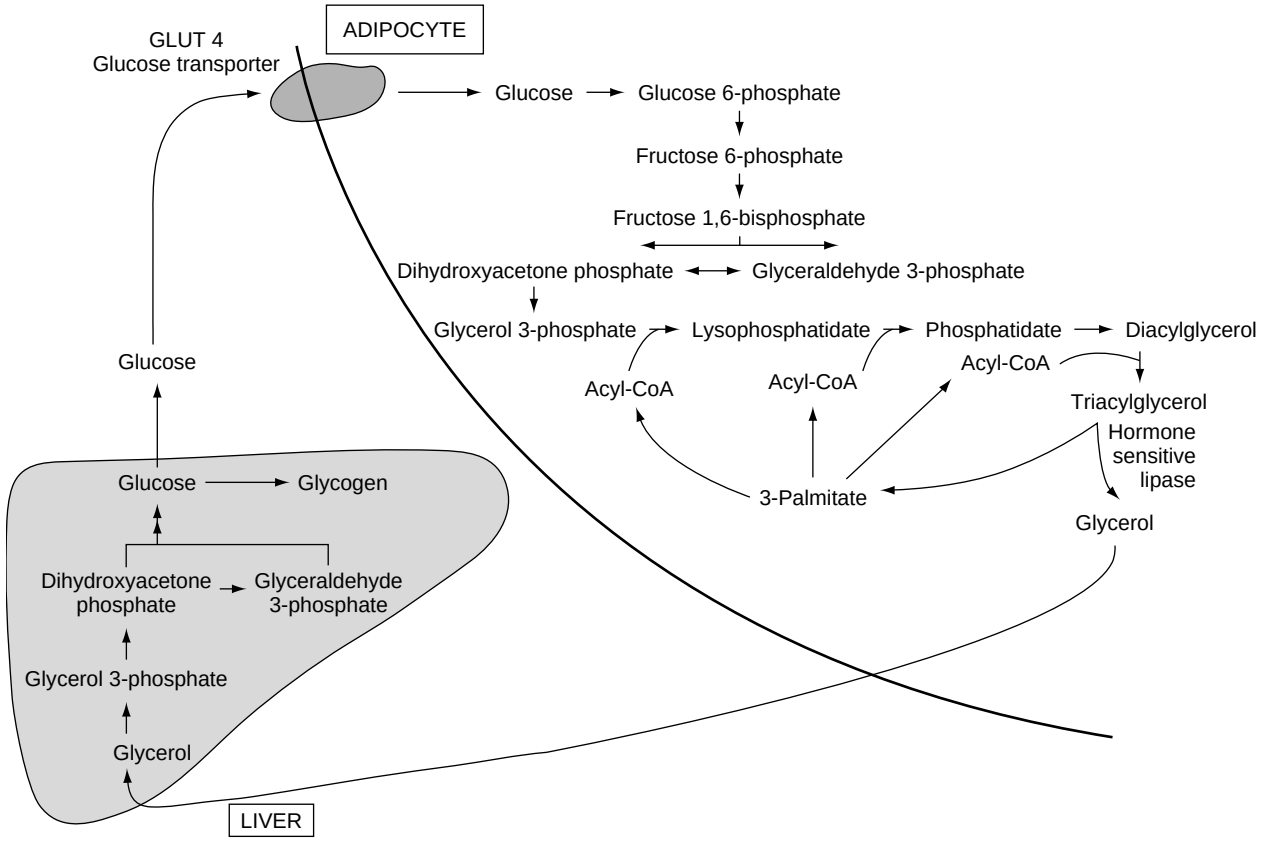

Figure 4 The triacylglycerol–fatty acid cycle.

the transcriptional level by malonyl-CoA. Although carbohydrates are the major energy source during high-impact exercise, LCFAs are the preferred substrate during endurance exercise. In human skeletal muscle, during exercise free carnitine appears to play a greater regulatory role on LCFA oxidation than malonyl-CoA. However, some aspects of the transport of LCFAs to the inner mitochondrial matrix in humans are not completely understood.

Most of the acetyl-CoA produced from fatty acid oxidation is metabolized to acetoacetate, which in turn may be converted to β-hydroxybutyrate and acetone. These products are known as ketone bodies. Acetyl-CoA is also converted to malonyl-CoA, catalyzed by the enzyme acetyl-CoA carboxylase. Although ketone bodies are produced in small quantities in the fed state, they are generally metabolized by the liver and are not released into the circulation. During fasting, the rate of production of acetoacetate and β-hydroxybutyrate significantly increases. These metabolites are released into the circulation and can be used by the brain and other tissues as an alternative energy source.

Metabolic Consequences of Fasting and Starvation

Postabsorptive State

The postabsorptive state commences when the last nutrient is absorbed from the previous meal and continues until the next meal or for approximately 12 h during a normal overnight fast. Metabolically, it is the period when there is a transition from exogenous energy consumption to reliance on endogenous energy sources. The release from the liver of approximately 200–250 g of glucose per day or 8–10 g per hour balances the rate of glucose utilization of the brain and other tissues. During an overnight fast, a significant proportion of the glucose requirements are met by the breakdown of liver glycogen. The remaining glucose is formed from noncarbohydrate sources: glycerol (from triacylglycerols), pyruvate, and lactate (from muscle).

Prolonged Fasting

In a normal adult, resting energy expenditure is proportional to lean body mass. Prolonged fasting is associated with a loss of lean body mass and in a reduction in resting energy expenditure. Fourteen to 21 days after commencing a starvation diet there is a 15% reduction in resting energy expenditure. However, at this time there is only a 5% reduction in lean body mass. Clearly, another mechanism contributes to the decreased resting energy expenditure observed in early starvation.

A number of hormonal changes occur as a response to starvation that may alter resting energy expenditure. Decreased activity of 5′-monodeiodinase in the liver and peripheral tissues resulting in a reduction in the conversion of thyroxine (T_4) to the metabolically active form, triiodothyronine (T_3), has been observed within hours to days in patients on a starvation diet. This effect is modified by both the carbohydrate intake and the total energy content of the diet. However, the mechanism linking low circulating T_3 levels to decreased resting energy expenditure in starvation is not well understood. Catecholamine secretion and turnover is decreased in uncomplicated starvation. This is clinically recognized as a reduction of core temperature, heart rate, and blood pressure in patients during starvation. Another factor contributing to the reduced resting energy expenditure observed in patients during starvation may be a reduction in the activity of the sodium–potassium pump. The activity of this pump is influenced by circulating T_3, catecholamines, and insulin—all known to be altered in starvation. There is evidence that in prolonged starvation increased intracellular sodium and decreased intracellular potassium are linked to decreased pumping of sodium from cells.

With increasing duration of the fast and depletion of liver and muscle glycogen stores, the conversion of amino acids to glucose contributes to the glucose requirements of the brain. The transition to metabolism of amino acids as an energy source is mediated by a change in balance of insulin and glucagon. Insulin levels decline, whereas glucagon levels tend to be maintained or even slightly increased. During early fasting, the muscle releases alanine and glutamine. The glucose–alanine cycle provides glucose to the muscle in exchange for alanine provided to the liver as a precursor for gluconeogenesis (**Figure 3**). Blood levels of the branched-chain amino acids double after 3–5 days of fasting but decrease if fasting is prolonged. This decrease in plasma levels results from the rapid uptake of alanine by the liver for conversion to glucose. Glutamine released from the muscle during fasting is preferentially taken up by the intestine, where it is used as an energy source, and by the kidney, where it is used for renal ammonia production. Although the metabolism of amino acids to glucose is a very important metabolic adaptation to fasting, it provides only approximately 45 g of glucose per day. This amount alone is insufficient to meet the glucose requirements of the brain and must be supplemented by energy produced from fat metabolism. Based on data from glucose balance studies, during a 24-h fast the liver contributes 80–90% of glucose production and the kidney 10–20%. However, if fasting is extended from

12 to 60 h there is a 2.5-fold increase in renal glucose production, whereas glucose production from the liver decreases by 25%.

The mobilization of triacylglycerol stores to provide energy is regulated by a number of factors. Insulin levels decrease by 35% within 24 h of fasting. This is associated with a 50–80% increase in the rate of lipolysis. Low circulating insulin levels cause a reduction in the uptake of glucose into adipocytes by altering the function of the GLUT4 glucose transporter (**Figure 4**). Lipolysis is also stimulated by glucagon and adrenocorticotrophic hormone (ACTH) during starvation. This effect is mediated by cyclic AMP-dependent protein kinase, which stimulates hormone-sensitive lipase (**Figure 5**). In prolonged starvation, cortisol increases hormone-sensitive lipase synthesis. Adequate amounts of glycerol 3-phosphate are therefore unavailable for the reesterification of fatty acids produced from triacylglycerol breakdown. Nonesterified fatty acids are released into the circulation and free fatty acid concentrations increase from 0.5–0.8 to 1.2–1.6 mmol l^{-1} within the first few days of fasting. Fatty acids circulate bound to albumin and can be oxidized in the liver or other tissues to produce energy. The switch to using ketone bodies as an energy source by the brain appears to be primarily controlled by the blood concentration of ketone bodies rather than a hormonal effect. Ketone body production by the liver peaks after 3 or 4 days of fasting. However, blood ketone body levels continue to increase rapidly for the first 7–10 days before stabilizing at approximately 6–8 mM at 2 or 3 weeks. The continued increase in blood ketone body levels despite achieving maximal liver production early in fasting is due to decreased renal excretion of ketone bodies.

As fatty acid oxidation and ketone body formation increase, there is a reduction in glucose production and oxidation. This may be mediated by inhibition of the pyruvate dehydrogenase complex activity. After a 3-week fast, a marked reduction in glucose metabolism throughout the brain is observed using positron emission tomography. Glucose uptake of the brain is more than halved after a fast of 5 weeks.

After a period of fasting longer than 2 weeks, there is a shift to conserve muscle protein and reduce body protein turnover. Urinary nitrogen losses decrease to 4–6 g per day and approximately half of this is excreted as ammonia required to buffer acid produced by ketoacids. This transition appears to be directly or indirectly dependent on increasing blood ketone body concentration. With prolonged fasting, muscles change from ketone body production to fatty acid oxidation. This may potentially conserve branched-chain amino acids, which may in turn limit proteolysis. There is evidence that leucine can stimulate protein synthesis. A small increase in insulin in response to high circulating ketone body levels may also influence protein metabolism.

With increasing ketone body production, the liver reduces the rate of gluconeogenesis. The kidney becomes the major gluconeogenic organ and produces half of the body's glucose requirements. Glutamine is the predominant substrate for kidney gluconeogenesis and the nitrogen product of this process provides the ammonia needed to buffer ketoacids in the urine.

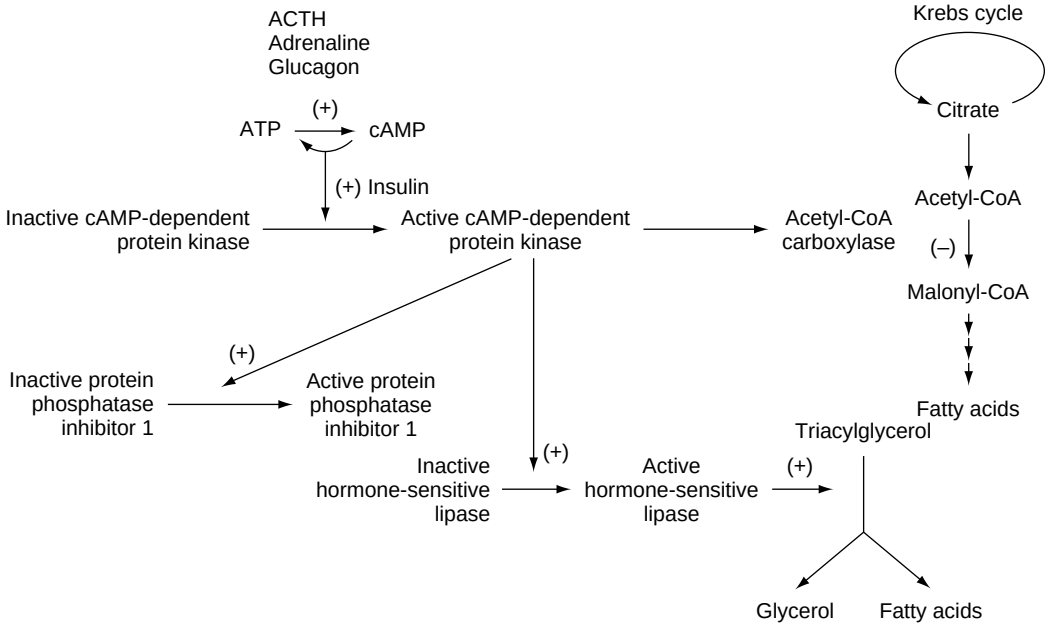

Figure 5 Lipolysis is stimulated by the action of glucagon, ACTH, and adrenaline. This effect is mediated by cyclic AMP-dependent protein kinase.

Death will occur when there is a failure to replenish fuel stores and insufficient available energy to maintain essential bodily functions. Because fat is the predominant source of energy, the time until death in uncomplicated fasting will depend on the size of the prefasting fat stores. In a normal adult, fat stores will be sufficient to sustain life for approximately 60–70 days. The extent of protein loss is also linked to survival. A loss of more than half of the lean body mass compartment (approximately half of total body protein) is predictive of death.

Structure and Function

J P Pearson and I A Brownlee, University of Newcastle, Newcastle-upon-Tyne, UK

Introduction

The stomach is an organ of the upper digestive tract and its major function is to store and liquefy food to allow its further digestion and absorption by the small intestine. Liquefaction is achieved by the action of acid, pepsin, and strong rhythmic muscle contractions. The stomach is well suited to carry out its digestive functions: it is expandable to accommodate a meal; it is muscular to allow strong contractions to mix and break up the food; and the acid and pepsin needed for digestion are released on demand from specific gland structures.

Structure

The stomach is an expandable chamber between the esophagus and the duodenum. Its volume is only about 50 cm^3 when empty, yet it can expand to up

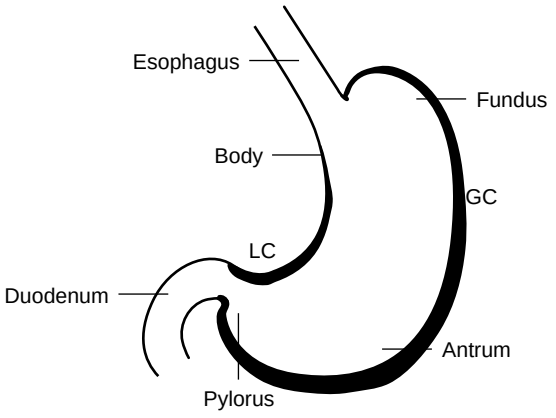

Figure 1 Stomach anatomy. The thickness of smooth muscle in the different regions of the stomach is shown by the darkened areas (■). LC, lesser curvature; GC, greater curvature.

to 1000 cm^3 when full with food. The stomach can be divided anatomically into four regions (**Figure 1**). The esophageal squamous epithelium ends at the gastroesophageal opening where the columnar epithelium of the stomach begins; the first region of the stomach is the fundus, which lies above the opening of the esophagus. The next region is the body or corpus, which together with the fundus forms a food storage reservoir. This allows control of the rate of food delivery to the small intestine, so as to synchronize it with maximal digestion and absorption. The distal part of the stomach, the antrum has a thicker muscle layer and its major function is to generate vigorous mixing of food with the gastric secretions to produce a slurry known as chyme. The stomach ends in the pylorus, a muscular sphincter that controls release of chyme into the duodenum.

Histology of the Stomach

The stomach wall consists of four types of tissue: connective, smooth muscle, neural, and epithelial (**Table 1**). Within these layers is a vascular system with arterioles supplying the external muscle layers and gastric arteries supplying a plexus of arterioles in the gastric submucosa, which in turn provide nutrients for the mucosal secretory cells.

The cells producing the gastric secretions are located in the mucosa of the stomach and are arranged in structures called gastric pits (**Figure 2**). Pits are made up of several gastric glands and are distributed throughout the mucosa. Glands in the body and fundus contain chief (peptic) cells deep within them, which synthesize, store, and secrete the inactive enzyme precursor pepsinogen. Parietal (oxyntic, from the Greek *oxys* meaning acid) cells are found more widely distributed within the gland extending towards the top. These cells secrete hydrochloric acid (HCl) and intrinsic factor into the gland lumen. Also present near the base of the glands in this region of the stomach are neuroendocrine cells, i.e., enterochromaffin cells secreting

Table 1 Layers of the stomach wall

Outside	Serosa	Connective tissue
	Muscularis	Longitudinal muscle
	arterioles distributed through this layer	Mysenteric autonomic nerve plexus
		Circular muscle
		Submucosal autonomic[a] nerve plexus
	Submucosa	Plexus of arterioles
	Mucosa	**Muscularis mucosa** – smooth muscle
		Gastric glands – endocrine cells, chief (peptic) cells, parietal cells and mucous neck cells
		Lamina propria – connective tissue and lymph nodes
		Epithelium – surface mucous cells
Inside (Lumen)		

[a]The submucosal plexus is an important structure in the human stomach, containing a number of transmitters, e.g., substance P, vasoactive intestinal peptide (VIP), nitric oxide, calcitonin gene-related peptide (CGRP), and gastrin-releasing peptide (GRP).

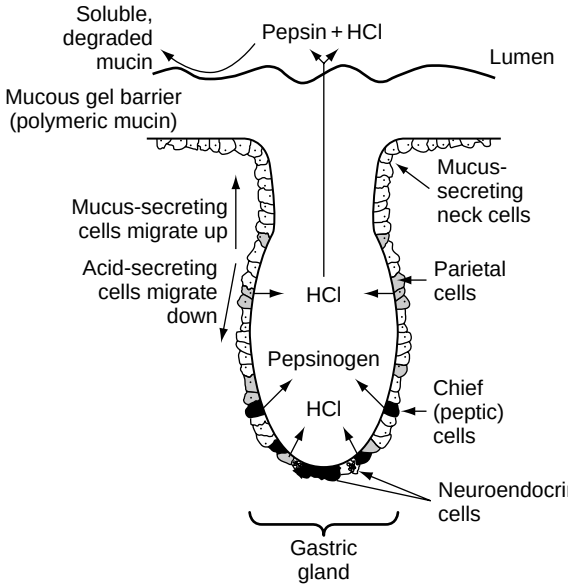

Figure 2 Structure of the body and fundus gastric mucosa. The secretory units of the oxyntic mucosa consist of apical pits with basal glands. The stem cells giving rise to all the cell types are located between the pit and the gland.

serotonin, enterochromaffin-like (ECL) cells secreting histamine, and D cells secreting somatostatin.

The antral glands lack parietal cells so no acid is secreted from this region. They do, however, contain peptic cells and therefore secrete pepsinogen. In addition, they contain endocrine G cells, which secrete the polypeptide hormone gastrin that together with histamine is involved in the control of acid secretion. G cells also contain intrinsic factor.

Throughout the gastric mucosa stem cells are continually dividing and migrating up the pits differentiating into mucus neck cells, which migrate out of the pits to replace shed surface epithelial cells. Consequently, the whole surface mucosa is replaced every 72–96 h. Stem cell progeny also migrate down the pits into the glands, differentiating into acid or pepsin secreting cells. The gastric glands do not turnover as rapidly as the surface mucosal cells with parietal cells having a life span of 150–200 days. The major secretion of the surface epithelial cells is mucus. Mucus forms a continuous surface layer and is the first line of defense against gastric juice; however, it does not extend up into the esophagus. The gastric mucus layer stops at the gastroesophageal junction, so the esophagus must have a different protection mechanism. Studies with human and animal gastric mucosa have demonstrated that the mucous layer in the stomach consists of two independent gel layers (**Figure 3**). The first is a firm adherent mucous layer (median thickness 150 μm) that protects the underlying epithelial cells against pepsin and acid; without this layer the mucosa would be destroyed. Bicarbonate secreted into this layer by the epithelial cells neutralizes the acid diffusing from the lumen in an unstirred aqueous environment. Consequently, a pH close to 7 is maintained at the epithelial cell surface. Overlying this firm gel layer is a sloppy (shear compliant) layer of variable thickness, which

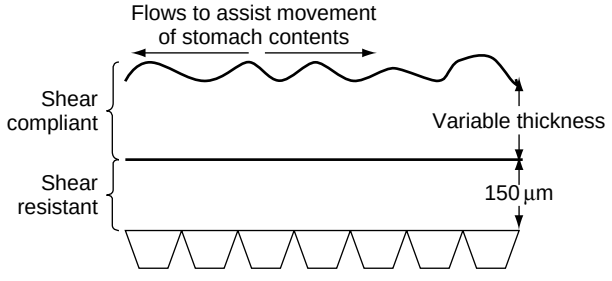

Figure 3 The gastric mucous layer. The shear resistant layer of the mucous bilayer remains at close to 150 μm, whereas the shear-compliant mucous layer thickness is always changing, due to its constant removal by shear stress and subsequent replenishment.

although a gel will flow easily when force is applied to it. This property is essential in reducing shear forces on the mucosa. When the stomach contains food the forces generated will convert the sloppy layer into a viscous liquid, the ideal lubricant reducing the shear forces between the food and the mucosal cells. The thickness of the bilayer is maintained by secretion of new mucus, balancing that lost by pepsin digestion and mechanical shear. Along with mucus the epithelial cells also secrete trefoil peptides, which have growth factor-like activities (see below).

Composition of Gastric Juice and Regulation of Production

Table 2 lists the components of gastric juice. The enzymes secreted by the gastric mucosa will be dealt with first.

Lipases

Lipases are a minor but significant enzyme secretion. Partial digestion of fat occurs in the adult stomach and preliminary digestion of triacylglycerols aids the action of pancreatic lipases. These enzymes are particularly important in infants with respect to breakdown of milk fat, 30–60% of which is lipolyzed in the gastric lumen. Gastric lipases are glycoproteins with molecular weights of about 45 000. Lipase secretion is highest in the body and fundus and very low in the antrum. Secretory granules containing lipases are located in peptic cells, particularly in the fundic mucosa. Gastric lipases have a broad pH optimum (2.5–7.0); they are stable down to pH 1.5 and therefore survive in the stomach's acidic environment and will be active during feeding when the gastric pH rises to around 5.0. Secretion of gastric lipase is coupled with pepsin secretion by peptic cells in response to pentagastrin (a functional analoge of gastrin). Lipase secretion from isolated human

gastric glands is stimulated by cholecystokinin (CCK) and carbachol but histamine has no effect. In the dog secretin and prostaglandin E_2 stimulate lipase secretion. There is also a feedback loop in gastric lipase secretion: release of long-chain fatty acids from triacylglycerols by lipases stimulates CCK secretion, which in turn stimulates the secretion of pancreatic and gastric lipases.

Pepsins

Pepsins are the major enzyme secretions of the stomach, digesting protein in the diet to yield peptide fragments. Pepsins are members of the aspartate proteinase family with two aspartate residues at the active site. They are broad specificity endopeptidases with a preference for peptide bonds between hydrophobic amino acids. Human gastric juice contains two groups of pepsins: pepsin A, which contains six isoenzymes; and pepsin C, which contains two isoenzymes (**Table 3**). Once secreted into the lumen, the acidic conditions convert pepsinogens to pepsin. Unlike the activation of other proteinases, e.g., trypsinogen to trypsin via a proteolytic cleavage by another enzyme (enterokinase), pepsinogen activation is autocatalytic.

The process is understood in detail for porcine pepsinogen, which when activated produces an enzyme very similar to human pepsin 3b. Secreted pepsinogen has an N-terminal peptide of 44 amino acids blocking the active site. On exposure to pH values below 5, carboxyl groups become protonated abolishing charge–charge interactions. This allows part of the N-terminal protein into the active site where it is cleaved, releasing a 16-amino acid peptide. The enzyme is now partially activated; full activation occurs with cleavage of a further 28 amino acids from the N-terminal by either another partially activated pepsin or a fully activated enzyme.

The majority of proteinase activity in human gastric juice is due to pepsin 3 ($70.3 \pm 2.6\%$); variable amounts of pepsin 5 are also present ($16.9 \pm 2.0\%$). The only other isoenzyme found in significant amounts is pepsin 1. This differs from other pepsins in that it is an ionic complex of a 14 500 molecular weight protein and proteoglycan. Also, unlike the other pepsins, pepsin 1 is secreted only in the fundic and not the pyloric glands and is only present in significant amounts in stimulated juice. Pepsin 1 has the highest molecular weight (44 500), while the other pepsins have molecular weights around 35 000. The pH optimum against protein substrates for all pepsins is in the acidic range 1.9–3.6. Pepsin 1 secretion is elevated in peptic ulcer disease (PUD) and is therefore the pepsin associated with ulcers. Also associated with peptic ulcer disease is the bacteria *Helicobacter pylori* (HP), which colonizes the stomach at the epithelia surface under the mucous layer. *Helicobacter pylori* is believed to protect itself from the acid environment of the stomach by the action of a membrane-bound urease, which generates ammonia from the urea present in gastric juice. Interestingly, approximately 50% of all people in the UK over 50 years old are HP positive, yet only a small proportion of these will develop peptic ulcer disease. The increased secretion of pepsin 1 in PUD may be explained by HP infection.

Table 3 Pepsins of human gastric juice

Pepsin group	*Chromosome location*	*Individual pepsins*
A	11q13	1, 2, 3a, 3b, 3c, 4
C (gastricsin)	6	5 and 6

These isoenzymes can be separated by agar gel electrophoresis at pH 5.0 or anion exchange high-performance liquid chromatography.

Pepsinogen secretion The initial stimulus for pepsinogen comes from feeding. There is a basal level of secretion, which is 20% of the stimulated secretion. Maximal secretion produces gastric juice with a pepsin concentration approaching $1\,mg\,ml^{-1}$. There is a biphasic response with initial release of stored pepsinogen in a rapid phase (20–40 min) followed by a less rapid steady state of secretion. Pepsinogen secretion is stimulated by CCK, forskolin, and by insulin induced hypoglycemia mediated by the vagus nerve. Gastrin also stimulates pepsinogen secretion; however, it is much less effective than CCK. Secretion is also stimulated by the peptide hormones secretin and vasoactive intestinal peptide (VIP) and by adrenaline acting through β_2 receptors and by prostaglandins and histamine. All these agents alter intracellular cAMP levels, which in turn activates cAMP-dependent protein kinase (PKA) associated with A-kinase anchoring protein-150 (AKAP-150). Pepsinogen secretion is stimulated by cholinergic agents acting on muscarinic M3 subtype receptors; these agents also stimulate acid secretion. Acetylcholine and the CCK/gastrin family act through altering intracellular Ca^{2+} and Inositol triphosphate (IP_3) levels. The elevation of intracellular calcium is produced by release from intracellular stores and an influx of calcium via a membrane cation channel. *Helicobacter pylori* is believed to increase pepsinogen secretion via this Ca^{2+} signal transduction pathway. Recently, the G protein-coupled protease activated receptor-2 (activated by partial digestion)

on chief cells has been shown to stimulate pepsinogen secretion when activated. Pepsinogen is secreted by compound exocytosis with granules fusing together and with the plasma membrane. The enzyme is condensed within the vesicle in association with a divalent cation, e.g., Ca^{2+}. Initial fusing with the plasma membrane produces a small pore releasing the Ca^{2+}, causing the vesicle contents to swell producing a larger pore through which the pepsinogen is released.

Acid

Acid is secreted by the gastric gland parietal cells via the action of the gastric H^+/K^+ ATPase, a transmembrane proton pump. In nonstimulated parietal cells the pump is present in cytoplasmic vesicles (the tubulovesicles) separated from the apical membrane. Electron microscopy studies have shown that these vesicles are in fact small stacks of cisternae and should be called tubulocisternae. On stimulation the pumps are transported in vesicles to the apical membrane along the actin cytoskeleton where they fuse to and greatly increase the surface area of the apical membrane forming numerous microvilli. When physiological stimuli for acid secretion is removed the pumps are recycled back to the tubulocisternae. These trafficking processes involve: (1) movement to the apical membrane of vesicles containing the H^+/K^+ATPase; (2) fusion with the apical membrane and formation of actin filament-based scaffolds to form surface microvilli; (3) dissolution of the actin scaffolds; and (4) transport of the endocytotic vesicles containing the H^+/K^+ATPase back to the tubulocisternae. Numerous proteins have been reported to be associated with these processes; rab11 (a GTPase), syntaxin 3, VAMPs (vesicle associated membrane protein), c-src (a nonreceptor tyrosine kinase), clathrin, dynamin, SCAMPs (secretory carrier membrane proteins), lasp-1, actin, ezrin, coronin, myosin Vb, and myosin light chain kinases. For activity the pump needs to be associated with K^+ and Cl^- conductive pathways. There is a huge H^+ concentration gradient across the parietal cells (the lumen has $2–4 \times 10^6$ greater H^+ concentration than the blood); consequently, the cells require a great deal of energy and, as a result, mitochondria make up 34% of cell volume. The processes of HCl secretion are shown in **Figure 4**.

The H^+/K^+ pump is a noncovalent dimer of an α (catalytic subunit) and a β glycosylated subunit. The β subunit targets the pump to the apical membrane and protects the catalytic subunit from degradation. Acid secretion requires both subunits. The α subunit (mol. wt 100 000) consists of 10 membrane-spanning

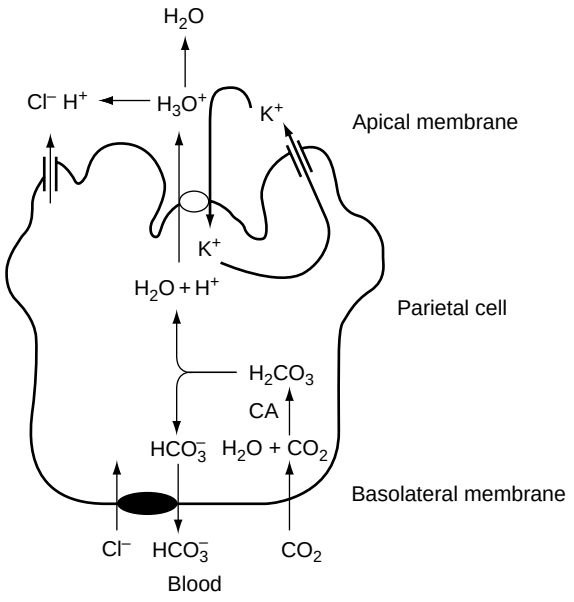

Figure 4 Ion movements in HCL secretion. Thick arrows at top show apical recycling of K^+. ‖, ion channel; ○, anion exchanger; ●, cation exchanger; CA, carbonic anhydrase. Na^+ may be transported instead of H_3O^+. HCO_3^- transport back into the blood during acid secretion is the so-called 'alkaline tide.' Cl^- entry via the basolateral membrane may be linked to Na^+ entry. Cl^- exiting across the apical membrane into the lumen may be linked to K^+ efflux.

segments with the intracellular loop between membrane spans 4 and 5 forming the ATP binding and phosphorylation sites. Hydrophilic amino acids in the membrane-spanning portions form the ion pathway. Proton pump inhibitors (PPI) are used clinically to treat acid-related diseases, e.g., gastroesophageal reflux disease (GORD) and peptic ulcer disease. PPIs are protonated in the stomach producing the active drug sulfenamide, which inactivates the H^+/K^+ATPase by binding to cysteine residues close to or in the extracellular loops between membrane segments 3 and 4, 5 and 6, and 7 and 8. The key cysteine for inhibition by omeprazole is in membrane segment 6 close to the extracellular loop between segments 5 and 6. Binding of sulfenamide to the cell surface prevents the movements of membrane domains relative to each other necessary to pump H^+. The membrane organization of the pump is shown in **Figure 5**.

Control of acid secretion Four cells are key in the control of acid secretion: the parietal, the enterochromaffin-like (ECL), the G, and the D cells. The three major stimulatory compounds are gastrin, histamine, and acetylcholine and the major inhibitory compound is somatostatin. The interaction between the four cell types and the four controlling

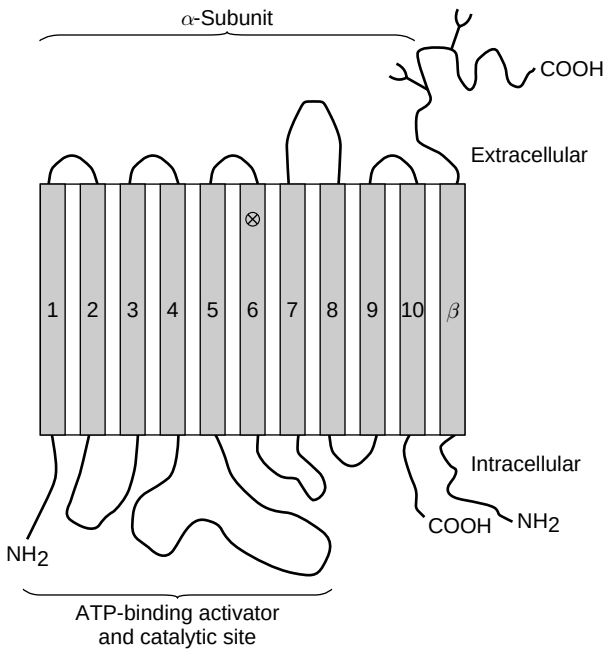

Figure 5 Organization of the H^+/K^+ ATPase in the parietal cell apical membrane. The α-subunit contains 10 transmembrane spans and the β subunit one. In addition the α-subunit has 4 intracellular loops. There is a large mass of protein in the loop between transmembrane spans 4 and 5, which contains the ATP binding and phosphorylation sites. The Activator domain is important for the conformational transitions and may work as an anchor for the ATP-binding domain. agents and other factors are shown in **Figure 6**. Acid secretion can be divided into four phases: basal, cephalic, gastric, and intestinal. Basal phase secretion makes up only 10% of the total secretion produced by all four phases, while cephalic phase secretion accounts for 45% of the total. In response to smell, taste, sight, chewing, and swallowing, the fundic and oxyntic mucosa are stimulated by the vagus (parasympathetic) nerve. Acid is secreted by the parietal cells following direct stimulation, with acetylcholine binding to M3 muscarinic receptors. Acetylcholine also stimulates histamine release from the ECL cells, which binds to H_2 receptors on the parietal cells causing an increase in cAMP, which in turn stimulates acid secretion. In addition pituitary adenylate cyclase-activating polypeptide (PACAP) is released from the mucosal nerves, stimulating acid secretion by increasing histamine release from ECL cells. The vagus also stimulates G cells of the antrum to release gastrin into the blood, which further stimulates the parietal cells via binding to CCK-2 receptors and increasing intracellular Ca^{2+} leading to an increase in HCl secretion. During the cephalic phase gastric leptin (a hormone thought to function as a satiety signal when released from adipocytes) is also released. Gastric leptin inhibits acid secretion and is believed to act on the central nervous system presumably to suppress further food intake.

Acid secretion during the gastric phase accounts for 45% of total acid secretion. Food entering the stomach causes distension and gastrin is released from the antrum via two mechanisms: (1) local enteric and long loop parasympathetic mediated reflexes; (2) stimulation by the products of protein digestion, i.e., peptides and amino acids, of the G cells to release gastrin directly, particularly hydrophobic amino acids. This second effect is interesting considering the fact that the G cells must be covered with a mucous gel layer and the amino acids need to diffuse through it before eliciting a response. The gastrin produced by both mechanisms stimulates the parietal cells to produce HCl directly and via histamine release from ECL cells. The intestinal phase is mainly an inhibitory phase; however, there is a small stimulatory phase via amino acids and peptides in the jejunum promoting release of gastrin from the intestine. Two groups of factors lead to the inhibitory phase. First, fat, acid, hypertonicity, and distension of the duodenum cause release of secretin from duodenal S cells, which inhibits gastrin release and thereby acid secretion. This works partly through the release of somatostatin from D cells in the stomach. In addition, a smaller effect on acid secretion results from gastric inhibitory peptide, released from intestinal K cells, VIP released from nerve endings, glucagon-like peptides (GLP-1 and GLP-2) from the enteroendocrine L cells in the small intestine, and CCK released by intestinal cells, again probably via a somatostatin-mediated pathway. Second, stimulation of G cells is reduced as food leaves the stomach and pH will fall as buffering from food is lost. This high H^+ concentration will stimulate the D cells to release somatostatin further inhibiting gastrin release. As well as inhibition of gastrin secretion, gastrin is also destroyed by a neutral endopeptidase present in stomach cells. With removal of stomach distension, the vagal and intrinsic nerve stimuli for acid secretion is lost.

Regulation of Appetite

The stomach plays an important role in the regulation of appetite, in particular via the peptide hormone ghrelin (the so called hunger hormone). This hormone is produced by the neuroendocrine cells of the fundus and is upregulated in response to a fasting state, for example ghrelin levels are highest just

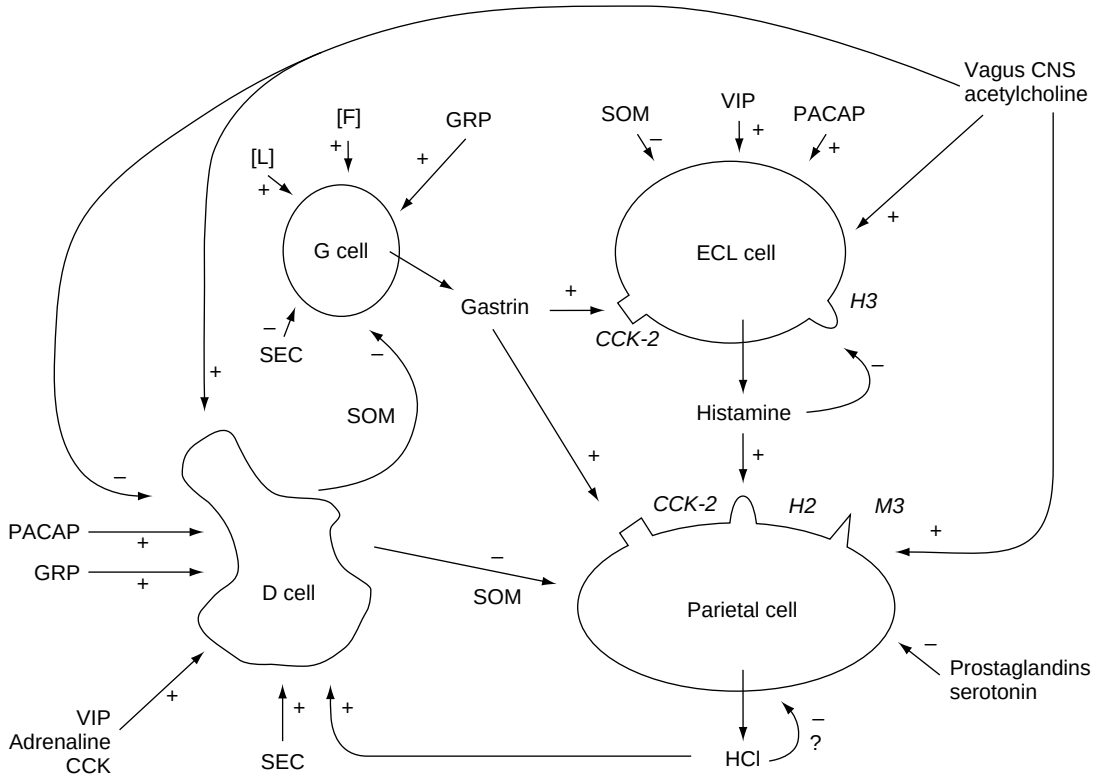

Figure 6 Control of gastric acid secretion. +Indicates a stimulatory effect on the cell; −Indicates an inhibitory effect on the cell. before a meal and lowest just after. Ghrelin is synthesized as a preprohormone which is cleaved by proteolysis to a 28 amino acid peptide (a 27 amino acid variant also exists). The serine residue at position 3 must be substituted with octanoic acid for activity. Ghrelin released into the circulation has several actions, stimulation of the release of growth hormone from the anterior pituitary, increasing the hunger signal by binding to receptors on the hypothalmic feeding centers and promoting gastric emptying to clear the stomach for the approaching meal. The effects of ghrelin are counter balanced by the hormones released in response to the feed state, somatostatin from the stomach D cells and GLP-1 and peptide YY from the L cells of the samll intestine.

Mucus

The mucus covering the surface of the stomach consists of a mixture of many secretions and exfoliated cells. The major viscous and gel-forming component of the mucus gel is mucin, present at approximately $40\,\mathrm{mg\,ml^{-1}}$ in the firm layer and approximately $15\,\mathrm{mg\,ml^{-1}}$ in the sloppy layer. Mucin is also present in gastric juice resulting from pepsin erosion of the surface of the gel. It is secreted by the surface epithelial cells and mucous neck cells and is a glycoprotein, about 80% carbohydrate. The core protein of mucin has large regions of amino acid tandem repeats, variable in number (VNTR), which are different for different mucins. The VNTR regions are the sites of heavy glycosylation. The N- and C-terminal regions of the protein core are globular and rich in cysteine and contain domains like those in von-Willebrand factor, a glycoprotein involved in blood clotting, which polymerizes via disulfide bridges. Mucin units are therefore polymerized via disulfide bridges into polymers with molecular weights of about 10×10^6 (**Figure 7**).

Polymerization is essential for gel formation, which results from noncovalent interactions between polymers. Also present in the gel and the gastric juice, secreted by mucin secretory cells are IgA, which combats bacterial invasion and trefoil peptides (mol. wt. 5000–10 000), which may interact with mucin to stabilize and strengthen the

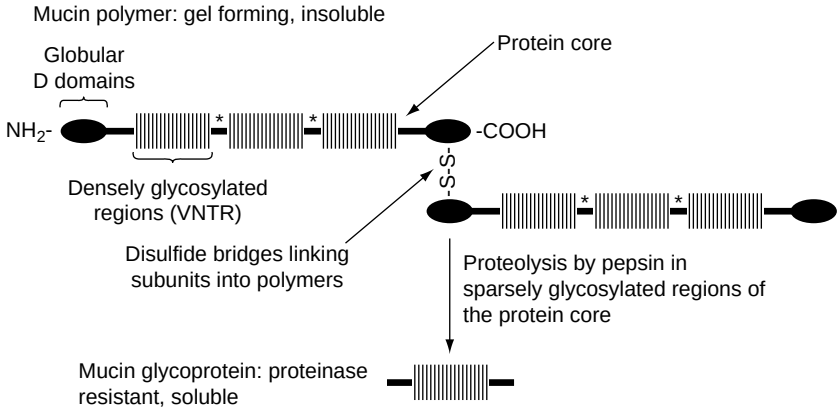

Figure 7 Model for the structure of gastric mucin. Mucin genes expressed in the stomach are MUC5AC and MUC6, both of which are encoded for on chromosome 11 on the p arm at position 15.5. Both MUC5AC and MUC6 have cysteine-rich globular domains on the C- and N-terminals of the mucin units, thus allowing end-to-end polymerization via disulfide bridges. The mucin D domains are homologous to the D domains present in the clotting factor von Willebrand factor, suggesting a common ancestor. MUC5AC has four D domains on its N-terminal and one D domain and a cysteine-rich structure called a cysteine knot on its C-terminal. MUC6 has the same N-terminal structure but only has the cysteine knot on its C-terminal. *Regions susceptible to proteolysis.

gel. IgA inhibit acid secretion and gastric motility, however their major function is as a growth factors, a promoters of gastric healing, and suppressors of tumor growth.

Mucin secretion Mucin secretion is by compound exocytosis and may be linked to Cl^- secretion, with the mucin polyanion stored inside granules condensed with Ca^{2+}-mediated charge shielding. The exocytosis mechanism is similar to that for pepsinogen. There are two routes: (1) constitutive, with a steady release from the cells; and (2) regulated, with release from storage granules. Muscarinic receptors mediate mucin secretion. Cholinergic agonists stimulate secretion via protein kinase C and IP_3 leading to an increase in intracellular Ca^{2+}. β-adrenergic agents, secretin and prostaglandins E_2 and $F_2\beta$ stimulate secretion via a cAMP-mediated mechanism and NO acts via cGMP. Inflammation and infection, mediated by the cytokines TNFα, Il-6, and Il-8 and bacterial cell wall components (e.g., lipopolysaccharides), as well as epithelial damaging agents (e.g., free radicals and mustard oil) stimulate mucin secretion.

Intrinsic Factor

Gastric intrinsic factor (IF) can be defined as a substance required for the absorption of vitamin B_{12} (cyanocobalamin, CNCb1), which is essential for the formation of red blood cells. Cyanocobalamin is a precursor for methylcobalamin, a cofactor for the enzyme methionine synthase, and 5′ deoxyadenosylcobolamin, a cofactor for methylmanonyl CoA mutase. In the absence of IF, CNCbl fails to be absorbed, erythrocyte production is defective, and pernicious anemia results. The most detrimental effect of gastric mucosal atrophy, which can result from long-term *H. pylori* infection, is the loss of intrinsic factor. Two other CNCbl binders exist in the body that are distinct from IF; these are haptocorrin (Hc), the ubiquitous binder, and transcobalamin II (TCII), the plasma binder that transports CNCbl from the terminal ileum.

Dietary CNCbl is always bound to proteins and is released by cooking and pepsin digestion. In gastric juice, free CNCbl is faced with both gastric IF and Hc mainly derived from saliva. At pH 2.0 CNCbl affinity for Hc is 50 times higher than for IF; therefore, free CNCbl binds to Hc in the stomach. However, in the small intestine trypsin degrades He and CNCbl is bound by IF. The CNCbl–IF complex is absorbed in the terminal ileum after interaction with a receptor (IFRC) specific to IF-CNCbl.

The gene for IF is found at chromosomal location 11q13. Purified IF is a glycoprotein of approximately 57 kD. Its protein component varies between 341 and 351 residues and the carbohydrate moiety, consisting of 30–37 residues, 49–68% hexoses, 27–37% hexosamines and 13–18% sialic acid, constitutes 9.2–15% of the molecule (6.1–6.6 kD). The sugar chains are either *O*-glycosidically or *N*-lactosaminically linked. *In vitro* transcription/translation studies have shown that removing 12% of the C-terminus of the molecule results in all CNCbl binding activity being lost; the receptor binding region is at residues 25–44.

IF is classically described as being secreted by stomach fundus and body parietal cells; however,

the use of immunocytochemistry, electron microscopy, and *in situ* hybridization has shown that it is also found in a subset of chief cells, enteroendocrine cells, G cells, and in secretory ducts of the salivary glands. This may explain the fact that control of IF secretion is apparently multifactorial in common with other gastric juice components and can be activated by gastrin, histamine, acetylcholine, and cholecystokinin. IF secretion in man varies between 50 and 100 nmol l^{-1} which far exceeds the daily requirement.

Absorption

Alcohol, drugs, and some fatty acids are absorbed in the stomach, whereas the products of carbohydrate and protein digestion are not. Partially digested carbohydrate and protein products are not lipid soluble and are too large to cross cell membranes. Unlike in the intestine, no specialized nutrient transporters are present in the stomach mucosa. The continuous mucous gel layer also provides a physical barrier to diffusion of anything other than low molecular weight solutes (mol. wt ~1300). There are also no specialized transport systems for ingested nonlipid soluble electrolytes such as Ca^{2+}.

Gastric lipase activity is largely overlooked. Initial digestion of dietary fat in the stomach is a prerequisite for efficient intestinal lipolysis. In infants gastric lipolysis of milk is extensive and the medium-chain fatty acids released in the stomach are absorbed through the gastric mucosa.

Ethanol and a number of drugs readily pass across the gastric mucosa. Ethanol is partially lipid soluble and can therefore diffuse through the epithelial cell membranes and into the submucosal capillaries.

Nonsteroidal anti-inflammatory drugs, e.g., acetylsalicylic acid (aspirin), oral anticoagulants (e.g., dicoumarol) and sulfonylurea oral antidiabetic agents, can all be absorbed through the gastric mucosa. These weakly acidic drugs are nonionized at gastric pH. In this form they are lipid soluble and can therefore be absorbed quickly by crossing the plasma membrane of the epithelial cells.

Alcohol and nonsteroidal anti-inflammatory drugs can cause gastric mucosal damage and have been used in models of gastroduodenal ulceration. They rapidly diffuse through the protective adherent mucous gel layer (in the case of ethanol causing its dehydration) and in these models cause epithelial damage, cell exfoliation, and, in more severe cases, vascular damage, hemorrhage, and visible lesions. Following acute damage rapid repair occurs by a process of re-epithelialization. The repairing epithelium is protected from the endogenous damaging agents of acid and pepsin by a thick gelatinous coat mainly composed of a fibrin gel formed on the mucous gel template.

Gastric Motility and Emptying: The Role of the Stomach as a Reservoir and a Churn

Motility of the stomach allows it to serve as a reservoir, act as a churn to fragment food and mix it with gastric secretions to aid digestion, and to empty gastric contents into the duodenum at a controlled rate. Gastric motility and storage are complex and subject to multiple regulatory mechanisms. The first aspect of gastric motility is gastric filling. Accommodation of large changes in volume when a meal is eaten is achieved by the plasticity of the stomach smooth musculature and by receptive relaxation. Plasticity means that smooth muscle can maintain constant tension over a wide range of lengths without changing tension. Mechanoreceptors in the proximal stomach signal the degree of distension and, beyond a certain level, a stretch-activated contraction is initiated and pacesetter cells are depolarized. These properties are augmented by receptive relaxation of the deep folds of the stomach (known as rugae), which is mediated by the vagus nerve and associated with eating, possibly via stimulation of the taste buds.

A group of pacesetter cells located high on the greater curvature of the stomach generates slow wave potentials, which sweep down the length of the stomach 3 times per minute. These spontaneous depolarizations are known as the basic electrical rhythm (BER) of the stomach. The stomach's circular smooth muscle layer may be stimulated to contract in peristaltic waves synchronized with the BER. The contractions in the thinly muscled fundus and body are weak but become stronger in the thickly muscled antrum. Food emptied into the stomach from the esophagus is therefore stored in the body of the stomach and gradually fed into the antrum where mixing takes place. The antrum can contain 30 ml of chyme but only a few milliliters of chyme are forced through the pyloric sphincter into the duodenum with each peristaltic wave. Each wave causes the sphincter to contract more forcefully, blocking passage into the duodenum. This process is called retropulsion and achieves thorough mixing of chyme in the antrum. These events are known as the gastric phase of digestion, which is initiated as soon as food enters the stomach. The dominant hormone of the gastric phase is gastrin (**Table 4**).

Table 4 Gastrointestinal peptide hormones affecting gastric motility and emptying

Hormone	*Amino acid no. (chromosomal location)*	*Cell source*	*Stimuli*	*Effects on stomach*
Gastrin	34(17q21) 17 14	G cells	Amino acids Distension pH > 3.0 Parasympathetic activity	↑ Antral motility
Gastric inhibitory peptide[a]	42(17q21.3–22) 30	K cells of intestinal mucosa	Glucose Distension Hypertonicity	↓ Gastric motility and secretion
Motilin	22(6p21)	Enterochromaffin cells of small intestine	pH > 5.0	↑ Gastric motility
Secretin	27(11p15.5)	Duodenal S cells	Hypertonicity pH < 4.5	↓ Gastric motility and secretion
Cholecystokinin	58(3p22–21.3) 39 12 8	Upper small intestinal mucosa	Fats Amino acids	↓ Gastric motility and secretion

[a]Also known as glucose-dependent insulinotropic polypeptide.

When gastrin levels are high the fundus and body of the stomach are relaxed and serve mainly to store chyme. Gastrin stimulates pyloric contraction and increases cardiac sphincter tone, preventing reflux. Gastrin also stimulates acid and pepsinogen secretion and antral motility, thus facilitating gastric digestion. These antral peristaltic contractions also provide the driving force for gastric emptying, which is regulated by multiple gastric and duodenal factors.

The main gastric factor influencing gastric emptying is the amount of chyme in the stomach. Simplistically, emptying rate is proportional to the volume of chyme. Distension triggers an increase in motility via stretching of smooth muscle as well as involvement of the intrinsic plexuses, the vagus nerve, and gastrin. The rate of emptying also depends on the degree of liquefaction of the contents.

Duodenal factors are, however, of prime importance in controlling gastric emptying rate. As soon as food begins to enter the duodenum the intestinal phase of digestion begins. Distension and the presence of acid, hypertonicity, and fat in the duodenum stimulates receptors triggering neural or hormonal factors to suppress gastric motility and emptying by reducing gastric smooth muscle excitability. Neural responses are mediated by intrinsic nerve plexuses (short reflex) and autonomic nerves (long reflex), collectively known as the enterogastric reflex. The hormonal respone is mediated by several hormones released from duodenal mucosa known as enterogastrones, including secretin, CCK, and GIP.

The volume of chyme in the duodenum is detected by mechanoreceptors and results in reflex inhibition of gastric motility and increase in pyloric tone by the vagally mediated enterogastric reflex.

The pH of duodenal contents affects gastric emptying; pH less than 4.5 inhibits further emptying by stimulating the release of secretin. This inhibits gastric motility and gastrin release while stimulating pancreatic bicarbonate secretion. Conversely, when the duodenal chyme is above pH 5.0, motilin is released, which increases the strength of the gastric contractions and the tone of the pyloric sphincter (**Table 4**).

Hypertonicity can result because digestion releases large amounts of amino acid and glucose molecules. If absorption does not keep pace, then the osmolarity of the duodenal contents increases. This results in large volumes of water entering the intestine from plasma causing circulatory disturbances and resulting in reflex inhibition of gastric emptying. Duodenal osmoreceptors trigger the release of GIP, which decreases gastric motility and secretion of both pepsin and acid.

The ingestion of fat is the most potent stimulus for inhibition of gastric motility, fat being digested more slowly than carbohydrates and proteins. Fats and fatty acids are detected by duodenal chemoreceptors stimulating the release of cholecystokinin. This hormone has multiple effects including inhibition of gastric emptying.

After a meal is completely emptied from the stomach there are no more gastric factors to enhance gastric excitability.

Introduction

This chapter will briefly discuss major stomach disorders such as stomach cancer, peptic ulcer disease, *Helicobacter pylori* infection, motility disorders and hypersecretory states as well as the less frequent congenital anomalies that may significantly affect early child growth and development. Epidemiological data are presented and current diagnostic and treatment modalities are discussed.

Stomach Cancer

Gastric Adenocarcinoma

The most common (85%) stomach cancers are adenocarcinomas; the rest are non-Hodgkin's lymphomas and sarcomas. The incidence of gastric adenocarcinoma has declined with time. In the early part of the twentieth century it was the leading cause of cancer-related deaths in men in the US. Although the incidence remains relatively high in Japan, China, Chile, and Ireland, a decrease in incidence and mortality has been seen in these countries as well. The risk of gastric adenocarcinoma is greater in the lower socio-economic classes. Migrants from high-incidence countries to low-incidence countries maintain the same risk of gastric adenocarcinoma but their offspring tend to have similar risks to those who are originally from the host nation. This suggests that early environmental exposures have an effect on the development of gastric cancer.

Gastric adenocarcinomas can affect different parts of the stomach. In the US, 37% of tumors arise from the proximal third, 20% arise from the mid-portion, 30% arise from the distal third, and 13% involve the entire stomach. They can be divided into two epidemiologically relevant histopathological classifications: the diffuse type and the intestinal type (**Table 1**). In the diffuse type, the cancer cells infiltrate the stomach without forming a discrete mass. In the intestinal type, the cancer cells form tubular gland-like structures. The differences in the epidemiology of these two types suggest that the etiologic factors involved may be different.

The large differences in incidence between populations and the decline over the last half-century suggest that environmental exposures play a major part in the etiology of gastric cancer. One hypothetical model for gastric carcinogenesis suggests that gastric cancer is the end result of a series of mutations and transformations that begin in the first decade of life. It also suggests that gastric hypochlorhydria (low acid output) predisposes to gastric carcinogenesis. Chronic atrophic gastritis, intestinal metaplasia, and pernicious anemia have

Table 1 Comparison of diffuse and intestinal types of gastric adenocarcinoma

Diffuse	*Intestinal*
Cells infiltrate the stomach, no discrete mass	Cells form tubular gland-like structures
Occurs throughout the stomach	Common in antrum and lesser curvature
Linitis plastica or 'leather bottle' appearance	Ulcerative
Poorer prognosis; affects younger age groups	Predominant in high-risk geographic regions

been associated with an increased risk of gastric cancer.

Dietary factors have been studied extensively, but results from various studies are inconsistent. There is an inverse relationship between the intake of vegetables and fruit and the risk of gastric cancer. Other food items such as processed meat and fish, milk, and salt have given inconsistent results. Vitamin C has been seen to be protective in observational studies in China, Italy, and Sweden, while results on tocopherol are contradictory. Vitamin A does not seem to have any effect on risk of cancer of the stomach; however, most reports indicate that beta-carotene, a vitamin A precursor, appears to be protective. Studies on protein, carbohydrate, fat, dietary fiber, and calcium have conflicting results. At the population level, dietary nitrate exposure has been correlated with risk of gastric cancer. Case–control studies on nitrate and nitrite consumption do not support their proposed role in carcinogenesis, probably because of the difficulty in measuring their levels in food constituents. It has been suggested that he decline in incidence of stomach cancer may be due to a reduction in salt intake and a departure from traditional food preservation practices such as salting and pickling with the advent of refrigeration.

Helicobacter pylori are Gram-negative, curved bacteria that live in the mucus layer of the stomach (see below). These bacteria cause a chronic infection, which results in long-standing inflammation. Infection with *H. pylori* is prevalent in populations with a high risk of gastric carcinoma. A recent study showed that the incidence and mortality rates of gastric cancer were associated with the prevalence of *H. pylori* seropositivity in 17 populations. However, there are populations (e.g., in Africa) where *H. pylori* is prevalent at young ages but gastric cancer is uncommon. Therefore, the role of *H. pylori* in the pathogenesis of cancer needs further clarification.

Clinical Features

Gastric adenocarcinoma can be asymptomatic for some time. As the tumor grows, a feeling of fullness or abdominal discomfort may be felt. Hemorrhage may occur in some cases. Difficulty in swallowing can occur in cancers near the esophagus. Anorexia, weight loss, nausea, and vomiting can also be seen. Spread of gastric cancer can occur by direct extension to surrounding tissues or through the lymphatic system to intra-abdominal or supraclavicular lymph nodes.

Diagnosis, Staging, and Prognosis

Double-contrast radiography is the simplest means of diagnosing gastric adenocarcinomas. However, it is difficult to distinguish mucosal lesions with radiographs. Endoscopy offers a greater advantage because of direct viewing plus the ability to obtain biopsy and cytological samples.

Cancers are staged according to the extent of tissue and lymph node involvement. The prognosis for adenocarcinomas that are limited to the mucosa can be good. The 5-year survival rate for cancer limited to the mucosa is 90%. Where there is invasion of the submucosa, the 5-year survival rates can drop to 60% and with nodal involvement, down to 30%. Thus, early diagnosis is key to reducing mortality rates and screening programs can be useful in countries with a high incidence of stomach cancer.

Treatment

Surgery is the best treatment option for the cure of adenocarcinomas. This involves removal of the tumor and any adjacent lymph nodes. However, this is only possible for one-third of patients. Usually, a subtotal gastrectomy is done for patients with distal stomach cancer and a total or near-total gastrectomy for more proximal tumors. In the US, the 5-year survival rate for those undergoing a complete resection of a gastric cancer is 20% for distal tumors and 10% for proximal tumors. Radiotherapy has very limited value but it can be used as a palliative measure.

Primary Gastric Lymphomas

Gastric lymphomas include those that arise primarily from the stomach (primary gastric lymphoma) and those that arise from systemic lymphomas with a gastric component. Systemic lymphomas commonly involve the gastrointestinal tract. The most common site is the stomach, followed by the small intestine, ileocecal area. and the colon.

Primary gastric lymphomas account for less than 15% of gastric cancers. They usually occur in the 6th decade of life and, as with gastric adenocarcinomas, there is a male predominance. They are difficult to distinguish clinically from gastric adenocarcinomas and definitive diagnosis can only be made through biopsy at the time of endoscopy or abdominal surgery. Histologically, these tumors can be well-differentiated superficial processes (mucosa-associated lymphoid tissue or MALT) or high-grade large cell lymphomas. *Helicobacter pylori* is particularly associated with the development of MALT lymphomas. For lymphomas without nodal

involvement, the 5-year survival rate is 80% and with nodal involvement this drops to 50%.

For primary gastric lymphomas, surgery is considered as the treatment of choice where feasible. Radiotherapy is often advocated as an adjunct to surgery for those with advanced disease, and combination chemotherapy and radiotherapy is sometimes used in those with unresectable disease. Eradication of *H. pylori* infection results in regression of low-grade MALT lymphomas. Thus, in these cases, a trial of *Helicobacter* therapy is warranted.

Gastric (Nonlymphoid) Sarcoma

Sarcomas are the least common gastric cancer. Of these, the most common are the leiomyosarcomas, which constitute between 1 and 3% of all gastric malignancies. These lesions often ulcerate and bleed, but rarely invade adjacent organs or lymph nodes. These tumors are slow growing and found deep within the stroma. The treatment is usually surgical resection with combined chemotherapy for patients with metastatic disease.

Peptic Ulcer Disease

Peptic ulcer disease refers to the mucosal lesion in the stomach (gastric ulcer, GU) or the duodenum (duodenal ulcer, DU) where acid and the enzyme pepsin contribute to tissue damage that extends into the submucosa. It is thought to occur when there is an imbalance between the protective factors and the aggressive factors in the gastric milieu.

The stomach relies on the different layers of mucosal defense (e.g., mucus/bicarbonate layer, cell membrane) to protect itself. If this is breached and epithelial cell injury occurs, then repair may occur by cellular restitution, replication, or formation of granulation tissue. A primary defect in these defense and repair mechanisms rarely causes ulcers. The hypothesis underlying the pathogenesis of peptic ulcer disease is that acid and pepsin are able to cause tissue damage if the normal defenses and repair mechanisms of the stomach are altered by *H. pylori* infection or the use of non-steroidal anti-inflammatory drugs (NSAIDs).

Helicobacter pylori-induced Ulcers

The majority of patients with peptic ulcers are infected with *H. pylori* (95–100% for DU; 75–85% for GU). Although only a small proportion of all *H. pylori*-positive individuals are found to have peptic ulcer disease (1–6%), this is a four- to tenfold increase of the number who are *H. pylori*-negative. The causal relationship between *H. pylori* infection and ulcers is further supported by the reduction of ulcer recurrence after *H. pylori* eradication. It is generally accepted, however, that other factors contribute to the pathogenesis of ulcers. It is known that smoking reduces healing and is also associated with peptic ulcer disease. Variations in bacterial strain virulence and host immune response may also be determinants of pathogenicity.

Infection with *H. pylori* results in a chronic, active gastritis in the antrum or the entire stomach. Peptic ulcers have long been associated with a diffuse antral gastritis. Gastritis is not a predominant feature in other forms of peptic ulcer (e.g., NSAID-induced) unless *H. pylori* is also present. The gastritis is present in both gastric and duodenal ulcers, but it is more severe in the former where it is also associated with gastric atrophy and intestinal cell metaplasia.

NSAID-induced Ulcers

NSAID-induced ulcers are more commonly gastric ulcers. The prevalence of ulcers is more than 15% among chronic NSAID users and less than 4% among those using NSAIDs for less than 1 year. Gastritis or *H. pylori* infection is not a prerequisite for NSAID-induced ulcers. The damaging effect of NSAIDs is thought to be due to their effect on prostaglandin synthesis. Endogenous prostaglandin aid in maintaining gastric mucosal blood flow and epithelial integrity and promote epithelial regeneration. NSAIDs reduce prostaglandin synthesis thus reducing the effect of prostaglandin in mucosal defense.

Gastric and Duodenal Ulcers

Duodenal ulcers are two to three times more common than gastric ulcers. Gastric ulcers are most frequent among those aged 40–70 years, whereas duodenal ulcers are most commonly seen between the age of 25 and 55 years. Thus, complications in gastric ulcers tend to be more severe because they tend to affect older individuals. Ulcer rates are declining rapidly for younger men and increasing for older individuals.

Acid secretion patterns differ with the location of the ulcer. Duodenal ulcers are associated with high-acid secretion while proximal gastric ulcers are associated with a low-acid output. Distal gastric ulcers can have a normal- or high-acid output. The difference in acid output is a reflection of the effects of inflammation on the underlying cell types. Inflammation of the antrum and the body is much more pronounced in gastric ulcer than in duodenal ulcer. In addition, there is usually a progression of inflammation in gastric ulcers. As a result, this could

eventually lead to hyposecretion of acid from glands in the fundus.

Clinical Manifestations, Diagnosis, and Treatment

The classic symptom of ulcer is dyspepsia, a burning epigastric pain usually occurring 2–3 h after meals and at night (between 11.00 p.m. and 2.00 a.m.) when acid secretion is maximal. Relief often occurs with ingestion of food and alkali. Although suggestive of peptic ulcer, dyspepsia is not a sensitive or specific measure of peptic ulcer. Only about 50% of DU patients have the typical symptom of dyspepsia. Some ulcer patients develop a stomach that is easily irritated by food, mechanical distention, or other chemical stimuli.

The sensitivity of radiography for the diagnosis of ulcers ranges from 50 to 90%, depending on the technical skill of the radiographer and the size and location of the ulcer. Fiberoptic endoscopy is a sensitive, specific, and safe method for diagnosing peptic ulcers. It gives the advantage of direct visualization and access to tissue for biopsy.

Data from placebo-controlled trials show that untreated peptic ulcers can heal within 4 weeks in 30% of GU and 40% of DU patients. Recurrence usually occurs in two-thirds of patients who have documented ulcer healing. Complications of ulcers might include hemorrhage, obstruction, and perforation. Treatment involves drugs that reduce acid output such as histamine-2 (H2) receptor antagonists, proton pump inhibitors, antacids, and antibiotics to treat *H. pylori* infection. In the case of NSAID-induced ulcers, treatment is targeted at reducing acid output and the cessation of NSAIDs, if possible. Surgery is reserved for those with complicated ulcer disease.

Helicobacter Pylori

Since its description in 1983, *H. pylori* has been implicated as a causative agent of gastritis, gastric adenocarcinomas, gastric B cell lymphoma, and peptic ulcer disease. In developed countries, the prevalence increases with age, whereas in developing countries, most children are infected by the age of 10 years. Transmission is believed to be by person-to-person spread, although the means of spread is unclear. Intrafamilial transmission is suggested by several epidemiologic studies.

The bacterium produces factors that allow it to colonize the gastric mucosa and, for some strains, gives it the ability to adhere to the epithelium. The flagella allow it to move quickly through the mucus layer to a region where the pH is neutral and thus favorable. The urease produced by *H. pylori* partly acts by producing ammonia from urea and locally neutralizing acid. *Helicobacter pylori* also produces factors that are associated with its virulence. The vacuolating toxin (vacA) causes vacuole formation in eukaryotic cells. Nearly half of the strains express vacA. Another protein, CagA, is often associated with more intense inflammation, duodenal ulceration, and gastric adenocarcinoma.

Acute infection with *H. pylori* induces a neutrophilic gastritis accompanied by transient hypochlorhydria. Chronic infection results in a chronic superficial gastritis characterized by neutrophils, eosinophils, and B and T lymphocytes. Inflammation is a result of bacterial products (e.g., VacA, CagA) and factors produced by gastric epithelial cells (e.g., cytokines). Most individuals with chronic infection remain asymptomatic. One in six chronically infected individuals will develop peptic ulcer disease. Atrophic gastritis, gastric lymphoma, and gastric adenocarcinoma are also thought to result from chronic infection, although these occur far less frequently.

Diagnosis of *H. pylori* infection can be made using an invasive endoscopic method or less-invasive breath tests and immunological assays (see **Table 2**). Endoscopy allows the collection of tissue biopsies that can subsequently be examined by histology, cultured for *H. pylori*, or measured for urease production. Histology with hematoxylin & eosin stain and special stains (Giemsa, Warthin-Starry) visualizes the bacteria as well as the surrounding inflammation. Culture is highly specific and it permits testing for antibiotic resistance, but its sensitivity is reduced by the risk of contamination. Urease tests on histological samples have a high sensitivity because the entire tissue sample is used to measure urease. Less-invasive tests that do not require gastric mucosal samples include serology, urea breath tests, and stool antigen tests. Serology is used to measure serum IgG antibodies.

Table 2 Diagnostic tests for *Helicobacter pylori*

Diagnostic test	*Notes*
Histology	Invasive; requires biopsy
Urease test	Invasive; requires biopsy
Culture	Invasive; requires biopsy
Serology	Not suitable for follow-up studies
Urea breath test	Noninvasive; can be used to monitor treatment
Stool antigen test	Noninvasive; can be used to monitor treatment

Table 3 Drug choices for treating *Helicobacter pylori* infections

Adjuvant	*Antibiotics*
Proton pump inhibitors	Amoxicillin
Bismuth subsalicylate	Metronidazole
Ranitide bismuth citrate	Clarithromycin
	Tetracycline

^{13}C urea breath tests require the ingestion of labeled urea, which releases labeled carbon atoms when urease is present. The labeled carbon atoms will subsequently be incorporated into carbon dioxide in the systemic circulation and measured in breath. Stool antigen detection kits offer a noninvasive way to measure infection and response to treatment. The sensitivity and specificity of the urease test on tissue samples, the breath test, and stool antigen tests range from 90–95%.

Treatment of *H. pylori* infection is clearly indicated for peptic ulcer disease (gastric and duodenal) and the rare MALT lymphomas. There may also be some benefit in treating patients with NSAID-induced ulcers who are *H. pylori* infected. The benefit for functional dyspepsia, gastric cancer, and gastroesophageal reflux disease is less certain. A consensus report by a European study group recommends a test and treat strategy for all patients less than 45 years of age with uninvestigated dyspepsia in whom there are no predominant symptoms of gastroesophageal reflux disease, no alarm symptoms, and no NSAID use.

Triple therapy is the gold standard for treatment of infections. This refers to the use of two antibiotics plus one adjunctive agent for 7 or 14 days. Fourteen days of treatment provide better cure rates. However, compliance is one of the factors reducing effectiveness of therapy. One therapeutic regime would be a proton pump inhibitor combined with clarithromycin and amoxicillin or metronidazole. Recent studies with various combinations show eradication rates mostly ranging from 80 to −95%. In cases of treatment failure, a second-line eradication therapy involves a 7-day quadruple therapy using a proton pump inhibitor, bismuth, metronidazole, and tetracycline. Eradication rates for second-line therapy range from 77 to 82%. The drug choices for treating *H. pylori* are given in **Table 3**.

Congenital Anomalies

Congenital anomalies of the stomach are infrequent. Depending on the degree of obstruction that occurs, they may present in the neonatal period or later. Gastric atresia refers to the arrest of development of part of the stomach. It usually occurs in the antrum or the pylorus as a fibrous cord remnant or as a membrane with mucosal and submucosal layers. At birth, children with gastric atresia will have signs of gastric outlet obstruction. Treatment of gastric atresia requires surgical excision of membranes or joining the stomach and duodenum (gastroduodenostomy).

Microgastria refers to a small, tubular stomach associated with a megaesophagus histologically normal. It may occur in association with other anomalies. Microgastria results in decreased gastric acid secretion that hampers iron absorption and causes iron deficiency. Decreased production of intrinsic factor may also result in vitamin B_{12} deficiency. Frequent small-volume feeding or continuous-drip feeding is used as conservative management. Surgical intervention can enable normal growth and development.

Infantile hypertrophic pyloric stenosis is caused by hypertrophy of the circular muscle layer around the pyloric channel, which results in gastric outlet obstruction. The incidence in the US is approximately 3 per 1000 live births, but it can vary among ethnic groups (highest among whites, then black Americans, then Africans, and lowest among Asians). Pyloric stenosis is the most common reason for abdominal surgery in the first 6 months of life. This usually presents as progressive projectile vomiting after feeding, and is often apparent at the 3rd or 4th week of age. The vomitus is never stained with bile but can contain signs of blood. Anorexia, dehydration, and wasting may occur with time. Owing to chronic vomiting, a metabolic alkalosis develops. Two classic physical signs in pyloric stenosis are the palpable pyloric mass (olive) and visible peristaltic waves. The typical clinical presentation may be enough for diagnosis; however, in a few infants, contrast radiography or ultrasonography may be required. Initial treatment is to correct fluid and electrolyte imbalance but definitive treatment is surgery involving a longitudinal incision in the hypertrophied pylorus. Prognosis after surgery is excellent and the infant grows and develops normally.

Gastric Volvulus

Gastric volvulus is the condition where the stomach twists upon itself. This can be transient, but it can also lead to obstruction, ischemia, and necrosis. Primary gastric volvulus occurs below the diaphragm and is found in a third of cases. Secondary gastric volvulus occurs above the

diaphragm and is associated with a defect in the diaphragm or a herniation of the stomach upwards towards the esophagus. One-fifth of cases are found in children (usually diagnosed before the age of 1 year) and are associated with a congenital diaphragmatic anomaly. Peak incidence is in the fifth decade of life.

Pain, violent retching, and inability to pass a nasogastric tube is very suggestive of acute gastric volvulus. Confirmation of the diagnosis is usually made with a plain abdominal radiograph. Treatment requires surgery. Mortality from acute gastric volvulus is around 15–20%, but in cases where blood supply to the stomach has been severely compromised, mortality rates can reach 40–60%.

Motor Disorders

Gastric stasis refers to the delayed emptying of gastric contents and this results in patients experiencing early satiety, bloating, nausea, and vomiting. Endoscopy can confirm the presence of gastric stasis by finding retained food after an overnight fast. Systemic disorders such as scleroderma and diabetes mellitus can have neuromuscular effects that can affect the stomach. Neurological disorders can likewise cause gut dysmotility.

Gastric dumping refers to the early delivery of large amounts of liquid and solids to the small intestines. Early satiety, abdominal discomfort, and hypotension are common manifestations. Hypotension is a result of fluid shifts from the plasma to the intestinal lumen. Hypoglycemia may occur secondary to the insulin surge that results from the increased glucose to the portal circulation. Gastric dumping is usually associated with resective gastric surgery. Dietary treatment alone is not really successful. Sensible advice would be to reduce fluid intake during meals. Octreotide, an analog of the hormone somatostatin, is effective in patients with dumping because it retards gastric emptying and inhibits insulin.

Zollinger-Ellison Syndrome

Zollinger-Ellison Syndrome (ZES) refers to the triad of severe ulcer disease, gastric acid hypersecretion, and non-beta islet cell tumors of the pancreas. These tumors release gastrin, a very potent stimulatory secretagogue; hence, they are referred to as gastrinomas. ZES is thought to be responsible for 1% of all duodenal ulcers. The most common presentation is that of a single duodenal ulcer that is persistent and progressive, and is less responsive to the usual therapy. Increased serum gastrin concentrations are a hallmark of ZES. Reducing gastric acid secretion via antisecretory agents is valuable in the medical management of patients with ZES while the patient is stabilized or being evaluated for definitive treatment. Surgery is the treatment of choice for the gastrinomas; successful resection of gastrinomas ranges from 20 to 45% of patients. Five-year survival rates for all patients with gastrinomas range between 60 and 75%.

STROKE, NUTRITIONAL MANAGEMENT

S McLaren, London South Bank University, London, UK

Introduction

Stroke is a common and devastating event, the incidence rising with age. It has been estimated that circa 125 000 and 500 000 new or recurrent strokes affect individuals each year in the UK and the US, respectively, creating a significant burden of long-term disability in survivors. Stroke is a syndrome that is sudden in onset, featuring signs of cerebral dysfunction of more than 24 h duration that are vascular in origin. In first strokes, thromboembolic infarction is the underlying pathophysiological event in approximately 80% of cases. Of the remainder, 10% have been attributed to primary intracerebral hemorrhage, 5% to subarachnoid hemorrhage, and 5% to uncertain types. Resulting neurological and functional impairments vary in range, combination, and severity. These can include altered consciousness, motor paralysis, and somatosensory, auditory, olfactory and visual loss. Impairments of memory, speech, language, and continence can also occur. Overall, the impairments and disabilities that result from stroke can exert a variable, negative impact on oral food ingestion, mobility, mood, social role-function, and quality of life.

The challenge of nutritional management is apparent in the scope and complexity of issues presented. These include the physical, psychological, and social impact of stroke on appetite and food ingestion, as well as prestroke nutritional status. Potential effects of metabolic injury responses, immobilization, and infective complications on energy, nitrogen, and micronutrient requirements must be considered. In individuals in whom oral feeding cannot be established, intravenous hydration and artificial nutritional support by the enteral route, utilizing either nasogastric catheters or percutaneous endoscopic gastrostomy, may be necessary. Finally, the presence of disorders such as obesity, diabetes mellitus, and hypertension, which are known risk factors for stroke, can require dietary modifications as part of the overall plan of treatment.

Effective nutritional management of stroke requires a multidisciplinary approach in which the skills and knowledge of physician, dietitian, nurse, speech and language therapist, physiotherapist, and occupational therapist are effectively and efficiently integrated to the benefit of the patient. Involvement of patient and carers in all aspects of a rehabilitation plan is vital. Ethical and legal issues relating to hydration and nutritional support can arise in stroke management.

Risks of Protein-Energy Malnutrition

The reported frequency of malnutrition after acute stroke has ranged from 8 to 34%. A number of factors may interact to impair the nutritional status of individuals who have suffered a stroke. These include factors that have led to a deterioration in prestroke nutritional status, direct physical and psychosocial effects of stroke on the consumption of food and fluids following hospital admission, and organizational factors that can hinder efficient, effective meal delivery and consumption in institutional and longer term residential settings.

Prestroke Nutritional Status

The prevalence of protein-energy malnutrition at the time of hospital admission following stroke has been variably reported as 8–30%. More detailed information obtained within 4 days of hospital admission has classified 9% of stroke patients as undernourished, 16% as overweight, and 75% as of normal nutritional status, based on a range of observational and nutritional assessment techniques. In relation to stroke outcomes at 6 months, the presence of undernutrition shortly after admission has been independently associated with a significantly greater mortality and increased likelihood of developing pneumonia, other infections, and gastrointestinal bleeds before hospital discharge. Furthermore, patients of normal nutritional status have been found to be less likely to develop pressure sores than those who were undernourished or overweight. Specifically, a low serum albumin concentration has been found to be a significant predictor of post-stroke functional impairment, morbidity, and mortality. Risk factors for malnutrition identified at the time of hospital admission have included increasing age, living alone, dementia, and inadequate dental status. These findings are consistent with those found in wider surveys of elderly populations where risk factors for protein-energy malnutrition also included social isolation, bereavement, poverty, physical disability, inadequate facilities for preparing and cooking food, and the impact of multiple medications on appetite. The presence of malnutrition in older adults may be associated with impaired

immune responses, increasing vulnerability to pneumonia and sepsis following hospital admission. The significance of a low serum albumin concentration in predicting clinical outcomes has been noted in other geriatric populations, where it may be more a reflection of disease severity than an indicator of nutritional status.

Poststroke Eating Problems

Neurological and functional impairments can result in eating problems following stroke, which can lead to an increased risk of protein-energy malnutrition or exacerbate prestroke undernutrition. Specifically, eating disability has been associated with an inadequate consumption of food and fluids and a deterioration in body mass index, triceps skin fold thickness, mid-arm muscle circumference, and serum protein concentrations during the acute phase of recovery. Specific eating problems contributing to this have included anorexia, impaired lip closure leading to oral repulsion of food and fluids, dysphagia, an inability to manipulate utensils linked to loss of motor skills in eating, and difficulties in maintaining an upright posture to aid food ingestion at mealtimes. The presence of visual field and/or perceptual deficits can result in an inability to see or perceive the contents of a meal tray, while aphasia, dysphasia, or dysarthria can hinder or prevent the expression of dietary preferences. Loss of concentration and short-term memory impairment are common sequelae to stroke and can make it difficult for individuals to sustain the sequence of activities necessary to complete a meal, or even to remember to eat and drink. A number of assessment instruments have been developed to enable health professionals to identify the extent of eating disability and ingestive skills, together with the nature of support needed.

Organizational Factors

A number of organizational factors can hinder dietary provision and consumption in institutional settings where dependent elderly people are recovering from a range of disorders including stroke. These include an inadequate mealtime environment, marked by poor lighting, noise, sterile decor, temperature extremes, and lack of facilities for socializing. Lack of manpower or involvement of untrained personnel in dietary selection, meal delivery, and supervision may result in the delivery of a meal is that inappropriate in relation to texture, portion size, and poststroke swallowing capacity, or lead to inadequate assistance being provided in relation to the level of physical dependency.

Management of Psychosocial and Physical Problems Impairing Food Consumption

Guidelines and Standards

The provision of effective nutritional care requires a concerted approach by health professionals in developing evidence-based standards and guidelines for nutritional screening, assessment, and all stages in the provision of dietary support that are linked to clinical audit. Recognition of the need for such guidance in the nutritional management of stroke patients has led to the development and dissemination of evidence-based guidelines by interprofessional expert groups, designed to inform professional judgment and bench-mark care within wider approaches to stroke management. Implementation of guidelines can be best achieved by multifaceted strategies, for example, combining education of health professionals with leadership and sensitive change management approaches.

Following acute stroke, guidelines emphasize the need for screening and assessment for nutritional risk to be undertaken within 48 h using a valid, reliable instrument by appropriately trained personnel. Individuals who are already malnourished at the point of admission or likely to become so can then be referred to dietitians for further assessment and an institution for prompt nutritional support. It is vital at an early stage to identify individuals who are capable of ingesting sufficient food via the oral route without risks of aspiration and those with abnormal swallowing, who require referral to a speech and language therapist for a more in-depth assessment. In order to achieve this, swallowing screening using a validated, reliable, and safe method should be undertaken within 24 h by appropriately trained personnel before patients are given food or drink. Following speech therapy referral, modification of dietary textures may be advised to ensure safe food ingestion in those with some degree of swallowing impairment. In others, artificial nutritional support using enteral routes may be necessary, owing to the severity of dysphagia or cognitive and functional impairments. In individuals who are capable of taking food orally, the provision of support for psychosocial and physical problems is a vital aspect of nutritional management. In order to achieve this, referral for specialist assessment, i.e., occupational and therapy, physiotherapy, psychology, and social therapy, should emanate where appropriate from other assessments.

Psychosocial Problems

In the acute phase following stroke, 25–30% of patients develop clinical signs of depression, 30% are anxious, and a similar proportion report loss of

confidence as a major psychological problem. Depression may result from an interaction of several factors including left frontal lobe damage, reactions to physical loss, and impaired performance of activities of daily living. Comparatively little is known of interactions between depression, anorexia, and nutritional status in the early stages of recovery following stroke in individuals with and without physical eating problems. However, patterns of behavioral disturbance characterized by verbal expressions of depressed mood, anorexia, and insomnia have been identified and associated with weight loss. Anxiety-evoking experiences relating to being fed, or choking in the presence of dysphagia, may also result in avoidance or withdrawal from eating. General approaches to the treatment of poststroke depression can involve the use of antidepressant drugs and behavioral and psychotherapeutic techniques. Specifically, the exercise of therapeutic skills in communication, assisting eating, and providing emotional support are vital in alleviating mealtime anxiety and increasing interest in food.

The enjoyment of eating as a social activity can be affected adversely by poststroke depression and impairments of speech, language, lip closure and, manual dexterity. Severely disabled individuals who are relearning swallowing techniques initially require a quiet environment with privacy. As swallowing and other difficulties abate, social integration at mealtimes can he achieved in conjunction with sensitive assistance.

Communication Problems

The aphasia/dysphasia present in 20–30% and anarthria/dysarthria in 40% of acute stroke patients result in difficulty in expressing thoughts in language or a total inability to do so (expressive motor aphasia/dysphasia) as well as difficulty in comprehending language (receptive aphasia/dysphasia) or producing speech (anarthria/dysarthria). Expressive aphasia, also known as Broca's aphasia, results from strokes affecting the prefrontal gyrus, while Wernicke's receptive aphasia results from lesions of the central sulcus. In contrast, dysarthria results from neurological damage affecting the neuromuscular systems that control the mechanisms of speech production. Since these systems are also concerned with swallowing, it is common to find difficulty with swallowing (dysphagia) present in dysarthric individuals.

The communication problems result in inabilities/difficulties in expressing meal preferences (aphasia/dysarthria), reading a menu, or writing preferences down (aphasia can occur in conjunction with dyslexia and dysgraphia). In contrast, receptive aphasia can impair the ability to comprehend instructions at mealtimes and thus affects compliance with rehabilitative advice. If paralysis and visual field and perceptual deficits are combined with expressive dysphasia and dysarthria, then nonverbal communication can also be limited, resulting in an inability to denote assent or dissent by nodding the head or to use gestures to convey meaning or point to food items/utensils. Early involvement of speech therapists is vital to enable individuals to regain lost functions in speech and language. In selected patients use of visual material, i.e., charts or pictures of food items and symbols, can he helpful. Use of short sentences, normal volume speech, avoidance of jargon, and patience in allowing individuals to respond to questions are also helpful in general communication.

Impairments of Arm Movement and Posture

Stroke can affect one or many of the areas and neural mechanisms controlling voluntary movement and posture. These include the motor cortex and associated pathways, cerebellum, basal ganglia, and brain stem. The impact on eating skills can be considerable, since weakness or paralysis affecting the arm occurs in 80% of strokes. Loss of coordination, spatial impairment, abnormal muscle tone, and sensory loss may also occur. Common problems resulting from this are difficulties manipulating cutlery, lifting/loading utensils, cutting food, inserting food in the mouth, drinking from a cup, or discerning the spatial relationships between objects.

If one arm is unaffected, then some degree of compensation is possible, particularly if this is dominant. Use of the unaffected hand is important in detecting temperatures of food and liquids where sensation is impaired. An occupational therapy assessment is necessary to identify appropriate aids to feeding. Lightweight plastic cups with molded handles and cutlery with built up indented handles may be useful, while plateguards and nonslip mats can be provided. Where upper limb impairment is severe, individuals may require continuous assistance with food preparation and ingestion.

Postural impairment following stroke can result in an inability to maintain an upright sitting position for effective food preparation, insertion, chewing, and swallowing. A physiotherapy assessment can identify the most effective postural techniques to counteract abnormal muscle tone (spasticity) and appropriate aids to seated balance. The latter can include molded seating, tilting chairs with table attachment, and limb stabilizers.

Visual Field Loss and Visual Neglect

It has been estimated that 30–60% of individuals who sustain an acute stroke suffer from visual field loss due to partial or complete hemianopia. Neurological damage affecting the parietal or temporal lobes and involving the sensory pathway between the optic chiasma and visual cortex underlies this problem. The impact of loss in up to half the visual field is that food items on a meal tray may not be seen and therefore may remain uneaten. Compensatory interventions include instruction in scanning the visual field, or placing items within it for those who are unable to do this. Consistent placement of items on a meal tray and verbal identification of contents using a clock system is also helpful.

Neurological damage affecting the visual cortex of the occipital lobe, common following right hemisphere strokes, can result in neglect of half the visual space. A classic feature of this problem is failure to eat food on the left side of a plate. Affected individuals need reminding to focus on food items in the neglected space; placing a colored marker on one side of the plate can be helpful. This problem may occur in conjunction with visual field loss.

Attention Span, Short-Term Memory

Impairment of attention span and short-term memory of a few minutes duration are common following stroke. Attention deficits result in an inability either to focus on immediate events or to establish a new focus unless a current stimulus is removed. As a consequence, an activity that requires a sequence of steps, such as eating a meal with two or three courses, cannot he completed. Lack of concentration is also unhelpful in relearning eating patterns. Removing or minimizing distractions at mealtimes, simplifying the complexity of information necessary to regain eating skills, and providing verbal, written or auditory alarms as reminders to eat are important in overcoming this problem.

Swallowing

Difficulty in swallowing (dysphagia) affects approximately 27–50% of the stroke population. Variable in severity, it is characterized by sensory and/or motor loss affecting one or more of the stages of swallowing, i.e., oral preparation, oral transport, pharyngeal transport, and reflex swallowing (**Table 1**). The effects of stroke on esophageal peristalsis are not fully known. It has been

Table 1 Stages of swallowing: effects of stroke

Stage	*Effects of stroke*
1. Oral preparation	Inadequate lip seal causes leakage of food/fluid chewing slower, food impacts in oral sulci
Duration variable	Hyposecretion of saliva
Lip closure forms anterior seal	Paralysis of tongue impairs bolus formation
Comminution of food by mandibular, maxillary teeth; chewing of food	Sensory loss leads to impaired bolus lateralization
Salivation evoked by parasympathetic nervous system	
Bolus formation controlled by tongue	
Sensory feedback from oral mucosa on volume and consistency determine timing of bolus ejection	
2. Oral transport	Slowed transport
Duration 1 s	Bolus localization, separation and formation impaired; can lead to food retention in oral cavity
Bolus of 5–15 cm^{-1} separated, moved to tongue midline	Lack of fine motor coordination may lead to loss of liquid bolus control; risk of aspiration
Oral cavity sealed, mandible raised, pressure exerted by tongue against palate propels bolus to posterior oral cavity	Abnormal positioning of bolus; diminished tongue elevation; inadequate bolus propulsion
3. Pharyngeal transport/reflex swallowing	Events may occur in abnormal sequence/timing
Duration 0.5–0.6 s	Impaired sensation, delay/absent swallowing reflex
Bolus impacts on sensory receptors in tissues of soft palate, pharynx, tongue, fauces	Velopharyngeal closure impaired; food regurgitated through nose/mouth
Swallowing reflex stimulated; elevation/closure of velopharyngeal mechanism, elevation of larynx, closure of vocal cords, pharyngeal peristalsis, relaxation of esophageal sphincter	Incomplete laryngeal elevation/vocal cord adduction Swallowing reflex delay/absence leading to coughing, aspiration
Respiration transiently ceases as bolus enters esophagus; breathing resumed; soft palate returned to resting position	
4. Esophageal transport	Effects of stroke little investigated
Duration 8–20 s	Aging results in slight impairment of peristaltic amplitude
Peristalsis moves bolus to stomach	

estimated that approximately 50% of dysphagic patients either die or recover spontaneously within the first 2 weeks of stroke onset, leaving half with swallowing impairment, which can exert a negative impact on functional, recovery and, thereby, quality of life.

Typical clinical features of dysphagia can include delayed oral and pharyngeal transit, oral repulsion of food/fluids, impaction and retention of food in the cheek cavity, choking or regurgitation of food/fluids through the nose and mouth, delay or absence of laryngeal cartilage elevation, abnormal gag, delayed or absent triggering of swallow, poor tongue coordination, wet, 'gurgly' voice after eating or drinking, dysarthria, and dysphonia. Complications resulting from dysphagia can be life threatening, i.e., aspiration of food/fluid into the respiratory tract, pulmonary infection, and dehydration. Longer hospital stay, strong inverse correlations with functional capacity, and an increased mortality have been associated with the presence of dysphagia. Early identification of the problem is therefore vital, encompassing screening as soon as possible after admission, clinical bedside assessment, videofluoroscopy and, if necessary, esophagoscopy.

Screening is a procedure intended to identify patients with potential swallowing problems, who can then be referred if necessary for more detailed assessment to provide information on phases of swallowing, together with judgment of extent of dysfunction and risk of aspiration. Systematic reviews have identified a number of screening methods of varying validity and reliability, which combine the identification of clinical features of dysphagia with or without swallowing water. Prescreen checking of conscious level and oromotor and laryngeal function, together with signs of respiratory aspiration and the extent to which the patient can safely cooperate with the screening examination are necessary. In the first few days following hospitalization, screening should be repeated to identify rapid recovery.

Currently, the definition of clinical bedside assessment (CBA) varies and no standardized tests are available for use by speech and language therapists or other specially trained health professionals. Bedside assessment methods of tested validity and reliability are available. General approaches can encompass the medical history relating to onset of swallowing problems: oral sensory and motor testing; laryngeal and pharyngeal assessment; presence/absence of swallowing, cough and gag reflexes; cognitive and language function; and alertness, attention span, and ability to follow instructions. Aspiration of food or fluid into the respiratory tract is not always accompanied by choking; it may be silent, or indicated by voice changes (wet, hoarse, gurgling) and breathlessness. Loss of swallowing and protective gag reflexes or the presence of features of dysphagia or aspiration when attempting to swallow a teaspoon of clear fluid at an initial screen are indications that nil should be given by mouth. Further detailed investigation is then necessary.

CBA is limited in its ability to detect some cases of oropharyngeal dysphagia and individuals who are aspirating food, fluids, or saliva into the respiratory tract. Recognition has been given to the need to develop and validate CBA as a standardized test that reaches acceptable levels of inter-rater reliability for use by trained health professionals.

Videofluoroscopy (VSS) using the modified barium swallow has been long regarded as the 'gold standard' in the assessment of dysphagia. It provides a more detailed radiological assessment of the oral, pharyngeal, and upper esophageal phases of swallowing and can detect functional impairments resulting in aspiration, evaluate the optimal head/neck position during swallowing, and determine the impact of food textures on the process. Limitations of videofluoroscopy include its labor-intensive nature, exposure to radiation, problematic accessibility in transporting disabled stroke patients to radiology departments, lack of standardization across centers with respect to volumes, consistencies, or textures of food and fluids used in the process, together with variable approaches to screening positions adopted. Some variability in the reliability of reporting has been identified both between and within raters judging the outcomes of VSS.

Fiberoptic endoscopic evaluation of swallow (FEES) in which a flexible endoscope is passed into the nares, over the velum and into the pharynx has been shown to provide an inexpensive and reliable alternative to VSS in the detection of laryngeal penetration and aspiration. Although useful in the observation of bolus transit through the hypopharynx, a limitation is that it cannot be used to investigate the oral stage of swallowing. This accessible, portable technique can be performed in a range of settings, overcoming the transport problems associated with VSS.

Where a specialist assessment has confirmed that an oral diet can be attempted with modified food textures and viscosity of fluids, the intent is to alter the rate at which nutrients pass through the pharynx, to assist the patient in control of swallowing and to reduce the risk of aspiration. Variations in

Table 2 Food textures suitable for different levels of dysphagia

Level	*Dysphagia severity*	*Designation*	*Food textures omitted*	*Food textures allowed*
I	Severely impaired oral preparatory stage Reduced pharyngeal peristalsis Reduced swallowing reflex[a]	Patients unable to chew solids or swallow thin liquids safely	Coarse, hard, or brittle textures Unsuitable foods: fruits, nuts, raw vegetables, sticky foods, all foods requiring bolus formation or controlled oral manipulation No thin liquids	Thick, homogeneous, smooth textures or semisolids; cold liquids thickened with commercial agent Suitable foods: poached eggs, soft puddings, thick vegetable/fruit purée
II	Moderately impaired oral preparation Reduced pharyngeal peristalsis	Patients who cannot swallow thin liquids and have minimum tolerance of chewed food	Coarse, hard, brittle textures No thin liquids	Thick, homogeneous purées, semisolids Suitable foods: cold thickened beverages, eggs, yogurt, cottage cheese, custards, puréed vegetables, fruits, tender meats
III	Mild impairment of oral preparation Mild chewing problems	Patients who can tolerate soft foods and liquids	Coarse, hard, brittle textures Unsuitable foods: nuts, minced meat, raw, stringy, crisp vegetables	Soft foods, not puréed or blended Suitable foods: soft bread, eggs, cottage cheese, casseroled small meat pieces, macaroni, hot/cold thick puddings
I	Mild oral preparation impairment Can chew soft textures	Patients who can tolerate soft food textures and liquids	Coarse, fibrous, hard foods Unsuitable foods: nuts, deep fried or raw, crisp foods	Soft foods not requiring grinding or chopping Suitable foods: soft, toasted bread, cold cereals, milk, pasta, eggs, cooked, canned or over-ripe fruit, fine moist meats, tender vegetables, soft desserts

[a]Videofluoroscopy screening essential for safety.
Adapted from Martin (1991) Dietary management of swallowing disorders. *Dysphagia* **6**: 129–134.

the degree of modification and textures suggested are apparent in published dysphagia diets. The aspiration-risk reduction diet outlined in **Table 2** was devised for the management of oropharyngeal dysphagia secondary to neurological impairment. This recognizes the potential risks of aspiration posed by purees and thin liquids, which are difficult to control in the oropharynx of individuals suffering from this type of dysphagia; therefore, the diet offers three choices based on no fluids, thickened fluids, and unaltered fluids. It is the responsibility of the speech and language therapist to recommend the most appropriate food textures for an individual. Dietitians should ensure that texture modified meals are adequate to meet nutrient requirements, offer choice, and are palatable. Skilled nursing interventions at mealtimes can also be of assistance in food ingestion. Impaired oral preparation can be compensated for by positioning food on, and tilting the head towards, the unaffected side; posterior positioning of food on the tongue can promote oral transport and in impaired pharyngeal transport/reflex swallowing, ensuring posture is upright, head stable in the midline with a slight forward flexion to protect the airway and synchronizing the sequence of inspiration, breath-holding, swallowing, expiration and coughing on expiration to clear food debris can be helpful. Maintaining an upright posture for at least 30 min after meals is advisable to prevent regurgitation/aspiration.

Many nondietary, therapeutic approaches to the management of dysphagia have been identified including: use of palatal training devices to assist triggering of the swallowing reflex; insertion of prostheses to lower the palatal vault to improve bolus formation; oral electrical stimulation; oral thermal stimulation; drug therapy (nifedipine); high-intensity swallowing therapy; exercises to improve where appropriate laryngeal closure, labial/mandibular closure, tongue elevation and lateralization; use of biofeedback involving mirrors and VSS. Although benefits have been described for many of these interventions, the lack of randomized, controlled clinical trials with adequate power has limited conclusions relating to effectiveness.

Nutrient Requirements

A variety of approaches to the estimation of energy requirements can he used. Predictive equations can

provide an estimate of resting energy expenditure based on body weight, height, age, and sex. Modifications to equations can be applied that incorporate activity and injury factors. Additional requirements for tissue repletion should be considered in malnourished individuals. Estimation of resting energy expenditure by indirect calorimetry using a portable metabolic monitor provides more accurate estimates derived from the respiratory quotient. Values obtained do not consider periods of activity, pyrexia, pain, or energy increments necessary for nutritional repletion. Further corrections are therefore necessary.

Following stroke a number of factors may affect energy requirements. Inactivity caused by paralysis will reduce energy expenditure, but the presence of pulmonary infection, a common complication of stroke, will increase it (a 1 °C rise in core temperature raises energy expenditure by 13%). The impact of the cerebral injury on poststroke metabolism, notably on resting energy expenditure at different levels of stroke severity, has not been fully investigated. Evidence for metabolic injury responses based on hormonal profiles and changes in blood glucose concentration in the acute phase is limited. Hyperglycemia is common following stroke and has been associated with an increased morbidity and mortality. Hyperglycemia can be attributed to overt or latent diabetes mellitus, stress responses, and effects of glucose intolerance in elderly subjects. Elevated plasma cortisol and catecholamine concentrations representing a transient stress response have been reported in the first 72 h following stroke.

Nitrogen requirements following stroke can be estimated using reference ranges based on body weight, or using nitrogen balance studies. The chronic disorders diabetes mellitus and hypertension are common in the stroke population, which is predominantly elderly. Both disorders require dietary manipulation.

Fluid balance requirements also require careful assessment, since dehydration is a serious risk in individuals with dysphagia and physical disabilities that impair fluid consumption. Oral intake of fluid is contraindicated where the swallowing and gag reflex are lost or swallowing and/or level of consciousness are impaired. Intravenous fluid replacement therapy is then necessary, usually in the short term. Fluid requirements can be calculated on the basis of 35 ml per kg body weight daily in adults, but sepsis and fever can increase needs. Fluid intake and output in conjunction with insensible losses should be monitored on a daily basis together with the symptoms of dehydration, i.e., thirst, dry mucous membranes, and loss of skin turgor.

Artificial Nutritional Support

The presence of severe dysphagia and cognitive and complex physical impairments may render oral feeding unsafe or insufficient to meet nutritional requirements. If the gastrointestinal tract is functional, the options for delivering enteral nutritional support are either via a fine-bore nasogastric tube or via a catheter inserted by percutaneous endoscopic gastrostomy (PEG). Decisions concerning the choice of route are influenced by the anticipated duration of dysphagia and benefits versus risks. Impact on nutritional status, rehabilitation, quality of life, safety, tolerance, flexibility, ease of use, costs of insertion, removal, and maintenance are all important considerations. In the majority of cases dysphagia resolves within the acute phase of stroke, i.e., approximately 2–3 weeks. For relatively short time periods, enteral feeding by fine-bore nasogastric catheter is usually undertaken. This can be preferable because of the technical simplicity of intubation, maintenance and removal, low cost, and ease of use. Discomfort and risks of aspiration, accidental endotracheal intubation, and displacement or perforation of the esophagus are the potential complications, most of which are uncommon, although aspiration may occur in up to 10% of patients.

For feeding over longer time periods, a PEG tube inserted under local anesthetic offers greater comfort, toleration, ease of use, and reported improvements in nutritional status. However, costs are greater and this more invasive procedure carries a technique-related fatality of 1–2%. Minor complications include stomal sepsis, leaking, and outlet blockage. Peritonitis, perforation, gastrointestinal bleeding, and intestinal obstruction can occur, but are rare. Most enterostomy catheters are made from nonacid-hardening polyurethane or silicone and can be left *in situ* for up to 6 months. No consensus exists concerning the time period within which gastrostomy feeding should be initiated following stroke, but it should he considered where dysphagia is likely to persist beyond 14 days, and earlier for those intolerant of nasogastric tube feeding. In a small number of cases, enteral nutrition may be contraindicated following stroke owing to gastrointestinal bleeding resulting from severe stress ulceration. Rarely, nonstroke-related contraindications may also be present, i.e., gastrointestinal failure, ascites, Crohn's disease, bleeding, and clotting disorders.

In considering the relative merits of PEG versus nasogastric feeding poststroke, a systematic review found that PEG was superior in terms of weight maintenance and other indicators of nutritional status. PEG was also associated with significantly

lower end-of-trial case fatality rates and treatment failures in the limited evidence derived from only two randomized, controlled clinical trials. Issues relating to the optimum timing of commencement of artificial feeding have not been clarified in systematic reviews; however, some guidelines emphasize the need to consider the institution of nutritional support within 5 days of a nil oral regime. Failure to provide nutritional support for patients who have not met or are unlikely to meet their nutritional requirements for >7 days is viewed as unethical. In the presence of dysphagia, those unable to meet their nutritional requirements by the oral route should be assessed for nasogastric feeding within 7 days.

Evaluation of Nutritional Support

It is vital that nutritional status is monitored in the acute phase of recovery and that dietary intakes are readjusted accordingly. Appropriate dietary, anthropometric, and clinical assessments, which can be performed on a weekly basis, are discussed (*See* 00201 and 00202). Other important components of monitoring include recovery of physical functions related to independence in eating including swallowing capacity and the complications of enteral support techniques. Providing effective nutritional management following stroke requires the coordination of the professional skills of doctor, nurse, speech therapist, dietitian, occupational therapist, and physiotherapist, ideally within the context of a nutrition support team. Dynamic leadership and clear accountability, lines of communication, and referral policies are essential for the team to deliver effective support. Follow-up services in the community are also necessary to prevent deterioration in nutritional status in the later stages of rehabilitation.

SUCROSE

Contents

Nutritional Role, Absorption and Metabolism

J Brand-Miller, University of Sydney, Sydney, NSW, Australia

Sucrose plays a unique role in human diets. It satisfies our instinctual desire for sweetness and contributes an average of 10% of the energy in modern Western diets. Sucrose has many functional roles in foods which extend beyond its sweetness, including preservative, textural, and flavor modifying qualities. Unfortunately, sucrose has a 'bad reputation,' especially in respect of dental caries. In the past, refined sucrose was suggested to cause diabetes, overweight, heart disease, micronutrient deficiencies, and even hyperactivity in children. But within the last decade a wealth of new research on sugars in the diet has shown most of these assumptions to be false. We now know that refined sucrose consumption is much lower than we originally estimated (45–65 g per day instead of 125 g per day in industrialized countries), that intake of sugars correlates inversely with the fat content of the diet (the higher the sugar intake, the lower the fat), and that high-sucrose diets are associated with *lower* body weight. In addition, new research shows that moderate intake of sugars is associated with the highest intakes of micronutrients and that sucrose-containing foods do not raise the plasma glucose level any more than most starchy foods. While dental caries is still associated with high sucrose consumption in nonindustrialized countries, there is no relationship in developed nations. The intake of fluoride, frequency of food intake, and dental hygiene are more important factors influencing the incidence of dental caries in these countries.

What Is Sucrose?

Sucrose is a pleasant tasting substance that contributes most of the sweetness in our diet. It has played a role in human diets ever since primates began evolving on a diet of fruit and berries in the tropical forests of Africa 50 million years ago. Sucrose is chemically classified as a carbohydrate and a simple sugar, specifically a disaccharide composed of glucose and fructose (**Figure 1**). Its proper scientific name is β-D-fructofuranosyl-α-D-glucopyranoside. The natural sweetness of fruit and honey comes from mixtures of sucrose, glucose, and fructose. The mild sweetness of milk comes from another disaccharide, lactose, composed of glucose and galactose.

Because sweetness comes from a mixture of sugars (not just sucrose) in many sources, we use different terms to define the original source, e.g., naturally occurring sugars, refined sugars, added sugars, concentrated sugars, intrinsic sugars, and extrinsic sugars. Refined sucrose is also known as table sugar, cane sugar, or beet sugar. Unfortunately, the term 'sugar' means different things to different people, and the literature can be confusing. In this article, as in everyday language, the word 'sugar' refers to refined sucrose, unless otherwise indicated.

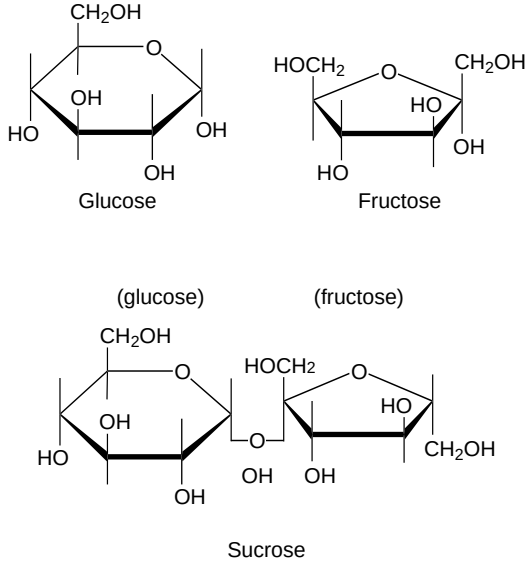

Figure 1 The chemical structure of glucose, fructose, and sucrose.

The Role of Sucrose in the Diet

Historical Perspective

Sugar cane and sugar beet have a naturally high content of sucrose and have been commercially exploited as a concentrated sources of sucrose since 1600 AD. Sugar cane was first cultivated in Papua New Guinea 10 000 years ago, and the practice spread gradually to Egypt (2300 years ago), Arabia (1300 years ago), and Japan (1100 years ago). Sugar beet was first grown in Europe 500 years ago. Prior to this, refined sucrose was still a rare and expensive commodity and honey was much cheaper. When the industrial revolution began 200 years ago, sucrose consumption increased dramatically, replacing honey as the major source of concentrated sweetness. Intake of refined sucrose peaked in about 1900 and consumption has remained, with minor variations, much the same over the past century. Since 1970 high-fructose corn syrup solids (glucose–fructose syrups made from hydrolyzed corn starch) have partially replaced refined sucrose in manufactured products, particularly in the USA.

Instinctual Liking for Sweetness

The appreciation of the sensation of sweetness runs deep in the human psyche. In literature and mythology sweetness is linked with pleasure and goodness, and in everyday language we use terms associated with sweetness to describe those we love (sweetie pie, honeybun). Our first food, breast milk, is sweet—in fact it is the sweetest of all mammalian milks. Newborn human infants drink more of a sweet solution than of plain water or of a salty, acidic, or bitter solution. It is not a learned taste: Everyone could be said to be born with a 'sweet tooth.' The reason for this sweet preference is not known. We could speculate that the brain's dependence on glucose as its sole source of fuel has coevolved in an environment where glucose or its precursor was not evenly distributed throughout the food supply. Perhaps those early primates who were able to detect sweetness best were most likely to survive.

Table 1 Sources of sweetness in human diets

- Honey
- Manna
- Honey ants
- Grape sugar
- Dates
- Maple sugar
- Sorghum
- Corn syrup solids
- High-fructose corn syrup solids
- Sugar beets
- Sugar cane
- Sugar alcohols (e.g., sorbitol)
- Intense sweetners (e.g., saccharin)

Hunter–gatherers of the past relished honey and other sources of concentrated sweetness such as maple syrup, dried fruit, and honey ants (**Table 1**). Wild honey was so highly prized that we went to great lengths to obtain it. Australian Aboriginals would attach a tiny feather to a bee and follow it all the way back to its hive. The Wild Men (Veddas) of Sri Lanka esteemed honey so highly that they regularly risked their lives to obtain it.

The Contribution of Sucrose to Energy Intake

The contribution of macronutrients and individual sugars to total energy intakes in industrialized nations is shown in **Table 2**. Sucrose is at the top of the league table for sugars, contributions coming from both the naturally occurring sources of sweetness such as fruit and vegetables and also from refined sucrose. Sucrose, like all carbohydrates, is burned (oxidized) in the body to yield energy, specifically 16 kJ g^{-1}. This is only half the energy yield of a gram of fat (37 kJ g^{-1}) and much less than that

Table 2 The contribution of different types of carbohydrate and sucrose to energy intake in industrialized nations

Macronutrients	*% energy (adults)*	*Men (g per day)*	*Women (g per day)*	*Children (g per day)*
Carbohydrate	45			
Starch	21–23			
Total sugars	21–24			
– Added (refined) sugars	9–11	60–70	40–50	40–50
– Naturally occurring sugars	11–16	60–80	60–75	60–70
Individual sugars				
Sucrose	9–10			
Glucose	4–5			
Fructose	4–5			
Lactose	2–4			
Maltose	<0.3			

of alcohol (29 kJ g^{-1}). Other carbohydrates such as starch, glucose, and fructose have the same energy content per gram as sucrose. The new 'intense' sweeteners such as aspartame contribute virtually no energy, hence their use in 'low joule' products.

In Western countries, total carbohydrate intake amounts to about 200–280 g per day for the average man and woman, or about 45% of all the food energy eaten (protein contributes 15–20%, fat 35–40%). About half of our carbohydrate is in the form of starch (100–140 g per day), the other half representing a mixture of sugars, with sucrose predominating (**Table 2**). A decade ago, the only figures we had for consumption of refined sucrose were derived from apparent consumption statistics (production plus imports minus export, wastage, and nonfood usage). These statistics suggested that the average intake was around 50 kg per head per year or 125 g per day for every man, woman, and child, equivalent to 25% of total energy intake. Only recently have we been able to estimate accurately intake of refined or added sugars (most of which is refined sucrose but includes small amounts of honey, molasses, high-fructose corn syrup solids, etc.). These more direct estimates show daily intakes of 40–50 g in women and 60–70 g in men in developed countries. Children ingest 40–50 g per day refined sugars. Thus apparent consumption or per capita calculations overestimated consumption by as much as three times. Refined sugars today contribute about 10% of total energy in industrialized nations in Europe, North America, and Australasia. Japan is an exception, with intakes of only 10–20 g per day. Intakes of refined sucrose in nonindustrialized countries are also small, averaging 1–20 g per day.

Some countries have made a distinction between the sugars that are consumed with intact cell wall structure (intrinsic sugars) and those which have been released from nature's original packaging (extrinsic sugars). In this classification, the sugars in an orange are intrinsic sugars while those in orange juice are extrinsic. The lactose in milk is also extrinsic because it is not inside a cell wall. The belief is that nonmilk extrinsic sugars are less desirable because they will be absorbed more quickly into the bloodstream and that the fiber and micronutrient content of the food or diet will be lower. However, recent research has shown that many of these assumptions are incorrect.

Functional Roles of Sucrose in Foods

Refined sucrose is added to foods for more than just its sweetness. The difficulties inherent in producing low-joule products using intense sweeteners attest to this. For example, sucrose contributes to the bulk and texture of cakes and cookies and it provides viscosity and mouth feel in liquids such as soft drinks and fruit juices. Sucrose is also a powerful preservative and contributes the long storage life of jams and confectionery. In frozen products like ice cream, sucrose has multiple functions: It acts as an emulsifier, preventing the separation of the water and fat phases; it lowers the freezing point, thereby making the product more liquid and 'creamier' at the temperature eaten. The presence of sucrose retards the crystallization of the lactose in dairy foods and milk chocolate (tiny crystals of lactose feel like sand on the tongue). In canned fruit, sucrose syrups are used to prevent mushiness caused by the osmotic movement of sugar out of the fruit and into the surrounding fluid. Because sucrose masks unpleasant flavors, sugar syrups are used as carriers for drugs and medicines, especially for young children who cannot swallow tablet formulations. In products like yogurt and coffee it masks the acidity or bitterness and balances the sugar–acid ratio in fruit juices and cordials. Lastly, sucrose is a substrate for fermentation. It is added as food for the yeast in bread-making and beer-making. But it is converted to alcohol and other products in the process and therefore not consumed as sucrose. For all these reasons, when manufacturers design a low joule–low sugar product, they find that many substances need to be added to perform all the roles that sucrose did alone.

Patterns of Consumption

Honey versus Sucrose

In preindustrial times, honey was the main source of concentrated sweetness in the diets of many peoples. There are no precise figures for historical consumption because honey was part of either a hunter–gatherer or subsistence economy. Until recently historians and food writers have proposed that it was a scarce commodity available only to a wealthy few. However, a reappraisal of the evidence in the Stone Age, Antiquity, the Middle Ages, and early Modern times suggests that ordinary people ate much larger quantities of honey than has previously been acknowledged. The Ancient Egyptians, for example, made frequent use of honey in their spiced breads, cakes, and pastries, and for priming beer and wine. In Roman times, half the recipes in a famous cookery book call for honey, and in Ancient Greece, those who died some distance from home were sometimes preserved in honey. These details give an impression of plenty. Even the poorest people could own a beehive because bees often made their homes

in a hollow log or a broken pot. Wealthy landowners might own dozens of beautifully constructed beehives and employ a beekeeper. During medieval times we know that honey was sold in large volumes (gallons and even barrels), units unlikely to be used for a scarce commodity. It was present in sufficient abundance to make mead a common alcoholic drink made from honey.

It is therefore possible that intakes of honey at various times during history may well have rivalled our current consumption of refined sugar. There are implications therefore for the role of sugar in modern diets. Refined sugar may not have displaced more nutrient-rich items from our present-day diets but only the nutritionally comparable food, honey.

Changes in Sucrose Consumption

It is a much more straightforward business to enquire about sugar (refined sucrose) consumption than honey consumption in preindustrial times. All sugar supplies, in Europe, came from imports, so customs records constitute a readily accessible record of national consumption. In the 1520s, the Dissolution of the Monasteries reduced demand for bees-wax for church candles and brought about a small decrease in the production of honey. Almost simultaneous with this came an increase in the supply of refined sucrose, imported from the new European colonies. Sugar was still considerably more expensive than honey, but this combination of events gained it a more complete following among the wealthy. Cookery books were used exclusively by the well-to-do at this time and clearly illustrate that, for this section of society, sugar had, by the 1550s, usurped honey's place in the diet.

It was not until the early 1700s, however, when the supply of sugar boomed, its price fell, and coffee, tea, and chocolate entered the British diet, that ordinary people finally began to buy significant amounts, and the per capita consumption reached 1.8 kg per year. The changeover from honey to sugar occurred more gradually in rural areas than in the cities. From this point sugar consumption rose inexorably, while honey consumption declined. Beekeeping ceased to be the general custom that it had been in former years—there was no longer a hive in every garden. By the beginning of the twentieth century the availability of refined sugar reached about 50 kg per head per year in most industrialized nations. Surprisingly, it did not continue to increase but remained at approximately this level or declined throughout the next 100 years. The 'steady state' suggests that the market and the taste buds have reached saturation.

Added versus Naturally Occurring Sugars

Recent studies also show that the intake of naturally occurring sugars from fruits and vegetables (including juices) is about 40–80 g per day, roughly equivalent to the intake of refined sugars. Thus all sugars contribute about 20–22% total energy intake in developed countries, or about half of all the carbohydrate eaten.

The Sugar–Fat Seesaw

In industrialized nations the intake of sugar varies from person to person, but there is a consistent relationship between sugars and fat intake. As refined sugar intake rises, fat falls, and vice versa. As the total sugars intake rises, most of the increase is due to refined sugars (refined sucrose, corn syrup solids, etc.). This relationship has important implications. The proportion of individuals achieving dietary guidelines for lower intakes of total and saturated fats is much higher among subgroups with higher intakes of total sugars and refined sucrose. In the past, we believed that sugar and fat went 'hand-in-hand' in foods and that a diet high in sugar was likely to be high in fat as well. But it turns out that the reverse is true: A high-sugar diet is more likely to be low in fat. It seems that very few people achieve a low-fat diet without also increasing sugars intake. Perhaps humans, consciously or not, strive to eat calories in their most concentrated energy-dense form.

One of the most important implications of these findings is that recommendations to reduce *both* sugar and fat may be counterproductive. A reduction in fat intake is certainly more likely to result in desirable changes in body weight, blood lipids, insulin sensitivity, and cardiovascular risk factors. Trying to reduce sugar intake as well may not only compromise the effort to reduce fat but reduce the palatability of the diet and hence long-term compliance with a low-fat diet.

Effect on Micronutrient Intake

Refined sucrose and other added sugars are regarded by many people as undesirable because they are 'empty calories' (energy without micronutrients). It was reasoned that sucrose would 'dilute' the micronutrient (vitamin, mineral) content of the diet and that high sugar intake would increase the likelihood of micronutrient deficiencies. When these assumptions were tested, diets containing moderate amounts of added sugars were found to be no less nutritious than diets low in sugar. This has been shown to be the case in both adults and children. Very high consumption of refined sugars is associated with low micronutrient intake, but so too is very low intake of sugars. Moderate consumption of sugars is associated with the highest intake of micronutrients.

One of the reasons for this unexpected result is the sugar–fat seesaw, i.e., low-sugar diets are higher in fat, which is essentially a poor source of micronutrients too. Another reason is that sweetened breakfast cereals and dairy products such as flavored milk, yogurts, and ice cream are a good source of micronutrients. Fruit juice drinks are a source of vitamin C as well as sugars. Thus refined sucrose aids the consumption of some nutritious but fairly unpalatable or bland foods.

Digestion and Absorption of Sucrose

Digestion

In the mouth, food is mixed with saliva and masticated. The physical matrix that encases the sucrose, e.g., the plant cell wall, is partially disrupted in the process. Mixing occurs very effectively in the stomach and sucrose is dispersed throughout the gastric contents. Peristaltic movements drive the semifluid material, called chyme, through the pyloric sphincter into the duodenum. The rate of stomach emptying varies as a function of the volume and acidity of the stomach contents as well as the osmolality of the chyme in the small intestine. Solutions that are acidic and hyperosmotic are emptied more slowly. Thus an acidic, high-sucrose food such as sweetened yogurt will be emptied relatively slowly.

Once in the small intestine, sucrose is too large to cross the epithelial cell membrane and must therefore be hydrolyzed for absorption to take place. The enzyme responsible for sucrose digestion is an α-glucosidase called sucrase, located in the microvillous brush border lining the small intestine (**Figure 2**).

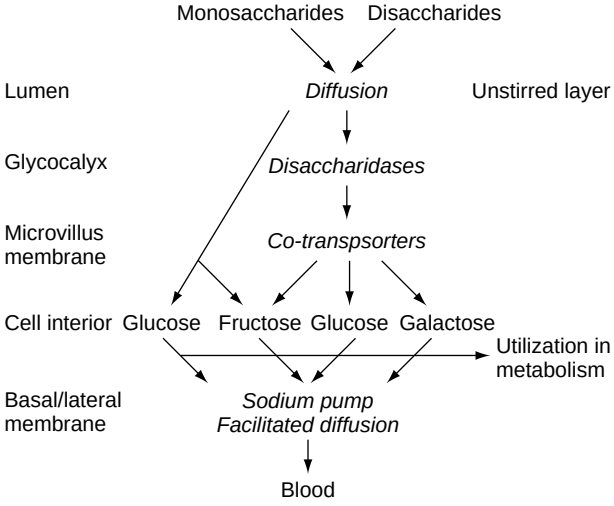

Figure 2 Disaccharidases such as sucrase are located on the luminal side of the brush border membrane of the small intestine. From Southgate D (1995) Digestion and metabolism of sugars. *American Journal of Clinical Nutrition* **62**: 203S–211S.

It digests some of the breakdown products of starch digestion as well as sucrose. Sucrose in foods is also easily hydrolyzed under weakly acidic conditions at room temperature such that considerable hydrolysis occurs even before ingestion, e.g., in soft drinks. Hydrolysis is accelerated by heating so that much of the sucrose used in food is actually swallowed as an equimolar mixture of glucose and fructose. Conditions in the stomach are also likely to hydrolyze sucrose, further increasing the monosaccharide concentration in the chyme.

Hydrolysis within the brush border is extremely rapid and the rate-limiting step is not digestion, but the transport of monosaccharides across the enterocyte. Sucrase, however, is located physically close to the monosaccharide cotransporter systems in the microvillus membrane.

Absorption of Glucose and Fructose

The glucose product of sucrose digestion is transported across the epithelial cell membrane more rapidly than is free glucose, a phenomenon that may be related to specific glucose transporters that are not dependent on sodium. The fructose released by sucrose digestion is absorbed more slowly across the brush border membrane by a process called facilitated diffusion (carrier-mediated). Fructose appears to be absorbed better when ingested with glucose (separately or combined in sucrose) than it is by itself. This explains why 100 g fructose gives rise to osmotic diarrhea, whereas 250 g sucrose does not. The absorption of free fructose is incomplete when intakes exceed about 35 g per day.

Once inside the epithelial cell, glucose and fructose are presumed to traverse the enterocyte by diffusion. The basal-lateral membrane acts as a barrier preventing the free movement of monosaccharides into and out of the enterocyte. Movement across the membrane appears to be energy-dependent but sodium-independent.

Metabolism of Glucose

From the epithelial cell, the monosaccharides pass into the portal circulation and to the liver where some of the glucose and virtually all the fructose is removed. The remainder of the glucose passes into the systemic circulation, entering the peripheral tissues by mass action and/or under the influence of the hormone insulin.

Metabolism of Fructose

When fructose reaches the liver, most is removed from the bloodstream and converted to glucose, lipid, or lactate. Some fructose is converted in the

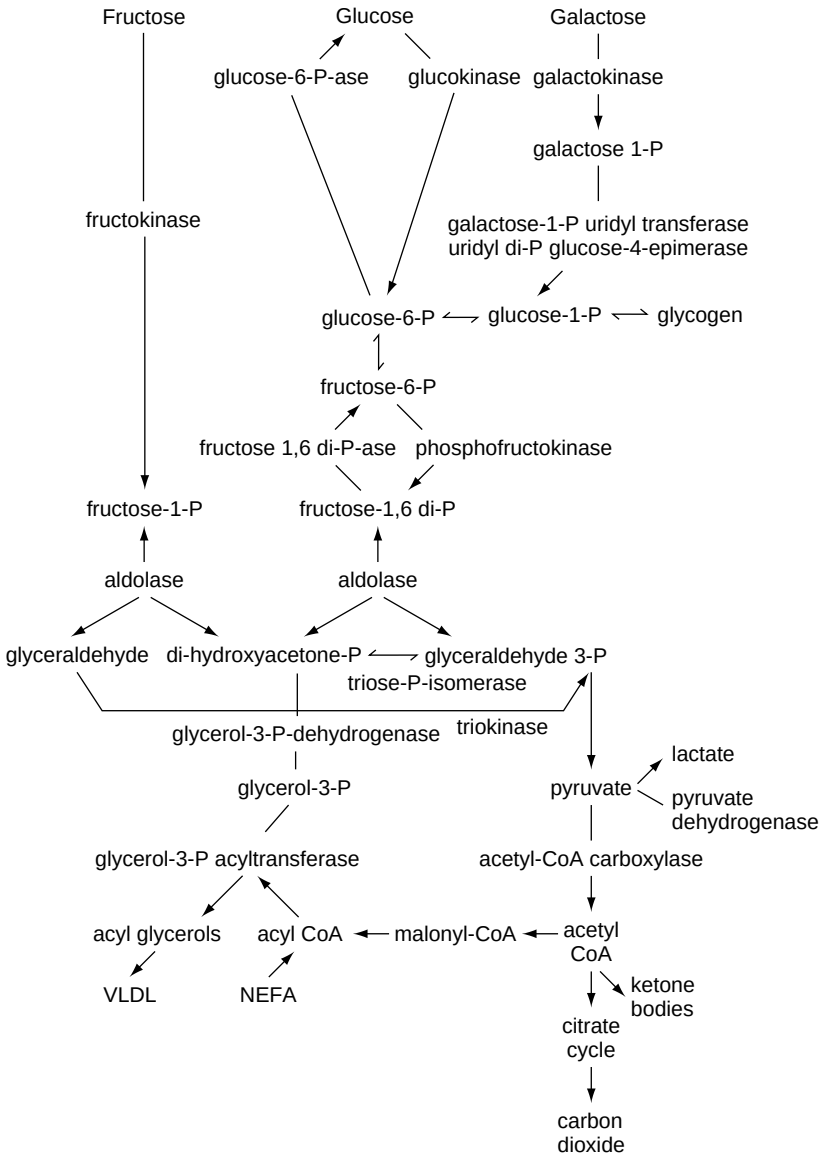

Figure 3 The monosaccharide products of sucrose digestion are metabolized to carbon dioxide and water via the tricarboxylic acid (TCA) cycle. From Southgate D (1995) Digestion and metabolism of sugars. *American Journal of Clinical Nutrition* **62**: 203S–211S.

liver to fructose-1-phosphate, which is spilt into two C_3 products, glyceraldehyde and dihydroxacetone phosphate. The latter is an intermediate for both the glycolytic and gluconeogenic pathways. The glyceraldehyde is phosphorylated and recombines with dihydroxyacetone phosphate to produce fructose-diphosphate and ultimately glycogen. The major metabolic effect of fructose is to increase the production of pyruvate and lactate. This has the effect of depressing fatty acid oxidation and increasing the esterification and the synthesis of very low-density lipoprotein (VLDL). There is only a small rise in plasma glucose (and insulin) levels because gluconeogenesis is strongly inhibited. A rise in plasma lactate is seen after fructose consumption.

Metabolic Sequelae

Consumption of sucrose (and other carbohydrates such as starch) produces a range of metabolic and hormonal responses, all of which serve to limit the rise in plasma glucose levels to within acceptable levels. Blood glucose levels above 10 mM will result in glycosuria (glucose in the urine), a waste of valuable energy, and levels below 3–4 mM will impair brain function. Insulin plays an important role in bringing blood glucose levels back to normal after a meal. It does that by promoting glucose uptake in the liver and muscle cells and inhibiting gluconeogenesis in the liver. Dietary carbohydrate, including sucrose, has four main metabolic fates: (1) oxidation in tissues,

mainly as glucose molecules; (2) storage as glycogen in liver and muscle cells; (3) storage as triacylglycerol (TAG), mainly in the liver; and (4) conversion of glucose into C_3 storage as precursors in the liver where they are used as substrates for gluconeogenesis. The latter is a futile cycle, but it seems that large amounts of glucose undergo this transformation.

During the 4 h after a typical meal, the amount of ingested carbohydrate far exceeds the amount of glucose that can be oxidized in the cells. As a result, most of the dietary glucose is stored as glycogen in liver and skeletal muscles and is subsequently released and oxidized within the next 12 h.

Insulin stimulates glucose oxidation by enhancing glucose transport into insulin-sensitive cells. Inside the mitochondria, insulin stimulates glycolysis at several steps and activates pyruvate dehydrogenase complex, the port of entry of glucose-derived acetyl-CoA into the tricarboxylic acid (TCA) cycle (**Figure 3**). Insulin also inhibits lipolysis in adipose tissue, thereby lowering plasma free fatty acid levels (FFA) and reducing lipid oxidation in the muscle cells. The inhibition of fat oxidation is directly related to reduced plasma FFA and mirrors the stimulation of glucose oxidation.

The body's glycogen reserves are small (250–500 g in a 50–70 kg adult human), although the capacity to store more can be developed by exercise, training, and diet. A normal diet provides about 200–280 g carbohydrate a day. Thus within any 24 h period, there is total oxidation of absorbed dietary carbohydrate, including sucrose. Other metabolic pathways for disposal of dietary carbohydrate, such as conversion into TAG or nonessential amino acids, are not quantitatively important.

Plasma Glucose and Insulin Responses

After a meal containing sucrose, the plasma glucose rises, reaching a peak within 15–30 min, and returns to baseline within 2 h. The classification of carbohydrates as sugars or starches does not predict the magnitude of this response. In the past it was assumed that refined sucrose caused a more rapid rise in blood glucose levels than starchy foods or naturally occurring sources of sugars like fruit. This view has been shown to be incorrect. Most starchy foods, including potatoes, bread, and many packaged breakfast cereals, are digested and absorbed rapidly and the blood glucose response is almost as high as that seen with an equivalent load of pure glucose. Foods containing refined sucrose, such as soft drinks and ice cream, have been shown to give moderate rises in blood glucose. Furthermore, the glycemic response to foods containing refined sugars is similar to that of foods containing naturally occurring sugars.

The 'glycemic index' approach has been used to classify foods according to their ability to raise the level of glucose in the blood. Foods are tested in equivalent carbohydrate portions according to standardized methodology. On a scale where glucose = 100, the glycemic index of refined sucrose (= 65) is similar to that of white bread (= 70). **Table 3** shows the glycemic index of a range of common foods. Refined sucrose elicits an insulin response commensurate with its glycemic response, i.e., it does not stimulate inappropriately high insulin secretion.

Dietary Sucrose and Disease

B Caballero, Johns Hopkins University, Baltimore, MD, USA

Introduction

For decades, sucrose (the disaccharide of glucose and fructose) has been the main sweetener added to human diets, particularly for sweetened beverages. But in the past 15 years, sucrose use has been progressively displaced by high-fructose corn syrup. Furthermore, the increasing popularity of diet sodas has also displaced some of the sweetened beverages, in favor of artificially sweetened ones. Still, sucrose continues to be an important dietary energy source in many parts of the world.

The term sugars includes a variety of refined carbohydrates, and its use in the literature is not always consistent, and it may refer to all refined carbohydrates present in a food item, or only sucrose, or only added sugars. The latter is particularly important for assessing health outcomes, because it is the fraction of dietary refined carbohydrates that can obviously be manipulated over a wide range, similar to the case of added sodium. These added sugars, contrary to natural sugars present in fruits or milk, contribute no essential nutrients to the diet, but do add to energy intake, and are thus 'empty' calories.

Several mechanisms have been suggested for the possible health effects of refined sugars: (1) favoring an increase in total energy intake, possibly mediated by changes in ingestive behavior or by metabolic effects on energy regulation; (2) displacement of nutrient-rich foods, with the consequent decrease in intake of essential nutrients; and (3) metabolic effects adversely affecting glucose homeostasis. It should be noted that few studies have evaluated sucrose's effects separate from that of other refined sugars that may also be present in the diet. Furthermore, some studies do not separate added sugars from other oligosaccharides naturally present in foods.

Effects on Energy Intake and Body Weight

The preponderance of evidence does show that increased consumption of added sugars is associated with increased total energy intake. A study by the US Department of Agriculture using national survey data found that 60% of individuals in the upper quartile of sugar intake exceeded their recommended energy intake, compared with 22% in the other quartiles. Individuals who did not exceed their energy allowance did so by reducing intake of fruits, vegetables, and milk, evidence of an undesirable displacement of nutrient-rich foods by added sugars. A similar displacement effect of sugars has been shown in 6–13-year-old children. However, it should be noted that several other cross-sectional studies have found no correlation between added sugars intake and total energy intake, but these studies did not adjust for physical activity, which is an important factor determining total energy intake and possibly fluid intake as well.

Sweetened Beverages

This issue is of interest given the dramatic increase in consumption of sweetened beverages over the past decade, which have become the main contributors to added sugars intake in the US. There is evidence that sweetened beverages may be the main source through which added sugars result in higher total energy intake. For example, adolescents who consumed at least 2 cans (12 oz) of soda per day had a total energy intake of 2600 kcals, compared to 1980 in those who did not consume sodas. Similarly, a randomized trial comparing sweetened and artificially sweetened beverages in overweight individuals showed a significantly higher ad libitum dietary energy intake in those consuming sweetened beverages.

In spite of consistent evidence of an effect of added sugars on total energy intake, linking that effect with excess weight gain has been more difficult, possibly due to the many factors affecting body weight homeostasis. Furthermore, there are still relatively few well-designed and adequately powered longitudinal studies assessing body weight and adiposity in relation to added sugar consumption. Some of the few available studies report relatively modest but significant effects on body weight, specifically for sweetened beverages. An observational study in 7-year-old children reported an increase of $\sim$0.20 in BMI for each additional serving of sweetened drink over a 19-month period. Another 9-year follow-up of adolescents found a significant correlation of sweetened beverage intake with BMI, but not with body fat. Other studies in children found no correlation. Almost all cross-sectional studies found no association between sugar intake and body weight, but it is well recognized that these types of studies are not the most appropriate to test this association.

Nutrient Dilution

Adding sugars to foods will increase their energy density (kcal per unit weight), and since they do not add nutrients, this will result in a net reduction

in nutrient content per kcal. This dilutional effect is evidenced in the increasing per cent of individuals who do not meet their RDA for one or more micronutrients as their consumption of added sugars increase. In adolescents, soft drinks tend to displace nutrient-rich milk and juices. Data from the US population indicate that this dilutional effect starts at around 20% of sugars in the diet, and becomes significant at around 25%. Thus, this level has been defined as a 'maximum' acceptable intake.

Some investigators have suggested that high-fructose corn syrup (HFCS), the most widely used sweetener, may have specific adverse effects on health. The rationale is that because of its rapid absorption, HFCS generates a steeper postprandial plasma insulin response, which may have adverse long-term consequences. But whether the dramatic switch from sucrose to HFCS that occurred in the US and in other countries has played a causal role in the increase in obesity or type 2 diabetes remains unclear. Similarly, while short-term, controlled experiments suggest that humans may not fully compensate for calories consumed in fluid form, there is insufficient data to assess the potential implications of such response on total energy intake and body weight regulation in the general population.

Dental Caries

Sucrose, glucose, lactose, and fructose are excellent substrates for the first step of caries formation, which involves bacterial fermentation. This process results in acidification and subsequent demineralization of the tooth surface, allowing bacterial invasion. The more substrate there is available, the more fermentation and subsequent enamel invasion.

In spite of that clear relational pathway, the precise contribution of sucrose intake to dental caries is not simple. Several experts consider that dental hygiene is a more powerful determinant of cavity prevalence than sucrose intake. For example, the National Health and Nutrition Examination Survey III (NHANES III) from the US showed no correlation between sucrose intake and dental caries in people under the age of 25 years, who were born after widespread use of fluoride. Conversely, the association is found in older people, before fluoridation was common. In studies in the UK, the correlation between socioeconomic status and caries was found to be three times that between sugar intake and caries, indicating a strong effect of dental hygiene and health practices in general. Thus, while the role of sucrose in the causative pathway of dental caries is unquestionable, it seems clear that there are other modulating factors that have come to the forefront in contemporary society, namely the use of fluoride and better oral hygiene practices. Nevertheless, sucrose continues to be one of the factors involved in caries formation, perhaps with more relevance for younger children. This is also affected by the food source, for example, hard candies that remain in the oral cavity for some time may allow longer periods of exposure than other sources of sucrose.

Type 2 Diabetes

Several prospective, observational studies have found no association between sugar intake or total carbohydrate intake and type 2 diabetes. Similarly, US national survey data (NHANES III) show no correlation between carbohydrate intake and HgbA1C. However, a recent analysis of the longitudinal Nurses' Health Study in the US reported an association between consumption of sweetened beverages and risk of type 2 diabetes in women. At least one study found an inverse association, i.e., higher sugar intake linked to reduced rates of diabetes.

Summary

While some of the putative adverse effects of sucrose require further study, there is consistent evidence that added sugars facilitate excess energy intake, particularly when consumed as sweetened beverages, while contributing no essential nutrients to the diet. Given that obesity is a major global public health problem, most experts advise to reduce consumption of added sugars as a means to avoid excess weight gain. Even acknowledging that the issue is still a matter of controversy, a recent WHO report has recommended that added sugars should not exceed 10% of total calories. The US dietary reference intakes established a maximum of added sugars of 25% of calories, based on the dilutional effect that added sugars have on micronutrient intakes, and on the obligatory glucose requirements of the brain and other organs. Nevertheless, all the experts are consistent in recommending that most of the carbohydrates in a healthy diet should be of the complex type, for which there is solid evidence of benefits to health maintenance and disease prevention.

Dietary Supplements

S S Percival, University of Florida, Gainesville, FL, USA

In 2004, global sales of dietary supplements represented a significant business. Worldwide sales have been estimated at $70–250 billion. The demand for herbal products worldwide increased at an annual rate of 8% from 1994 to 2001, although this growth has slowed in recent years.

Issues and controversies in the dietary supplement market are related to defining exactly what is a dietary supplement, understanding how sales and marketing data are derived, defining the regulatory environment, safety issues, product quality issues, labeling and health claim issues, and scientific evidence for benefit. This article describes some of these controversies and provides examples to illustrate these issues.

How Is the Sales Data Derived?

Global sales have been estimated to be between $70 billion and $250 billion. This approximately 3-fold difference in estimates is due to the variation in what products are actually included in product sales results. As will be discussed, the definition of dietary supplements varies greatly from country to country; therefore, deriving sales data is complex.

Another difficulty in assessing sales of dietary supplements is the source from which sales data are gathered. Many business surveys rely on only one or two of the following sales outlets to derive their results:

- Supermarkets and mass merchandisers
- Natural food and health food stores
- Direct sales from Internet, mail order, practitioners, and multilevel marketing
- Pharmacies and drugstore chains

What Is a Dietary Supplement? How Are They Regulated in Different Countries?

Each country has developed regulatory definitions and systems that place dietary supplements, particularly botanicals, into categories of drugs, traditional medicines, or foods. However, in the late 1980s, many countries launched major changes in regulations that may or may not have been approved at the time of this writing. Many regulations are still in draft form.

The US Congress defined the term 'dietary supplement' in the Dietary Supplement Health and Education Act (DSHEA) of 1994. A dietary supplement is a product, taken orally, that contains a 'dietary ingredient' that is intended to supplement the diet. The dietary ingredient includes vitamins, minerals, herbs or other botanicals, amino acids, a dietary substance for use by man to supplement the diet by increasing the total dietary intake (e.g., enzymes or tissues from organs or glands), or a concentrate, metabolite, constituent, or extract. Dietary supplements may be found in many forms, such as tablets, capsules, softgels, gelcaps, liquids, or powders. They may also be produced in other forms, such as a beverage, spread, or bar, in which case information on the label must clearly state that the product is a dietary supplement and it is not represented as a conventional food or a sole item of a meal or diet.

Whatever their form, DSHEA places dietary supplements in a special category under the general umbrella of 'foods,' not drugs, and requires that every supplement be labeled a dietary supplement and carry a Supplement Facts Label.

In the United Kingdom, there is a distinct separation of food supplements and herbal medicines. The Food Standards Agency developed the Food Standard Act of 1999 and is responsible for protection of public health. The Food Supplement Directive 2002/46/EC, which harmonizes European Community legislation on food supplements, was published in 2002. This directive is stricter than existing UK standards and regulations but is relatively more liberal than what exists in other European countries. The directive defines the term 'food supplements,' contains a list of vitamin and mineral sources that may be used in the manufacture of food supplements, states labeling requirements, and, in the future, will provide a framework for maximum and minimum levels for vitamins and minerals in food supplements. Herbals and botanicals are not discussed in this directive.

The Foods Supplement Directive defines a food supplement as any food the purpose of which is to supplement the normal diet and which is a concentrated source of a vitamin or mineral or other substance with a nutritional or physiological effect, alone or in combination, and is sold in dose form. Dose form means capsules, pastilles, tablets, pills, and other similar forms, and also powders, ampoules, drops, or other similar forms of liquids or powders, designed to be taken in small measured quantities. Because the directive defines a food supplement as something to supplement the diet, products that are not meant to supplement the diet (e.g., a weight loss product) are outside the scope of the regulations. There remains a complex legal area between food supplements and medicinal products, although the directive indicates that if a product is used for treating or preventing disease, or restoring, correcting, or modifying a physiological function, then it falls under the Medicines Directive 2001/83/EEC, Medicines Act 1968, or Medicines for Human Use Regulations 1994.

The *Trans*-Atlantic Business Dialogue (TABD) approved a position statement regarding dietary supplements in 2002. The TABD is a group of corporations that promote closer commercial ties between the European Union and the United States. This position statement established industrywide consensus on standards and definition of permissible claims, as well as defining what is necessary for substantiation of those claims. In keeping with the Foods Supplement Directive, the TABD dealt only with vitamins and minerals, with the understanding that some of the conclusions may be revisited when warranted for herbals, botanicals, or other dietary supplements.

Herbal medicines, on the other hand, are regulated by the Medicine and HealthCare Products Regulatory Agency based in London. A herbal remedy is defined as

> a medicinal product consisting of a substance produced by subjecting a plant or plants to drying, crushing or any other process, or of a mixture whose sole ingredients are two or more substances so produced, or of a mixture whose sole ingredients are one or more substances so produced and water or some other inert substance.

There are two alternative regulatory routes in the United Kingdom for herbal medicines:licensing and exemption from licensing requirements:

- Licensed herbal medicines:To receive a product license prior to marketing, herbal medicines are required to meet safety, quality, and efficacy criteria in a similar manner to any other licensed medicine.
- Herbal remedies exempt from licensing requirements:The exemption applies to herbal remedies meeting certain conditions set out in Section 12 of the Medicines Act 1968. Section 12 allows a person to make, sell, and supply a herbal remedy during the course of his or her business provided the remedy is manufactured or assembled on the premises and that it is supplied as a consequence of a consultation between the person and his or her patient. Section 12 also allows the manufacture, sale, or supply of herbal remedies where the processing of the plant consists only of drying, crushing, or comminuting; the remedy is sold without any written specification as to its use; and the remedy is sold under a designation that only specifies the plant and the process and does not apply any other name to the remedy.

Canada has been estimated to have approximately 3% of the market share of the global nutritional market. Health Canada established the Office of Natural Health Products. Premarket assessment, labeling, licensing, and monitoring of herbal supplements are items in its mandate. The definition of a natural health product includes products for the use in "diagnosis, treatment, mitigation, or prevention of a disease, disorder, or abnormal physical state or its symptoms in humans; restoring or correcting organic function in humans; or modifying organic functions in humans, such as modifying those functions in a manner that maintains or promotes health." These products include homeopathic preparations, substances used in traditional medicine, a mineral or trace element, a vitamin, an amino acid, an essential fatty acid or other botanical-, animal-, or microorganism-derived substance. Foods are not included in this product category called natural health products. Canada's Food and Drugs Act of 1953 regulates foods and drugs but does not specifically deal with natural health products. Therefore, these types of products are regulated as either a food or a drug depending on the type and concentration of active ingredient and whether claims are made on the products.

Germany regulates vitamins and minerals as food if they are sold to complement the nutritive value of the diet and do not exceed safe levels. However, if the vitamin or mineral is used for disease treatment or prevention and is used at pharmacological levels, then it is considered a drug. Safety and efficacy of drugs must be established by clinical research. Medicinal plants are regulated differently depending on what plant and in what form it is sold. In general, extracts of plants are considered drugs and must be prescribed. Teas, on the other hand, are sold over-the-counter in pharmacies. Other teas, such as those that contain alkaloids, must be sold by prescription only. Beginning in 1980, an extensive analysis of the literature on more than 300 herbal remedies was undertaken by the German Kommission E. Approximately two-thirds of the herbals were listed as safe and at least minimally effective. The results were published as a series of monographs by the German Kommission E, and this body of work was summarized and translated into English by the American Botanical Council. These substances are generally purchased at the pharmacy and are reimbursable through health insurance. One caveat regarding the German herbal preparations is that they are not likely to be the same preparations that are produced by other countries; thus, the safety and efficacy statements in the Kommission E are only for the preparations that are prepared in German pharmacies.

Australia regulates therapeutic goods under the Therapeutic Goods Act of 1989. Therapeutic goods include vitamins, minerals, plants and herbals, nutritional food supplements, naturopathic and homeopathic preparations, and some aromatherapy. The Therapeutic Goods Administration (TGA) developed the Office of Complementary Medicine to evaluate new substances and products. Basically, the TGA regulates these therapeutic goods as they do pharmaceutical products, and thus their criteria are more rigorous than the criteria of other countries. Most of the therapeutic goods are 'generally listed' rather than regulated. Listed medicines are considered to be relatively harmless, so the regulations allow for manufacturers to 'self-assess' their products in some situations. The majority of listed medicines are self-selected by consumers and used for self-treatment, and they are all manufactured with well-known established ingredients, such as vitamin and mineral products or sunscreens. These are assessed by the TGA for quality and safety but not efficacy. This does not mean that they do not work; rather, it means that the TGA has not evaluated them individually to determine if they work. It is a requirement under the act that sponsors have information to substantiate all of their product's claims.

The Japanese Ministry of Health and Welfare does not define or recognize a distinct category known as dietary supplements. Instead, there are only two

Table 1 Regulatory categories of different countries

Country, act	*Definition*
United States, DSHEA	Vitamins, minerals, herbal, other botanical, amino acid, enzymes, organs, glands
Europe, Food Supplement Act	Vitamin and minerals
United Kingdom, Medicine and Health Care	Medicinal plants
Canada, Office of Natural Products	Mineral; trace element; vitamin; amino acid; essential fatty acid; botanical-, animal-, or microorganism-derived substances; homeopathic preparation; traditional preparations
Germany, Kommission E	Vitamin and mineral as both foods and drugs, botanicals (approved and not approved), teas as prescription and as over-the-counter
Australia, Therapeutic Goods Administration	Vitamin and mineral, plants, herbs, nutritional food supplements, naturopaths and homeopathic preparations, aromatherapies
Japan, Ministry of Health and Welfare	No definition of dietary supplements, regulations for foods, drugs, and Kampo

classifications, food and drugs. In 1993, Japan defined a group of foods known as Foods for Specific Health Use (FOSHU). As of 2004, approximately 342 foods had been approved as FOSHU. The dietary ingredients are sold in the form of foods, not in the form of capsules, tablets, or powders.

The herbal supplements market in Japan has been strongly influenced by the practice of Kampo. Kampo (or Kanpo) is the adaptation of Chinese herb formulas to Japanese medicine. Approximately 25 years ago, the Japanese Ministry of Health formally recognized that certain traditional Chinese herb formulas (and a few formulas of similar nature developed in Japan) were suitable for coverage by national health insurance. These formulas are prepared in factories under strict conditions.

In summary, developing global data on dietary supplement sales depends on how they are defined. **Table 1** summarizes the differences in regulatory categories of different countries.

Product Quality and Safety Issues

Product quality is an issue derived from the explosive growth of the industry in the post-DSHEA world. Quality issues revolve around products that contain wrong ingredients, incorrect claims, contamination, or incorrect amounts—either too much or not enough.

An example plant misidentification was published in 1998 by Slifman *et al*. Two patients were admitted to hospital emergency rooms with palpitations, vomiting, nausea, and chest pressure, among other symptoms. Both individuals, having been admitted 1 month apart, had each consumed a program of dietary supplements, one containing 14 herbs, a tablet containing 11 herbs, liquid clay, a bulking powder, and capsules containing microorganisms. Of the five supplements, the one made up of 14 herbs tested positive for cardiac glycosides. The investigators determined that *Digitalis lanata* was present in the supplement. *Digitalis lanata* contains cardiac glycosides, which resulted in the cardiac symptoms. Further investigation revealed that raw material labeled as plantain (genus *Plantago*) had been contaminated with *D. lanata* due to misidentification in the field.

Another quality issue that has safety manifestations was an incorrect claim on a product. PC-SPES, a combination of eight herbs, is claimed to be a nonestrogenic treatment for prostate cancer. However, several of the herbs used in this preparation do in fact have estrogenic activity. In 1998, DiPaola *et al.* showed a significant amount of estrogenic activity in both *in vitro* (yeast) and *in vivo* studies (mice and humans) with PC-SPES. Use of the supplement by men with prostate cancer resulted in similar side effects as would develop with estrogen therapy and theoretically could confound the results of standard therapy.

By law (DSHEA), the manufacturer is responsible for ensuring that its dietary supplement products are safe before they are marketed. Unlike drug products that must be proven safe and effective for their intended use before marketing, there are no provisions in the law for the US Food and Drug Administration (FDA) to 'approve' dietary supplements for safety or effectiveness before they reach the consumer. Also unlike drug products, manufacturers and distributors of dietary supplements are not required by law to record, investigate, or forward to the FDA any reports they receive of injuries or illnesses that may be related to the use of their products. Under DSHEA, once the product is marketed, the FDA has the responsibility to show that a dietary supplement is 'unsafe' before it can take action to restrict the product's use or remove it from the marketplace.

In 2003, the FDA banned all products containing ephedra alkaloids. Ephedra-containing products were, until the ban, marketed in conjunction with enhancing athletic performance

and/or promoting weight loss. Recent studies provided enough additional evidence that ephedra presents a significant and unreasonable risk of illness and injury that the FDA banned all ephedra-containing products from the market and advised consumers to stop taking such supplements. Strong statements were issued cautioning about the use of ephedra-containing products, especially when strenuously exercising or in combination with other stimulants, such as caffeine.

Interactions

An issue that has become of concern is the interaction of dietary supplements with herbs and other dietary supplements, drugs, foods, lab tests, and diseases or other conditions. There are literally hundreds of potential interactions that have not yet been recognized. Both practitioners and consumers must be aware of the possibilities. In some cases, knowledge about interactions comes from documented reports. However, in other cases, the knowledge is theoretical, based on the pharmacological profile or mechanism of action of the supplement and the drug, food, test, or condition. For example, ginkgo biloba contains ginkgolides in the leaf that competitively inhibit platelet-activating factor (PAF). PAF inhibition decreases platelet aggregation among other many other physiological effects. Inhibition of PAF may increase cardiac contractility and coronary blood flow. Concomitant use of herbs and supplements that affect platelet aggregation could theoretically increase the risk of bleeding in some people due to ginkgo's effects on platelet aggregation. Spontaneous hematomas (broken blood vessels) and hemorrhaging in the anterior chamber of the eye have been reported in ginkgo users, although it is not known what other drugs or supplements these individuals were taking.

Herbs and supplements that promote platelet inhibition include angelica, anise, capsicum, celery, chamomile, clove, fenugreek, feverfew, fish oil, garlic, ginger, horse chestnut, horseradish, licorice, meadowsweet, onion, Panax ginseng, red clover, vitamin E, and willow. Similarly, concomitant administration of drugs, including aspirin, clopidogrel (Plavix), dalteparin (Fragmin), enoxaparin (Lovenox), heparin, indomethacin (Indocin), ticlopidine (Ticlid), and warfarin (Coumadin), may increase the risk of bleeding in some people. This is just one example of the interactions between drugs with herbals and herbals with other herbals. There may be an infinite number of interactions.

Currently, there are no mandated US federal guidelines to report adverse events or consumer health complaints associated with the use of dietary supplements. MedWatch reporting is voluntary. In 2004, the Life Sciences Research Office published a report, *Recommendations for Adverse Event Monitoring Programs for Dietary Supplements*.

Label Claims

Label claims regarding dietary supplements are a complex issue that varies from country to country. Yet no matter what specific claims are allowed or disallowed by a country, it is reasonable to assume that any global regulation requires that the claim be true, not misleading, and be clear to the consumer. A summary of US label claims follows.

The Nutrition Labeling and Education Act (NLEA) was passed in 1990 as a result of a pre-1984 FDA position that prohibited making any therapeutic or disease-related claims on a food or dietary supplement label. The NLEA permits certain claims describing a positive relationship between a supplement and a health-related condition (or disease). These claims are considered 'health claims' in order to distinguish them from nutrient content claims. A health claim must be authorized by the FDA, and the FDA can only authorize a claim if there is "significant scientific agreement among qualified experts" or by the 1997 amendment that permits a manufacturer to rely on a statement from an "authoritative scientific body" of the US government or the National Academy of Sciences. This is a rigorous assessment and only 14 claims have been authorized to date.

In addition to health claims, dietary supplement labels are permitted to have qualified health claims or structure-function claims. The rationale behind the development of a qualified health claim was the idea that the First Amendment should allow disclaimers to be considered as solutions to making claims nonmisleading (Pearson v. Shalala). In other words, the First Amendment does not allow the FDA to reject health claims unless it shows that disclaimers would fail to remedy harm from misleading statements. The criteria for a qualified health claim were released in 2003 and in this context the FDA will not take enforcement action against a manufacturer using the following specified qualifiers provided the FDA is satisfied that the qualifiers are not misleading:

- "Although there is scientific evidence supporting the claim, the evidence is not conclusive."
- "Some scientific evidence suggests .... However, FDA has determined that this evidence is limited and not conclusive."

- "Very limited and preliminary scientific research suggests .... FDA concludes that there is little scientific evidence supporting this claim."

Qualified health claims for dietary supplements recognized by the FDA as part of its enforcement discretion include such examples as the relationships between phosphatidylserine and cognitive function, B vitamins and cardiovascular disease, omega-3 fatty acids and cardiovascular disease, selenium and cancer, and antioxidant vitamins and cancer.

Dietary supplements are not permitted to carry labeling statements that imply such issues as 'cure,' 'mitigate,' 'treat,' or 'prevent disease' because these statements are considered within the definition of a drug and drugs are subjected to a rigorous premarket approval process. However, under DSHEA, structure–function claims are permitted on dietary supplements because dietary supplements may have effects on the structure or function of the body without the implication that they act as a drug and/or are related to disease. Structure–function claims include those that describe the role of the dietary supplement in affecting the structure or function in humans or the documented mechanism in which a dietary supplement acts to maintain such structure or function. In addition, dietary supplement label claims allow statements of benefits related to classical nutritional deficiency or statements regarding the general feeling of well-being derived from consumption.

Potential Benefits of Dietary Supplements

The 2000 *Dietary Guidelines for Americans* (new release due 2005) emphasizes choosing foods sensibly, maintaining a healthy weight, and exercising regularly. It acknowledges that some people may need a vitamin–mineral supplement to meet specific needs. Similarly, the Food and Nutrition Board and the American Dietetic Association also recognize that dietary supplements may be desirable for some nutrients and for some individuals. The following is a compilation of recommendations by these groups:

- Folic acid supplements for women of childbearing age due to the risk of neural tube defects
- Vitamin B_{12} supplements for people older than age 50 years due to inefficient absorption
- Vitamin B_{12} supplements for vegans who eat no animal products
- Calcium for people who seldom eat dairy products
- Vitamin D for elderly people who do not consume fortified dairy products and for others with little exposure to sunlight
- Iron supplementation for pregnant women
- Multivitamin–mineral supplement for people who are following a severely restricted weight-loss diet

Specifically for athletes, the position of the American Dietetic Association, Dietitians of Canada, and the American College of Sports Medicine is that physical activity, athletic performance, and recovery from exercise are enhanced by optimal nutrition. These organizations recommend appropriate selection of food and fluids, timing of intake, and supplement choices for optimal health and exercise performance. In sports, athletes who are at greatest risk of micronutrient deficiencies are those who restrict energy intake or use severe weight-loss practices, eliminate one or more food groups from their diet, are sick or recovering from injury, or consume high-carbohydrate diets with low micronutrient density. In practice, athletes should consume diets that provide at least the RDAs/DRIs for all micronutrients from food. It follows that, in general, no vitamin and mineral supplements are required if an athlete is consuming adequate energy from a variety of foods to maintain body weight. Supplementation may be necessary under conditions of inadequate food intake. Athletes, as for the general population, should follow supplementation recommendations unrelated to exercise, such as folic acid in women who may become pregnant.

Conclusions

One of the difficulties in assessing the nature of the worldwide dietary supplement industry and its regulations is largely in understanding what products are considered dietary supplements. In the United States, only pills, capsules, tablets, and the like are considered dietary supplements. Globally, it is sometimes difficult to discuss dietary supplements without discussing functional foods or nutraceuticals. Functional foods are similar in appearance to conventional foods but have demonstrated physiological benefits beyond the traditional nutritional value. Nutraceuticals may to go so far as to declare not only health benefits but also medical benefits that reduce the risk of chronic disease beyond basic nutritional functions. Canada regulates functional foods, nutraceuticals, and dietary supplements under one regulatory agency. The United States clearly distinguishes between foods and dietary supplements, although both fall under the category of food, which is distinct from drugs. The United

Kingdom distinguishes between herbal medicines and dietary supplements containing vitamins and minerals. Japan regulates functional foods as FOSHU and has no regulatory definition for dietary supplements as defined in the United States. Moreover, these regulations are in a constant state of flux as the industry changes and develops over time. Issues that must be monitored regarding dietary supplements consumption are product quality and potential harmful interactions among supplements, foods, and drugs. Health claims that have been approved by regulatory agencies worldwide stress that the claims be truthful, clear, and not misleading to the ultimate consumer. Current scientific expertise acknowledges that dietary supplements, specifically some of the vitamins and minerals, have potential benefits in certain populations.

Role of Micronutrient Supplementation

R D W Klemm, Johns Hopkins University, Baltimore, MD, USA

Introduction

Globally, almost two billion people (one-third of the human race) are affected by vitamin A, iron, iodine, and/or zinc deficiencies that put them at an increased risk of poor growth, morbidity, intellectual impairment, and/or mortality. Since the mid-1980s micronutrient supplementation has been a major public-health strategy in developing countries to prevent and control deficiencies in vitamin A, iron, and, to a lesser extent, iodine. More recently, zinc supplementation has come to be considered as an efficacious adjunctive therapy for diarrhea in populations with an elevated risk of zinc deficiency. This article will define micronutrient supplementation, examine the role of supplementation as a strategy for the prevention and control of micronutrient deficiencies, and examine evidence for vitamin A, iron, iodine, and zinc supplementation interventions with respect to efficacy, recommended dose, frequency of administration, safety, and program effectiveness.

Definition of Micronutrient Supplementation

Supplementation refers to the provision of added nutrients in pharmaceutical form (such as capsules, tablets, or syrups) rather than in food. Micronutrients are substances required by the body in small amounts for vital physiological functions. They cannot be synthesized by the body and therefore must be consumed in foods and/or in supplements.

Choice of Interventions

Micronutrient supplementation is one of three major categories of nutrition intervention strategies – the other two being fortification and dietary change. The choice of strategy or mix of strategies will depend on multiple factors including the magnitude, severity, and distribution of the micronutrient deficiency in the population, the relative intervention efficacy, the in-country resources available to deliver the intervention to the target group effectively, the target groups' acceptance of the intervention, and the ability to sustain the intervention.

The theoretical relative advantages of micronutrient supplementation over fortification and dietary-improvement interventions include rapid coverage of a high-risk population, the ability to provide directly a controlled and concentrated dose of the micronutrient(s) to the target group, an immediate impact on micronutrient status and associated functional outcome(s), the relatively low cost of training workers compared with nutrition counselling for diet improvement, and high coverage if supplements are delivered using existing services that already reach a high proportion of the target group. Most supplementation

programs have been shown to be cost-effective in achieving their nutritional goals and health impacts, although sustaining large-scale programs over the long-term may be more costly than either fortification or dietary improvement.

Generally, prophylactic micronutrient supplementation is intended as a short-term means of rapidly preventing nutrient deficiency in high-risk individuals and populations until adequate and sustainable food-based programs become effective. However, in many cases, supplementation programs may be the only effective means of reaching specific vulnerable groups, particularly those who have limited or no access to processed fortified foods or those, such as young children and pregnant women, who have high micronutrient requirements that may not be met even with fortification and dietary-improvement interventions. In these situations and populations, supplementation should be sustained over a longer period until nutrient intake from fortified and non-fortified food is adequate.

Based on experiences from vitamin A, iron, and iodine supplementation programs, the key limitations of supplementation are inadequate targeting or coverage (where deficient individuals are missed or reached irregularly), an inability to sustain high coverage over long periods of time as financial, political, or other health priorities change, and poor compliance by target individuals who are expected to take a daily supplement for extended periods of time (e.g., iron supplementation during pregnancy). As illustrated in **Figure 1**, in many countries – particularly those with high regional variability in socio-economic status, food availability, and market-access – a mix of strategies, rather than any single strategy, is more likely to reach a greater proportion of the at-risk population.

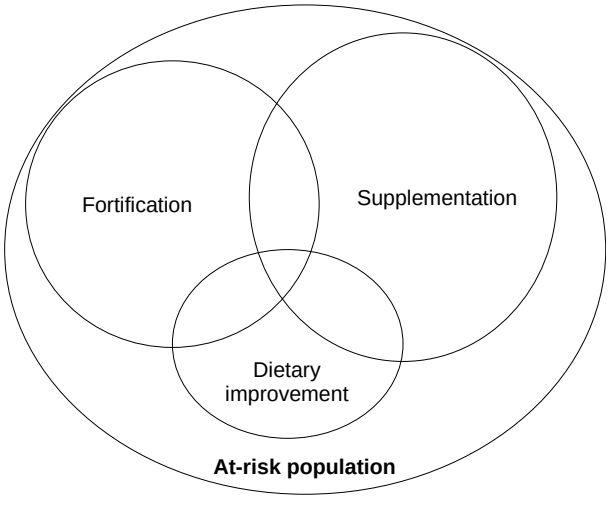

Figure 1 Micronutrient supplementation in combination with other nutrition-focused interventions to prevent micronutrient deficiencies in a target population.

Cost of Micronutrient Interventions

The World Bank's World Development Report 1993 found micronutrient programs to be among the most cost-effective of all health interventions. The cost of micronutrient supplementation needs to be balanced against the cost of other food-based and public-health interventions as well as against the cost of not addressing the insidious effects of micronutrient deficiencies. Costs are likely to vary depending on the scope of the program, existing delivery mechanisms, the nutrient involved, and other factors. Based on World Bank estimates, the costs of vitamin A, iron, and iodine supplementation programs are relatively modest, ranging from US$0.20 to US$1.70 per beneficiary per year. These costs are slightly higher than the estimated relative costs of fortification (US$0.05–0.15 per beneficiary per year) but are considerably lower than the unit costs of education programs (US$5–10) and feeding programs (US$70–100 per beneficiary per year).

Prophylactic Micronutrient Supplementation

Micronutrient supplementation has been the method of choice for the treatment of severe clinical nutrient deficiencies for several decades. Prophylactic supplementation, however, gained wider acceptance only in the late 1980s with the publication of results from a randomized trial in Aceh, Indonesia, showing a 34% reduction in young-child mortality among preschoolers given vitamin A supplements. The introduction of routine vitamin A supplementation to preschool children in developing countries has encouraged this approach and the development of other micronutrient supplementation programs. Each single-nutrient or multiple-micronutrient supplementation strategy should be evaluated separately for efficacy, feasibility, safety, cost, and appropriateness for the cultural and political context in which it will be implemented.

Vitamin A Supplementation

Periodic distribution of high-dose vitamin A supplements, either universally to all preschool children or to targeted high-risk groups, has been the most widely practiced intervention for the prevention and treatment of vitamin A deficiency throughout the world. Giving a high dose of vitamin A every

4–6 months is based on the assumption that vitamin A is stored in the liver and mobilized, as needed, to meet the demands of target tissues. This is in contrast to iron supplements, which need to be given on a daily or weekly basis.

Efficacy of Prophylactic Supplementation

Preschool children Giving children living in areas where vitamin A deficiency is prevalent a large dose (i.e., 200 000 IU or 60 mg Retinol Equivalent (RE)) of vitamin A every 4–6 months has been shown to reduce the risk of both noncorneal and corneal xeropthalmia by 90%, increase serum retinol levels for 1–2 months following supplementation, and reduce young-child mortality by an average of 23% when coverage levels of at least 80% are achieved in deficient populations. In populations deficient in vitamin A, prophylactic supplementation of preschool children is one of the most cost-effective public-health interventions to improve the survival of children aged between 6 months and 6 years.

Post-partum women High-dose vitamin A supplementation is also recommended for post-partum mothers within 6 weeks of delivery, when the chance of pregnancy is remote, because the physiological demands of pregnancy and lactation deplete the mother's vitamin A stores. The provisional recommendation of the International Vitamin A Consultative Group is to give two doses of 200 000 IU at least 24 h apart to all women living in areas where vitamin A deficiency is prevalent and to give the supplement as soon as possible after delivery in order to maximize the beneficial effects on maternal vitamin A status, breast-milk vitamin A concentrations, and subsequent infant vitamin A status. Spacing the two doses by at least a day minimizes the risk of raising breast-milk retinoic acid (a short-lived metabolite of vitamin A) to potentially toxic levels.

Newborns and young infants Two randomized controlled trials in Asia that provided 50 000 IU of vitamin A to infants in the first 2 days of life found significant reductions in infant mortality among the vitamin A supplemented newborns. A third, confirmatory, trial is currently underway in Bangladesh, which, depending on the findings, may lead to newborn dosing recommendations. The current World Health Organization (WHO) recommendation is to provide 50 000 IU of vitamin A to infants with each of the three doses of diphtheria, pertussis, and tetanus at 6, 10, and 14 weeks of age to improve vitamin A status. Further trials, however, are needed to confirm the benefit of implementing this recommendation for early infant vitamin A status, morbidity, and survival.

Pregnant women Where maternal night blindness or biochemical vitamin A deficiency is highly prevalent, prophylactic supplementation with up to 10 000 IU daily or 25 000 IU weekly has been given safely. The efficacy of low-dose maternal supplementation is still under investigation, but a recent community-based randomized placebo-controlled study in Nepal reported a 40% reduction in pregnancy-related maternal mortality among women given low doses of vitamin A or β-carotene, provided as a weekly supplement, during pregnancy and for 3 months post-partum. This is the first trial to link vitamin A supplementation and maternal survival. Confirmatory efficacy trials are underway in Bangladesh and Ghana and should provide guidance on future maternal vitamin A supplementation recommendations.

Form of Supplement

Vitamin A in the form of a gelatinous capsule is the overwhelming choice of delivery mode used in large public-health programs, although there are reports of the successful use of liquid vitamin A in a bottle using a calibrated dispenser. Vitamin A has also been dispensed from an inhalation device in children with parasitic infections as an alternative delivery mode in the very small number of children who exhibit extreme intestinal malabsorption of vitamin A.

Safety

High doses of vitamin A are safe and well accepted by preschool children, although evidence from program evaluations and a randomized trial in the Philippines suggests that up to around 9% of preschool children may experience acute transient side-effects including nausea, vomiting, headache, and/or fever after dosing. Most episodes begin within 24 h of capsule receipt and resolve spontaneously within 12–24 h of onset.

Earlier animal experiments linked high doses of vitamin A to birth defects; however, experimental data proving the teratogenic effect of vitamin A in pregnant women are limited and, for ethical reasons, very difficult or even impossible to obtain rigorously. Nonetheless, high doses of vitamin A should be avoided during pregnancy because of the theoretical risk of teratogenesis.

Delivery Mechanisms

There are a variety of ways to deliver high-dose vitamin A supplements to at-risk populations including restricting delivery to clinic settings for

treatment purposes, integrating delivery with existing services such as immunization contacts or routine growth monitoring, or universal delivery, to attain the widest coverage of preschool children, through semi-annual campaigns that specifically promote vitamin A capsule distribution or that are combined with other national programs such as national immunization days or child-health weeks. Each delivery mode has advantages and disadvantages. Restricted delivery targets those most likely to be deficient in vitamin A and requires few additional resources (apart from the supplements); however it may result in poor coverage if those who are most at risk do not regularly access health clinics. 'Piggybacking' vitamin A distribution onto existing community services can be cost-effective but may also miss the children at greatest risk of vitamin A deficiency if their access to and use of these services is limited. Finally, universal distribution requires strong community mobilization and social marketing to attain coverage levels of at least 80%. Sustaining this coverage level every 4–6 months can be challenging, but there are numerous examples of countries where such levels have been sustained for at least 5–8 years.

Iron Supplementation

Globally, supplementation with iron tablets is the most widely used strategy for the prevention and control of iron-deficiency or anemia in pregnancy. Pregnant women require nearly three times as much iron as non-pregnant women owing to the physiological demands of pregnancy (expanded red-blood-cell volume, the needs of the fetus and placenta, and blood loss at delivery). This high requirement is unattainable by most pregnant women in developing countries, especially those who struggle to meet the $1.5\,\mathrm{mg\,day^{-1}}$ requirement when not pregnant, and therefore iron supplementation is recommended during pregnancy.

Efficacy

Pregnancy The rationale for iron supplementation during pregnancy in developing countries is based on a combination of considerations including the high prevalence of anemia in pregnancy (the majority of which is probably associated with iron deficiency), carefully conducted trials that show that consuming iron tablets during pregnancy improves maternal iron status, the higher maternal mortality risks associated with severe anemia, and the postulated risks of iron deficiency in pregnancy (i.e., increased risk of fatigue, cardiovascular stress, impaired resistance to infection, and poor tolerance to heavy blood loss and surgical interventions at delivery) and for fetal development. Although evidence supports the efficacy of iron supplementation in improving the iron status of pregnant women, no trials have examined the impact of iron supplementation on maternal mortality in severely anemic women. Also, there is a lack of causal evidence from controlled studies linking mild-to-moderate iron-deficiency anemia – which is much more prevalent than severe anemia – with an increased risk of low birth weight, preterm delivery, or obstetrical or perinatal complications.

Infancy Iron supplementation in infants is sometimes advised to prevent iron deficiency, even in populations with a relatively low prevalence of iron-deficiency anemia. The US Institute of Medicine, for example, recommends iron drops for exclusively breast-fed infants between 4 and 6 months of age. There is ample evidence from well-designed and controlled studies to show that iron supplementation in infancy significantly improves hemoglobin and ferritin levels, and studies are currently investigating the impact of iron supplementation on dimensions of cognitive development. The benefits and risks of infant iron supplementation, however, remain controversial, particularly in iron-replete children. This is because, although iron is an essential nutrient for adequate infant growth, immune function, and development, it may also contribute to a greater risk of infection if the excess iron increases a pathogen's access to free iron for its own growth and reproduction. Some studies have reported a higher prevalence of diarrhea in iron-supplemented infants, which calls into question the appropriateness of existing hemoglobin and ferritin cut-offs for defining true deficiency in infants and points to the need to clarify the cut-off issue in order to determine an appropriate age for starting iron supplementation.

Low-birth-weight infants Low-birth-weight infants are born with low iron stores and have higher iron requirements for growth. Their iron needs cannot be met from breast milk alone, and, therefore, they are a priority target for iron supplementation.

Preschooler and school-age children Several, but not all, placebo-controlled supplementation trials have demonstrated that iron supplements improve hemoglobin concentrations in preschoolers in developing countries, and there is substantial evidence that iron supplementation of anemic children improves their school performance and verbal and other skills.

Dose

The WHO has published global guidelines for iron supplementation and recommends daily prophylactic iron supplementation with 60 mg of iron for all women in developing countries in the second and third trimesters of pregnancy (**Table 1**). In other countries, iron supplementation is recommended only for women with proven iron-deficiency anemia (in Great Britain) or for women with low pre-pregnancy iron stores (in Canada). The efficacy of maternal iron supplementation increases with daily iron doses of up to 60 mg. The WHO also recommends providing low-birth-weight infants with supplemental iron drops from 2 months of age.

Table 1 Micronutrient supplementation: target groups and prevention schedules

Micronutrient	*Target group*	*Dosage*	*Frequency and duration*
Vitamin A[a]	Children at risk of vitamin A deficiency		
	<6 months	50 000 IU	One dose at 4, 10, and 14 weeks[e]
	6–11 months	100 000 IU	One dose every 4–6 months[f]
	1–5 years	200 000 IU	One dose every 4–6 months
	Post-partum women	400 000 IU[g]	One dose before 8 weeks post-partum
Iron (plus folate)[b]	Pregnant women (living in areas where anemia prevalence is less than 40%)	60 mg iron and 400 μg folic acid[i]	Daily for 6 months[h] in pregnancy
	Pregnant women (living in areas where anemia prevalence is at least 40%)	60 mg iron and 400 μg folic acid[i]	Daily for 6 months[h] in pregnancy, and continuing to 3 months post-partum
	6–24-month-old children of normal birth weight (living in areas where the prevalence of anemia in children is less than 40%)	12.5 mg iron and 50 μg folic acid	Daily to 6–12 months of age
	6–24-month-old children of normal birth weight (living in areas where the prevalence of anemia in children is greater than or equal to 40%)	12.5 mg iron and 50 μg folic acid	Daily to 6–24 months of age
	2–24-month-old children of low birth weight (less than 2500 g)	12.5 mg iron and 50 μg folic acid	Daily to 2–24 months of age
Iodine[c]	Pregnant women in areas where iodine deficiency is endemic[j]	300–480 mg	One dose annually
	Non-pregnant fertile women[j]	400–960 mg	One dose annually
	Children in areas where iodine deficiency is endemic[j]	240 mg iodine	One dose annually
Zinc[d]	Children with persistent diarrhea[k]	10–20 mg	Daily for 14 days
	Children with an elevated risk of zinc deficiency; children who are severely stunted, or have low plasma zinc, or both	Further research needed on relative efficacy of different frequencies and doses

Multiple Micronutrient Supplements with Iron

Currently, folic acid is added to most iron supplements for women of fertile age because it reduces the risk of neural-tube defects and because lack of folic acid may limit the hemoglobin response to iron supplements. In the absence of these nutrients such as vitamin A, vitamin B_{12}, and riboflavin may also limit the efficacy of iron supplements, and studies are underway to assess the effect of multiple micronutrient supplements on anemia.

Safety

Iron supplements can cause unpleasant gastrointestinal symptoms (e.g., nausea, constipation, vomiting, and diarrhoea), which may contribute to poor compliance, but these usually occur at higher doses. When iron tablets are taken with meals or if slow-release tablets are used, any side-effects may be mitigated. Complications of excessive iron storage, including hemochromatosis and hemosiderosis, are possible but uncommon in women consuming iron tablets. Another potential danger of iron supplements is accidental overdosing by children in the home, and therefore supplements should be kept out of the reach of children.

Frequency

A perceived concern about the side-effects, compliance, and potential toxicity of a daily regimen of iron supplementation generated research to assess the relative efficacy of weekly versus daily supplementation in pregnant women, adolescents, and children. A review of these studies concluded that both daily and weekly iron supplementation reduces the prevalence of iron deficiency and anemia, daily supplementation is more effective than weekly supplementation in increasing hemoglobin and ferritin, and while daily supplementation produces only a slightly higher average hemoglobin response (approximately $2\,g\,l^{-1}$) than weekly supplementation, its relative impact on reducing anemia risk is 34%, largely because daily supplementation is more effective at increasing low hemoglobin concentrations.

From the results of two other studies, in Bangladesh and Indonesia, that carefully monitored the number of iron tablets consumed, it appears that the size of the hemoglobin response to iron appears to depend on the total amount of iron consumed. In these studies, most of the hemoglobin response was produced by the first 20–50 tablets consumed. But more research is needed before recommendations can be made about consuming a fixed number of tablets over a defined period of time while permitting flexibility about the consumption interval (i.e., daily, two or three times per week, weekly, etc.).

Taken together, the available evidence suggests that iron supplements should be taken daily to treat iron-deficiency anemia, especially in pregnant women. Weekly supplementation may offer a more feasible preventive strategy, particularly if it reduces costs, improves compliance, and reduces side-effects; however, more information is needed to assess the relative effectiveness of daily versus weekly supplementation under program conditions.

Form of Iron

In tablets, the most common form of iron is ferrous sulphate (which contains 20% iron), but ferrous fumarate (33% iron) and ferrous gluconate (12% iron) are also used. Infant supplements are usually in liquid form and more costly, but when crushed or mixed with food, tablets can also be used.

Effective Iron-Supplementation Programs

Reviews of large-scale iron-supplementation programs in developing countries have reported limited effectiveness in reducing maternal anemia. The limited effectiveness is often attributed to implementation constraints including low compliance, short intervention duration, inadequate supplement supply, or poor coverage of pregnant women. For iron-supplementation programs to achieve improved effectiveness, careful attention must be given to ensuring an adequate supply of iron tablets at the distribution points, access of pregnant women to the distribution points, promotion of the benefits of iron supplementation, counselling about managing possible side-effects, and communication strategies to encourage pregnant women to consume the supplement.

Iodine Supplementation

Salt iodization is the recommended means of population-based intervention to prevent and control iodine deficiency disorders, but, in isolated communities with an urgent need for iodine prophylaxis, direct supplementation of priority groups can be rapidly implemented as an interim measure while salt iodization is being established.

Efficacy

Intramuscular iodine injections Numerous studies have confirmed that iodine supplementation by injection before a woman becomes pregnant can prevent endemic cretinism and that a single injection can prevent goitre for up to 3–4 years. Other documented benefits of maternal supplementation observed

in several controlled studies include reduced infant and young-child mortality, improved birth weight, and better manual function in children born to iodine-supplemented mothers.

Oral iodized oil Although efficacious, injections of iodized oil have largely been replaced by oral iodized oil owing to the concern over the AIDS pandemic and use of needles as well as the higher cost of supplies (syringes) and personnel (skilled injectors). Oral delivery of iodized oil appears to be as effective as intramuscular injection but is less costly, carries no infection risk (through a contaminated needle), is painless, and can be administered by untrained personnel. Oral iodized oil is considered to be safe for pregnant women and can be given at any time during pregnancy; however, it appears to protect against moderate and severe neurological abnormalities in the infant only when given during the first two trimesters. The best outcomes are likely to occur when supplementation is given during the first trimester, but even if it is given in late pregnancy or to the infant after birth slight improvements in brain growth and developmental quotients, but not neurological status, are evident.

Dose

Owing to the fact that damage to the developing brain is the most severe consequence of iodine deficiency, women of child-bearing age and children are the first priorities for receiving iodized oil. Recommendations are to give a single dose of 460 mg of iodine to all females below the age of 40 years. A single annual dose of 240 mg of iodine appears to be adequate for children. Larger doses do not necessarily provide longer protection because of increased urinary loss after administration. It is possible that smaller more frequent doses may be more effective, although this issue requires further study. Evidence from studies using 200–500 mg of iodized oil suggests that the protective effect lasts for between 6 months and 2 years.

Safety

Oral iodine supplementation is safe, although side-effects can include transient submandibular swelling and subclinical hypothyroidism.

Zinc Supplementation

During the past decade, zinc supplementation has received increasing attention as results from research trials reveal the extent of zinc deficiency in developing countries and the role of zinc supplementation in reducing intrauterine growth retardation and disease incidence and severity and improving children's cognitive development, growth, and survival. However, most of what is known about zinc supplementation is based on the results of research trials and not of large-scale programs that deliver zinc supplements.

Efficacy

Diarrhoea and pneumonia Short-term treatment of diarrhoea and possibly pneumonia with zinc supplementation has proven efficacious in numerous randomized controlled trials. A pooled analysis of nine randomized controlled trials reported an 18% lower incidence and a 25% reduction in prevalence of diarrhoea in zinc-supplemented children regardless of age, baseline zinc status, wasting prevalence, or sex, suggesting that zinc supplementation may benefit many subgroups of children living in areas at high risk of zinc deficiency. Studies have also investigated the efficacy of a combination of micronutrients given together with zinc and have shown that zinc alone is just as efficacious as a multiple micronutrient that includes zinc in reducing the severity of acute diarrhoea.

There is growing evidence that zinc supplementation reduces the risk of pneumonia. A pooled analysis of five randomized controlled trials reported a 34% reduction in the incidence of pneumonia in zinc-supplemented children, but evidence from three short-course zinc-supplementation trials suggests a non-significant reduction in the incidence of pneumonia and in hospitalization rates for acute lower respiratory infection.

Other outcomes Evidence from a limited number of trials suggests a potential benefit of zinc supplementation on morbidity related to *Plasmodium falciparum* infections, child survival, weight gain in low-birthweight infants and severely malnourished children, length gain in stunted children, and a host of maternal health and pregnancy outcomes; however, more research is required to determine the benefits of a large-scale zinc-supplementation program targeted at groups of infants, children, and pregnant women.

Dose

There is a need for systematic studies to determine the appropriate dose of supplemental zinc for preventing zinc deficiency in different age groups and under different clinical conditions. However, based on therapeutic studies, giving zinc supplements in doses ranging between one and four times the recommended dietary allowance per day (15 $mg.day^{-1}$ for children aged less than 1 year, and 20–30 $mg.day^{-1}$ for children aged more than 1 year) for 14 days is efficacious in reducing the severity of

diarrhoea and the duration of the episode significantly. In hospitalized children, zinc can be given as two or three divided doses each day, although in community interventions a single dose of $20\,mg.day^{-1}$ appears both safe and efficacious. Studies are underway to determine the feasibility and efficacy of adding zinc to oral rehydration solution.

Form of Zinc

There are many zinc compounds that can be used to produce zinc supplements. They differ in color (from colorless, to white, grey, or yellowish white), taste (bitter, astringent, slightly sour, or bitter), odour (odourless, vanilla odour, or faint odour of acetic acid), solubility in water (insoluble, slightly soluble, or soluble), cost, side-effects, and safety. Water-soluble compounds (e.g., zinc acetate, zinc sulfate, and zinc gluconate) are more easily absorbed and therefore preferred. Zinc supplements have been prepared in flavored syrups, chewable tablets, single-dose 'sachets' to be added to food, as a high-fat spread to be consumed alone or with other food for infants and young children, and as dry supplements (tablets, capsules, or powders) alone or with other nutrients. The choice of supplement form will depend on the age of the target group, preference, and whether other nutrients will be included.

Effectiveness of Zinc-Supplementation Programs

There is little information about the effectiveness of zinc-supplementation programs implemented on a large scale. There is a need to conduct such studies to assess the best ways to deliver zinc supplements to children with diarrhoea, paying particular attention to the feasibility, sustainability, and cost-effectiveness of different zinc-delivery mechanisms.

Summary

The feasibility of micronutrient supplementation and the degree to which it should be pursued in combination with other strategies to prevent and control micronutrient deficiencies depend on the local needs, resources, capabilities, commitment, and evidence of benefit. The successful prevention and control of vitamin A, iron, and zinc deficiencies will probably result from a combination of repetitive distribution of high-dose nutrient supplements, fortification of staple foods, and behavioral change, whereas fortification of salt alone with iodine has already achieved much success in combating iodine deficiency disorders. The adoption of supplementation approaches should be guided by evidence of a need for targeting, impact potential, costs, and potential sustainability.

Developing Countries

R Shrimpton, Institute of Child Health, London, UK

Micronutrient supplementation is the distribution of specially formulated preparations of one or more nutrients, usually in the form of a pill, a capsule, or syrup. It seems to be the Cinderella of nutrition

interventions, more than capable of dancing but not quite good enough to be invited to the Ball. It is often described as a 'short-term' option and a 'medical' approach and considered more appropriate for the treatment of severe micronutrient deficiencies in those most affected than to prevent deficiencies in whole populations. However, for the half of humanity affected by micronutrient deficiencies, the overwhelming majority of whom are the poor concentrated in the developing world, solving these problems through food-based approaches is only likely to happen in the very long term. The immune system is compromised by vitamin A deficiency in 40% of children younger than 5 years old in the developing world, leading to approximately 1 million deaths each year. In the 6- to 24-month-old age group, mental development is impaired due to iron deficiency in 40–60% of the developing world's children. Severe iron deficiency also causes more than 60 000 deaths of women during pregnancy and childbirth every year. Approximately 18 million infants per year are born mentally impaired as a result of iodine deficiency during pregnancy. Providing vulnerable groups, such as children and women of childbearing age, with low-cost vitamin and mineral supplements is the least that governments can do to protect the growth and development of the next generation as a first step toward realizing the right of every individual to be adequately nourished.

Experience in achieving high coverage of those most at risk with micronutrient supplements is quite varied, with both successes and failures. A good communication strategy is an essential part of achieving high levels of adherence in micronutrient supplementation programs, but these aspects are not particular to nutrition programs and are not considered here. Deficiencies of iodine, iron, vitamin A, and folate are the most commonly recognized deficiencies for which there are programs, but in practice most of those affected have multiple vitamin and mineral deficiencies that overlap and interact at great cost. This article reviews the policy dimensions of the efforts to establish programs aimed at eliminating iodine deficiency, iron deficiency anemia, and vitamin A deficiency through supplementation, and it provides a perspective on zinc supplementation and multiple micronutrient supplementation as future components of nutrition programs in developing countries.

Iodine Supplementation

Today, approximately 70% of the world's salt is iodised, compared to just 10% in 1990, and therefore iodine supplementation programs are greatly reduced. Until universal salt iodization is guaranteed in the third of the world in which iodized salt is not yet available, especially in remote populations in which goiter is endemic, supplements should be used during pregnancy and early childhood. In the past, it was common to provide annual intramuscular injections of iodized oil to women of reproductive age in order to ensure iodine status during the first months of pregnancy when the risk of cretinism is greatest. In more recent years, oral iodized oil capsules have proven to be as efficacious and more effective in controlling iodine deficiency in both women of reproductive age and schoolchildren. Oral iodine supplements initially based on expensive poppy seed oil have since been replaced by cheaper rapeseed and peanut oil preparations, which are equally effective.

Vitamin A Supplementation

The use of supplements to eliminate vitamin A deficiency is a notable success, with remarkable advances achieved within the past decade. Although the elimination of vitamin A deficiency by year 2000 was one of the goals set at the World Summit for Children in 1990, little progress was evident at mid-decade. Clinical vitamin A deficiency was estimated to affect approximately 3.3 million children younger than the age of 5 years in 1995, with an additional 100 million subject to subclinical deficiency. The periodic distribution of high-dose vitamin A supplements, originally employed in Indonesia during the 1970s for the prevention of blindness in children, was shown in the 1980s to also impact young child mortality. The supplements have the advantage of ensuring requirements for 4–6 months after administration, such that two or three capsules per year can meet vitamin A requirement of preschool children.

The lack of perception of vitamin A deficiency as a problem was a substantial barrier to establishing large-scale preventive supplementation programs. The prevalence of clinical signs of frank vitamin A deficiency, such a Bitot's spot and corneal lesions, that make it a 'public health problem' is very small at just 0.5%. Since clinical signs are often more common in rural populations, a significant vitamin A deficiency problem can easily go undetected. National representative surveys were thus a prerequisite for taking action. Another barrier is the voice of those who advocate for food-based approaches and view supplements as technical fixes or golden bullets that are of questionable sustainability promoted by the pharmaceutical sector. In reality, of course, these are not either/or options.

Convincing proof of the efficacy of vitamin A capsules for child mortality reduction in the early 1990s helped to create increased momentum for populationwide preventive supplementation programs. The turning point for increasing the coverage of vitamin A supplements was undoubtedly the publication of a meta-analysis of the efficacy trials of massive-dose vitamin A capsules. The analysis of eight mortality trials indicated that improving the vitamin A status of children aged 6 months to 5 years by massive-dose capsule distribution reduced child mortality rates by approximately 23%. The important conclusion of the meta-analysis was that increased risk of mortality from vitamin A deficiency was not just limited to those portions of the population with severe vitamin A deficiency problems but was present across the whole population distribution.

What consisted of 'the justification' for carrying out vitamin A supplementation programs evolved rapidly during the latter half of the 1990s. Many of these discussions were held at the meetings of the International Vitamin A Consultative Group and the working group on vitamin A of the Standing Committee on Nutrition of the United Nations. A broad technical consensus was finally accepted that even in the absence of survey data, it was highly likely that the benefits of vitamin A supplements would be evident in populations in which the mortality rates for those younger than 5 years old were higher than 70 per 1000. Prior to this, vitamin A supplements were targeted to those children with illnesses such as measles and diarrhea. The most recent programmatic recommendations are that if mortality for those younger than 5 years old is higher than 50 per 1000, then supplements should be employed routinely as a preventive measure for all young children. Subsequent to this consensus, a global policy to integrate vitamin A capsule distribution into regular immunization schedules, and also to incorporate vitamin A capsules into the national immunization campaign days being promoted to achieve the eradication of polio, was rapidly adopted.

Programmatic vitamin A interventions received considerable impetus from the Vitamin A Global Initiative, an informal interagency advocacy group that worked to promote the adoption of vitamin A supplementation programs. The initiative included WHO and UNICEF, together with CIDA from Canada, DIFID from the United Kingdom, USAID from the United States, and the Micronutrient Initiative (MI). Through their networks, these various organizations worked together to convince governments with high mortality rates for children younger than age 5 years to introduce periodic vitamin A capsule distribution programs. Vitamin A capsules were made available by CIDA through UNICEF to any developing country that wanted them, and UNICEF and MI with USAID and DIFID funds developed a global communication campaign.

By the end of the 1990s, vitamin A supplementation programs had seen a remarkable expansion. Most countries with high mortality rates for children younger than 5 years old adopted vitamin A supplementation programs, with the most notable exception being India. The number of countries with vitamin A programs increased from 10 in 1995 to 72 in 2000. The ways in which the vitamin A capsule programs were developed and implemented varied by country, but the most common strategy was to use national immunization days for polio eradication to piggyback vitamin A supplements. The use of this approach doubled from 30 countries in 1997 to 60 in 1999. Because the polio eradication strategy requires two nationwide campaigns not more than 2 months apart, some countries also promoted separate micronutrient days, or child health days, so that children would get at least two capsules during the course of a year, 6 months apart. UNICEF procured through its central warehouse in Copenhagen and supplied through its country programs an average of 289 million capsules per year from 1993 to 1998, which was estimated to be only 38% of the worldwide need.

Estimates of the coverage of vitamin A capsules indicate a remarkably high coverage of supplements by the turn of the century, with remarkable saving of life. Based on multiple sources, UNICEF estimates that in 1999 half of all children aged 6–59 months in developing countries outside of China, and 80% of such children in the least developed countries, received a vitamin A capsule within the past 6 months. Coverage was highest in sub-Saharan Africa, where 70% of children aged 6–59 months received a capsule in the past 6 months. Extrapolation of the protective effect of a 23% reduction in child mortality shown by the meta-analysis to the increased coverage of capsules achieved between 1998 and 2000 suggests that 1 million lives were saved in this short period.

The challenge that remains for vitamin A supplementation is one of sustainability. Although supplements are traditionally viewed as a short-term solution, in reality they need to be maintained during at least the medium term if continued gains in mortality reduction are to be realised. Increases in other sources of vitamin A, be it through diet and/or fortification, are unlikely to be achieved in the short

term. The eventual phasing out of national immunization days, as polio eradication becomes a reality, will cause problems for maintaining the high coverage of vitamin A capsules. Alternate strategies are needed and are being put in place in many countries. Bangladesh and Nepal are two examples of countries that successfully promote biannual micronutrient days with large-scale social mobilisation efforts. Sustaining the provision of the vitamin A capsules is also likely to become a problem. Until now, supplements have predominantly been provided by the Canadian government and supplied through UNICEF, and how long this will be sustained is not known. The costs for individual governments to take on are small, however, and the benefits in terms of lives saved will likely remain enormous for many decades.

Iron/Folate Supplementation

Although iron deficiency is the most widespread of nutritional problems, supplementation with iron has not proven to be a very successful intervention. Global policy recommendations to routinely provide iron/folate supplements for women during pregnancy and lactation have changed little in almost three decades, and all anemic pregnant women should receive such supplements in almost all contexts. Approximately half of the developing countries in the world are reported to have national iron supplementation policies. The World Summit for Children's goal to reduce anemia in women by one-third was given little or no priority by the principal actors involved such that no progress was made during the past decade. Anemia still affected 44% of nonpregnant women and 56% of pregnant women in developing countries at the end of the twenty first century.

Although there is ample evidence that iron deficiency and the anemia associated with it are a great burden on society, especially the poor, the advocacy base for pushing for program implementation is still weak. The link of iron deficiency to maternal and child survival has not been concretely proven. The effect of iron deficiency on cognitive deficits in children and on adults later in the life course has been established. The absolute losses in Southeast Asia are estimated to be approximately $5 billion annually, and for India the median value of productivity losses due to iron deficiency alone is approximately $4 per capita or 0.9% of gross domestic product. The efficacy of iron/folate supplements for controlling anemia is well documented, and there is a considerable amount of descriptive evidence linking maternal anemia to both low birth weight and maternal mortality.

Despite high cost-effectiveness, little or no priority has been given to iron deficiency anemia reduction programs. At $0.002 per tablet, the iron supplement is relatively cheap, and the cost per disability adjusted life year of $13 makes the supplementation of pregnant women with iron a very cost-effective intervention. At the national level, despite the existence of national policies, rarely is there a budget for the provision of supplements and/or supervision of iron deficiency anemia programs. Although UNICEF is a major supplier of iron/folate supplements to the developing world, the level of supply is far lower than that believed to be needed. In the period 1993–1996, 2.7 billion tablets were shipped to 122 countries at a cost of $7.5 million as part of UNICEF assistance to programs aimed at eliminating maternal anemia. This was less than 5% of that needed to cover all pregnancies in developing countries. There have been few, if any, attempts to gauge the coverage of iron/folate supplements at any level, be it district, national, or international. Neither has there been any effort put into creating political accountability to ensure high coverage.

Many meetings and publications during the past few decades that have examined the causes and solutions of iron deficiency anemia conclude that lack of effectiveness of iron supplementation programs for anemia control is largely related to problems with supply of the supplement. Although the side effects of iron pills are often cited as the reason why iron supplementation programs do not work, this rarely seems to be the case. One of the major causes of nonadherence seems to be lack of understanding of the benefits the supplements can bring among health staff that deliver the tablets. Most of the program reviews have concluded that where supportive community-level delivery mechanisms are put in place that encourage adherence, and the supply of supplements is ensured, high levels of coverage can be achieved and sustained. It is often the case, however, that in health systems in developing countries, nutrition is everybody's business and nobody's responsibility, and iron supplements have ended up low on the list of things to do.

Despite an international consensus that supplementation has a key role to play in the control of iron deficiency anemia, there are still those that question such programs. In 1998, a technical consensus meeting on what was needed to solve the problem of iron deficiency made the recommendation that although the interventions already existed for reducing both iron deficiency and iron deficiency anemia, more work was needed to develop large-

scale programs with packages of interventions delivered through multiple sectors. Despite the consensus, there are still those who question the advisability of iron supplementation programs, suggesting that hemoglobin cutoffs may be set too high and/or that receiving excessive amounts of iron is dangerous for those who are iron replete. Another complicating factor is undoubtedly related to the fact that adequate coverage of iron supplements alone will not ensure anemia control in many settings. A global review of anemia causality revealed that perhaps only half of anemia is solely due to iron deficiency, with other micronutrient deficiencies such as vitamin A contributing as well. Infections such as malaria and helminth are also important causes. Programs to eliminate anemia thus require packages of interventions, of which iron supplements are but a part.

Zinc Supplementation

There is strong evidence for the efficacy of therapeutic zinc in improving the prognosis of children being treated for diarrheal disease, and a new WHO/UNICEF recommendation is to give supplemental zinc for 10 days as part of the treatment of diarrhea. A pooled analysis of randomized controlled therapeutic zinc trials in children with diarrhea showed that zinc-supplemented children with acute diarrhea had a 15% lower probability of continuing diarrhea on a given day, and in those with persistent diarrhea there was a 24% lower probability. In addition, children with persistent diarrhea had a 42% lower rate of treatment failure or death if zinc supplemented. The WHO/UNICEF recommendation is to give zinc in the form of a tablet for 10 days to all children that are treated for diarrhea. Given that even the current interventions included in child health programs for diarrheal disease treatment, such as oral rehydration therapy, face enormous barriers to achieving and maintaining high levels of coverage, the challenge for achieving high levels of coverage of zinc supplements in the treatment of diarrhea is likely to be considerable. If these efforts are successful, however, then the impact is likely to be great. The most effective way to give preventive zinc supplements is an ongoing research question.

Multiple Micronutrient Supplementation

In recent years, the case has increasingly been made for providing multiple micronutrient supplements instead of iron supplements for young children and women of reproductive age in developing countries. A woman's or an infant's diet that is deficient in iron is likely to be deficient in many other micronutrients. Outside of emergency situations, such as natural catastrophes, famine, and civil strife, poor dietary quality rather than quantity is the determinant of inadequate micronutrient status among infants and women. The nutrient-to-energy ratios of iron, zinc, folate, vitamins B_6 and B_{12}, vitamin A, riboflavin, and calcium are commonly below the recommended levels needed, assuming energy needs are met.

Although the incremental cost of distributing a multiple micronutrient supplement is likely to be small, the increased benefits may be large. The main cost of the delivery of a nutrient supplement for women of reproductive age is not the cost of the supplement but the cost of the delivery system. Although it may not be working very well, a delivery system already exists for the iron/folate supplements that could be used to provide these other micronutrients. There has been much speculation about the costs of a multiple micronutrient supplement compared to the iron/folate tablet currently procured and provided by UNICEF. Adding the extra nutrients to the iron/folate tablets will not add more than 20% to the cost of the tablet, as long as they are procured in bulk on the international market, as is the case for the current iron/folate tablets supplied by UNICEF.

The potential benefits for pregnant women from improving not only iron and folate but also zinc, vitamin A, and other antioxidant nutrient status are likely to be great. Providing women with vitamin A supplements together with iron supplements has been shown to improve the hematinic effects of the iron supplements. The findings that vitamin A supplements to women of reproductive age reduced maternal mortality by approximately 40% in Nepal and that zinc supplementation improved birth weight among poor women in the United States point to the possible multiple benefits, beyond anemia reduction, of introducing a multiple micronutrient supplement for use by women in developing countries.

The composition of a multiple micronutrient supplement for use in trials among pregnant and lactating women in developing countries has recently been agreed on. The proposed formulation contains physiological doses of the micronutrients based on the recommended daily allowance (RDA). The US/Canadian recommendations were used since they are the most recent and best documented. The selection of nutrients included in the supplement was based on evidence of deficiencies, possible consequences of deficiencies for mother and child, weighing of risks and advantages, and interaction between

nutrients. Furthermore, information about toxicity levels, cost of nutrients, the size of the resulting supplement, and possible side effects related to supplement intake were considered. The formulation agreed upon includes 15 micronutrients (vitamins A, D, E, B_1, B_2, B_6, B_{12}, and C, niacin, and folic acid and minerals Fe, Zn, Cu, I, and Se), all at the RDA level, except for folic acid, which was included at the 400-μg level—considered sufficient to prevent neural tube defects if taken periconceptually.

The multiple micronutrient tablet formulation for supplementation during pregnancy was developed with various users in mind. For pregnant women, the tablet should be taken on a daily basis for as long as possible during pregnancy. For lactating women, the supplement should be taken daily until at least 3 months postpartum. The tablet can also be taken by adolescent girls on a once-a-week basis as a way of improving micronutrient status before getting pregnant. Another possible target group is refugees, who can take the supplement according to their biological state (pregnant or not) and, in case of severe deficiency, can take two tablets per day.

Although the supplement is not considered a dangerous product, it was still recommended for use in trials, with special attention to monitoring and evaluation. Tablets of similar composition are regularly prescribed by physicians and/or purchased by mothers in developed countries, and they can be found in the pharmacies of the capitals of most developing countries and are widely consumed by the richer segments of the population. Despite the relative safety of the supplement, it was recognized that many issues related to multiple micronutrient supplements remain to be investigated. Research topics identified included the assessment of risks as opposed to benefits of regular supplement intake in environments in which many disease agents are present. Factors that influence adherence to tablet intake were also considered a crucial area for investigation.

The need to carry out both efficacy and effectiveness studies of the multiple micronutrient supplements in various different populations is well recognized. The need for micronutrient supplementation in pregnancy is likely to be great because of widespread maternal malnutrition. However, it has to be recognized that public health resources are always limited and priority is given to interventions that are both efficacious and effective. Proving the efficacy of multiple micronutrient supplements is thus essential for being able to advocate for their widescale use. However, multiple micronutrient supplements are almost always going to be part of a package of interventions, especially in developing countries. Indeed, the micronutrient supplements will likely be most effective as part of a package that also seeks to control the major diseases afflicting the mothers, be that malaria, sexually transmitted diseases, or intestinal parasites. Being part of a package obviously makes it difficult in field conditions to test the relative merits of the individual pieces, including the micronutrient supplement. For these reasons, both 'plausibility'- and 'probability'-based approaches are recommended for measuring performance of the multiple micronutrient supplements so that experience can be gained on how to develop programs that promote fetal and infant growth and it can be determined whether micronutrient supplements are truly efficacious in developing countries.

UNICEF has incorporated the multiple micronutrient supplements into ongoing programs as part of an initiative to prevent low birth weight. A total of 18 million infants are born low birth weight (<2.5 kg) every year, accounting for approximately 14% of all live births. These infants are at increased risk of infections; to have weakened immunity, learning disabilities, and impaired physical development; and of dying soon after birth. UNICEF has started promoting programs to reduce the prevalence of low birth weight in Indonesia, the Philippines, Vietnam, China, Bangladesh, India, Pakistan, Nepal, Tanzania, Mozambique, and Madagascar. Low birth weight prevention programs are being fashioned to fit local circumstances, in accordance with the nutrition strategy approved by the UNICEF executive board. The approach being developed in each country elaborates on the 'care for women' element of the care initiative that has been developed to facilitate improvements in caring practices among families and communities. In addition to the multiple micronutrient supplements, other interventions that form part of low birth weight prevention efforts include promoting increased child spacing, increased rest and food for the mother during pregnancy, improved reproductive health, deworming, and malaria control during pregnancy as appropriate. Reducing teenage pregnancy rates is also part of the package, but it is a major challenge since, although the mortality risks for both the teenage mother and her child are known to be considerably increased, teenage pregnancy rates are very high in most developing countries. Prepregnancy weight, weight gain during pregnancy, and birth weight all receive special attention as the principal evaluative indicators of program success.

WHO and UNICEF recommend the use of syrup and/or tablets containing iron for the treatment of anemia in young children, and such products are available through UNICEF supply division in Copenhagen. These products have very little penetration considering the size of the infant anemia problem in most developing countries, where half of all children are commonly affected. Despite the recognition that iron deficiency often coexists with zinc deficiency, together with inadequate intakes of other B vitamins (B_6, riboflavin, and niacin) in infant dietaries, there is no multiple micronutrient supplement available for infants. UNICEF has also been testing the efficacy of a foodlet (a large crumbly pastille that is a cross between a tablet and a food) containing multiple micronutrients during infancy through the Infant Research on Infant Supplementation trials. Trials of multiple micronutrients as preventive supplements are also being carried out by many different groups using supplements provided in the form of sprinkles, tablets, and even as a beverage. Preliminary results of these trials point to a greater impact on anemia and enhancement of multiple micronutrient status by the multiple micronutrient supplements than that of iron supplements, as well as small improvements in growth.

There is a need to bring all of this broad spectrum of experimental and programmatic work together to reach conclusions and achieve consensus before policy and program recommendations can be made on how best to include multiple micronutrient supplements in programs to improve maternal and child health in developing countries. Whether this happens will depend on the continued efforts of the agencies interested in and responsible for promoting maternal and health, to champion the importance of micronutrient supplementation in their programs.

A dietary supplement is a product that is intended to supplement the diet and contains at least one or more of certain dietary ingredients, such as a vitamin, mineral, herb or other botanical, or an amino acid. These products may not be represented as conventional foods; rather, they are marketed in forms that include capsules, tablets, gelcaps, softgels, and powders. Although manufacturers must have evidence to support their claims of a dietary supplement's safety and efficacy, US Food and Drug Administration (FDA) approval is not required before a product is marketed. Micronutrient dietary supplements (vitamins and minerals for purposes

of this discussion) are commonly purchased and consumed in developed countries, even though taking greater quantities of micronutrients than recommended may not have proven benefits for the general population and, for some micronutrients (e.g., vitamin A), may have harmful effects. It may seem logical to assume that the majority of people who live in developed countries can use food sources to obtain the amounts of micronutrients required to maintain overall good health. However, the possibility of helping to prevent chronic diseases through micronutrient supplementation is attracting the interest of many people. A rigorous research approach must be used to determine in what circumstances micronutrient dietary supplements can have beneficial, including preventive, health effects. Special attention must be given to possible differences in micronutrient requirements at different life cycle stages. These stages include infancy (birth to 12 months), childhood (1–18 years), adulthood, and older adulthood (70 years and older). Evidence supporting dietary supplementation at different lifestyle stages is summarized here for several micronutrients.

Prevalence of Micronutrient Supplement Use

In the United States, vitamins and minerals are the most widely used dietary supplements. Between 1993 and 2003, total retail sales of vitamins and minerals more than doubled, increasing from approximately $3 billion to $6.7 billion for vitamins and from approximately $0.6 billion to $1.8 billion for minerals. These figures include sales of multivitamin and multimineral combinations as well as individual vitamins and minerals. Multivitamin/mineral preparations, accounting for almost half of micronutrient purchases, consistently have been the best-selling micronutrient supplements, with sales increasing from $2.64 billion in 1997 to $3.68 billion in 2003.

Findings by several research groups show that micronutrient supplement use generally is more common among people with higher education levels, higher incomes, and better diets. Survey results in The Netherlands indicate that micronutrient supplements are used by approximately 20% of adults in that country, fewer than in the United States. Data collected in the 1988–1994 National Health and Nutrition Examination Survey (NHANES III) showed that approximately 40% of the US population 2 months of age and older (44% females versus 35% males) were taking a vitamin, mineral, or other type of dietary supplement during the month before the NHANES III interview. Data from NHANES 1999–2000 (post-DSHEA) indicate that 52% of U.S. adults were taking at least one dietary supplement. Supplement users were more likely to be toddlers and preschool-aged children and middle-aged and older adults. Across all age groups, vitamin/mineral combinations and multivitamins were the most common types of supplements used by individuals who took only one supplement. Collection of these type of data is important to monitor use, identify usage trends, and help understand the popularity of micronutrient supplement use.

Motivation for Micronutrient Supplement Use

People choose to use micronutrient supplements for various reasons. Survey data indicate that many individuals decide to take micronutrient supplements based on advice from health professionals, family, and friends. A majority of supplement users regard micronutrient supplements as 'insurance' against general poor health or becoming ill, even though they recognize that scientific evidence for this belief may be lacking. Generally, people report that they use supplements either because they think that it is difficult to consume a balanced diet or because they believe that even consuming a balanced diet cannot supply the quantity of micronutrients they need for optimal good health.

Major health reasons given for taking supplements include a sense of well-being and 'feeling better' (especially multivitamins/minerals), preventing colds and flu (especially vitamin C), preventing chronic disease (especially vitamin E and calcium), increasing 'energy,' coping with stress, and improving the immune system. Many vitamin E users believe that the vitamin helps prevent heart disease, and most calcium users know that calcium use helps prevent osteoporosis. Using micronutrient supplements is one way by which people who may be at high risk for certain diseases try to gain some degree of personal control over their health outcomes. Ironically, many individuals who take supplements regularly report that they do not discuss the supplement use with their physicians because they believe that physicians are biased against supplements and are not knowledgeable about the products.

Research Approach for Determining the Health Impact of Micronutrient Supplements

A micronutrient supplement will be beneficial to a person's health only when the person's normal

dietary micronutrient intake is lower than the amount required for maximum biological benefit. Every person does not have the same micronutrient requirements. The amount of micronutrients required by any person is determined by metabolic, genetic, and environmental factors unique to that person. It may not be readily apparent when micronutrient supplements are needed by certain groups of people. Therefore, as new information becomes available, recommendations for supplementation must be revised. For example, it was observed that pregnant women with periconceptual folate intake at the low end of the range of recommended intake, which was still considered adequate, had an increased risk of giving birth to an infant with neural tube defects (NTDs) such as spina bifida. NTDs originate during the first 4 weeks of pregnancy, before a woman may even realize that she is pregnant. United States survey data (1988–1994) indicated that typical dietary folate intake by women of reproductive age was less than the 400 μg/day believed to be required to reduce the risk of NTDs. Therefore, in 1992, the Centers for Disease Control and Prevention recommended that all women who could become pregnant should take a daily 400 μg folic acid supplement as a preventive measure. In addition, the FDA mandated that, as of January 1998, enriched grain products must be fortified with folic acid, adding an estimated 100 μg folic acid/day to the average diet of US women. Fortification refers to adding nutrients to commonly consumed foods at levels greater than the levels that are part of the standards of identity for the foods; other examples of fortification are vitamin D in milk and calcium in orange juice.

Any recommendations for supplementation must be based on scientific evidence that the supplements are both effective and safe. Ideally, a rigorous systematic research approach (**Table 1**) is carried out and the results are evaluated to assess whether a micronutrient supplement is beneficial to health and whether its recommendation is warranted. All available evidence, including epidemiologic and survey data, as well as preclinical evidence from in vitro laboratory research and in vivo animal studies, is reviewed thoroughly and objectively to determine whether the evidence regarding effectiveness and safety justifies proceeding to clinical trials. If so, the trials are normally conducted in three phases: (1) human safety trials; (2) small efficacy trials, usually in defined target groups; and (3) large-scale trials that are essential in moving from the basic science to evidence-based recommendations that have human health benefits. In fact, the large-scale, double-blind, randomized, placebo-controlled clinical trial, which is designed to eliminate all possible bias, is considered to be the gold standard of scientific intervention research. In such trials, some people receive the substance being tested (e.g., drug, micronutrient, or other dietary constituent) and some receive an inactive placebo. These trials may not be possible in all circumstances, however, because of ethical issues that make it inappropriate to withhold the substance being tested from any trial participants. For example, now that it is established that low periconceptual folate intake by women is linked to NTDs, a placebo-controlled intervention trial to test the minimum effective supplemental amount would be unethical. In such cases, all available evidence from in vitro laboratory research and in vivo animal studies, as well as epidemiologic studies and surveys, must be reviewed systematically and objectively to draw conclusions about the possible effectiveness and safety of the substance of interest and to make recommendations for supplementation. However, convincing evidence is currently unavailable to indicate that lowering homocysteine through folate and other vitamin (vitamin B-6 and B-12) supplementation will reduce risk of CVD. A number of randomized, placebo-controlled clinical trials are on-going to test the effects of vitamin supplementation on primary and secondary prevention of CVD and stroke.

Research to determine a possible impact of micronutrient supplements on the nutritional status and health status of people has been under way for many

Table 1 Components of a research approach to evaluate dietary micronutrient supplements

Basic biomedical laboratory research
In vitro experiments (e.g., in cell culture and tissue culture)
In vivo animal experiments (e.g., in mice and rats)
Human observational epidemiologic studies to identify possible links between micronutrients and nutrition/health status (includes surveys of micronutrient intake)
Hypothesis development: Evaluation of existing laboratory and epidemiologic evidence on micronutrient safety and effectiveness as related to human health benefits (decision point: proceed or do not proceed)
If proceeding
Human safety trials to identify adverse side effects and determine safe doses
Small trials in defined populations to measure micronutrient effectiveness at various safe doses (e.g., vitamin D supplementation in elderly Scandanavians with low serum 25-hydroxy-vitamin D)
Large-scale, double-blind, placebo-controlled, randomized clinical intervention trials to test whether micronutrient supplementation has the hypothesized human health benefit
After health benefits are confirmed, develop recommendation for supplementation

years. Considerable preclinical evidence related to human health effects from in vitro laboratory research and in vivo animal studies exists for many micronutrients. In addition, many epidemiologic studies throughout the world have focused on the possible relationship between specific micronutrients and chronic disease. Small clinical studies related to chronic disease also have been carried out for many micronutrients, and human safety data are available for most micronutrients. A comprehensive review of epidemiologic studies and randomized controlled trials of vitamin supplementation to prevent either cancer or cardiovascular disease (CVD) was conducted by the US Preventive Services Task Force. The Task Force concluded that findings did not demonstrate a consistent or significant effect of any single vitamin or combination of vitamins on either incidence of CVD or death from this disease. Also, the Task Force concluded that β-carotene supplements and combinations including β-carotene appeared to be harmful to those at risk for lung cancer but not to the general population.

Important issues to be addressed in research aimed at determining the effects of micronutrient supplements on health include developing better methods to measure the contribution of micronutrient supplements to total micronutrient intake for various population groups and to monitor these contributions over time to identify usage trends. Having accurate data for micronutrient supplement intake and intake trends is essential to help identify possible associations between supplements and health outcomes; such associations can then be tested for validity in future randomized, controlled trials. Collecting data to measure and ultimately monitor consumer use of micronutrient supplements can be expensive and time-consuming, however, particularly if detailed data are required. Currently, in the United States, NHANES interviewers collect the most detailed information about micronutrient supplement intake, including data on supplement brand, labeled ingredients, dose, and frequency of dose. Available dietary supplement databases are based on values declared on product labels rather than direct analysis. Evidence suggests, however, that supplement labels may not always give the true supplement content; this can decrease the accuracy of survey results.

A major concern associated with clinical trials designed to evaluate the health effects of micronutrients (as well as other dietary supplements and drugs) is that participants might take additional micronutrient supplements, which could influence trial outcomes. In the Prostate Cancer Prevention Trial (PCPT) of the drug finasteride, for example, almost half of the participants reported using a multivitamin/mineral supplement, about one-third used single supplements of either vitamin C or E, and one in five used calcium supplements. Very little evidence is available on how individual micronutrient substances may interact with one another to influence health outcomes. For minerals, particularly, supplementation with one mineral may compromise the bioavailability of another. Also, much remains to be learned about how individual genetic susceptibilities may influence the health-related effects of micronutrient supplements. This issue also must be addressed when designing clinical trials.

Evidence Supporting Recommendations for Micronutrient Supplement Use

Importance of Life Cycle

Evaluation of existing evidence related to effects of micronutrient supplements on nutrition and health, aimed at formulating recommendations for supplementation, must take into account the influence of a person's stage of life and general health status on the absorption, usefulness, and need for any particular micronutrient. Physiological needs for specific micronutrients and, consequently, for micronutrient supplements differ at various stages in the life cycle. For example, infants require additional iron after 6 months of age, women who may become pregnant benefit from additional folate, and elderly people who lose their ability to absorb naturally occurring vitamin B_{12} in food require an alternative source of the vitamin. When studies are designed to investigate the relationship between micronutrient supplements and specific health outcomes, the outcomes that are chosen to be measured usually depend on the specific life cycle stage of the study participants. For any life cycle stage, a person's genetic makeup and lifestyle behaviors will also influence his or her individual micronutrient requirements (**Figure 1**).

Infants

Iron Iron is a component of a number of proteins including hemoglobin, which is essential for transporting oxygen to tissues throughout the body for use in metabolic processes. The most well-known consequence of iron deficiency is anemia. A full-term infant normally has a high hemoglobin concentration and a large amount of stored iron. Based on research evidence, this stored iron plus the iron provided in human milk is assumed to be adequate for solely breast-fed infants during the first 6 months after birth. Even though the amount of iron in

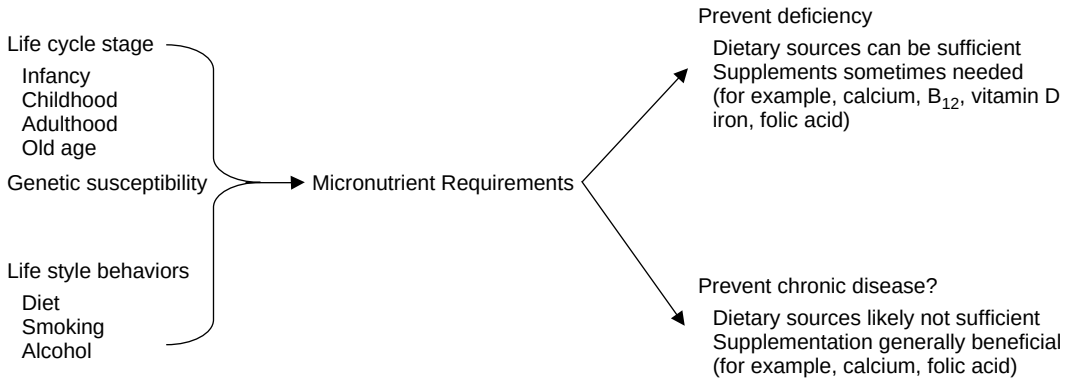

Figure 1 Factors that influence micronutrient requirements.

human milk is low, its bioavailability is greater (>50%) than that of the iron in infant formula (<12%). The body stores of iron in infants decrease during the fourth through sixth months after birth. After 6 months of age, most of the infant's iron needs must be met from food intake. In Western countries, the primary food introduced after 6 months is infant cereal, usually fortified with iron that has low bioavailability. Evidence suggests that infants benefit from iron supplementation after 6 months, and that administration of iron drops between 6 and 9 months has a significant influence on iron status. The American Academy of Pediatrics (AAP) discourages using low-iron infant formulas. AAP recommends that infants who are not breast-fed or who are only partially breast-fed should receive an iron-fortified formula from birth to 12 months of age.

Vitamin D Vitamin D enhances the efficiency of the small intestine to absorb calcium and phosphorus from the diet and thus helps to maintain normal serum levels of these minerals. Vitamin D deficiency in infants and children results in inadequate mineralization of the skeleton, causing rickets, which is characterized by various bone deformations. The major source of vitamin D is its formation in the skin as a result of exposure to sunlight. Dietary sources include fortified foods, such as milk and cereals, and certain fish. Infant formula is fortified with vitamin D in many countries. Because human milk contains only low amounts of vitamin D, breast-fed infants who do not receive either supplemental vitamin D or adequate exposure to sunlight are at risk for developing vitamin D deficiency. Subclinical vitamin D deficiency can be assessed by measuring serum 25-hydroxyl-vitamin D; deficiency occurs months before rickets is obvious on physical examination. Rickets in infants continues to be reported in the United States as well as in other countries. Epidemiologic evidence indicates that African American infants and children are more likely to develop nutritional rickets than Caucasian infants and children. In the US, the AAP recommends that all breastfed infants receive a daily supplement of 200 IU vitamin D/day, beginning within the first two months of life, unless they are weaned to at least 500 mL per day of vitamin D-fortified formula (<1 year old) or milk (>1 year old).

Children

Calcium Bone is a dynamic tissue that is constantly being formed and resorbed; in children, bone formation is greater than resorption. Adequate calcium intake during childhood is essential for bone mass development. Data for calcium intake, presented in **Table 2**, indicate that for children in the United States, only those younger than 8 years of age are meeting their recommended intake. Factors that may contribute to low calcium intake are restriction of dairy products, low vegetable consumption, and high intake of low-calcium beverages such as juices and sodas. The highest calcium intake levels are required during the preteen and adolescent years to support the rapid growth and bone mineralization associated with pubertal development. In girls, peak calcium absorption and deposition takes place at or near menarche; at this life cycle stage, the bone calcium deposition rate is five times greater than that in adults. During peak bone mass development, calcium intakes of less than 1000 mg/day are associated with lower bone mineral density. Epidemiologic studies have found a direct correlation between calcium intake and bone density in children. Evidence suggests that low intake of dairy products during childhood and adolescence may result in less bone mass and greater risk of fracture as an adult. In addition, evidence from randomized trials suggests that increasing the calcium intake of girls is

Table 2 Average calcium intake and recommended adequate intake levels for US children

	Age/gender

associated with increased bone mineral deposition, especially during prepuberty. Although it is best to obtain as much calcium as possible from foods, because calcium-rich foods also provide nutrients involved in calcium utilization, calcium supplements may be necessary for children who do not eat calcium-rich foods.

Adults

Vitamin E Vitamin E (α-tocopherol) functions as an antioxidant that promotes normal formation of red blood cells and normal function of the nervous and immune systems. The main dietary sources of vitamin E are vegetable oils; normally, it is possible, unless people consume a very low-fat diet, to obtain amounts of vitamin E intake from foods that are sufficient to prevent signs of deficiency. However, vitamin E is a commonly consumed supplement, likely because of its hypothesized role in decreasing risk of CVD, prostate cancer, and various other chronic diseases.

Evidence from epidemiologic studies suggests that vitamin E supplementation is beneficial for reducing CVD risk. Nevertheless, data from randomized clinical trials, in populations both with and without a history of CVD, generally do not support the epidemiologic findings. The review of evidence by the US Preventive Services Task Force included five well-designed, large cohort studies that investigated the association between vitamin supplementation and CVD mortality, three clinical trials of primary prevention of CVD, and seven clinical trials of secondary prevention of cardiac events. As stated earlier, the Task Force concluded that findings did not demonstrate a consistent or significant effect of vitamin E on either incidence of CVD or death from this disease. Four large clinical trials are currently in progress in the United States to study the effect on CVD of vitamin E supplements alone or combined with other antioxidants: the Women's Health Study, the Women's Antioxidant and Cardiovascular Study, the Physicians' Health Study II, and the Heart Protection study.

Laboratory studies suggest that vitamin E can inhibit the growth of human prostate cancer cell lines. Results of epidemiologic studies, however, do not consistently support a beneficial effect of vitamin E on risk for prostate cancer. Findings from the Alpha-Tocopherol, Beta-Carotene Cancer Prevention (ATBC) study, a large, randomized clinical trial conducted in Finland, suggest a substantial benefit of vitamin E in decreasing prostate cancer risk. This study reported a decrease of 32% in prostate cancer incidence and a decrease of 41% in deaths from prostate cancer among current and former male smokers who received supplemental vitamin E (50 mg/day). Additional information on the relationship between vitamin E supplementation and prostate cancer likely will be available from the Prostate Cancer Prevention Trial (PCPT), which was stopped in June 2003 when analysis showed that the test drug, finasteride, reduced the risk of developing prostate cancer by 25%. In PCPT, 35% of the study population took vitamin E supplements, and study analyses will include interactions between vitamin E and other supplements and between vitamin E and finasteride. The Selenium and Vitamin E Prevention Trial (SELECT), described later, is also expected to help clarify the association between vitamin E and prostate cancer.

Selenium Selenium, a strong antioxidant, also shows other biological activity, such as enhancing the immune response and inhibiting cell growth. Laboratory and epidemiologic studies support a beneficial effect of selenium on cancer risk. In a large clinical trial, selenium supplementation did not prevent the recurrence of nonmelanoma skin cancer, but it did significantly decrease the total number of deaths and deaths from cancer. In addition, the incidences of prostate, colorectal, and lung cancers all were significantly decreased in the group that received selenium supplements. These findings and the results of the ATBC study linking vitamin E supplementation with decreased prostate cancer risk led to the development of SELECT. Started in 2001, SELECT is a randomized,

double-blind trial designed to test whether selenium (200 μg/day) alone, vitamin E (400 mg/day) alone, or selenium and vitamin E combined reduce the risk of prostate cancer among healthy men. Men who join SELECT are required to stop taking any purchased vitamin supplements that contain either selenium or vitamin E. An ongoing intervention trial in France, the Supplementation en Vitamines et Mineralaux AntioXydants (SU.VI.MAX) study, is testing nutritional levels of both selenium and vitamin E, as well as vitamin C, β-carotene, and zinc, for reducing incidence of cancer and CVD. In addition to cancer and CVD, French researchers are investigating a possible beneficial role for selenium in arthritis and HIV/AIDS.

Folate Folate, a B-complex vitamin, includes the naturally occurring form found in foods as well as the synthetic form (folic acid) found in fortified foods and supplements. The rationale for the recommendation that all women who may become pregnant should take a daily 400 μg folic acid supplement, a preventive measure to reduce the risk of NTDs, has already been discussed. Folate intake is important throughout pregnancy because of its key role in nucleic acid synthesis, which is essential for cell growth and replication.

A deficiency of folate, vitamin B_{12}, or vitamin B_6 may increase the level of homocysteine, an amino acid normally found in the blood. Evidence indicates that a high homocysteine level increases the risk for CVD and stroke, possibly by either damaging coronary arteries or making it easier for blood platelets to clump together and form a clot. However, no evidence is available to suggest that lowering homocysteine through vitamin supplementation will reduce the risk of CVD. Clinical intervention trials to test the effects of vitamin supplementation on CVD and stroke are needed.

Because folate is involved in the synthesis, repair, and functioning of DNA, some have hypothesized that a deficiency of folate may result in DNA damage that can lead to cancer. A comprehensive review of epidemiologic, preclinical, and clinical evidence linking folate deficiency with increased cancer risk concluded that the evidence is strongest for colorectal cancer. Also, it has been suggested that folate deficiency may increase the effects of other cancer risk factors. Researchers are continuing to investigate whether increasing folate intake from foods or folic acid supplements may reduce cancer risk.

Folate is important for cells and tissues that divide rapidly; therefore, high-dose methothrexate is often used to treat cancer because this compound interferes with folate metabolism. Methothrexate, however, has undesirable side effects, including inflammation in the digestive tract. It is not known whether folic acid supplementation can help control these side effects without decreasing the effectiveness of methrothrexate. Low-dose methothrexate is used to treat a variety of diseases, such as rheumatoid arthritis, lupus, psoriasis, asthma, and inflammatory bowel disease. Low-dose treatment can deplete folate stores and cause side effects similar to folate deficiency. In this case, supplemental folic acid may help reduce the undesirable effects of low-dose methothrexate without decreasing treatment effectiveness.

Calcium Bone formation and resorption are balanced in healthy adults, but formation becomes slower than resorption after menopause and also with aging in both men and women. In menopausal women, decreased estrogen production is associated with accelerated bone loss in the first 5 years after menopause, particularly from the lumbar spine. Evidence indicates that although increasing calcium intake at menopause does not prevent this bone loss, it is beneficial for reducing bone loss in compact bones (e.g., hips, legs, and arms). Furthermore, data suggest that calcium supplementation also reduces lumbar spine bone loss in women who are more than 5 years beyond menopause. In the United States, the recommended calcium intake is 1000 mg/day for men and women ages 19–50 years and 1200 mg/day for men and women ages 51–70 years. People who are not able to obtain this amount of calcium from foods should consider taking calcium supplements to help decrease the risk of reduced bone mass and osteoporosis.

Elderly

Physiological changes that may occur during the natural course of aging can affect micronutrient requirements. Given the same amount of sun exposure, the skin of young adults synthesizes much more vitamin D than the skin of the elderly; thus, choosing good dietary sources of vitamin D becomes essential. Vitamin D deficiency can be a factor in reduced calcium absorption in the elderly. Furthermore, it is estimated that atrophic gastritis, a change in gastrointestinal physiology that results in low-acid conditions in the stomach, is present in approximately 20% of elderly people. Atrophic gastritis has been related to infection with the bacterium *Helicobacter pylori* and is not necessarily a result of normal aging. The low-acid conditions, however, can decrease the absorption of vitamin B_{12} from food and of folate and calcium in general.

Vitamin D Vitamin D is important in the elderly for enhancing calcium absorption, inhibiting cellular growth, and activating lymphocyte function. Vitamin D deficiency may lead to osteoporosis and osteomalacia and possibly increase the risk for some cancers; it has been associated with increased incidence of hip fractures. More than 50% of elderly people have been reported to be vitamin D deficient in some studies. In addition to the skin's decreased ability to synthesize vitamin D as people age, the kidneys, which help to convert vitamin D to its active form, sometimes do not function as well when people age. All elderly people, particularly people with limited sun exposure, such as those who are either homebound or live in northern latitudes, should include vitamin D-fortified foods and fish in their diets. If elderly people are unable to meet their vitamin D needs using dietary sources, they may require a supplement. Evidence suggests that vitamin D supplementation may reduce the risk of osteoporotic fractures in elderly people with low serum levels of vitamin D.

Vitamin B_{12} Vitamin B_{12} is essential for proper brain and nerve development and for DNA synthesis; also, it improves learning and supports methylation metabolism. Dietary vitamin B_{12} must be separated from food proteins before the vitamin can be bound to intrinsic factor and then be absorbed by the body. Under low-acid conditions in the stomach, neither the separation from protein nor the binding to intrinsic factor can take place, significantly decreasing the bioavailability of vitamin B_{12}. Elderly adults with atrophic gastritis and low stomach acid should consume a source of unbound vitamin B_{12} such as that found in supplements or food that has been fortified with the vitamin to ensure adequate intake. In addition, evidence suggests that the use of antibiotics can improve vitamin B_{12} absorption in these elderly adults.

Folate Atrophic gastritis greatly reduces the ability of elderly people to absorb folate. This problem can be corrected by administering folic acid with dilute hydrochloric acid to increase stomach acidity and thus increase absorption. There is concern, however, about the possibility that supplemental folic acid could mask the signs of vitamin B_{12} deficiency. Folic acid can remedy the anemia that results from vitamin B_{12} deficiency, its key diagnostic sign. It cannot, however, correct the permanent nerve damage that is possible if vitamin B_{12} deficiency is not treated. Intake of supplemental folic acid should not be greater than 1000 μg per day to prevent the masking of signs of vitamin B_{12} deficiency.

Calcium Adequate calcium intake is required to maintain bone mineral density and reduce the risk of osteoporosis in the elderly. In addition to the reduced absorption of calcium by elderly people that results from age-related changes in vitamin D metabolism, the elderly also show a reduced ability to increase the efficiency of calcium absorption as an adaptive response to low-calcium diets. Also, as noted earlier, the low-acid conditions resulting from atrophic gastritis can reduce calcium absorption. Dietary calcium reacts with hydrochloric acid in the stomach to form soluble calcium chloride, which is absorbed in the small intestine. In the United States, the recommended calcium intake is 1200 mg/day for men and women older than age 70. Many elderly people may benefit from calcium supplements.

Perioperative Feeding

E Kelly, Harvard Medical School, Boston, MA, USA

Introduction

Resumption of normal oral feeding following surgery can be complicated or delayed. Many factors can contribute to the inability to maintain sufficient oral intake in the postoperative period. Some of these factors are attributable to complications of surgery, some are attributable to the use of medication for anesthesia and analgesia, such as narcotics, some are attributable to mechanical swallowing impairment (dysphagia) or mechanical bowel obstruction, and some are attributable to host factors in advanced disease or critical illness. Our review will examine the expected normal resumption of oral feeding as well as focus on the above complications of postoperative feeding using physiologic principles and discuss the standard alternative nutritional support strategies for these complications.

Normal Resumption of Oral Feeding

With minor surgical procedures, involving only local anesthetics or sedation, normal oral feeding can be safely resumed once the sedative effect has worn off. Even in procedures involving general anesthesia, most patients can start a clear liquid diet once the postoperative nausea has passed, and can rapidly advance to a regular diet if clear liquids are tolerated.

Postoperative Dysphagia

Oropharyngeal dysphagia can occur in the postoperative setting for a number of reasons. Procedures involving the upper aerodigestive tract for either benign or malignant disease can result in varying degrees of dysphagia with or without aspiration due to alteration in the anatomical mechanism of swallowing. In addition, procedures in the neck can be complicated by inadvertent injury to the aerodigestive tract or to the nerves innervating the muscles of deglutition, resulting in dysphagia. The recurrent laryngeal nerves, which control the motion of the vocal chords, have a long and tortuous course that goes into the chest and back into the neck. These nerves are especially vulnerable to injury during operations in the neck or chest, particularly esophagectomy, as the nerves run parallel to the esophagus. The superior laryngeal nerves have a course that is not so tortuous and is entirely within the neck; however, due to their anatomical proximity to the thyroid gland and to the carotid sheath, they are especially vulnerable to injury during thyroidectomy and carotid endarterectomy.

In addition, the normal reflexes of swallowing depend on normal sensation of the pharyngeal mucosa. Thus, postoperative dysphagia can result from direct injury or irritation of the pharyngeal mucosa from endotracheal tubes or esophageal tubes. In cardiac surgical procedures, an esophageal ultrasound probe is frequently used for monitoring. While the overall incidence of postoperative dysphagia following cardiac surgery is 4%, the use of this device is associated with a 7-fold higher incidence. In addition to those discussed above, other procedures that are associated with high risk of

postoperative dysphagia include anterior cervical spine operations, operations for Zencker's diverticulum, and radical lymph node dissection.

Operations for gastroesophageal reflux disease (GERD) have a 6% rate of postoperative esophageal dysphagia, characterized by a sensation of swallowed food sticking in the lower esophagus, and delayed esophageal emptying. While there is no increased risk of aspiration in these patients, postoperative feeding can be significantly impaired, leading to weight loss and malnutrition. Esophageal dysphagia can also complicate other esophageal procedures, such as esophagectomy.

Swallowing is a complex reflex and treatment of postoperative dysphagia requires a thorough understanding of normal swallowing and the surgical complications of swallowing. Dysphagia can be clinically silent, leading to a dangerous condition where no complication is suspected until the patient is orally fed, and develops aspiration pneumonia. When clinical signs do occur, they may be subtle, such as delay in initiation of swallow, regurgitation, or gurgling voice. Clinically apparent aspiration is characterized by cough, regurgitation, and gurgling. Bedside evaluation by a certified speech pathologist is often required for the subtle signs of postoperative dysphagia. Bedside evaluation is up to 90% sensitive for clinical signs and symptoms of aspiration, but cannot detect truly silent aspiration. If silent aspiration is suspected, due to pneumonia or respiratory compromise during feeding, a modified barium swallow is indicated. This examination is conducted in the radiology suite under the supervision of a radiologist and a speech pathologist using real-time fluoroscopy. It enables detection of silent aspiration and allows the speech pathologist to test varying thicknesses of food, in order to determine which thicknesses are safe for the patient, and which are aspirated. The diet can be modified accordingly. If no oral diet can be safely used, then patients with oropharyngeal dysphagia should be fed via an alternate route.

Patients with postoperative esophageal dysphagia should undergo evaluation for structural causes such as anastomotic stricture, and functional causes, such as failed antireflux surgery, or failed procedure for esophageal dysmotility. Barium swallow and upper endoscopy will disclose most anatomic cause of esophageal dysphagia, and some esophageal strictures will respond to endoscopic dilatation. Esophageal dysphagia due to dysmotility requires evaluation with esophageal manometry. Disorders of motility can sometimes be managed medically or with surgical procedures. Alternative routes of feeding can be used in conjunction with these treatments, or can be used as salvage treatment when other treatments fail.

Postoperative Ileus

Ileus is a condition of generalized bowel dysmotility that frequently impairs feeding in the postoperative setting. Ileus typically occurs after abdominal surgery, even if the bowel itself is not altered. It has been shown that laparotomy alone, without intestinal manipulation leads to impaired gastrointestinal motility. The small bowel is typically affected the least, and can maintain organized peristaltic contractions throughout the perioperative period. The stomach usually regains a normal pattern of emptying in 24 h, and the colon is last to regain motility, usually in 48–72 h.

The exact mechanism that causes postoperative ileus is not completely known; however, physiologic studies have demonstrated the significant contribution of both inhibitory neural reflexes and local mediators within the intestinal wall. Inhibitory neural reflexes have been shown to be present within the neural plexes of the intestinal wall itself, and as reflex arcs traveling back and forth from the intestine to the spinal cord. These neural pathways may account for the development of ileus during laparotomy without bowel manipulation. In addition, inflammatory mediators such as nitric oxide are present in manipulated bowel and in peritonitis and may play a role in development of ileus.

Clinically, ileus can be recognized from clinical signs. Abdominal distension, nausea, and the absence of bowel sounds and flatus should prompt the diagnosis. Abdominal X-ray imaging typically shows dilated loops of small bowel and colon. Bowel obstruction must also be considered with these clinical findings, however, and CT or other contrast imaging may be required to confirm or rule out obstruction.

Ileus can also appear following nonabdominal surgery, and can result from effects of medications, most often narcotics, electrolyte abnormalities, especially hypokalemia, and a wide variety of other factors.

Occasionally, the patient sustains a prolonged period of postoperative ileus. This can be due to a large number of contributing factors, such as intra-abdominal infection, hematoma, effects of narcotics and other medications, electrolyte abnormalities, and pain. In addition, there can be prolonged dysmotility from certain bowel operations, such as intestinal bypass.

The role of laparoscopic surgery in prevention of ileus is controversial. In theory, with less handling of the bowel laparoscopically and with smaller incisions, there should be less stimulation of the local mediators and neural reflexes. Animal studies

comparing open and laparoscopic colon surgery indicate earlier resumption of normal motility studies and bowel movements with the laparoscopic approach. Human trials have not been conclusive. Several series demonstrate earlier tolerance of postoperative feeding with the laparoscopic approach to colon resection; however, these have been criticized for selection bias, and such studies are impossible to conduct in a blind fashion.

Early mobilization has long been held to be useful in prevention of postoperative ileus. While standing and walking in the early postoperative period have been proven to have major benefits in pulmonary function and prevention of pneumonia, mobilization has no demonstrable effect on postoperative ileus.

In the expected course of uncomplicated abdominal surgery, the stomach is frequently drained by a nasogastric tube for the first 24 h after surgery, and the patient is not allowed oral intake until there is evidence that colonic motility has returned, usually best evidenced by the passage of flatus. Earlier feeding, and no gastric drainage after bowel surgery can be attempted for healthy patients undergoing elective abdominal surgery, with a high rate of success, provided clinical symptoms of ileus are not present. In such patients, the use of effective preventive strategies is highly effective. These include maintenance of normal serum electrolytes, use of epidural analgesia, and avoidance of complications such as infection and bleeding. The routine use of nasogastric tubes for drainage in the postoperative period after abdominal surgery has come into question since the mid 1990s.

The most effective strategy for management of postoperative ileus following abdominal surgery has been the development of epidural analgesia. Randomized trials have shown that the use of nonnarcotic (local anesthetic based) epidural analgesia at the thoracic level in the postoperative period results in decreased period of postoperative ileus in elective abdominal surgery. Ileus reduction is not seen in lumbar level epidural analgesia, suggesting that inhibitory reflex arcs involving the thoracic spinal cord may play a major role in postoperative ileus.

Narcotic analgesia, while effective for postoperative pain, has been shown to lengthen the duration of postoperative ileus, especially when used as a continuous infusion or as patient-controlled analgesia (PCA). Patients report better control of postoperative pain with continuous infusion or PCA as compared to intermittent parenteral dosing. Many studies have been done comparing various types of opioid analgesics, in attempts to find a type that does not prolong ileus. There has been no clearly superior drug identified; all currently available opioids cause ileus. Opioid antagonists such as naloxone have been used in trials to decrease ileus in chronic narcotic use, and there is evidence that antagonists are effective in that setting; however, in postoperative ileus the antagonists have not been shown to be clinically useful, again suggesting that other mechanisms are contributing to it.

Early Postoperative Bowel Obstruction

Early postoperative bowel obstruction refers to mechanical bowel obstruction, primarily involving the small bowel, which occurs in the first 30 days following abdominal surgery. The clinical picture may frequently be mistaken for ileus, and these clinical conditions can overlap. The clinical presentation of early postoperative bowel obstruction is similar to bowel obstruction arising *de novo*: crampy abdominal pain, vomiting, abdominal distension, and obstipation. The incidence of early postoperative bowel obstruction has been variable in published series, due to difficulty in differentiating ileus from early postoperative bowel obstruction, but the reported range is from 7 to 9.5% of abdominal operations.

Retrospective large series show that about 90% of early postoperative bowel obstruction is caused by inflammatory adhesions. These occur as a result of injury to the surfaces of the bowel and peritoneum during surgical manipulation. The injury prompts the release of inflammatory mediators that lead to formation of fibrinous adhesions between the serosal and peritoneal surfaces. As the inflammatory mediators are cleared, and the injury subsides, these adhesions eventually mature into fibrous, firm, band-like structures. In the early postoperative period, the adhesions are in their inflammatory, fibrinous form and, as such, do not usually cause complete mechanical obstruction.

Internal hernia is the next most common cause of early postoperative bowel obstruction, and can be difficult to diagnose short of repeat laparotomy. Internal hernia occurs when gaps or defects are left in the mesentery or omentum, or blind gutters or sacs are left in place during abdominal surgery. The typical scenario is colon resection involving extensive resection of the mesentery for lymph node clearance. If the resulting gap in the mesentery is not securely closed, small bowel loops may go through the opening and not be able to slide back out. A blind gutter may be constructed inadvertently during the creation of a colostomy. When the colostomy is brought up to the anterior abdominal wall, there is a space between the colon and the lateral abdominal wall, which may also 'trap' the mobile loops of small bowel. Defects in the closure of the fascia

during open or laparoscopic surgery can cause obstruction from incarcerated early postoperative abdominal wall hernia. Fortunately, internal hernia is a rare occurrence in the early postoperative period; however, it must be suspected in cases where bowel anastomoses or colostomies have been constructed. Unlike adhesive obstruction, internal hernia requires operative intervention due to the high potential for complete obstruction and strangulation of the bowel.

Intussusception is a rare cause of early postoperative bowel obstruction in adults, but occurs more frequently in children. Intussusception occurs when peristalsis carries a segment of the bowel (called the lead point) up inside the distal bowel like a rolled up stocking. The lead point is usually abnormal in some way, and typically has some intraluminal mass, such as a tumor or the stump of an appendix after appendectomy. Other rare causes for early postoperative bowel obstruction include: missed causes of primary obstruction at the index laparotomy, peritoneal carcinomatosis, obstructing hematoma, and ischemic stricture.

Management of early postoperative bowel obstruction depends on differentiation of adhesive bowel obstruction (the majority) from internal hernia and the other causes, and from ileus. Clinicians generally rely on radiographic imaging to discern ileus from obstruction. For many years plain X-ray of the abdomen was used: if the abdominal plain film showed air-distended loops of bowel and air/fluid levels on upright views, the diagnosis of obstruction was favored. However, plain radiographs can be misleading in the postoperative setting, and the overlap of ileus and obstruction can be confusing. Upper gastrointestinal (GI) contrast studies using water-soluble agent has better accuracy, and abdominal computed tomography (CT) using oral contrast has been shown to have 100% sensitivity and specificity in differentiating early postoperative bowel obstruction from postoperative ileus.

Once the diagnosis is made, management is tailored to the specific needs of the patient. Decompression via nasogastric tube is usually indicated, and ileus can be treated as discussed. Adhesive bowel obstruction warrants a period of expectant management and supportive care, as the majority of these will resolve spontaneously. Most surgical texts recommend that the waiting period can be extended to 14 days. If the early bowel obstruction lasts longer than 14 days, less than 10% resolve spontaneously, and exploratory laparotomy is indicated. The uncommon causes of early postoperative bowel obstruction, such as internal hernia, require more early surgical correction, and should be suspected in the setting of complete obstipation, or when abdominal CT suggests internal hernia or complete bowel obstruction.

Nutritional Support in the Postoperative Setting

Nutritional support in the postoperative patient, as with any patient, begins with a thorough evaluation of nutritional status. The standard assessment including recent eating habits, changes in weight, physical examination, and relevant laboratory values applies to all patients. Ideally, the surgical patient should undergo this assessment preoperatively, and have postoperative feeding planned appropriately. The majority of patients who undergo elective operation are nutritionally replete, and return to normal oral alimentation soon after surgery. Unfortunately, patients undergoing emergency surgery frequently do not get a nutritional assessment, and their nutritional risk should be assessed promptly postoperatively.

In addition to the patient's nutritional status at time of surgery, the clinician must make some estimate of the time until resumption of normal intake. As discussed above, postoperative complications can make this prediction uncertain, but early recognition of complications should be stressed, to enable prompt initiation of nutritional support and prevent worsening of nutritional status. The type of operation and individual patient risk factors such as age and existing diagnoses of dysmotility or obstruction should also be taken into account when planning postoperative nutritional support.

Postoperative dysphagia can frequently be managed by alteration of the oral diet. Evaluation of swallowing by a speech pathologist will enable the selection of the appropriate diet. The patients that most often benefit from modification of the oral diet are those who have undergone procedures in the neck or in the thoracic cavity. Occasionally, these patients have severe dysphagia and cannot take any oral diet. Enteral feeding via tubes (inserted nasally or surgically) can be provided until the dysphagia resolves. In elective procedures on the esophagus or upper aerodigestive tract, a feeding tube is often placed at the index operation to facilitate postoperative feeding, when the preoperative nutritional assessment indicates a high risk of postoperative dysphagia. A surgically placed feeding tube can remain in place indefinitely; a nasal feeding tube should not remain in place longer than a few weeks, due to the risk of nasal erosion and sinusitis.

The standard enteral formulas can be used in the postoperative setting, and as with all patients, the enteral nutritional prescription must be individualized. The postoperative patient's estimated nutrient goals should take into account the added stress of wound healing, especially if there are large open wounds, such as in the trauma and burn population, and infection, if present. Tolerance of enteral feeding can be a difficult clinical problem in the postoperative setting. These patients may have lingering ileus or unsuspected early postoperative bowel obstruction, and gastrointestinal motility may be impaired by critical illness, preexisting conditions such as diabetes, and pain control medication. Tolerance can be enhanced by advancement of the tip of the feeding catheter into the small bowel, which is resistant to ileus. Advancement of a nasogastric catheter can be accomplished at the bedside, and chances of success are improved by positioning of the patient with the right side dependent and with the use of promotility agents such as metoclopramide and erythromycin. Advancement of a percutaneous or surgically placed feeding catheter usually requires endoscopic or fluoroscopic guidance in the endoscopy suite or in radiology.

Postoperative bowel obstruction can be a difficult clinical problem, as this patient population may have some increased nutritional risk preoperatively, the duration of the bowel obstruction is difficult to predict, and some of these patients may require reoperation to relieve the obstruction. In addition, nutritional support options are limited, as both the oral and enteral routes are not available. This patient group should be considered for postoperative parenteral nutrition. Most nutritional guidelines, including the American Society for Parenteral and Enteral Nutrition (ASPEN), call for initiation of parenteral nutrition if the anticipated duration of obstruction is 7 days or greater. If the patient is already nutritionally compromised at the time of surgery, parenteral nutritional support is indicated sooner.

In the case of prolonged postoperative ileus, parenteral nutrition may be required especially if the patient is nutritionally compromised preoperatively. As with bowel obstruction, an estimate of the duration of impaired intake is required, but unlike obstruction, there is no clear guideline as to how long the ileus may last. As discussed, all measures to avoid or curtail ileus should be undertaken: avoidance of opioid analgesia, correction of electrolyte abnormalities, and treatment of infection. Opioid antagonists and most promotility agents have not been proven clinically effective in treating postoperative ileus. There are two motility agents in clinical use that have shown some promise and are under investigation: cisapride and neostigmine. Cisapride increases motility throughout the gastrointestinal tract by stimulation of acetylcholine release in the intrinsic myenteric nerve plexes and has been shown to shorten the duration of postoperative ileus in randomized trials when administered intravenously. Unfortunately, this drug has severe cardiac side effects and was withdrawn from use in the US and the UK in 2000. Neostigmine inhibits the removal of acetylcholine neurotransmitter from nerve synapses and thereby increases intestinal motility. This drug has been used effectively in cases of dysmotility syndromes and has been used successfully in case reports and in small prospective trials for postoperative ileus. Larger trials await completion to gain acceptance in general use.

In general, the same guidelines for early postoperative bowel obstruction apply to ileus: if resolution within 7 days is not anticipated, or if the patient is nutritionally compromised, parenteral nutrition is indicated.

Summary

The vast majority of postoperative patients resume their preoperative feeding plan without significant delay. Complications of surgery can interfere with or permanently alter the patient's ability to resume normal intake. These complications can take many forms and cause functional or anatomic dysfunction of any portion of the gastrointestinal tract. Specific procedures have well documented rates of complication, enabling the clinician to individualize treatment of postoperative feeding disorders. Nutritional support in the postoperative setting may be required, depending on nutritional risks of the patient and the anticipated length of nutritional impairment.

Long-term Nutritional Management

E Lin and T R Ziegler, Emory University, Atlanta, GA, USA

Long-Term Nutrition Support

The initial goal of nutritional support in the surgical patient is to prevent or reverse the catabolic effects of disease or injury. This article addresses the clinical application of nutritional support once the patient is stabilized and the initial injury contained. Long-term nutritional support usually refers to transition from the acute hospital setting into a long-term chronic care setting or the patient's home. The ability to transition nutrition therapy is the result of innovations in central venous catheters, enteral catheters, nutrient formulations, and infusion pumps and the availability of dedicated home health industry. However, in considering a patient for home nutritional support, one of the most important criteria is the availability of strong family support systems.

The indications for long-term nutrition support, specifically for home, include any patient who is unable to meet nutrient requirements by oral intake to avert the consequences of malnutrition. In the United States, cancer patients represent the most frequent use (>40%) of home parenteral and enteral nutrition support. Inflammatory bowel disease is the second most common reason for home parenteral nutrition, and swallowing disorders are the second most common reason for home enteral nutrition. Other indications for long-term home nutrition support are outlined in **Tables 1** and **2**.

Table 1 Body fuel reserves in a 70-kg man

Component	*Mass (kg)*	*Energy (kcal)*	*Days available*
Water and minerals	49	0	0
Protein	6	24 000	13
Glycogen	0.2	800	0.4
Fat	15	140 000	78
Total	70	164 800	91.4

Energy Requirements

Overall nutritional assessment is undertaken to determine the severity of nutrient deficiencies or excess and to aid in predicting nutritional requirements. Pertinent information is obtained by determining the presence of weight loss, chronic illnesses, or dietary habits that influence the quantity and quality of food intake. Social habits predisposing to malnutrition and the use of medications that may influence food intake or urination should also be investigated. Physical examination seeks to assess loss of muscle and adipose tissues, organ dysfunction, and subtle change in skin, hair, or neuromuscular function reflecting frank or impending nutritional deficiency. Anthropometric data (arm circumference and muscle area) and biochemical determinations (creatinine excretion, albumin, prealbumin, total lymphocyte count, and transferrin) may be used to substantiate the patient's history and physical findings. It is imprecise to rely on any single or fixed combination of the previous findings to accurately assess nutritional status or morbidity. Appreciation for the stresses and natural history of the disease process, in combination with nutritional assessment, remains the basis for identifying patients in acute or anticipated need of nutritional support.

A fundamental goal of nutritional support is to meet the energy requirements for metabolic processes, core temperature maintenance, and tissue repair. Failure to provide adequate nonprotein

Table 2 Energy equivalent of substrate oxidation (per gram)

Substrate	*O_2 consumed (l/g)*	*CO_2 produced (l/g)*	*Respiratory quotient*	*kcal/g*	*Recommended daily need g/kg/day*
Glucose	0.75	0.75	1.0	4.0	7.2
Dextrose	—	—	—	3.4	—
Lipid	2.0	1.4	0.7	9.0	1.0
Protein	1.0	0.8	0.8	4.0	0.8

Table 3 Caloric adjustments above basal energy expenditure (BEE) in hypermetabolic conditions

Condition	*kcal/kg/day*	*Adjustment above BEE*	*g Protein/kg/day*	*Nonprotein calorie:nitrogen*
Normal/moderate malnutrition	25–30	1.1	1.0	150:1
Mild stress	25–30	1.2	1.2	150:1
Moderate stress	30	1.4	1.5	120:1
Severe stress	30–35	1.6	2.0	90–120:1
Burns	35–40	2.0	2.5	90–100:1

energy sources will lead to dissolution of lean tissue stores. The requirement for energy may be measured by indirect calorimetry or estimated from urinary nitrogen excretion, which is proportional to resting energy expenditure. Basal energy expenditure (BEE) may also be estimated by the equations of Harris and Benedict:

$$\text{BEE(men)} = 66.47 + 13.75\ (W) + 5.0\ (H) - 6.76\ (A)\ \text{kcal/day}$$

$$\text{BEE(women)} = 655.1 + 9.56\ (W) + 1.85\ (H) - 4.68\ (A)\ \text{kcal/day}$$

where W is weight (kg), H is height (cm), and A is age (years).

These equations, adjusted for the type of surgical stress, are suitable for estimating energy requirements in more than 80% of patients. It has been demonstrated that the provision of 25–30 kcal/kg/day will adequately meet energy requirements in most postsurgical patients, with low risk of overfeeding. The prescribed nutrient substrate requirements during long-term nutrition are to replace body nutrient stores and facilitate protein synthesis (**Table 3**). An appropriate nonprotein calorie:nitrogen ratio of 150 to 1 (1 g N = 6.25 g protein) should be maintained, which is the basal calorie provided to prevent use of protein as energy source. In the absence of severe renal or hepatic dysfunction precluding the use of standard nutritional regimens, approximately 0.25–0.35 g of nitrogen/kg of body weight should be provided daily.

Vitamins and Minerals

The requirements for vitamins and essential trace minerals usually can be easily met in the average patient with an uncomplicated postoperative course. Therefore, vitamins are usually not given in the absence of preoperative deficiencies (**Table 4**). Patients maintained on elemental diets or parenteral hyperalimentation require complete vitamin and mineral supplementation. Commercial enteral diets contain varying amounts of essential minerals and vitamins. It is necessary to ensure that adequate replacement is available in the diet or by supplementation. Numerous commercial vitamin preparations are available for intravenous or intramuscular use, although most do not contain vitamin K and some do not contain vitamin B_{12} or folic

Table 4 Common manifestations of vitamin and mineral deficiencies in adults

Deficiency	*Major manifestations of deficiencies*
Vitamin	
Vitamin A	Night blindness, corneal/conjunctiva drying
Vitamin D	Rickets, osteomalacia, bone pain
Vitamin E	Chronic cholestasis, spinaocerebellar ataxia, hyporeflexia
Vitamin K	Hemorrhagic disorders
Thiamin (B_1)	Dry beriberi (mental status changes, peripheral neuropathy), wet beriberi (heart failure)
Riboflavin	Sebaceous gland inflammation
Niacin	Dermatosis, pellagra
Pyridoxine (B_6)	Peripheral neuropathy
Biotin	Dry and scaling skin, glossitis
Vitamin B_{12}	Pernicious anemia, neuropathy, myelopathy, glossitis
Folic acid	Similar to B_{12} deficiency
Pantothenic acid	Headache, insomnia, paresthesia
Vitamin C	Scurvy (weakness, listlessness, musculoskeletal pain), perifollicular hemorhage
Essential fatty acids	Hair loss, dry skin, eczematoid dermatosis
Minerals	
Calcium	Dementia, encephalopathy, tetany
Phosphorus	Mental status changes, erythrocyte hemolysis, paresthesia
Potassium	Respiratory failure, paralytic ileus, tetany, arrhythmias
Magnesium	Hypocalcemia, hypokalemia, neuromuscular spasms, gut malabsorption
Iodine	Goiter
Iron	Microcytic anemia, fatigue, dyspnea
Copper	Hypochromic anemia (unresponsive to iron), neutropenia, osteoporosis
Zinc	Dermatosis, photophobia, night blindness, impaired wound healing, alopecia, diarrhea
Fluoride	No acute clinical signs
Selenium	Cardiomyopathy, myalgia, white nail beds
Chromium	Glucose intolerance,
Cobalt	No acute clinical signs known
Molybdenum	Headache, night blindness, lethargy
Manganese	Hair thinning, weight loss, dermatitis

acid. Supplemental trace minerals may be given intravenously by commercial preparations. Essential fatty acid supplementation may also be necessary, especially in patients with depletion of adipose stores.

Overfeeding

Overfeeding usually results from overestimation of caloric needs. Overestimation occurs when actual body weight is used, such as in critically ill patients with significant fluid overload and in obese patients. Indirect calorimetry can be used to quantify energy requirements. Estimated dry weight should be obtained from preinjury records or family members. Adjusted lean body weight can also be calculated. Clinically, increased oxygen consumption, increased carbon dioxide production, fatty liver, suppression of leukocyte function, and increased infectious risks have been documented with overfeeding.

Enteral Nutrition

Rationale for Enteral Nutrition

Enteral nutrition is generally preferred over parenteral nutrition based on reduced cost and associated risks of the intravenous route. Laboratory models have long demonstrated that luminal nutrient contact reduces intestinal mucosal atrophy when compared with parenteral or no nutritional support. Studies comparing postoperative enteral and parenteral nutrition in patients undergoing gastrointestinal surgery have demonstrated reduced infection complications and acute phase protein production when fed by the enteral route. However, prospective randomized studies for patients with adequate nutritional status (albumin $\geq$4 g/dl) undergoing gastrointestinal surgery demonstrate no differences in outcome and complications when administered enteral nutrition compared to maintenance of intravenous fluids alone in the initial days following surgery. Furthermore, intestinal permeability studies in well-nourished patients undergoing upper gastrointestinal cancer surgery have demonstrated normalization of intestinal permeability by postoperative day 5. At the other extreme, a meta-analysis of critically ill patients demonstrated a 44% reduction in infection complications in those receiving enteral nutritional support compared to those receiving parenteral nutrition. In addition, most prospectively randomized studies of severe abdominal and thoracic trauma demonstrate very significant reductions in infection complications for patients given early enteral nutrition compared to those who are unfed or receiving parenteral nutrition. The exception has been in studies of patients with closed-head injury because no significant differences in outcome are demonstrated between early jejunal feeding and other nutritional support modalities. Moreover, early gastric feeding following closed-head injury was frequently associated with underfeeding and calorie deficiency due to difficulties in overcoming gastroparesis and the high risk of aspiration.

The early initiation of enteral feeding in burn patients, although sensible and supported by retrospective analysis, is an empiric practice supported by limited prospective trials.

Recommendations for instituting early enteral nutrition to surgical patients with moderate malnutrition (albumin = 2.9–3.5 g/dl) can only be made by inferences due to a lack of data directly pertaining to this population. For these patients, it is prudent to offer enteral nutrition based on measured energy expenditure of the recovering patient or if complications arise that may alter the anticipated course of recovery (e.g., anastomotic leaks, return to surgery, sepsis, and failure to wean from ventilator). Other clinical scenarios with substantiated benefits from enteral nutritional support include permanent neurologic impairment, oropharyngeal dysfunction, short bowel syndrome, and bone marrow transplantation.

Collectively, the data support the use of early enteral nutritional support following major trauma and in patients who are anticipated to have prolonged recovery after surgery. Healthy patients without malnutrition undergoing uncomplicated surgery can tolerate 10 days of partial starvation (i.e., maintenance intravenous fluids only) before any significant protein catabolism occurs. Earlier intervention is likely indicated in patients with poorer preoperative nutritional status.

Initiation of enteral nutrition should occur immediately after adequate resuscitation, most readily determined by adequate urine output. The presence of bowel sounds and the passage of flatus or stool are not absolute requisites for initiating enteral nutrition, but feedings in the setting of gastroparesis should be administered distal to the pylorus. Gastric residuals $\geq$200 ml in 4–6 h or abdominal distention will require cessation of feeding and adjustment of infusion rate. Concomitant gastric decompression with distal small bowel feedings may be appropriate in certain patients, such as closed-head injury patients with gastroparesis. There is no evidence to support withholding enteric feedings for patients following bowel resection or in those with low-output enterocutaneous fistulas of $<$500 ml/day, but low-residue formulations may be preferred. Enteral feeding should also be offered to patients with short bowel syndrome or clinical malabsorption, but caloric needs, essential minerals,

and vitamins should be supplemented with parenteral modalities.

Enteral Formulas

The functional status of the gastrointestinal tract determines the type of enteral solutions to be used. Patients with an intact gastrointestinal tract will tolerate complex solutions, but patients who have not been fed via the gastrointestinal tract for prolonged periods are less likely to tolerate complex carbohydrates such as lactose. In patients with malabsorption, such as in inflammatory bowel diseases, absorption may be improved by provision of dipeptides, tripeptides, and medium-chain triglycerides (MCTs). However, MCTs are deficient in essential fatty acids, which necessitates supplementation with long-chain triglycerides (LCTs).

In general, factors that influence the choice of enteral formula include the extent of organ dysfunction (e.g., renal, pulmonary, hepatic, and gastrointestinal), the nutrient needs to restore optimal function and healing, and the cost of specific products. There are no conclusive data to recommend one category of product over another, and nutritional support committees typically develop the most cost-efficient set of enteral formulary for the most commonly encountered disease categories within the institution.

Low-residue, isotonic formulas Most low-residue, isotonic formulas provide a caloric density of 1.0 kcal/ml and approximately 1500–1800 ml is necessary to meet daily requirements. These low-osmolarity compositions provide baseline carbohydrates, protein, electrolytes, water, fat, and fat-soluble vitamins (some do not have vitamin K) and typically have a nonprotein calorie:nitrogen ratio of 150:1. These contain no fiber bulk and therefore leave minimum residue. These solutions are usually considered 'standard' or first-line formula for stable patients with an intact gastrointestinal tract.

Isotonic formulas with fiber These formulas contain soluble and insoluble fibers that are most often soy based. Physiologically, fiber-based solutions delay intestinal transit time and may reduce the incidence of diarrhea compared with nonfiber solutions. Fibers stimulate pancreatic lipase activity and are degraded by gut bacteria into short-chain fatty acids, an important fuel for colonocytes. There are no contraindications for using fiber-containing formulas in critically ill patients.

Immune-enhancing formulas These solutions are fortified with special nutrients that are purported to enhance various aspects of immune or solid organ function. Such additives include glutamine, arginine, branched-chain amino acids, omega-3 fatty acids, nucleotides, and β-carotene. Although several trials have proposed that one or more of these additives reduce surgical complications and improve outcome, results have not been uniformly corroborated by other trials. From the addition of amino acids, these formulas generally double the amount of protein (nitrogen) found in standard formula. The severalfold higher cost for these solutions prohibits liberal use of these formulas.

Calorie-dense formulas The primary distinction of these formulas is a larger amount of calories for the same volume. Most commercial products of this variety provide 1.5–2 kcal/ml and therefore are suitable for patients requiring fluid restriction or those unable to tolerate large-volume infusions. As expected, these solutions have higher osmolality than standard formulas and are very suitable for intragastric feedings.

High-protein formulas This variety is available in isotonic and nonisotonic mixtures and is proposed for critically ill or trauma patients with high protein requirements. These formulas comprise nonprotein calorie:nitrogen ratios between 80 and 120:1.

Elemental formulas These formulas contain predigested nutrients and provide proteins in the form of small peptides. Complex carbohydrates are limited and fat content, in the form of MCTs and LCTs, is minimal. The primary advantage of such a formula is ease of absorption, but the inherent scarcity of fat, associated vitamins, and trace elements limits its long-term use as a primary source of nutrients. Due to its high osmolarity, dilution or slow infusion rates is usually necessary, particularly in critically ill patients. These formulas have been used frequently in patients with malabsorption, gut impairment, and pancreatitis, but cost is significantly higher than that of standard formulas.

Renal failure formulas The primary benefits of the renal formula are the lower volume required to meet daily requirements and the lower concentrations of potassium, phosphorus, and magnesium. This formulation almost exclusively contains essential amino acids and has a high nonprotein calorie:nitrogen ratio, but does not contain trace elements or vitamins.

Pulmonary failure formulas In these formulas, fat content is usually increased to 50% of total calories, with a corresponding reduction in carbohydrate content. The goal is to reduce carbon dioxide production and alleviate ventilation burden for failing lungs.

Hepatic failure formulas Approximately 50% of the proteins in this formula are branched-chain amino acids (leucine, isoleucine, and valine). The goal of such a formula is to reduce aromatic amino acid levels and increase branched-chain amino acids, which can potentially reverse encephalopathy in patients with hepatic failure. However, the use of this formula is controversial because no clear benefits have been derived from clinical trials. In fact, protein restriction should be avoided in patients with end-stage liver disease because they have significant protein–energy malnutrition, predisposing them to additional morbidity and mortality.

Access for Enteral Nutritional Support

The available techniques and repertoire for enteral access have provided multiple options for feeding the gut. Currently utilized methods and preferred indications are summarized in **Table 5**.

Nasoenteric tubes Nasogastric feeding should be reserved for those with intact mental status and protective laryngeal reflexes to minimize risks of aspiration. Indeed, even in intubated patients, nasogastric feedings can often be recovered from tracheal suction. Nasojejunal feedings are associated with less pulmonary complications, but access past the pylorus requires greater effort to accomplish. Blind insertion of nasogastric feeding tubes commonly results in misplacement, and air instillation with auscultation is inaccurate for ascertaining proper positioning. Radiographic confirmation is usually required to verify the position of the nasogastric feeding tube.

Several methods have been recommended for the passage of nasoenteric feeding tubes into the small bowel, including prokinetic agents, right lateral decubitus positioning, gastric insufflation, tube angulation, and clockwise torque. However, the successful placement of feeding tubes by these methods is highly variable and operator dependent. Furthermore, it is time-consuming, and the success rate of intubation past the duodenum into the jejunum by these methods is less than 20%. Fluoroscopy-guided intubation past the pylorus has a greater than 90% success rate and more than half of these intubations result in jejunal placement. Similarly, endoscopy-guided placement past the pylorus has a high success rate, but advancing the tube beyond the second portion of the duodenum by a standard gastroduodenoscope is difficult.

Small bowel feeding is more reliable for delivering nutrition than nasogastric feeding. Furthermore, the risks of aspiration pneumonia can be reduced by 25% with small bowel feeding compared with nasogastric feeding. The benefits of nasoenteric feeding tubes are limited by clogging, kinking, inadvertent displacement or removal, and nasopharyngeal complications. If nasoenteric feeding is required for more than 30 days, access should be converted to a percutaneous one.

Table 5 Options for enteral feeding access

Access option	*Comments*
Nasogastric tube	Short-term use only; aspiration risks; nasopharyngeal trauma; frequent dislodgement
Nasoduodenal/ nasojejunal	Short-term use; lower aspiration risks in jejunum; placement challenges (radiographic assistance often necessary)
Percutaneous endoscopic gastrostomy (PEG)	Endoscopy skills required; may be used for gastric decompression or bolus feeds; aspiration risks; can last 12–24 months; slightly higher complication rates with placement and site leaks
Surgical gastrostomy	Requires general anesthesia and small laparotomy; may allow placement of extended duodenal/ jejunal feeding ports; laparoscopic placement possible
Fluoroscopic gastrostomy	Blind placement using needle and T-prongs to anchor stomach; can thread smaller catheter through gastrostomy into duodenum/ jejunum under fluoroscopy
PEG-jejunal tube	Jejunal placement with regular endoscope is operator dependent; jejunal tube often dislodges retrograde; two-staged procedure with PEG placement, followed by fluoroscopic conversion with jejunal feeding tube through PEG
Percutaneous endoscopic jejunostomy	Direct endoscopic placement with enteroscope; placement challenges; greater injury risks
Surgical jejunostomy	Commonly applied during laparotomy; general anesthesia; laparoscopic placement usually requires assistant to thread catheter; laparoscopy offers direct visualization of catheter placement
Fluoroscopic jejunostomy	Difficult approach with injury risks; not commonly done

Percutaneous endoscopic gastrostomy The most common indications for percutaneous endoscopic gastrostomy (PEG) placement include impaired swallowing mechanisms, oropharyngeal or esophageal obstruction, and major facial trauma. It is frequently utilized for debilitated patients requiring caloric supplementation, hydration, or frequent medication dosing. It is also appropriate for patients requiring passive gastric decompression. Relative contraindications for PEG placement include ascites, coagulopathy, gastric varices, gastric neoplasm, and lack of a suitable abdominal site. Most tubes are 18–28 Fr in size and may be used for 12–24 months.

Identification of the PEG site requires endoscopic transillumination of the anterior stomach against the abdominal wall. A 14-gauge angiocatheter is passed through the abdominal wall into the fully insufflated stomach. A guidewire is threaded through the angiocatheter, grasped by snares or forceps, and pulled out through the mouth. The tapered end of the PEG catheter is secured to the guidewire and pulled into position out of the abdominal wall. Once the PEG tube is secured without tension against the abdominal wall, many have reported using the tube within hours of placement. It has been the practice of some to connect the PEG tube to a drainage bag for passive decompression for 24 h prior to use, allowing more time for the stomach to seal against the peritoneum.

If endoscopy is not available or technical obstacles preclude PEG placement, the interventional radiologist can attempt the procedure percutaneously under fluoroscopic guidance by first insufflating the stomach against the abdominal wall with a nasogastric tube. If this is unsuccessful, surgical gastrostomy tube placement can be considered, particularly with minimally invasive methods. When surgery is indicated, it may be wise to consider directly accessing the small bowel for nutrition delivery.

Although PEG tubes enhance nutritional delivery, facilitate nursing care, and are superior to nasogastric tubes, serious complications can occur in approximately 3% of cases, including wound infection, necrotizing fasciitis, peritonitis, aspiration, leaks, dislodgement, bowel perforation, enteric fistulae, bleeding, and aspiration pneumonia. For patients with significant gastroparesis or gastric outlet obstruction, feedings through PEG tubes are obviously hazardous. In this instance, the PEG tube can be used for decompression and allows access for converting the PEG tube to a transpyloric feeding tube.

PEG–jejunostomy and direct percutaneous endoscopic jejunostomy Although gastric bolus feedings are more physiologic, patients who cannot tolerate gastric feedings or have significant aspiration risks should be fed directly past the pylorus. In the PEG–jejunostomy method, a 9- to 12-Fr tube is passes through an existing PEG tube, past the pylorus, into the duodenum. This can be achieved by endoscopic or fluoroscopic guidance. With weighted catheter tips and guidewires, the tube can be further advanced past the ligament of Treitz. However, long-term PEG–jejunostomy malfunction has been reported to be greater than 50% as a result of retrograde tube migration into the stomach, kinking, or clogging.

The same techniques are used for direct percutaneous endoscopic jejunostomy (DPEJ) placement as for PEG tube placement, but DPEJ requires an enteroscope or colonoscope to reach the jejunum. DPEJ malfunctions are probably less frequent than PEG–jejunostomy malfunctions, and kinking or clogging are usually averted by placement of larger caliber catheters. The success rate of DPEJ placement is variable because of the complexity of endoscopic skills required to locate a suitable jejunal site. In such cases, surgical jejunostomy tube placement is more appropriate, especially when minimally invasive techniques are available.

Surgical gastrostomy and jejunostomy In a patient undergoing complex abdominal or trauma surgery, thought should be given during surgery to the possible routes for subsequent nutritional support because laparotomy affords direct access to the stomach or small bowel. The only absolute contraindication to feeding jejunostomy is distal intestinal obstruction. Relative contraindications include severe edema of the intestinal wall, radiation enteritis, inflammatory bowel disease, ascites, severe immunodeficiency, and bowel ischemia. Needle catheter jejunostomies can also be used with a minimal learning curve. The drawback is usually related to clogging and knotting of the 6-Fr catheter.

Abdominal distention and cramps are frequent complications of early enteral nutrition. Some have also reported impaired respiratory mechanics as a result of intolerance to enteral feedings. These are mostly correctable by temporarily discontinuing feeds and resuming at a lower infusion rate.

Pneumatosis intestinalis and small bowel necrosis are infrequent, but significant, problems associated with patients receiving jejunal tube feedings. Several contributing factors have been proposed, including the hyperosmolar consistency of enteral solutions, bacterial overgrowth, fermentation, and metabolic breakdown products. The common pathophysiology is believed to be bowel distention and consequent

reduction in bowel wall perfusion. Risk factors for these complications include cardiogenic and circulatory shock, vasopressor use, diabetes mellitus, and chronic obstructive pulmonary disease. Therefore, enteral feedings in the critically ill patient should be delayed until adequate resuscitation has been achieved. Alternatively, dilution of standard enteral formula, delaying the progression to goal infusion rates, or using monomeric solutions with low osmolality requiring less digestion by the gastrointestinal tract have been successfully employed.

Parenteral Nutrition

Parenteral nutrition involves the continuous infusion of a hyperosmolar solution containing carbohydrates, proteins, fat, and other necessary nutrients through an indwelling catheter inserted into the superior vena cava. In order to obtain the maximum benefit, the ratio of calories to nitrogen must be adequate (at least 100–150 kcal/g nitrogen) and both carbohydrates and proteins must be infused simultaneously. When the sources of calories and nitrogen are given at different times, there is a significant decrease in nitrogen utilization. These nutrients can be given in quantities considerably greater than the basic caloric and nitrogen requirements, and this method has proved to be highly successful in achieving growth and development, positive nitrogen balance, and weight gain in a variety of clinical situations. Clinical trials and meta-analysis of parenteral feeding in the perioperative period have suggested that preoperative nutritional support may benefit some surgical patients, particularly those with extensive malnutrition. Short-term use of parenteral nutrition in critically ill patients (duration <7 days) when enteral nutrition may have been instituted are associated with higher infection complications.

Rationale for Parenteral Nutrition

The principal indication for parenteral nutrition is when use of the gastrointestinal tract for feedings is not possible. In some instances, intravenous nutrition may be used to supplement inadequate oral intake. The safe and successful use of parenteral nutrition requires proper selection of patients with specific nutritional needs, experience with the technique, and an awareness of the associated complications. As with enteral nutrition, the fundamental goals are to provide sufficient calories and nitrogen substrate to promote tissue repair and to maintain the integrity or growth of lean tissue mass. The following are cases in which parenteral nutrition has been used in an effort to achieve these goals:

1. Newborn infants with catastrophic gastrointestinal anomalies, such as tracheoesophageal fistula, gastroschisis, omphalocele, or massive intestinal atresia
2. Infants who fail to thrive from gastrointestinal insufficiency associated with short bowel syndrome, malabsorption, enzyme deficiency, meconium ileus, or idiopathic diarrhea
3. Adult patients with short bowel syndrome secondary to massive small bowel resection (<100 cm without colon or ileocecal valve, or <50 cm with intact ileocecal valve and colon)
4. Enteroenteric, enterocolic, enterovesical, or high-output enterocutaneous fistulas (>500 ml/day)
5. Surgical patients with prolonged paralytic ileus following major operations (>7–10 days), multiple injuries, or blunt or open abdominal trauma, or patients with reflex ileus complicating various medical diseases
6. Patients with normal bowel length but with malabsorption secondary to sprue, hypoproteinemia, enzyme or pancreatic insufficiency, regional enteritis, or ulcerative colitis
7. Adult patients with functional gastrointestinal disorders such as esophageal dysmotility following cerebral vascular accident, idiopathic diarrhea, psychogenic vomiting, or anorexia nervosa
8. Patients with granulomatous colitis, ulcerative colitis, and tuberculous enteritis, in which major portions of the absorptive mucosa are diseased
9. Patients with malignancy, with or without cachexia, in whom malnutrition might jeopardize successful delivery of a therapeutic option
10. Failed attempts to provide adequate calories by enteral tube feedings or high residuals
11. Critically ill patients who are hypermetabolic for more than 5 days or when enteral nutrition is not feasible

Conditions contraindicating hyperalimentation include the following:

1. Lack of a specific goal for patient management, or where instead of extending a meaningful life, inevitable death is prolonged
2. Periods of hemodynamic instability or severe metabolic derangement (severe hyperglycemia, azotemia, encephalopathy, hyperosmolality, and fluid-electrolyte disturbances) requiring control or correction before attempting hypertonic intravenous feeding
3. Feasible gastrointestinal tract feeding (in the vast majority of instances, this is the best route by which to provide nutrition)
4. Patients in good nutritional status

5. Infants with less than 8 cm of small bowel, since virtually all have been unable to adapt sufficiently despite prolonged periods of parenteral nutrition
6. Patients who are irreversibly decerebrate

Total parenteral nutrition Also referred to as central parenteral nutrition, total parenteral nutrition requires access to a large-diameter vein to deliver the entire nutritional requirements of the individual. Dextrose content is high (15–25%) and all other macro- and micronutrients are deliverable by this route.

Peripheral parenteral nutrition The lower osmolarity of this solution secondary to reduced dextrose (5–10%) and proteins (3%) allows administration via peripheral veins. Some nutrients cannot be supplemented due to inability to concentrate them into small volumes. Therefore, peripheral parenteral nutrition is not appropriate for repleting patients with severe malnutrition. It can be considered if central routes are not available or if supplemental nutritional support is required. Typically, peripheral parenteral nutrition is used for less than 2 weeks. Beyond this time, total parenteral nutrition should be instituted.

Initiating Parenteral Nutrition

The basic solution contains a final concentration of 15–25% dextrose and 3–5% crystalline amino acids. The solutions are usually prepared sterilely in the pharmacy from commercially available kits containing the component solutions and transfer apparatus. Preparation in the pharmacy under laminar flow hoods reduces the incidence of bacterial contamination of the solution. Proper preparation with suitable quality control is absolutely essential to avoid septic complications. The proper provision of electrolytes and amino acids is dependent on routes of fluid and electrolyte loss, renal function, metabolic rate, cardiac function, and the underlying disease state.

Intravenous vitamin preparations should also be added to parenteral formulas. Rarely to deficiencies of vitamin occur if such preparations are utilized. In addition, because vitamin K is not part of any commercially prepared vitamin solution, it should be supplemented on a weekly basis. During prolonged fat-free parenteral nutrition, essential fatty acid deficiency may become clinically apparent, manifested by a dry, scaly dermatitis and loss of hair. The syndrome may be prevented by periodic infusion of a fat emulsion at a rate equivalent to 10–15% of total calories. Essential trace minerals may be required after prolonged total parenteral nutrition and may be supplied by direct addition of commercial preparations. The most frequent presentation of trace mineral deficiencies is the eczamatoid rash developing both diffusely and in intertriginous areas in zinc-deficient patients. Other rare trace mineral deficiencies include microcytic anemia associated with copper deficiency and glucose intolerance presumably related to chromium deficiency. The latter complications are seldom seen except in patients receiving parenteral nutrition for extended periods of time. The daily administration of commercially available trace mineral supplements will obviate most such problems.

Depending on fluid and nitrogen tolerance, parenteral nutrition solutions can generally be increased over 2 or 3 days to achieve the desired infusion rate. Insulin may be supplemented as necessary to ensure glucose tolerance. Occasionally, additional intravenous fluids and electrolytes may be necessary with persistently high fluid losses. The patient should be carefully monitored for development of electrolyte, volume, acid–base, and septic complications. Vital signs and urinary output are regularly observed, and the patient should be weighed regularly. Frequent adjustments of the volume and composition of the solutions are necessary during the course of therapy. Electrolytes are drawn daily until stable and every week thereafter. Blood counts, blood urea nitrogen, liver functions, phosphate, and magnesium are determined at least weekly.

Capillary blood sugar level is checked at least once daily during the first few days of the infusion and at frequent intervals thereafter. Relative glucose intolerance may occur following initiation of parenteral nutrition, which often manifests as glycosuria. If blood sugar levels remain elevated or glycosuria persists, the dextrose concentration may be decreased, the infusion rate slowed, or regular insulin added to each bottle. The increase in blood glucose concentration observed after initiating an parenteral nutrition may be temporary because the normal pancreas increases its output of insulin in response to the continuous carbohydrate infusion. In patients with diabetes mellitus, additional insulin may be required.

Potassium is essential to achieve positive nitrogen balance and replace depleted intracellular stores. In addition, a significant shift of potassium ion from the extracellular to the intracellular space may take place because of the large glucose infusion, with resultant hypokalemia, metabolic alkalosis, and poor glucose utilization. In some cases, as much as 240 mEq of potassium ion daily may be required.

Hypokalemia may cause glycosuria, which should be treated with potassium, not insulin. Thus, before giving insulin, the serum potassium level must be checked to avoid exacerbating the hypokalemia.

Patients with insulin-dependent diabetes mellitus may exhibit wide fluctuations in blood glucose during parenteral nutrition. Partial replacement with lipid emulsions for dextrose calories may alleviate these problems in selected patients. Lipid emulsions derived from soybean or safflower oils are widely used as an adjunctive nutrient to prevent the development of essential fatty acid deficiency. There is no evidence of enhanced metabolic benefit when more than 10–15% of calories are provided as lipid emulsions. Although the administration of 500 ml of 20% fat emulsion one to three times per week is sufficient to prevent essential fatty acid deficiency, it is common to provide fat emulsions on a daily basis to provide additional calories. The triple mix of carbohydrate, fat, and amino acids is infused at a constant rate during a 24-h period. The theoretical advantages of a constant fat infusion rate include increased efficiency of lipid utilization and reduced impairment of reticuloendothelial function normally identified with bolus lipid infusions. The addition of lipids to an infusion bag may alter the stability of some micronutrients in a dextrose–amino acid preparation.

There are several advantages to infusing parenteral nutrition in a cyclic manner over 12–16 h during the hours of sleep. First, it permits the patient to pursue a normal lifestyle during the day hours. Second, it minimizes the risks of fatty liver and hepatomegaly that are associated with long-term continuous calorie and protein infusions.

Intravenous access methods Temporary or short-term access can be achieved with a 16-gauge percutaneous catheter inserted into a subclavian or internal jugular vein threaded into the superior vena cava. More permanent access, with the intention of providing long-term or home parenteral nutrition, can be achieved by placement of a catheter with a subcutaneous port for access, by tunneling a catheter with a substantial subcutaneous length, or by threading a long catheter through the basilic or cephalic vein into the superior vena cava. In some patients, implanted vascular access ports are an acceptable option.

Complications of Parenteral Nutrition

Technical complications One of the more common and serious complications associated with long-term parenteral feeding is sepsis secondary to contamination of the central venous catheter. Contamination of solutions should be considered but is rare when proper pharmacy protocols have been followed. This problem occurs more frequently in patients with systemic sepsis and in many cases is due to hematogenous seeding of the catheter with bacteria. One of the earliest signs of systemic sepsis may be the sudden development of glucose intolerance (with or without temperature increase) in a patient who previously has been maintained on parenteral alimentation without difficulty. When this occurs or if high fever (>38.5 °C) develops without obvious cause, a diligent search for a potential septic focus is indicated. Other causes of fever should also be investigated. If fever persists, the infusion catheter should be removed and cultured. If the catheter is the cause of fever, removal of the infectious source is usually followed by rapid defervescence. Some centers are replacing catheters considered at low risk for infection over a guidewire. Should evidence of infection persist for 24–48 h without a definable source, the catheter should be replaced in the opposite subclavian vein or into one of the internal jugular veins and the infusion restarted. It is prudent to delay reinserting the catheter by 12–24 h, especially if bacteremia is present.

Other complications related to catheter placement include the development of pneumothorax, hemothorax, hydrothorax, subclavian artery injury, thoracic duct injury, cardiac arrhythmia, air embolism, catheter embolism, and cardiac perforation with tamponade. All these complications may be avoided by strict adherence to proper techniques. The use of multilumen catheters may be associated with a slightly increased risk of infection. This is most likely associated with greater catheter manipulation and intensive use. Catheter infections are highest when catheters are placed in the femoral vein, lower when placed in the jugular vein, and lowest when placed in the subclavian vein. When catheters are indwelling for less than 3 days, infection risks are negligible. If indwelling time is 3–7 days, the infection risk is 3–5%, and an indwelling time of more than 7 days is associated with a catheter infection risk of 5–10%.

Metabolic complications Hyperglycemia may develop with normal rates of infusion in patients with impaired glucose tolerance or in any patient if the hypertonic solutions are administered too rapidly. This is a particularly common complication in latent diabetics and in patients subjected to severe surgical stress or trauma. Treatment of the condition consists of volume replacement with correction of electrolyte abnormalities and the administration of

insulin. This complication can be avoided with careful attention to daily fluid balance and frequent monitoring of blood sugar levels and serum electrolytes.

Increasing experience has emphasized the importance of not 'overfeeding' the parenterally nourished patient. This is particularly true of the depleted patient in whom excess calorie infusion may result in carbon dioxide retention and respiratory insufficiency. In addition, excess feeding has also been related to the development of hepatic steatosis or marked glycogen deposition in selected patients. Cholestasis and formation of gallstones are common in patients receiving long-term parenteral nutrition. Mild but transient abnormalities of serum transaminase, alkaline phosphatase, and bilirubin may occur in many parenterally nourished patients. Failure of the liver enzymes to plateau or return to normal over 7–14 days should suggest another etiology.

Intestinal atrophy Lack of intestinal stimulation is associated with intestinal mucosal atrophy, diminished villous height, bacterial overgrowth, reduced lymphoid tissue size, reduced IgA production, and impaired gut immunity. The full clinical implications of these changes are not well realized, although bacterial translocation has been demonstrated in animal models. The most efficacious method to prevent these changes is to provide nutrients enterally. In patients requiring full parenteral nutrition, it may be feasible to infuse small amounts of trophic feedings via the gastrointestinal tract.

Special Formulations

Glutamine and arginine Glutamine is the most abundant amino acid in the human body, comprising nearly two-thirds of the free intracellular amino acid pool, of which 75% is found within the skeletal muscles. In healthy individuals, glutamine is considered a nonessential amino acid because it is synthesized within the skeletal muscles and the lungs. Glutamine is a necessary substrate for nucleotide synthesis in most dividing cells and hence provides a major fuel source for enterocytes. It also serves as an important fuel source for immunocytes, such as lymphocytes and macrophages, as well as a precursor for glutathione, a major intracellular antioxidant. During stress states such as sepsis or in tumor-bearing hosts, peripheral glutamine stores are rapidly depleted and the amino acid is preferentially shunted as a fuel source toward the visceral organs and tumors, respectively. These situations create, at least experimentally, a glutamine-depleted environment of which the consequences include enterocyte and immunocyte starvation.

The beneficial effects of glutamine supplementation demonstrated experimentally are multifaceted (**Table 6**). However, glutamine metabolism during stress in humans may be more complex than in previously reported animal data. More advanced methods of detecting glutamine traffic in patients with gastrointestinal cancer have not demonstrated more tumor sequestration of glutamine than in normal intestine. There are data demonstrating decreased dependency on total parenteral nutrition in severe cases of short bowel syndrome when glutamine therapy with modified diets and growth hormones are used. However, in patients with milder forms of short bowel syndrome and better nutritional status, glutamine supplementation did not demonstrate appreciable enhancement in intestinal absorption. In healthy subjects, glutamine-supplemented total parenteral nutrition did not attenuate endotoxin-induced symptoms or proinflammatory cytokine release compared to standard total parenteral nutrition. Although it is hypothesized that provision of glutamine may preserve immune cell and enterocyte function and enhance nitrogen balance during injury or sepsis, the pool of clinical evidence in support of this phenomenon in human subjects remains inconclusive.

Arginine, also a nonessential amino acid in healthy subjects, first attracted attention for its immunoenhancing properties, wound-healing benefits, and improved survival in animal models of sepsis and injury. As with glutamine, the benefits of experimental arginine supplementation during stress states are diverse. Clinical studies in which arginine was administered enterally have demonstrated net nitrogen

Table 6 Experimental benefits of glutamine and arginine supplementation

Glutamine
Enhances bowel absorptive capacity after intestinal resection
Decreases intestinal permeability
Early resolution of experimental pancreatitis
Maintains nitrogen balance
Promotes liver regeneration after hepatectomy
Restores mucosal IgA function
Enhances bacterial clearance in peritonitis
Protects postradiation enterocyte viability
Restores intracellular glutathione levels
Facilitates tumor sensitivity to chemotherapy and radiation therapy
Enhances natural killer (NK) and lymphocyte-activated killer (LAK) cell function
Arginine
Minimizes hepatic ischemia–reperfusion injury
Reduces intestinal bacterial translocation
Enhances NK and LAK cell function
Increases nitrogen retention and protein synthesis

retention and protein synthesis compared to isonitrogenous diets in critically ill and injured patients and following surgery for certain malignancies. Some of these studies are also associated with in vitro evidence of enhanced immunocyte function. The clinical utility of arginine in improving overall patient outcome remains an area of investigation.

Omega-3 fatty acids The provision of omega-3 polyunsaturated fatty acids (canola oil or fish oil) displaces omega-6 fatty acids in cell membranes, which theoretically reduce the proinflammatory response from prostaglandin production.

Nucleotides RNA supplementation in solutions is purported, at least experimentally, to increase cell proliferation, provide building blocks for DNA synthesis, and improve T-helper cell function.

Patient monitoring In the first month of home nutrition support, nutrition and metabolic assessments should be performed weekly. In the stable patient, the frequency of these assessments can be reduced to monthly and then quarterly. Hepatic steatosis, cholestasis, and cholelithiasis are all known sequelae of long-term parenteral nutrition. Regular assessments are necessary because specific nutrient deficiencies, such as selenium, vitamin C, iron, and thiamin, are known in patients on long-term parenteral nutrition support. Patients on a fat-free diet or who receive infrequent lipid infusions are at risk of developing essential fatty acid deficiencies that manifest as dermatitis, scaling, and sparse hair growth. These can be circumvented by the provision of long-chain fatty acids in the diet on a regular basis. Zinc and copper deficiencies are particularly prevalent in patients who have short bowel syndrome or malabsorptive states. In many instances, routine biochemical screening may not adequately reflect the functional level of a particular nutrient but, rather, the concentration in a body compartment such as the intravascular space. In these instances, treatment for any nutrient deficiencies should be initiated based on anticipation or clinical suspicion.

TEA

D J Baer and S C Chen, US Department of Agriculture, Beltsville, MD, USA

Published by Elsevier Ltd.

Throughout the world, tea is one of the most consumed beverages, second only to water. Based on data from the Tea Association of the United States, the estimated wholesale value of the tea industry increased 273% between 1990 and 2002, and it is now valued in excess of $5 billion. The greatest increase has been in the ready-to-drink market (925% increase). One reason for the popularity in tea consumption is the interest of consumers to improve their health. Although tea is a poor source of most classically defined essential nutrients, it is a good and important source of many phytochemicals that have been presumptively linked to reduction of risk of cancer, cardiovascular disease, and diabetes. Many of these phytochemicals have strong antioxidant properties, and presumably these antioxidant properties are associated with improved health.

Epidemiological studies have provided the evidence suggesting an association between the consumption of plant-based foods and diets with a reduced risk of diseases, especially cardiovascular disease and cancer. These findings, together with experimentally data, have spurred further research activities and encouraged the consumption of fruits, vegetables, and other foods and beverages with high concentrations of nutrient (e.g., vitamin C, vitamin E, and carotenoids) and nonnutrient antioxidants (e.g., polyphenols). Epidemiologic studies that focus on food consumption indicate great potential benefit from consumption of foods high in antioxidant phytonutrients. Experimental studies include *in vitro* and cell culture studies; *ex vivo* studies using biological material from experimental animals and humans (e.g., determination of susceptibility of low-density lipoprotein to oxidation); and investigations using animal models of cancer, cardiovascular disease, diabetes, arthritis, macular degeneration, and the diseases of most other organ systems. Many experimental studies focus on the antioxidant compounds that are found in foods and not on the foods per se as they are typically consumed. Although disease prevention based on inference from these studies seems promising, results from dietary intervention studies are inconclusive or contradictory. Moreover, the number of well-designed, carefully controlled dietary intervention studies, which show cause and effect, is limited, and this represents a critical gap in our understanding of these compounds as they relate to health promotion and disease prevention.

More than 8000 phenolic compounds have been identified in plants. The structure of these compounds ranges from simple monomers to highly complex, heterogeneous polymers with molecular sizes in excess of 30 kDa. Of these phenolic compounds, more than 5000 are structurally defined as polyphenolic 'flavonoids.' Although there is an abundance of these compounds in our food supply, many studies have focused on the activity of flavonoids from tea, wine, and cocoa because these are the most common sources of flavonoids in typical American diets. Compared to most foods, tea contains a much higher concentration of flavonoids (in the form of flavan-3-ols), which are provided with a minimal amount of additional energy. The high concentration of water-soluble polyphenols, limited contribution of other nutrients (especially other antioxidants), ease of product preparation and administration, and subject acceptability make tea an ideal source for these potentially important compounds for human intervention studies.

Tea Composition

The predominant phytochemicals of beverage tea are catechins, theaflavins, and thearubigins. Catechins are one form of a class of polyphenolic compounds termed 'flavonoids,' which are all 2-phenyl benzopyran-based compounds. The flavonoids include six major structurally related subclasses of compounds: flavones, flavonols, flavanones, anthocyanidins, isoflavones, and flavanols. Catechins belong to the

flavanol subclass and are structurally defined as flavan-3-ols. The major catechins of the tea leaf are epicatechin, epicatechin gallate, epigallocatechin, and epigallocatechin gallate. These four catechins comprise approximately 25% of the weight of a dry tea leaf. Flavonols (kaempferol, quercetin, and myricitin glycosides) are minor flavonoid components of the tea leaf (approximately 3% of dry weight). Polysaccharides and cellulose (approximately 20% of dry weight) and protein (approximately 15% of dry weight) are other major components of tea leaf, and other nutrients and compounds comprise less than 5% of dry weight each.

Green, oolong, and black are the predominantly consumed types of tea. They are produced from the leaf of the same plant, *Camellia sinseis*. Green tea, which is consumed largely in Asia, is processed with the intent to minimize leaf damage and fermentation. Catechins constitute 30–40% of the green tea solids. To produce oolong and black tea, the leaves are rolled and fermented. This processing releases polyphenol oxidase that initiates polymerization and oxidation of the catechins to theaflavins and thearubigins. In contrast to the heterogeneous and unknown chemical structure of thearubigins, theaflavins are chemically well defined. There are four primary theaflavins in black tea and they represent between 1 and 6% of the dry weight of the solids (theaflavin, theaflavin 3-gallate, theaflavin 3′-gallate, and theaflavin 3,3′-digallate). Thearubigins represent between 10 and 20% of the dry weight of black tea solids. Oolong tea is processed and fermented to a lesser degree than black tea, and therefore it contains a higher concentration of the theaflavins and lower concentration of thearubigins than black tea. Black tea is popular in Western countries, and oolong tea is sold commercially in the United States and is often served in Chinese restaurants. Theaflavins and thearubigins are responsible for the red-amber color of oolong and black tea and for its astringency.

Another important group of flavan-3-ol compounds are the procyanidin polymers. These compounds are catechin polymers linked by C4 to C6 and C4 to C8 bonds. The most predominant polymers are those ranging from dimers to decamers and are found in a variety of foods, including chocolate, cocoa, cereal grains, nuts, fruits, and vegetables.

In Vitro and *Ex Vivo* Evidence of Antioxidant Properties of Polyphenols

One reason for the interest in polyphenols is their excellent *in vitro* ability to scavenge stable free radicals and reactive oxygen species. In fact, *in vitro*, many polyphenols found in fruits and vegetables are better scavengers than the essential nutrient antioxidants. For example, compared to vitamin E and vitamin C, flavonols (quercetin, kaempferol, and rutin) are 1.3- to 4.7-fold more effective at scavenging free radicals. Flavan-3-ols and theaflavins are 2.5–6.9 times more effective than vitamin C and vitamin E at free radical quenching. Tea beverage has strong antioxidant properties, being 3.5–3.8 times more effective than vitamin C and vitamin E at free radical scavenging. Green tea is more effective than oolong tea, which is more effective than black tea. In comparison, carotenoids (lycopene, α-carotene, and β-carotene) and xanthophylls (β-cryptoxanthin, zeaxanthin, and lutein) are 1.3- to 2.9-fold more effective at *in vitro* free radical scavenging.

In addition to scavenging radicals and oxidants, tea polyphenols have also been demonstrated *in vitro* to be able to chelate metals, inhibit redox-sensitive transcription factors, inhibit prooxidant enzymes, and induce phase II enzymes. These activities may explain, at least in part, the mechanisms for the antioxidant effects of tea.

An *in vitro* and *ex vivo* test of the biological activity of an antioxidant is to assess its ability to protect LDL particles from oxidation that, theoretically, can be critical for the prevention of atherosclerosis since modified LDL particles (e.g., oxidized LDL) may play an important role in the etiology of atherosclerosis. There is considerable but not overwhelming evidence that flavonoids and foods rich in flavonoids protect LDL from oxidation, which may be one mechanism by which these foods decrease risk of cardiovascular disease. Catechins are more effective than vitamins E and C at protecting LDL particles from oxidation. Green tea is more effective than black tea. Notwithstanding these *in vitro* data, results from many studies have demonstrated that there is no effect of tea consumption on *ex vivo* LDL oxidizability.

Similar to tea polyphenols, resveratrol, a major polyphenol in red wine, has also been found to have a protective effect against LDL oxidation in some but not all studies. In contrast to the disparate findings from wine and tea and their flavonoids on LDL protection, studies consistently suggest that cocoa, chocolate, and the procyanins found in cocoa protect LDL from oxidation, both *in vitro* and *ex vivo*. *In vitro* studies of apples, apple juice, and apple extracts (rich in anthocyanins, flavan-3-ols, and flavonols) indicate that these foods also protect LDL.

The effect of antioxidants to protect lipids (fatty acids), protein, and DNA from oxidation is also

important to disease prevention. Of particular interest is the prevention of damage to the vasculature. Maintaining proper endothelial function and reactivity (a nitric oxide-mediated event) is critical since endothelial dysfunction is associated with the risk, etiology, and complications of cardiovascular disease and diabetes. Overproduction of reactive oxygen species, such as peroxynitrite, prevents the NO-facilitated vasodilation and leads to impaired endothelial function. In addition to impaired endothelial function, peroxynitrite induces other detrimental cellular changes and apoptosis. Nutrient antioxidants (vitamins E and C) have been shown to reverse oxidative stress and restore endothelial function in diabetics. Polyphenols from tea, wine, cocoa, and other foods have been found to be effective at *in vitro* scavenging of peroxynitrite. In addition to the effect of peroxynitrite on endothelial function, this and other reactive oxygen intermediates can damage protein, lipids, and DNA.

In summary, flavonoids from tea, wine, cocoa, and other food sources are very effective free radical and reactive oxygen species scavengers *in vitro*. However, *ex vivo* data, especially for the protection of LDL particles, are not consistent. Polyphenols are also effective at scavenging reactive oxygen intermediates. These reactive oxygen species can have a detrimental effect on endothelial function and can damage macromolecules. These events are thought to be important in the etiology of cardiovascular disease, cancer, and diabetes. Confirmation that these effects occur *in vivo* in humans with consumption of foods high in antioxidant phytonutrients is needed.

Epidemiologic Studies of Flavonoids and Tea Intake

Flavonoids

An association of flavonoid intake with a reduction of risk of cardiovascular disease has been suggested from several but not all epidemiologic studies. Among the first studies to demonstrate that flavonoid intake is inversely related to risk of coronary heart disease mortality was the Zutphen Elderly Study. Incidence of first fatal and nonfatal stroke is also lower in this population for individuals with the highest quartile intake of flavonoids compared to those with the lowest quartile. Despite the fact that intake of only a few flavonoids was measured (quercetin, kaempferol, myricetin, apigenin, and luteolin), tea, which is relatively low in these compounds, was identified as the most important dietary source. Onions and apples are also important sources of these flavonoids in this population. In the Seven Countries Study, flavonoid intake is inversely associated with coronary heart disease mortality. However, in Wales, flavonol intake (mainly from tea) is not associated with a decrease in risk of ischemic heart disease. In fact, in this population there is an increase in risk of ischemic heart disease between men consuming more than eight cups of tea per day and those consuming less than two cups per day. In other countries, such as Finland, the association between flavonoid intake and total and coronary mortality is not significant. However, in a Finnish cross-sectional study, quercetin intake was associated with a lower risk of ischemic heart disease and a trend in reduction of risk of type 2 diabetes. In the United States, the Health Professionals Study data suggest that there is no relationship between flavonol and flavone intake and risk of coronary heart disease in men. However, these data suggest that flavonoids may be protective for men with established coronary heart disease. Moreover, moderate and heavy tea drinkers in the year prior to an acute myocardial infarction had lower mortality compared to nondrinkers.

Tea

In epidemiologic studies designed to link tea intake with risk for cardiovascular disease, the data are inconsistent. Studies conducted in Norway and Scotland found no association between tea consumption and coronary heart disease and mortality. In the Netherlands, tea consumption is inversely related to severe aortic atherosclerosis but unrelated to mild or moderate aortic atherosclerosis. Moreover, tea consumption is inversely related to fatal myocardial infarction but not to nonfatal events. In Japan, green tea consumption is inversely related to the degree of stenosis for those consuming more than four cups per day but not for those consuming two or three cups per day compared to those consuming one cup per day. In the United States, tea consumption is associated with lower risk of myocardial infarction. In a meta-analysis of several studies, the incidence of myocardial infarction decreased 11% with an increase in tea consumption of three cups per day. However, data on tea consumption tend to be heterogeneous and biased, and geographic region explained much of the heterogeneity. For example, there was an increase in risk of coronary heart disease in the United Kingdom and an increase in risk of stroke in Australia but a decreased risk in other regions.

Results of epidemiologic data on cancer prevention from tea consumption are also mixed. An

inverse relation between urinary levels of tea polyphenols and gastric cancer was found in Chinese but not Japanese men. In the United States, tea consumption is related to a reduced risk of colon cancer. However, a comparable study was conducted in The Netherlands in which no association was found between black tea consumption and the risk of colorectal, stomach, lung, or breast cancer. A review of 30 papers examining populations in 12 countries found no consistent support for tea being a chemopreventive agent against colon and rectal cancers.

Wine and Chocolate

Epidemiologic studies of wine and alcohol have found a J-shaped curve, with nondrinkers and heavy drinkers at increased risk for all-cause mortality compared to moderate consumers. It is difficult to separate the effects of flavonoid and alcohol in these studies. There are limited epidemiologic data linking chocolate consumption with risk of chronic disease: The available data suggest that there is no association between chocolate consumption and risk of coronary heart disease.

In summary, epidemiologic evidence relating the consumption of flavonoids from tea or other foods to risk of cardiovascular disease and cancer is inconclusive. Geographic region appears to impact the results. This confounding factor may relate to other dependent dietary factors, lifestyle, environment, genetics, type of tea consumed and the quality of the flavonoid databases being used, and the quality of food intake data.

Antioxidant and Biomarker Evidence from Intervention Studies in Humans

There are limited data from diet-controlled randomized crossover studies of humans on tea and other flavonoid-containing foods. Most intervention studies, apart from design considerations, suffer from lack of diet control, making them difficult to interpret. Results from intervention studies that employ dietary recalls, food records, and self-administered diets are notorious for introducing error that can mask treatment effects. Clinical studies in humans have focused on the antioxidant capacity of blood and oxidative damage to protein, lipid, and DNA as well as a number of risk factors associated with cardiovascular disease, including lipids, hemostasis, platelet aggregation, endothelial function, and blood pressure. Interventions have included high- and low-flavonoid diets, tea, chocolate, cocoa, wine, grape extracts, and fruit juices.

Changes in Antioxidant Capacity

Antioxidant capacity of the blood may be one indicator of a food's ability to act as an *in vivo* antioxidant. Two commonly used measures of overall antioxidant capacity are the ORAC assay (oxygen radical absorbance capacity) and the FRAP assay (ferric reducing ability of plasma). Dietary interventions do alter the antioxidant capacity of blood. For example, individuals consuming a high cocoa and chocolate diet for 2 weeks have higher serum ORAC than when they consume a control diet. However, these results are not always consistent. For example, in individuals consuming procyanidins in similar amounts of cocoa powder and chocolate, there is no change in plasma ORAC after 6 or 12 weeks.

Green tea consumption rapidly increases FRAP but the effect appears to be short-lived and is perhaps related to the short half-life of the antioxidant tea phytochemicals in plasma. Moreover, green tea appears to have a greater antioxidant capacity (FRAP) than black tea, and the consumption of black or green tea with or without milk does not appear to effect the rise of the blood's antioxidant capacity. Extracts of food such as green tea extract and grape seed extract also increase postprandial antioxidant status. Although these findings are compelling, a more important outcome than a change in plasma antioxidant capacity is the protection of lipid, protein, and DNA from damage. This is particularly true since some studies show no effect on total antioxidant capacity but do show a change in the degree of protein or lipid oxidation.

DNA Oxidation and Damage

Protecting DNA from oxidative damage is thought to be an important mechanism in cancer prevention. Flavonoids may be important in reducing DNA damage, especially in smokers, who are exposed to significant, self-induced oxidative stress. For example, the rate of sister chromatid exchange in mutagen-stimulated peripheral lymphocytes was higher in smokers than nonsmokers, but the rate in smokers was reduced to that of the nonsmokers after 6 months' consumption of two or three cups of green tea per day. Another marker of DNA oxidation is 8-hydroxy-2′-deoxyguanosine. White blood cell content and urinary excretion of 8-hydroxy-2′-deoxyguanosine are reduced in smokers and nonsmokers following consumption of green tea compared to no tea. Furthermore, the reduction is greater for smokers than for nonsmokers. However, not all results are consistent. For example, in a study of healthy subjects consuming a

high- and low-flavonol diet (primarily from tea and onions), there was no difference in DNA base damage after 2 weeks, despite a significant increase in plasma quercetin after consumption of the high-flavonol diet.

Protein Oxidation and Damage

There are fewer data on the role that flavonoids may play on protecting protein from oxidative damage, and as with protection of DNA from oxidation, results of studies on their effect are not consistent. Quercetin provided from black current and apple juice increases the concentration of plasma 2-amnio-adipic semialdehyde residues (a marker of protein oxidation), and the increase in concentration of these semialdehyde residues increases with increasing intake of quercetin. These results suggest a prooxidant effect of the diet on protein (there was no effect on total antioxidant capacity and a decrease in lipid oxidation). However, consumption of grape seed extract (three times per day for 1 week) does not affect plasma 2-amnio-adipic semialdehyde concentration. Moreover, consumption of a green tea extract does not alter hemoglobin protein oxidation.

Lipid Oxidation and Damage

Whereas intake of quercetin from black current and apple juice appears to increase protein oxidation, it decreases plasma malondialdehyde concentration, a marker of lipid oxidation. Isoprostanes, which are specific and sensitive markers of lipid peroxidation, are not different after consumption of a high-flavonoid or low-flavonoid diet, after consumption of green or black tea, or after consumption of black tea and hot water. Similarly, there is little change in urinary isoprostane excretion after supplementation of dark chocolate and cocoa or after consumption of red and white wine (although dealcoholized wine does decrease urinary isoprostane).

Biomarkers of Diseases

Perhaps the most important outcomes in intervention studies are changes in risk factors or biomarkers of disease, especially for cardiovascular disease. Lipoprotein cholesterol (HDL and LDL) concentrations are considered important biomarkers for risk of cardiovascular disease. In a large ($N = 65$) study of men and women consuming six cups of black tea per day, there was no change in plasma LDL-cholesterol, HDL-cholesterol, or triglycerides compared to a control beverage. However, in a controlled diet study of 12 individuals with slightly elevated LDL-cholesterol, consumption of five cups of black tea per day compared to a control, caffeine-containing beverage resulted in a 6.5% decrease in total cholesterol and an 11.1% decrease in LDL-cholesterol after 3 weeks of consumption. There were no concomitant changes in HDL-cholesterol or triglycerides. A cholesterol-lowering effect of a theaflavin-enriched green tea extract has also been observed in a large ($N = 240$), double-blind, randomized outpatient study of individuals with mild to moderate hypercholesterolemia. In this study, individuals consumed either a capsule containing 375 mg of theaflavin-enriched green tea extract or a placebo capsule. After 12 weeks, the individuals taking the theaflavin-enriched green tea extract capsule had an 11.3% decrease in plasma total cholesterol and a 16.4% decrease in LDL-cholesterol from their pretreatment concentrations. The were no significant changes in total cholesterol or LDL-cholesterol in the placebo group and no change in HDL-cholesterol or triglyceride concentration in either group. In an average US diet supplemented with cocoa powder and dark chocolate, no change in LDL-cholesterol or the ratio of total cholesterol to HDL-cholesterol was found but HDL-cholesterol increased.

Although black tea was found to decrease platelet aggregation *in vitro*, similar to water, it had no acute or chronic effect on platelet aggregation in patients with coronary artery disease or in healthy individuals. Chocolate procyanidins increase plasma prostacyclin and decrease plasma leukotrienes, a possible mechanism by which chocolate flavonoids can decrease platelet activation. These changes occur rapidly (within 2 h) after consumption of chocolate and quickly disappear. However, in a well-controlled intervention, there was no effect of chocolate and cocoa powder on thromboxane and 6-keto-prostaglandin $F_{1\alpha}$ urinary excretion.

In addition to traditional biomarkers of cardiovascular disease, there are newer markers associated with cardiovascular disease that are related to endothelial function. One measure is brachial artery reactivity. In response to acute and chronic tea consumption, black tea consumption improves arterial reactivity in individuals with coronary artery disease. Tea consumption also improves arterial reactivity in mildly hypercholesterolemic individuals. Similar improvement in endothelial function occurred in individuals consuming purple grape juice.

Changes in whole body concentration of cytokines (especially those that control synthesis of acute phase proteins such as IL-6 and TNF-α), acute phase proteins (especially C-reactive protein), and soluble adhesion molecules (especially eSelectin, ICAM, and VCAM) are important indicators of

changes in cell signaling pathways, subclinical inflammation, and interactions of circulating cells with the endothelium. Some of these proteins have been identified as independent risk factors of cardiovascular disease and they remain important, emerging markers of disease. Despite the improvement in vascular reactivity associated with tea consumption, cell adhesion molecules do not appear to be altered by tea consumption in smokers and nonsmokers. These adhesion molecules are also related to endothelial function and are involved in the early etiology of atherosclerosis. Similar to tea, cocoa powder and chocolate consumption also do not alter proinflammatory cytokines, adhesion molecules, and acute phase proteins.

In summary, the observation that total circulating antioxidant capacity increases with consumption of foods high in flavonoids appears to be consistent in most studies, and tea is an important source of dietary flavonoids. However, improved circulating antioxidant status is not always consistent with a decrease in oxidative damage to DNA, protein, or lipid. Endothelial function, an important risk factor for cardiovascular disease, also appears to improve in response to catechins. A potential limitation of many studies is the lack of a controlled diet, which may account for the variability in results observed.

THIAMIN

Contents
Physiology
Beriberi

Physiology

D I Thurnham, University of Ulster, Coleraine, UK

Thiamin is a water-soluble vitamin and the structure comprises a pyrimidine and a thiazole ring linked by a methylene bridge (**Figure 1**). In its metabolically active forms, the hydroxyl group on the thiazole moiety is replaced by one, two, or three phosphate groups to form three phosphorylated coenzymes. A well-nourished human adult body contains approximately 30 mg of thiamin—approximately 80–90% as thiamin diphosphate (TDP), 10% as thiamin triphosphate (TTP), and a small amount of thiamin monophosphate (TMP) and thiamin. Like most water-soluble vitamins, there is no definable store in the body; the only reserves are thiamin coenzymes that are present in most cells in combination with appropriate thiamin-requiring enzymes. The predominant need for thiamin is linked to energy production but there is increasing evidence that thiamin is also needed for additional neurological functions. Thiamin is found in the aleuron layer of cereal grains as well as in animal food products such as liver. Man's desire for high-extraction cereal products in situations in which the diets contained little more than the cereal was a main contributory factor to the scourge of beriberi throughout much of Southeast Asia at the end of nineteenth and beginning of the twentieth century. Thiamin is relatively unstable and destroyed by poor cooking habits, and it is susceptible to degradation in foods that are not stored properly. Thiamin turnover is also quite rapid, and the absence of stores means that a continuous supply of thiamin is required. So thiamin status can be fairly rapidly impaired by factors affecting intake (e.g., vomiting and alcohol abuse) or excessive excretion (e.g., induced by diuretics). Thus, thiamin deficiency is sometimes a problem in pregnancy, in alcohol abuse, and in the elderly. Seasonal outbreaks can also occur in poor developing countries when energy output is high and cereals may have been stored for many months and food supplies are restricted.

Dietary Sources of Thiamin

Thiamin is present in most foods but cereal products provide most thiamin for most people in the world, although the source is fundamentally different in developing and more industrialized countries. In the developing world, unrefined cereal grains and/or starchy roots and tubers provide 60–85% of dietary thiamin, whereas most dietary thiamin in industrialized countries is obtained from fortified cereal products. In the United Kingdom, for example, wheat flour is fortified with 2.4 mg thiamin per kilogram and many breakfast cereals contain 30% or more of the daily thiamin requirement per portion. Thiamin is present in greatest amounts in brewers yeast, the germ and aleuron layers of fresh wheat, egg yolk, and mammalian liver. It is also present in meat flesh, particularly pork, and vegetables, nuts, and legumes (**Table 1**). Milk from both humans (0.49–0.79 μmol/l; 0.23 μg/4.2 MJ (1000 kcal)) and cows (1.18–1.48 μmol/l) is a poor source of thiamin. Thiamin is actively secreted into milk by the lactating mother, and it is of interest that the amount of thiamin in human milk is not increased by supplements, but the concentration

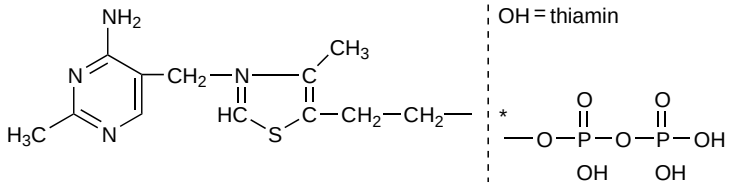

Figure 1 Thiamin and thiamin diphosphate (asterisk). Thiamin monophosphate and triphosphate are formed by the similar addition of one or three phosphate groups at the asterisk.

Table 1 Thiamin content of common foods

Food group	*Food item*	*Thiamin content (mg/100 g)*
Bread	Wholemeal	0.26
	White	0.18
	Hovis	0.52
Breakfast cereals	Cornflakes (fortified)	1.8
	Rice Krispies	2.3
	Weetabix	1.0
Flour	Wholemeal (100%[a])	0.46
	Brown (85%)	0.42
	White (fortified) (70%)	0.28–0.33
Milk, cheeses		0.03–0.06
Eggs	Cooked (various)	0.07–0.09
	Yolk raw	0.30
Vegetables (cooked)	Various leaf and root types	0.02–0.07
	Dahl, chick peas, green, beans, etc.	0.05–0.14
Pork products	Gammon rashers (lean)	1.0
	Bacon (various)	0.36–0.55
	Pork meat	0.5–0.88
	Liver (stewed)	0.21
Other meats	Beef (various)	0.03–0.09
	Lamb (various)	0.04–0.14
	Lamb liver	0.56
	Chicken (various)	0.04–0.10
	Game	~0.30
Yeast (dried)		2.33

[a]Percentages indicate the level of extraction in flour preparation.

and of course the volume consumed increase during the first 6 weeks of lactation.

Refined foods in general, such as fat, sugar, and alcohol, are poor sources of thiamin. Polished rice is particularly low in thiamin (80 μg/100 g) and is especially important because of its widespread consumption and importance as a source of calories. Cereal grains lose thiamin during refining, but the process of parboiling rice before milling enables most of the thiamin to be retained (190 μg/100 g) since it migrates into the starchy endosperm during the procedure. Proper storage of cereal grains is also important to maintain thiamin activity. Studies in The Gambia, West Africa, found that old season millet, which had been stored under thatch and in high humidity, when consumed in the middle of the rainy season had thiamin concentrations (11 μg/100 g) that were 6–12 times lower than cooked samples obtained immediately postharvest. Imported rice used in the village likewise only contained 10 μg/100 g at the time of consumption.

Because of the water-soluble properties of thiamin, it can be leached from food during cooking. Thiamin is stable in slightly acid water up to boiling point but is unstable in alkaline solution that oxidizes it

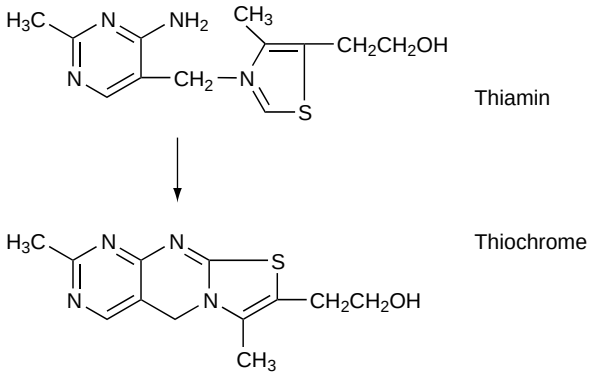

Figure 2 Structures of thiamin and thiochrome.

quantitatively to thiochrome (**Figure 2**). In addition, anti-thiamin factors in food can accelerate thiamin losses. Paralysis in foxes fed raw carp led to the discovery of the thiaminase enzymes. Two thiaminases are found in food. Thiaminase I is found in fish, shellfish, ferns, and some bacteria and catalyzes a base exchange reaction between thiazole and another base. Thiaminase II is a hydrolytic enzyme that cleaves the vitamin at the methylene bridge and is found mainly in bacteria. The thiaminases are heat labile, so only food that is eaten raw or fermented may loose thiamin during its preparation or in the gastrointestinal tract. There are also heat-stable anti-thiamin factors that are found in ferns, tea, betel nuts, large numbers of plants and vegetables, and some animal tissues. Anti-thiamin factors bind with varying degrees of attachment to thiamin and may or may not interfere with the bioavailability of thiamin. Diphenols, especially those with the hydroxyl groups in the *ortho* position, tend to react to give products that are both thiochrome negative and microbiologically inactive (i.e., thiamin is deactivated). Thus, in areas of northern and northeastern Thailand where tea drinking, chewing fermented tea leaves, chewing betel nuts, and consuming raw/fermented fish are common practices, thiamin deficiency still occurs despite thiamin intakes of 0.44–0.50 mg/4.2 MJ.

Absorption and Ethyl Alcohol

In food, thiamin occurs mainly as phosphate coenzymes and the predominant form is TDP (also called thiamin pyrophosphate and cocarboxylase). The phosphate coenzymes are broken down in the gut by phosphatases to give free thiamin for absorption. Thiamin is absorbed mainly from the upper intestine, and less thiamin is absorbed on an empty stomach than when taken with a meal. The latter could be due to the alkaline conditions in the duodenum, which are prevented by the presence of food.

Absorption of up to 2 mg per meal occurs by an active saturable process involving a sodium-dependent adenosine triphosphatase and against a concentration gradient. During absorption, thiamin is phosphorylated to the monophosphate ester (TMP). Thiamin is absorbed via the portal venous system. Further phosphorylation to TDP occurs on entry into all tissues. TDP can cross the blood–brain barrier, where a portion is converted to TTP, although even in the brain, TDP is the predominant form of thiamin. A second passive absorption process operates when intakes of thiamin are >5 mg but the maximum that can be absorbed from an oral dose is 2–5 mg.

The active process of absorption is impaired by ethyl alcohol. For example, 55% of a 5 mg dose of orally administered, labeled thiamin was recovered over 72 h in healthy adults, but this was reduced by 25–40% if they were previously given 1.5–2 g alcohol/kg. In people with fatty livers who had previously been abusing alcohol, mean thiamin absorption was reduced by 60%. However, the passive absorption of thiamin is not inhibited by alcohol, nor does it block entry of thiamin into the liver or interfere with thiamin metabolism in the tissues. Absorption of thiamin may also be reduced by gastrointestinal disturbances, such as vomiting and diarrhea, ulcerative colitis, and neoplasia, and in patients with hepatic disease and achlorhydria.

Transport, Storage, and Excretion

Thiamin with some TMP (19–75 nmol/l) circulates in the blood bound to albumin. When the binding capacity of plasma albumin is exceeded, or thiamin is in excess of tissue needs, it is rapidly excreted in the urine. Most thiamin in erythrocytes is present as TDP principally bound to the enzyme transketolase. Likewise, in most other tissues, there is very little free thiamin and it is mostly present as TDP (90%) in coenzymes bound to respective enzymes and a smaller amount of TTP (10%) in nervous tissues. The concentration of thiamin in specific tissues is on the order of 2–3 μg/g for heart muscle; 1 μg/g for brain, liver, and kidney; and 0.5 μg/g in skeletal muscle. Thiamin supplements can increase these concentrations slightly and prolonged febrile illnesses are likely to reduce them. Thiamin is mainly excreted intact in the urine but there are small amounts of thiochrome (**Figure 2**) and other thiazole and pyrimidine metabolites. A linear relationship exists between intake and excretion of thiamin until intake falls to an amount approaching minimum requirements when excretion decreases rapidly indicating a renal conservation mechanism.

There is concern that the long-term use of diuretics in the management of chronic congestive heart failure (CHF) may impair thiamin status and, as a consequence, impair myocardial function. The diuretic drug furosemide has been the subject of much attention. In healthy volunteers, a dose-dependent increase in urine flow accompanied by an increase in the urinary thiamin excretion rate have been demonstrated. In furosemide-treated patients, the concomitant presence of thiamin in the urine and biochemical deficiency of thiamin from measurements in blood has been shown. These results suggest that furosemide treatment can override the renal conservation mechanism. In one study, 23 patients with chronic CHF receiving 80–240 mg furosemide daily for 3–14 months were studied along with 16 age-matched controls without heart failure and not taking diuretics. No subjects in either group were identified as consuming inadequate thiamin intake or having increased thiamin requirements. However, biochemically, 21 of the 23 CHF patients and 2 of the controls were thiamin deficient. Furthermore, 5 of the CHF patients were treated with intravenous thiamin (100 mg thiamin HCl twice daily for 7 days). Biochemical thiamin status normalized and echocardiographic assessment of left ventricular ejection fraction increased in 4 of the 5 patients. Because no other changes were made in the patients' therapeutic regimen, the results suggest that the improvement in cardiac contractility was due to the correction of the thiamin deficiency.

Biological Functions

Thiamin functions as the coenzyme TDP in the metabolism of carbohydrates and branched-chain amino acids (α-keto-isocaproic, α-keto-β-methyl valeric, and α-keto-isovaleric acids). In association with Mg^{2+} ions, TDP is important (1) in various dehydrogenase complexes for the oxidation of α-keto acids (pyruvate, α-ketoglutarate, and the branched-chain α-keto acids) and (2) in the formation of α-ketols among the hexose and pentose phosphates catalyzed by transketolase (EC 2.2.1.1). Thus, a deficiency of thiamin has severe consequences for energy generation and amino acid interconnections, and these have important links with lipid metabolism, cell replication, and neural activity.

Two principal dehydrogenase complexes that require the participation of TDP are pyruvate dehydrogenase, which generates acetyl-CoA, and the oxidative decarboxylation of α-ketoglutarate to succinyl-CoA (**Figure 3**). Pyruvate dehydrogenase is situated at the junction of the glycolysis pathway,

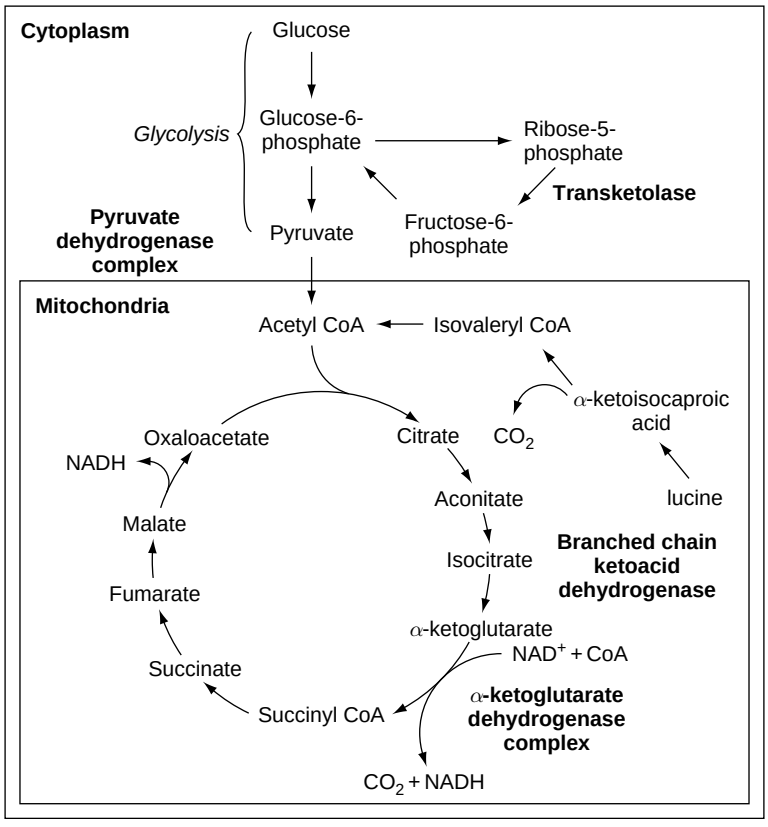

Figure 3 The four principal sites of action of thiamin diphosphate coenzyme in carbohydrate metabolism.

where it enters the tricarboxylic acid cycle. Acetyl-CoA is a key source of energy for mitochondrial oxidation and the production of adenosine triphosphate (ATP) as well as an important precursor in lipid metabolism. The impaired functioning of pyruvate dehydrogenase leads to a lactic acidosis, with increased concentrations of serum pyruvate and/or lactate especially as a result of exercise. The lactate acidosis can be explained by the fact that ATP depletion stimulates glycolysis, thus generating more pyruvate. As pyruvate concentrations increase, lactate dehydrogenase converts some of the pyruvate to lactate, producing the lactic acidosis. The increases in these compounds formed the basis of the earliest biochemical test for thiamin deficiency, which was later made more reproducible by taking the blood soon after moderate exercise (e.g., climbing a few steps).

Many features of beriberi indicate that thiamin plays an important role in neural tissues. TTP is specifically found in nervous tissues, but although this triphosphorylated metabolite of thiamin has been known for approximately 30 years, its precise role is still in doubt. TDP in the dehydrogenase complexes is undoubtedly also required for normal function. Some of the earliest biochemical studies on the brain documented abnormalities in the oxidative metabolism of glucose and a disruption in energy supply may underlie many of the neurochemical changes and structural lesions associated with thiamin deficiency. For example, acetyl-CoA produced by pyruvate dehydrogenase is a precursor of the parasympathetic transmitter molecule acetylcholine, but the obligatory requirement of glucose as an energy source for nervous tissue indicates the essentiality of TDP. Likewise, the cytosolic enzyme transketolase is also present in nervous tissue, and as a key enzyme in the HMS it may be important in minimizing oxidant stress. The HMS generates NADPH, which is required to maintain glutathione in the reduced state.

The cellular and subcellular localization of the enzymes responsible for metabolism of thiamin phosphates in nervous tissues may indicate possible sites of action of the specific metabolites. Thiamin that enters the brain is phosphorylated by thiamin pyrophosphokinase to form TDP. The concentration of thiamin phosphates is 3 or 4 times higher in neurons than in neuroglia, and the activity of thiamin diphosphatase (TDPase), which converts TDP to TMP, is 20 times higher in neurons than neuroglia. Thiamin monophosphatase is only detected in neuroglia. Within the neuron, TDPase is mostly

localised in the microsomal fraction. Thiamin triphosphatase (TTPase), which converts TTP to TDP, is particularly enriched in presynaptic terminals. Stimulation of nerves or treatment with certain neuroactive drugs result in decreases in TDP and particularly TTP in the nerve, with an increase in free TMP in the surrounding fluid. It is postulated that TTP plays an essential role in nerve transmission involving a gating mechanism for sodium and potassium ion transport via the specific ATPase. Some evidence for this comes from patients with Leigh's disease (pathologically similar to Wernicke–Korsakoff syndrome), in whom severe neurological disease is accompanied by a deficiency in TTP but normal TDP concentrations.

The well-documented role of mitochondria in programmed cell death and the importance of thiamin for oxidative metabolism have stimulated investigators to examine brain thiamin homeostasis in neurodegenerative diseases. Diminished thiamin-dependent processes, abnormal metabolism, and oxidative stress accompany the neurodegeneration of Alzheimer's disease (AD), Huntington's disease, Wernicke–Korsakoff syndrome, progressive supranuclear palsy, and the adult-onset neurodegenerative diseases that are caused by genes containing variable numbers of CAG repeats within their coding regions. Abnormalities in the thiamin-dependent processes have also been linked with thiamin-responsive maple syrup urine disease, Leigh's disease (a subacute necrotizing encephalomyelopathy), sudden infant death syndrome, cerebellar degeneration, thiamin-responsive anemia, ataxia, and disorders of energy metabolism including pyruvate dehydrogenase deficiency. The extent to which disturbances in thiamin metabolism are a cause or a consequence of the disease process is still under examination.

Assessment of Thiamin Status

Thiamin status can be assessed using methods that measure thiamin or its metabolites in plasma, erythrocytes and urine (**Table 2**). Samples are acidified to stabilize the thiamin and precipitate any protein. Usually, thiamin is oxidized to thiochrome (**Figure 2**) using cyanogen bromide in alkaline solution and measured by fluorescence with or without chromatography. Concentrations of thiamin in urine and plasma tend to reflect dietary intake, being high when intake is adequate and low when dietary sources are poor. Erythrocyte thiamin is mainly in the form of the coenzyme TDP, which can be extracted from washed erythrocytes, derivatized as described previously, and quantified by high-performance liquid chromatography. The most popular test, however, is the erythrocyte transketolase (ETKL) stimulation test, which measures enzyme activity with and without added TDP. The reference range for ETKL activity in well-nourished, thiamin-adequate people is reported to be 570–830 mU/g hemoglobin. The stimulation test measures the proportion of the apoenzyme in red cell homogenate (i.e., the proportion that is not bound to TDP and represents the degree of thiamin deficiency). Studies have shown that results from the urinary assay for thiamin agree reasonably well with those obtained by the ETKL stimulation test.

Table 2 Biochemical assessment of thiamin status

Test	*Acceptable*	*Marginal risk*	*High risk*
Urinary thiamin (μmol/mol creatinine)[a]			
1–3 years	>66	45–66	<45
4–6 years	>45	32–45	<32
Adults	>25	10–25	<10
Erythrocyte transketolase activity			
Activity coefficient	<1.11	1.11–1.25	>1.25
TDP effect (%)	<11	11–25	>25
Red cell thiamin concentrations (nmol/l)	749 ± 196		~560[b]
Whole blood thiamin concentrations (nmol/l)	166–266		<133

[a]Converted from μg/g creatinine using the factor (×0.376).
[b]Based on a decrease of 25% in red cell thiamine diphosphate (TDP).

One of the reasons for the popularity of the ETKL stimulation test is that sensitivity is still good even in the presence of thiamin deficiency. In all other measurements of thiamin status, as deficiency approaches, the quantity of thiamin or its metabolites diminishes in the biological fluid. Low concentrations of a product are usually more difficult to measure and precision deteriorates, or the amount of sample has to be increased to provide sufficient material to detect. In contrast with the ETKL stimulation test, in an acute thiamin deficiency, ETKL activity is maintained and only the amount of TDP decreases, so the test becomes more sensitive. However, in chronic thiamin-deficient states, the apoenzyme of ETKL is reported to be unstable *in vivo*, and in the absence of the coenzyme, concentrations of the apoenzyme decrease, with the result that *in vitro* stimulation may show normal thiamin status. Thus, in situations in which chronic thiamin deficiency is suspected as a result of a long-term marginal thiamin intake, alcohol abuse, or use of diuretics for many months, one or more of the concentration tests may be useful as an adjunct to the stimulation test.

Certain precautions should be taken in handling samples for thiamin analysis. Urine should be acidified to avoid degradation and stored below −20 °C. Heparinized whole blood should be collected and immediately put on ice. For total erythrocyte TDP measurements, cells are separated from plasma within 2 h when possible, washed in saline, and diluted 1:1 with saline prior to acidification. Centrifugation of the acidified mixture provides a clear extract that can be stored for no more than 5 days at 4 °C or longer at ≤−20 °C. Washed red cells are also used for the ETKL assay. Duplicate tubes of the red cells in saline suspension with and without added TDP are mixed and can be stored at −70 °C prior to enzymatic analysis of ETKL activity. Even at −70 °C, however, storage should be for no more than a few weeks. The ETKL apoenzyme is unstable, and even in the tubes to which TDP has been added, if mixing did not thoroughly expose all apoenzyme to the added coenzyme, deterioration will occur and results will be unreliable.

Recommended Dietary Allowances

Quantifying thiamin requirements is based on a variety of biochemical data. Early results indicated that a thiamin intake of 0.4 mg/day on a low-energy intake was close to the absolute minimum requirement. Epidemiological evidence suggested that beriberi occurred when the intake of thiamin was <0.2 mg thiamin per 4.2 MJ (1000 kcal); however, when 0.188 mg/4.2 MJ was fed to sedentary elderly men for 2 years, no indisputable alteration in clinical state occurred. Thiamin requirements are strongly influenced by physical activity and at higher energy intakes with liquid formula diets containing 11.76 and 15.12 MJ (2800 and 3600 kcal), there was good agreement between thiamin excretion and ETKL stimulation to interpret thiamin status at different levels of thiamin intake. Increasing intake from 0.2 to 0.23 mg/4.2 MJ moved first the urinary excretion and then ETKL activation out of the deficient range. Both measurements were normalized at intakes of 0.3 mg/4.2 MJ, and to allow for variance the recommended nutrient intake adopted by the Department of Health in the United Kingdom was 0.4 mg/4.2 MJ. This amount is recommended for all groups of the population since additional needs in pregnancy and lactation are met by increased energy intakes. It was recommended that formula feed should contain not less than 0.3 mg/4.2 MJ.

Women are less affected by beriberi than are men even when they are consuming the same diet, but there is no consistent indication that men have greater needs than women. Differences between the sexes that may affect susceptibility to beriberi need further investigation (e.g., the amount of food eaten by the sexes when supplies are short or of poor quality, metabolic responses to infection during illness, and differences in energy requirements). The close association between thiamin metabolism and carbohydrate metabolism means that thiamin requirements are determined by basal metabolic rate (BMR) and physical activity. BMR of men is slightly higher than that of women of the same weight, but total energy expenditure can vary 1.4 to 2.5 times BMR depending on physical activity.

Drug–Nutrient Interactions

Mention has already been made of the influence of alcohol and diuretics on thiamin status. Oral contraceptives are reported to have no effects on thiamin status.

Toxicity

High intakes of thiamin administered orally are nontoxic. The rapidly saturable thiamin absorption mechanism limits the amount taken up from a single dose to ~2.5 mg, and thiamin present in excess of protein binding capacity is excreted. However, there are reports of toxicity from chronic intakes in excess of 50 mg/kg or >3 g/day with a wide variety of clinical signs, including headache, irritability, insomnia, rapid pulse, weakness, rapid pulse contact dermatitis, pruritus, and, in one case, death.

Beriberi

D I Thurnham, University of Ulster, Coleraine, UK

Beriberi is caused by a deficiency of thiamin (also called thiamine, aneurin(e), and vitamin B_1). Classic overt thiamin deficiency causes cardiovascular, cerebral, and peripheral neurological impairment and lactic acidosis. The disease emerged in epidemic proportions at the end of the nineteenth century in Asian and Southeast Asian countries. Its appearance coincided with the introduction of the roller mills that enabled white rice to be produced at a price that poor people could afford. Unfortunately, milled rice is particularly poor in thiamin; thus, for people for whom food was almost entirely rice, there was a high risk of deficiency and mortality from beriberi. Outbreaks of acute cardiac beriberi still occur, but usually among people who live under restricted conditions. The major concern today is subclinical deficiencies in patients with trauma or among the elderly. There is also a particular form of clinical beriberi that occurs in patients who abuse alcohol, known as the Wernicke–Korsakoff syndrome. Subclinical deficiency may be revealed by reduced blood and urinary thiamin levels, elevated blood pyruvate/lactate concentrations and α-ketoglutarate activity, and decreased erythrocyte transketolase (ETKL) activity. Currently, the *in vitro* stimulation of ETKL activity by thiamin diphosphate (TDP) is the most useful functional test of thiamin status where an acute deficiency state may have occurred. The stimulation is measured as the TDP effect.

Epidemiology

Beriberi presents in several different clinical forms (**Table 1**). Beriberi became endemic following the introduction of steam-powered rice mills, which enabled milled rice to be produced cheap enough so that almost everybody could afford it and consume it. It was particularly serious at the end of nineteenth and the beginning of the twentieth centuries when seasonal epidemics of wet beriberi occurred with many deaths. The disease affected mainly the Chinese and Japanese populations, although outbreaks were reported in India and among settlers in the New World during the long cold winters, and the disease was not necessarily confined to rice-eating populations. Where acute cardiac beriberi occurred, dry beriberi was also present but usually in the older members of the community.

Milled rice has a thiamin concentration that is particularly poor (80 μg/100 g), but social conditions

Table 1 Forms of beriberi in man

Subclinical beriberi	Identified by transketolase activity or other biochemical tests of thiamin status. May be associated with early subjective symptoms such as anorexia, weakness, dysthesie, and depression. Responds rapidly to treatment with thiamin.
Wet beriberi	Subacute or cardiac beriberi frequently having muscular pains, oedema of feet and legs, enlarged heart, and tachycardia. Responds rapidly to treatment with thiamin. Major form and was typically seasonal in endemic areas. Acute fulminant type of beriberi in which the main feature is dominated by insufficiency of the heart and blood vessels. Responds rapidly to treatment with thiamin.
Dry beriberi	Chronic, atrophic type of polyneuropathy in which the main features are of a weak wasted person, with painful musculature making walking difficult, impaired sensory nerves and tendon reflexes, and flaccid paralysis of the motor nerves. Poor or no response to treatment with thiamin.
Infantile beriberi	Usually acute wet beriberi. Responds rapidly to treatment with thiamin.
Wernicke–Korsakoff syndrome	Predominantly neurological, affecting walking and vision in most and memory and cardiac function in over 50% of patients. Wernicke or ocular component responds rapidly to treatment but the Korsakoff psychosis responds slowly or not at all.

Modified from Thurnham DI (1978) Thiamin. In: Rechcigl M Jr (ed.) *Nutrition Disorders*, pp. 3–14. West Palm Beach, FL: CRC Press.

at the time of the large epidemics contributed to the problems. Bonded labor was common, with workers living on the work premises most of the time and paid mainly in the form of rice. In addition, reports at the time suggest that the rice was of uncertain freshness and quality, and that it could be so mouldy, matted, and lumpy that it had to be remilled and washed, with a further loss of thiamin. The social conditions prevented natural eating practices because workers had little money to purchase additional food and they were dependent on what they were given. Likewise, badly stored cereals can lose up to 90% of the thiamin content, and toxins associated with mould growth have been implicated in causing sickness that may well precipitate clinical beriberi.

Reports suggest that the acuteness of the outbreak of beriberi and the interrelationship of thiamin deficiency with deficiencies of other nutrients probably had a major role in determining the nature of the pathological changes and lesions produced. For example, it is reported that protein energy malnutrition almost always accompanied subacute beriberi, reflecting the link between impoverishment and the disease. In contrast, it is also suggested that severe beriberi more often affected the more active, stronger, or supposedly better nourished members of the community. The younger, stronger rickshaw puller was most likely to suffer severe beriberi. Likewise, infantile beriberi appeared to affect the male infant who 'tended to be overfed.' This enigma may be due to thiamin intakes from a diet containing a high proportion of rice being insufficient to meet the thiamin requirement posed by the higher calorie intakes of the more active community members. In the case of infantile beriberi, slightly deficient mothers probably produced milk that was only marginally adequate in thiamin and/or infants were given supplements of thiamin-poor rice. It is a common habit even today for rural mothers to give very young infants, even beginning at 1 week of age, a bolus of masticated rice to supplement the milk intake. The inability to match thiamin intake to energy needs may also explain why nonspecific pyrexia was a precipitating factor for beriberi. A 1 °C rise in body temperature is associated with a 10% increase in basal metabolic rate. It has been suggested that more than half the mild cases of beriberi were associated with a nonspecific bout of fever, and such cases responded less readily to treatment with thiamin.

Parboiled rice is partially cooked before milling, and this prevents beriberi because the thiamin is dispersed through the grain (190 μg/100 g). The advantages of this were clearly seen in Malaya, where at the end of nineteenth century there were large-scale immigrations of young, able-bodied Chinese to work in the tin mines and Indians to work on the rubber estates. In both cases, immigrants often lived in remote regions where there was little opportunity to purchase local food and they were dependent on imported rice. It was the Chinese who, because of their dietary preference for milled rice, died in enormous numbers.

Although ways of avoiding the disease were known to the Japanese navy at the end of the nineteenth century, since the director general of the medical department had demonstrated that the disease was almost eradicated if the traditional rice diet was supplemented with fish, vegetables, meat, and barley, this information was not widely available, and supplementation was not feasible by the vast majority of people. It was widely believed that the cause of beriberi was an infection or toxin resulting from bad food. In particular, Pasteur's work on the microbiological cause of infections led many to search for an infectious agent, but none could be consistently identified. The scale of the problem for the colonial powers in Southeast Asia in the latter part of the nineteenth and early twentieth centuries should not be underestimated. Labour was cheap but the death toll posed enormous problems. Extracts from reports at the time are illuminating: In 1887, there were 690 deaths out of 1931 native government officers in Sumatra, infant mortality was 445 per 1000 live births in the Philippines in 1910, and one report stated that there were so many deaths that "there was insufficient earth to bury the corpses."

The Dutch government sought to resolve the situation by appointing a medical bacteriologist, Christiaan Eijkman, to travel to Indonesia to investigate the problem. Working in Java, he showed within 6 years that beriberi was a nutritional problem and that a paralytic condition closely resembling the polyneuritic symptoms of beriberi could be produced in chickens by feeding them both stale and freshly cooked polished rice. However, it was Funk in 1911 who first reported the isolation of a 'vital amine' from rice polishings that had anti-beriberi properties. Funk was the first person to coin the word 'vitamine' as a substance essential for life. The structure and synthesis of thiamin were reported in 1936.

Currently, clinical beriberi no longer occurs with the devastating effects of former years. Considerable improvements have occurred in nutrition worldwide, the diversity of foods available, the quality of food due to improved storage methods, and social and economic structures in many countries, especially in Southeast Asia. However, sporadic

outbreaks do occur, which are usually of the acute, fulminating type of beriberi, and deaths still, occur often in young men aged 20–40 years. Usually, a combination of factors is responsible, but once the cause is identified, treatment is cheap and readily available and, if given rapidly, tragic circumstances can be averted.

Two iatrogenic causes of subclinical beriberi are known, namely that associated with diuretic treatment and one resulting from alcohol abuse. Both are of concern because the use of diuretics is introduced to manage cardiovascular disease, a condition that will deteriorate if thiamin status is impaired, and alcohol abuse can lead to Wernicke–Korsakoff syndrome, which can have many of the features of both wet and dry beriberi.

Severe multisystem trauma, endotoxemia, or situations in which there is a raised metabolic demand for thiamin, such as pregnancy, thyrotoxicosis, and intercurrent illness or impaired absorption (e.g., alcohol abuse or gastrointestinal disease or resection), can produce subclinical evidence of thiamin deficiency or more severe life-threatening aspects of beriberi, such as renal and/or cardiovascular failure. The elderly may be particularly at risk of subclinical thiamin deficiency. One Belgian study on patients with a mean age of 83 years reported that 40% had a raised TDP effect (>15%), in whom there was a high proportion of Alzheimer's disease, depression, cardiac failure, and falls. The diuretic furosemide was also more frequently taken by the thiamin-deficient patients.

Table 2 Aetiological factors contributing to thiamin deficiency

Dietary thiamin deficiency	Commonly milled rice
High dietary carbohydrate to fat ratio	Metabolism of carbohydrate requires thiamin, whereas metabolism of fat spares thiamin requirements
Heavy physical activity	Predisposes to beriberi when accompanied by low intake of thiamin
Protein energy malnutrition	Older literature reports sometimes accompanies subacute beriberi indicating importance of impoverished diet
Poor storage conditions for food	Fall 6- to 10-fold in thiamin content of cereals. Moulds may accelerate decay as well as increase risk of toxins
Thiaminases	Two known, but only of importance when uncooked foods are consumed
Anti-thiamin factors	Factors in food that chelate with thiamin and potentially reduce bioavailability
Alcohol abuse	Alcohol impairs the active absorption mechanism for thiamin
Infection and trauma	Increase requirements for thiamin to support increased carbohydrate metabolism and energy production
Diuretics, long-term use	Accelerate thiamin excretion and appear to block thiamin control mechanism
Seasonal factors	Combination of heavy work load, impoverished diet, and last season's (badly stored) cereals
Male sex	Some evidence that men have higher thiamin requirements than women but more likely to be a combination of the first three factors listed here

Etiology

The factors associated with the various forms of beriberi are listed in **Table 2**. Beriberi is caused by a lack of thiamin in the diet, but the onset of the disease and the symptoms associated with the disease are influenced by one or more of the other etiological factors. Wet beriberi (i.e., cardiac beriberi) and Wernicke's encephalopathy are conventionally described as acute manifestations of the disease and respond most rapidly to treatment. In contrast, dry beriberi is described as due to a chronic deficiency of thiamin and does not respond well to treatment. However, experimental acute deficiency studies, which very rapidly produced subjective feelings of malaise and weakness at the slightest exertion, very rarely produced evidence of oedema and peripheral pain. These observations suggest that all forms of beriberi are probably preceded by an indeterminate period of chronic thiamin deficiency during which pathophysiological adaptations to the marginal nutritional state occur. Thus, physiological adaptations to the vascular system may well have occurred particularly in those who did heavy physical work and needed to overcome the weakness and malaise imposed by a low thiamin diet. The factor(s) that precipitated the clinical disease may not be thiamin at all. Platt, in his descriptions of beriberi in China, recounts how humid weather and infections such as malaria increased the number of cases of wet beriberi. The extra energy needed to cool the body in hot conditions or fuel the rise in temperature during infection may have imposed a critical burden on energy production that the system could not meet, and beriberi ensued.

However, the increased number of cases associated with heat, humidity, and malaria may also be due to a seasonal decline in the quality of food. A 6- to 12-fold decline in thiamin content is reported for millet when stored under traditional thatched storage houses in The Gambia, and reports suggest that much of the rice consumed late in the

season was not in the best condition. Some of the products introduced by mould growth may possess anti-thiamin properties that impair thiamin bioavailability. Thus, the ratio of thiamin to calories is likely to fall during the agricultural year and to be at its worst when calorie requirements are at their highest for land preparation and weeding. Land preparation also takes place just prior to or at the beginning of the rainy season, when the prevalence of malaria and diarrhoeal diseases increases.

Thiaminases are inactivated by cooking; thus, the enzymes are only a problem where certain foods are eaten raw. It has been suggested that in northern Thailand, where consumption of fermented raw fish products is widely practised and raw molluscs are eaten, thiamin status may be impaired by these food habits. Even as recently as 2001, marginal thiamin status was reported in more than 50% of women 3 months postpartum despite thiamin supplements of 100 mg/day during pregnancy. The deficiencies were found in Karen refugee women living on the Thai–Burmese border and whose diet contained fermented fish, tea leaves, and betel nuts—substances suspected of containing thiaminases. Polyphenol compounds in tea and many vegetables may also posses anti-thiamin properties and impair bioavailability, but their etiological importance in causing thiamin deficiency is difficult to assess.

Alcohol is an important factor in causing thiamin deficiency because it inhibits the active transport of thiamin across the gut and when abused it impairs the quality of the diet consumed. Diuretics accelerate the excretion of thiamin and appear to override the renal conservation mechanism. Their use is of potential concern in elderly people whose diet may be poor for other medical reasons and their physicians may be unaware of their need for supplemental nutrient.

Both sexes are vulnerable to the effects of thiamin deficiency, but in many of the sporadic outbreaks that have been reported, there appears to have been a male excess. This may be due to higher thiamin requirements in men than women because of their higher lean body mass or to hormonally driven sex differences. However, it is also possible that the cause is due to a higher risk of a thiamin:calorie imbalance in men compared to women. In many rural communities, men traditionally eat first and may satisfy their calorie requirements, whereas their womenfolk make do with the leftovers. Because of their greater physical strength, men frequently do heavier work than women, requiring more energy (i.e., more food to meet their requirements). Thus, men may consume more of the thiamin-depleted cereals in the diet to satisfy calorie needs and in so doing achieve a poorer thiamin:calorie ratio than women.

Experimental Thiamin Deficiency in Man and Measurement of Thiamin Status

In young and healthy nonalcoholic subjects, subjective symptoms appear after 2 or 3 weeks of deficient diet but urinary thiamin will already be falling (**Table 3**). Characteristic early symptoms include anorexia, weakness, dysthesiae, and depression. At this stage, urinary thiamin will be almost zero, ETKL activity depressed, and the TDP effect approximately 15–30%. After 6–8 weeks the only objective signs at rest may be a slight fall in blood pressure and moderate weight loss, although urinary thiamin will now be negligible and the TDP

Table 3 Effects of thiamin deficiency on urinary thiamin, the erythrocyte transketolase TDP effect, and early clinical symptoms of thiamin deficiency in human volunteers

Days of deficiency	*Urinary thiamin (μg/day)*[a]	*TDP effect (%)*[a]	*Clinical signs of deficiency following diets containing 150–350 μg thiamin/day*[b]
5	50	0–10	Mostly studies report no signs but one study (360 μg/day) found within 1 week chest
10	25	~15	pains, extreme lassitude, anorexia, palpitation, and burning feet
21–28	<25	~30	Loss of body weight, anorexia, general malaise, insomnia, increased irritability, fatigue on slightest exertion
30–40	Negligible	≥40	Increased malaise, loss of body weight, intermittent claudication and polyneuritis, bradycardia, peripheral oedema,[a] cardiac enlargement,[a] ophthalmoplegia
>45	10–20	>40	Additional signs of nausea and dizziness appeared
~75	10–20		Additional signs of vomiting, low blood pressure, and tenderness of calves

[a]Biochemical data and report of oedema and cardiac enlargement from Brin (1964), in which healthy male medical students were fed 200 μg thiamin per day for 6 weeks. TDP effect is a measure of thiamin status obtained by measuring the activity of erythrocyte transketolase in the presence and absence of added thiamin diphosphate.

[b]Clinical signs adapted from several studies. Investigators were impressed by the rapid degree of debility induced by the specific withdrawal of thiamin from the diet. In one group (150 μg/day for 75 days, four female mental patients), the authors reported that the condition more closely resembled 'neurasthenia' than beriberi and noted that oedema, cardiac dilation, and peripheral pain characteristic of classic beriberi were all absent (reported by Carpenter, 2002).

effect ≥35%. After 2 or 3 months, apathy and weakness become extreme, calf muscle tenderness develops, and there is loss of recent memory, confusion, ataxia, and sometimes persistent vomiting. Urinary thiamin will be negligible and the TDP effect may be normal (because apo-ETKL is unstable even *in vivo*), but ETKL activity should be considerably depressed.

The clinical symptoms resulting from experimental thiamin deficiency in man have usually responded rapidly to treatment with thiamin. In one feeding study, however, two mental patients were kept for 110 days on a diet providing 200 μg thiamin daily and 1 mg of thiamin by injection 1 day each week; thus, their overall weekly average was 350 μg/day. They developed a polyneuropathy characterised by defects in the sensory nervous pathways, loss of tendon reflexes, and paralysis of the legs, which took many weeks to respond to large doses of thiamin, and in one case response was still incomplete after 4 months of treatment. The slow cure suggested that degeneration of peripheral nerves had occurred, as is indicated in the dry form of beriberi, in which the neurological lesions are irreversible.

Clinical Features of Beriberi

Depletion and repletion studies suggest that intakes >300 μg/4.2 MJ are compatible with normal biochemistry and good health, and clinical signs of thiamin deficiency occur at intakes of thiamin below 200 μg/4.2 MJ (1000 kcal). The disease as studied from the 1880s onward in Asians subsisting on white rice began typically with weakness, 'wandering pains' in the legs, and lack of feeling in the feet. Some patients then developed oedema (the presence of excessive amounts of fluid in the intercellular tissue spaces of the body) of the legs, trunk, and face. In severe cases, sufferers found it increasingly difficult to catch their breath and would die of heart failure. The clinical features of subacute and acute wet beriberi are summarized in **Table 4**. The main form was subacute beriberi, which was typically seasonal in endemic areas. There are reports that the peripheral muscles most severely affected were those most frequently used; thus, in male laborers it was the legs. Aching pain, tightness, and cramps in the calf and associated muscles were usually a first cause of complaint, and pain on squeezing the calves was one of the most useful diagnostic tests for beriberi. In women who performed repetitive tasks involving hands and arms, a loss of sensation in the fingers was frequently a first cause of complaint.

Dry beriberi is essentially a chronic condition showing muscular atrophy and polyneuritis and frequently occurring in older adults. Walking is usually difficult because of the weak wasted and painful musculature, and in the later stages feeding and dressing may also become impossible. When bed-ridden and cachetic (extreme state of malnutrition and wasting), patients become very susceptible to infections. Sensory nervous function is impaired (hypoesthesia) almost to the point of anesthesia. Hypoesthesia is particularly evident in the extremities and progressively extends over the outer aspects of the legs, thighs, and forearms. Motor nerve disturbances also begin in the extremities and ascend progressively. Flaccid paralysis of the extensor muscles precedes that affecting the flexors and results in 'wrist drop' and 'foot drop' (**Figure 1**). Loss of the Achilles tendon reflex usually precedes an impaired patellar reflex.

Mortality from infantile beriberi mainly affected breast-fed infants between the second and fifth months of life, when solid foods were often first introduced. The introduction of white rice porridges, poor in thiamin, to a rapidly growing child and/or the increased exposure to infections when solids are introduced may both have contributed to infantile beriberi. The onset of the disease was rare in the first month and early signs could be mild and somewhat subjective (e.g., vomiting, restlessness, anorexia, and insomnia). Early signs could progress to subacute infantile beriberi, the acute and usually fatal condition, or a chronic form. Features of acute infantile beriberi are presented in **Table 5**. The subacute form was characterized by slight oedema in the form of puffiness, vomiting, abdominal pain, oliguria, dysphagia, and convulsions. In addition, aphonia (soundless cry) was often a feature of subacute infantile beriberi and may have been due to nerve paralysis or oedema of vocal cords. Vomiting was also a feature of chronic infantile beriberi and could be accompanied by inanition, anemia, aphonia, neck retraction, opisthotonus, oedema, oliguria constipation, and meteorismus (swelling of the abdominal cavity from gas in the intestine). Opisthotonus is a characteristic of acute thiamin deficiency in birds and is described as due to a tetanic spasm in which the spine and extremities are bent backwards.

In alcoholic and other malnourished subjects, one of the early signs of thiamin deficiency is anorexia. In alcohol abuse, the overwhelming desire for alcohol may outweigh all other interest in food, leading to generalized malnutrition. Alcohol specifically blocks the active absorption of thiamin and alcohol abuse can progress to the potentially fatal condition known as Wernicke–Korsakoff syndrome. The typical clinical features of Wernicke's encephalopathy comprise ophthalmoplegia, nystagmus (usually

Table 4 Common features of wet beriberi

	Subacute beriberi	*Acute fulminating beriberi*[a]
Digestive system	Anorexia is common; constipation more frequent than diarrhea	Vomiting is common, often with intense thirst Liver enlarged and tender and the epigastric region spontaneously painful
Neurological	Aching pain, stiffness, tightness, or cramps in calf or associated muscles Increasing muscular tenderness and weakness with fatigue pains resembling muscular ischemia, especially at night Pain on squeezing calves Inability to rise from squatting position without use of hands Diminished reflexes of ankle and knees usually bilaterally Hypoesthesia or paraesthesia presenting as 'pins and needles,' numbness particularly over the tibia, formication (like ants running on the skin) or itching	Pupils dilated with anxious expression on face Aphonia frequently present and patient moans with cries of a special kind as a result of hoarseness produced by paralysis of laryngeal muscles Reflexes of ankle or knee lost or diminished
Cardiac	Oedema of feet and legs often appearing first on dorsa of feet and extending up legs but may also appear on back of hands and as puffiness in face Heart enlarged with tachycardia and bounding pulse Raised venous pressure (see **Figure 2**) with percussion sometimes revealing dilation of right auricle and ventricle Heart murmurs if present are usually systolic Apex beat is downward and outwardly displaced Neck vein possibly distended showing visible pulsations Dyspnea upon exertion Palpations, dizziness, and giddiness Extremities possibly cold and pale with peripheral cyanosis but where circulation is maintained, skin warm due to vasodilatation Electrocardiograms often undisturbed but QRS complex may show low voltage and inversion of T waves indicating disturbed conduction	Patients severely dyspneic, have violent palpitations of the heart, are extremely restless, experience intense precordial agony but accessory muscles of respiration on slightly brought into action Widespread and powerful undulating pulsations visible in the region of the heart, epigastrium, and neck due to a tumultuous heart action Facial cyanosis more marked during inspiration Pulse is moderately full, regular, even with frequency of 120-150/min A wavelike motion may be felt over the heart On percussion, the heart is enlarged both to the left and right but mainly the latter, and the apex beat may reach the axilla Raised systolic pressure and low diastolic pressure give the 'pistol shot' sound on auscultation over the large arteries Rapidly increasing oedema may extend from legs to trunk and face with associated pericardial, pleural, and other serous effusions
Urine	Nocturia; no albuminuria	Oliguria or anuria; no albuminuria or glycosuria

[a] The whole picture of acute fulminating beriberi is dominated by insufficiency of heart and blood vessels and this tends to mask all other features of the subacute form, although these are often present and accentuated. Death is accompanied by a systolic pressure falling to 70–80 mm, the pulse becomes thinner, and the veins dilate. The rough whistling respiration deteriorates and rales appear. The patient dies intensely dyspneic but usually fully conscious.

horizontal), ataxic gait, and an abnormal mental state that can range from mild delirium to global confusion. Liver disease and tachycardia occur in more than 50% of cases. Korsakoff's psychosis is characterized by a profound amnesia, disorientation, and often confabulation. The clinical features of Wernicke–Korsakoff syndrome are listed in **Table 6**.

Management/Treatment

Patients in whom cardiac and renal signs of thiamin deficiency are identified usually respond well to treatment. The dose given and route used will vary with the seriousness of the deficiency. Intravenous doses as high as 250 mg/day for 14 days and intramuscular doses of 25 mg followed by thrice daily oral doses of 10 mg have been reported for wet beriberi and are followed by a marked increase in urinary output and improvement in cardiac function. Peripheral neuropathy (dry beriberi) is more resistant to treatment. Patients with the ocular signs of Wernicke's disease usually respond to two or three daily injections of 50 mg thiamin. Long-term oral treatment of other manifestations of Wernicke–Korsakoff syndrome with doses up to 50 mg/day is reported, although benefit is variable and considerably influenced by patients' ability to avoid further alcohol consumption. It is unlikely that patients receiving oral thiamin will absorb more than 5–7 mg/day, but in patients likely to abuse alcohol, absorption by passive diffusion of high thiamin doses

Figure 1 Patient with dry beriberi showing evidence of motor nerve disturbances resulting in a flaccid paralysis of the extensor muscles and 'wrist drop' and 'foot drop'.

is the only way to ensured that the patient will receive any thiamin. In addition, as in all patients who show evidence of nutritional deficiency, the likelihood of other coexisting deficiencies should not be overlooked and multinutrient treatment is probably desirable.

Table 5 Features of acute infantile beriberi and frequency of occurrence

	Features	*Frequency (%)*
Appearance	Pale and cyanotic appearance, oedematous, ill-tempered with abdominal distension	40
Voice	Hoarseness	80
	Sometimes groaning	50
Digestive system	Vomiting	80
	Dyspepsia	46
Cardiac	Tachycardia, <200 beats/min	83
	Heart dilated	31
	Femoral sound on ascultation	5
Lungs	Rapid breathing	83
	Accentuation of the 2nd pulmonary sound	
Neurological	Tendon reflex usually increased	74
	Less frequently decreased	26
	Convulsions	17
Urinary	Oliguria	65
Other	Slight fever	50
	Uneasiness	50

Finally, it is important to realise that untreated thiamin deficiency can result in sudden death.

Lipid-Soluble Thiamin Derivatives

In recent years, several lipid-soluble derivatives of thiamin have been introduced, of which the best known is benfotiamine. Advantages of these compounds appear to be increased absorption, but by the diffusion mechanism only, and greatly increased transketolase activity. Transketolase is the rate-limiting enzyme of the nonoxidative branch of the pentose phosphate pathway. Benfotiamine has been shown to be useful for the management of rare genetic disorders in thiamin transport and may also prove useful to prevent damage from diabetic hyperglycemia. One study demonstrated that benfotiamine prevented experimental retinopathy. Diabetic hyperglycemia is accompanied by an increase in the potentially pathogenic glycolytic metabolites glyceraldehyde-3-phosphate and fructose-6-phosphate. Benfotiamine, by increasing transketolase activity, stimulates the pentose phosphate pathway to metabolise these glycolytic intermediates into pentose-5-phosphates and prevent the intracellular increase of potentially toxic products.

Case Study

A good example of the specific effect of thiamin in the treatment of beriberi is illustrated by the response of a 29-year-old male who was admitted with an unexplained acute renal failure and had been anuric for 24 h. The physicians' report on his symptoms should be compared with the common clinical features of wet beriberi shown in **Table 4**. The patient's physical state and voice were extremely weak but speech was copious and confused. He complained intermittently of severe central chest and epigastric pain. A central cyanosis was present and he had a respiratory rate of 36 beats per minute. His temperature was normal and peripheries were lukewarm. He had gross generalised oedema. The jugular venous pressure became grossly elevated (**Figure 2**). Pulse rate was 100 beats per minute, regular, and weak at the wrist, although the carotid pulses were visibly bounding. Blood pressure was 80/60. There was a marked parasternal heave present, with a loud pulmonary second heart sound. The chest was clear; the abdomen was obese.

The father reported that the patient's usual beer intake was 6–12 pints daily and his one regular meal was usually no more than a sausage roll or a pie. Prior to admission, for 6 weeks he had felt too

Table 6 Clinical features of Wernicke–Korsakoff syndrome and frequency of occurrence

	Features	*Frequency (%)*[a]
Ocular disorders	Nystagmus (ocular ataxia — rhythmical oscillation of the eyeballs), almost always horizontal and in 50% of cases associated with vertical nystagmus on upward gaze	85
	Paralysis of one or more of the ocular muscles	50
	Sluggish reaction by pupils to light	19
Ataxia (inability to coordinate muscles)	Gait	87
	Legs	20
	Arms	12
	Speech	87
Polyneuropathy	Limbs only affected, mainly the legs only	82
	Of arms and legs	18
	Common symptoms include weakness, paresthesia, pain, loss of tendon reflexes and of sensation and motor power	
	Some cases of foot drop or wrist drop or both	
Cerebral function	Global confusional state, profound disorientation, apathy, deranged perception and of memory, drowsiness, inattentiveness, indifference	56
	Disorder of memory: both retrograde and ante-retrograde amnesia, confabulation	57
	Alcohol abstinence syndrome	16
Cardiac	Tachycardia	51
General medical abnormalities	Disorders of skin and mucous membranes	36
	Redness and/or papilliary atrophy of the tongue	29
	Liver disease	60

[a]Percentages based on 188–245 cases.
Modified from Thurnham DI (1978) Thiamin. In: Rechcigl M Jr (ed.) *Nutrition Disorders*, pp. 3–14. West Palm Beach, FL: CRC Press.

tired to go out in the evening, and for 2 weeks he had suffered epigastric discomfort and had eaten nothing. Eight days before admission, he developed painful calf stiffness and he became too weak to go to work. He had a painful dry cough and dyspnoe on the slightest exertion. Finally, confusion, cyanosis, and intermittent vomiting led to admission.

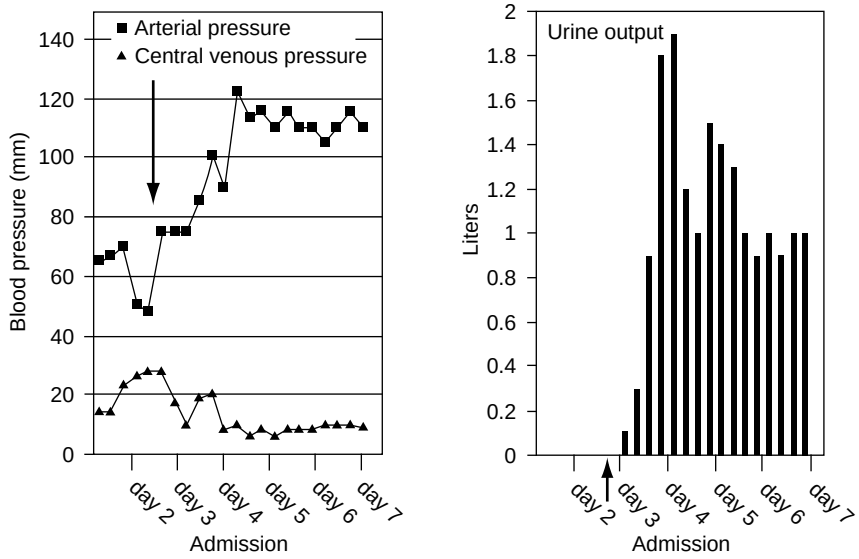

Figure 2 (Left) Arterial and central venous blood pressure and (right) urine output of a patient who was admitted with unexplained acute renal failure in a very weak physical state and whose speech (although very weak) was copious and confused. The patient was discovered to be a regular beer drinker consuming 6–12 pints daily, and his usual food intake amounted to no more than a sausage roll or pie. He had become progressively weaker over the past 8 weeks and had eaten nothing at all in the past 2 weeks. After excluding other diagnoses, it was suspected that the patient had fulminant beriberi and he was treated with thiamin after 36 h. The figures display the rapidly increasing arterial pressure, fall in venous pressure, and a rapid resumption in renal function following thiamin treatment. The patient lost ~20 l of urine during the first 7 days in the hospital. (Modified from Anderson SH, Charles TJ and Nicol AD (1985) Thiamine deficiency at a district general hospital: Report of five cases. *Quarterly Journal of Medicine* **55**: 15–32.)

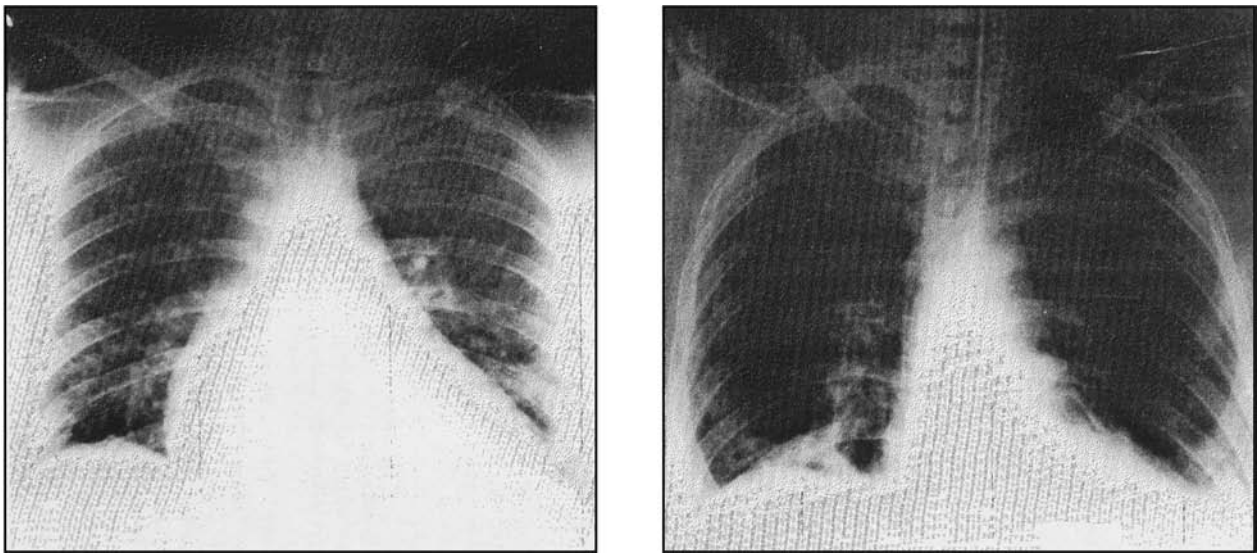

Figure 3 Chest radiographs of the patient described in **Figure 2** obtained on admission (left) and 14 days after high-dose, parenteral thiamin treatment (right). On admission, the heart was grossly enlarged, extending downward and to the right, with a cardiothoracic ratio of 0.63. After treatment for 14 days, the cardiothoracic ratio was 0.44. (Modified from Anderson SH, Charles TJ and Nicol AD (1985) Thiamine deficiency at a district general hospital: Report of five cases. *Quarterly Journal of Medicine* **55**: 15–32.)

The first diagnoses considered were myocardial infarction, pulmonary embolism, and overwhelming septicaemia, and he was placed on dialysis and received appropriate treatments. His lack of response at 36 h, continuing low systolic pressure (70 beats per minute), increasingly gross hyperdynamic precordial signs, and moribund appearance led to a diagnosis of beriberi. Treatment with intravenous thiamin (250 mg for 14 days) brought about a dramatic response (**Figure 2**). Within 6 h peripheral pulses were strong, blood pressure had risen to 105 systolic, and central venous pressure had fallen by half. By 12 h the parasternal heave was less marked and diuresis of up to 6 l per day ensued. After 24 h, plasma urea concentration peaked at 50.4 mmol/l and creatinine at 832 μmol/l, and thereafter there was a steady fall over the next 2 weeks during which thiamin treatment continued and dialysis stopped. He lost a net 20 l of fluid over the first 7 days in the hospital and creatinine clearance 3 weeks after admission was 178 ml/min, indicating a return to normal kidney function. Other biochemical abnormalities resolved over the 2 weeks on high-dose thiamin, including the chest radiograph (**Figure 3**). It is interesting to note, however, that when he was discharged 3 months after admission, he was walking with a calliper because of a right-sided foot drop (**Figure 1**). The persistence of the foot drop is a further indication of the greater difficulty in reversing neurological consequences, in contrast to the cardiac effects, of thiamin deficiency.

Toxicity

Chronic intakes in excess of 50 mg/kg, or more than 3 g/day, are toxic to adults with a wide variety of clinical signs, including headache, irritability, insomnia, rapid pulse, weakness, contact dermatitis, pruritis, and, in one case, death. Early researchers also indicated that regular administration or contact with thiamin occasionally led to allergic response, contact dermatitis, or hypersensitivity.

THIRST

J Leiper, University of Aberdeen, Aberdeen, UK

Role of Thirst in Water Balance

Approximately 70% of the lean body mass of an individual is composed of water, with approximately two-thirds of the total body water (TBW) volume being held within the cells of the body (intracellular pool) and the remaining one-third (extracellular pool) is divided between the circulating blood plasma (intravascular pool) and the fluid-filled spaces between the cells (interstitial pool). The volume and distribution of the body fluids are mainly determined by the amounts of body water and sodium. In man, TBW content is regulated daily to within approximately 0.2% of lean body mass in normal, temperate conditions by factors that control input and output. The kidneys regulate water excretion in excess of the evaporative loss and the fecal and obligatory urine losses. Water intake occurs in the form of food and drink, with the sensation of thirst underpinning drinking behavior.

The mechanisms that monitor the body's hydration status also interact with the thirst control centers in the brain to regulate the desire to drink. This article is concerned with the physiological factors that govern the perception of thirst and how this is altered by drinking.

Perception of Thirst

Thirst is a sensation that is best described as the desire to drink. The reason for drinking may not be directly involved with a physiological need for water intake, but it can be prompted by habit, ritual, taste, nutrients, craving for alcohol, caffeine, or other drug in a beverage, or a desire to consume a fluid that will give a warming or cooling sensation. Much of the perception of thirst is a learned or conditioned process, with signals such as dryness of the mouth or throat initiating drinking, whereas a feeling of fullness of the stomach can stop ingestion before a fluid deficit has been restored.

The thirst response is thought to be regulated by neural modulators that operate as a reward mechanism, integrating the effective requirement for water intake with the sensations of taste and pleasantness of the fluid ingested. Thus, when the individual is hypohydrated multiple areas of the brain are activated, promoting the intensity of the thirst sensation. As the water deficit is restored the feeling of thirst diminishes and this subjective sensation correlates well with a reduction in neural activation. However, areas of the brain associated with taste that are activated by water when thirsty remain as active following drinking to satiety when water is ingested.

Although it is true that thirst in man is a poor indicator of acute hydration status and that daily fluid intake is normally in excess of obligatory water loss, the preservation of TBW volume under a variety of environmental and nutritional stresses is remarkably robust and is mainly due to the drive to drink, which the sensation of thirst chronically provokes.

Assessment of Thirst

In humans two main techniques have been used to identify the perception of thirst and its alleviation by drinking. The first method is to monitor the volume

of drink voluntarily ingested by an individual within an allotted time period and to compare the amount drunk with the volume of fluid required to restore a given water deficit or other imbalance of the body water pools. The other method is to assess the individual's perceived rating of thirst by asking him or her to record on a visual analog scale his or her responses to a series of questions that are thought to relate to the sensation of thirst (**Figure 1**). The questionnaire technique has the advantages that it allows a series of measurements to be made before, during, and following the period of drinking, and it appears to give an indication of the relative strength of a given stimulus. Although in many studies both methods are used to gauge the sensation of thirst and the responses have been correlated to a number of physiological parameters that are known to influence the drive to drink, it is widely recognized that there is no consistently reliable measure of the thirst sensation.

A more recently introduced technique has been the use of noninvasive methods of imaging to identify the specific regions of the brain that are activated during the genesis and satiation of the thirst response. Different techniques are used to image brain activation. Positron emission tomography and functional magnetic resonance imaging are both being used to visualize brain activation by detecting either temporal changes in blood flow or changes in the chemical composition of regions in the brain that occur when individuals are exposed to specific stimuli. The number of brain regions, their

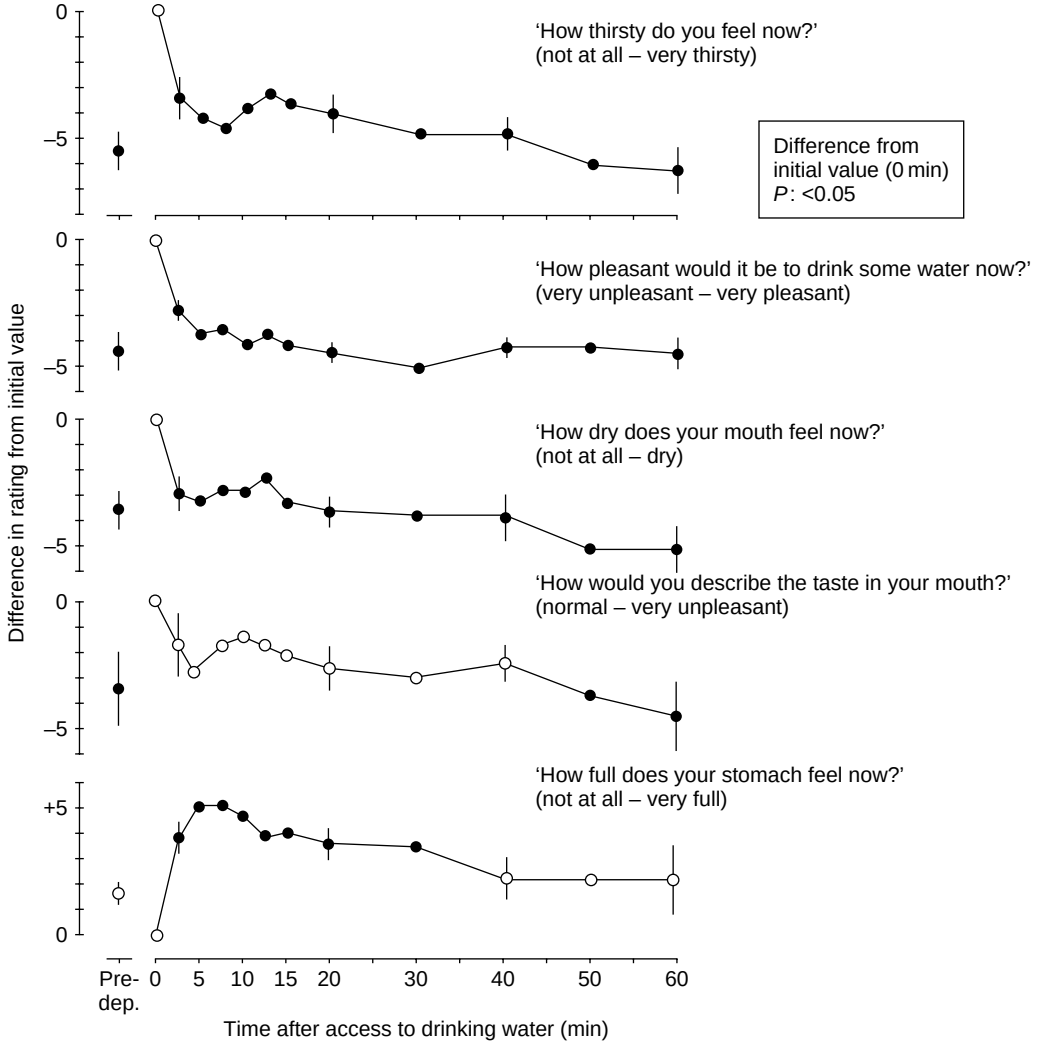

Figure 1 Subjective responses to a series of five questions assessed by visual analog scale ratings from individuals deprived of water for 24 h. Questions were asked before and during a 60-min rehydration period. The data are shown as differences (in cm) from initial values and significant differences are indicated by filled symbols. (Redrawn with permission from Rolls BJ, Wood RJ, Rolls ET *et al.* (1980) Thirst following water deprivation in humans. *American Journal of Physiology* **239**: R476–R482.)

specificity, and the intensity of activation has also been correlated with the subjective perception of thirst.

Physiological Regulation of Thirst

Because thirst is the major factor controlling water intake, the physiological regulation of thirst is associated with the need to maintain a relatively stable volume of TBW. Although water is lost from the body continually, albeit usually in relatively small amounts, and hence the body is almost always developing a water deficit, water intake is intermittent. The amount of fluid usually ingested is in excess of that required to replace the losses incurred since the last water intake. The factors that initiate, maintain, and end the drinking response are various and are not fully understood. However, because the regulation of the volume and composition of the various water pools of the body play an essential role in controlling the perception of thirst, an understanding of the homeostatic mechanisms involved has given us the best insight we have into the complexities of the perception of thirst.

The total volume, distribution, and composition of body fluids must be regulated within narrow limits for normal cellular function to be maintained. Body water is passively distributed between the extracellular and intracellular pools according to osmotic, oncotic, and hydrostatic forces as shown in **Figure 2**. The sodium and chloride contents of the extracellular fluid constitute the two greatest osmotically active components of this fluid and are therefore important in maintaining its volume. Potassium, phosphate, and protein fulfill a similar role in regulating the intracellular fluid volume. The distribution of water between the intravascular and extravascular pools is dependent on the balance of hydrostatic and oncotic pressures across the capillaries and postcapillary venules.

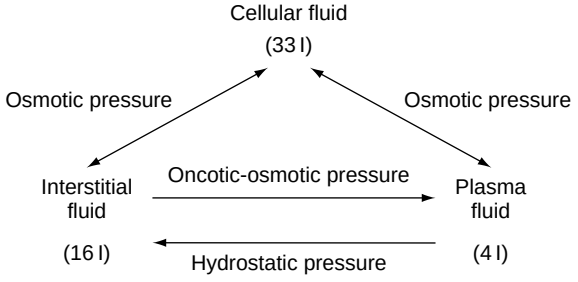

Figure 2 Diagramatical representation of the forces that regulate the distribution of the body water pools. The volumes given are those determined in a single male subject with a lean body mass of 75.8 kg.

Variation in the water-to-solute ratio of a body fluid pool results in changes in the tonicity and hence effective osmolality of the fluid. Because the various body water pools are in dynamic equilibrium with each other (**Figure 2**) there is a tendency for adjustments to occur throughout the body as water moves from regions of low solute concentration to those of higher solute concentration. Changes in plasma osmolality are relatively easy to monitor; therefore, there is a tendency to equate changes in the circulation as the effector of fluid balance control. However, it is important to remember that any alteration in one body pool will affect the others and that receptors that initiate responses affecting water balance may reside at sites far removed from the circulation.

Loss of water from the body or an increase in the circulating solute concentration cause an increase in the osmolality of primarily the extracellular fluid; water then moves into the extracellular space from the cells producing a reduction in cell volume. Changes in plasma osmolality are therefore thought to be signaled to the effector mechanisms by changes in the cell volume of specific specialized cells, collectively termed osmoreceptors. Because the main solute determining the tonicity of the extracellular fluid is sodium, there has been debate about whether the receptor cells detect changes in osmolality or changes in sodium ion content. The evidence suggests that at least the majority of the receptors respond to osmolality rather than to sodium concentration. These osmoreceptors have a regulatory role not only in the perception of thirst but also in the maintenance of the circulating levels of hormones that regulate the excretion of water and solute by the kidneys (**Figure 3**). Because increases in the extracellular osmolality effectively decrease the volume of the cells in the body, this form of dehydration is termed cellular dehydration.

Alteration in the volume of the extracellular fluid pool without changes in its osmolality also affects the fluid balance hormone concentrations and the sensation of thirst. Changes in the volume of blood in the circulation affect the blood and capillary pressures and atrial filling pressure. The effect on capillary pressure will tend to redistribute body water and help to adjust the circulating fluid volume, and the change in venous return to the heart will alter the cardiopulmonary and arterial stretch receptor (baroreceptor) activity. The level of afferent activity from these baroreceptors directly affects both the sensation of thirst and the secretion of some fluid balance hormones. Additionally, modifications to the arterial blood pressure can directly affect renal perfusion, which together with

baroreceptor activity to the kidneys regulates the renin–angiotensin system (**Figure 4**). Although the effect on the kidneys can influence the perception of thirst, the main renal response is to regulate urine water and solute excretion. A decrease in the volume of the extracellular pool with no concomitant change in plasma osmolality is termed extracellular dehydration.

When humans are given access to fluids after the development of a water deficit, their drinking response usually follows a pattern of rapid ingestion of more than 50% of the total intake followed by intermittent consumption of relatively small volumes of drink over a longer period. Although initiation of the response to drink is due mainly to osmotic or blood volume (volemic) changes, there appear to be

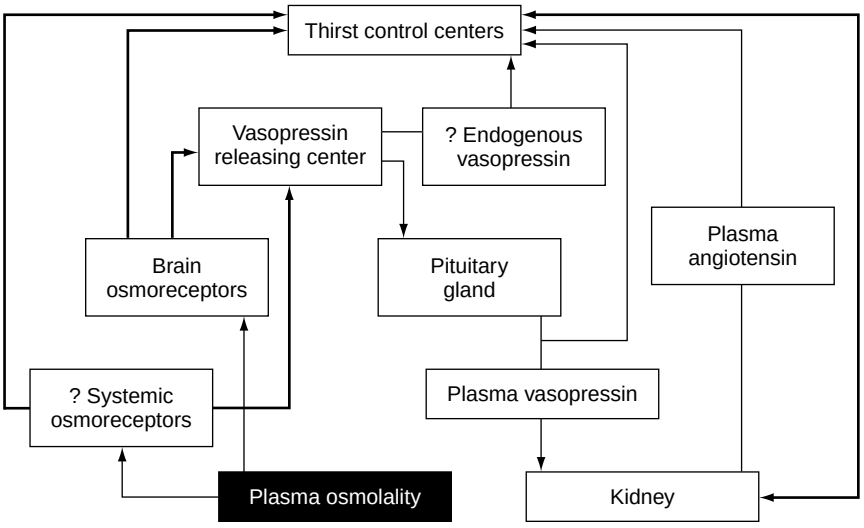

Figure 3 Schematic representation of the main factors proposed in osmotically induced regulation of the sensation of thirst and their interaction with the control of diuresis. A rise in plasma osmolality will tend to stimulate greater excitatory activity, whereas a decrease in osmolality will activate more inhibitory inputs. Neural pathways are indicated by thick arrows and hormonal input by thin arrows.

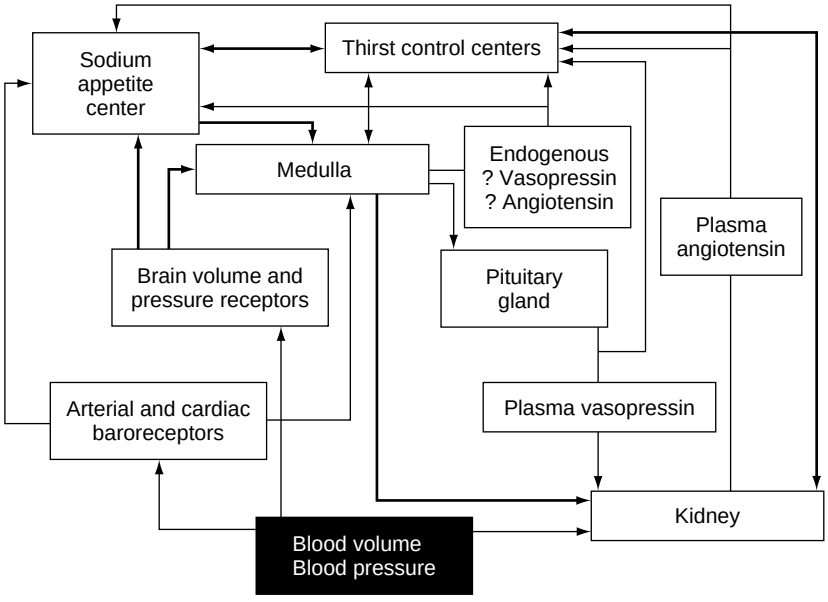

Figure 4 Schematic representation of the main factors proposed in volemic-induced regulation of the sensation of thirst and their interaction with the control of diuresis and sodium appetite. A fall in circulating blood volume will decrease baroreceptor activity, which will increase excitatory activity, whereas a rise in volume will have the opposite effect. Reduction in blood pressure will decrease renal perfusion, which will activate the renal renin–angiotensin system. Neural pathways are indicated by thick arrows and hormonal input by thin arrows.

other mechanisms involved in the control of the continuation and satiety responses. Receptors in the mouth, oesophagus, and gastrointestinal tract appear to be major factors in the acute regulation of thirst satiation, with the effects that the volume and solute content of the ingested drink have on restoring the fluid deficits controlling the chronic regulation of thirst (**Figure 5**). There is a close relationship between eating and drinking, with approximately 70% of daily fluid intake normally being associated with meals (**Figure 6**). The desire to drink while eating is probably produced by a series of responses, including the mechanochemical composition of the food before absorption, the neuroendocrine response to digestion, the movement of water into the intestine during digestion, and the osmotic solute load that occurs following absorption. The intake of minerals is essential to replace those lost from the body and for growth. The majority of mineral intake is supplied by the food ingested, and indications of a desire or appetite for ingesting specific minerals have been shown in animals and man. Although sodium appetite has been linked to the sensation of thirst, anatomically and functionally the controlling mechanisms are distinct and separate.

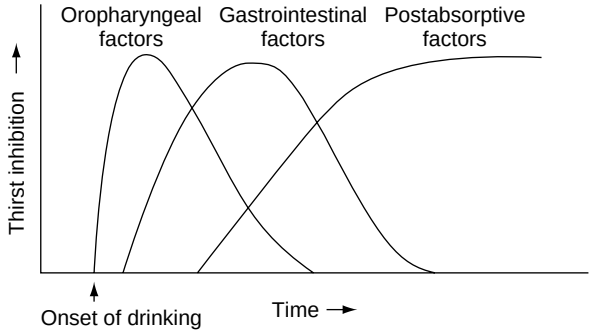

Figure 5 Schematic diagram depicting the proposed onset, duration, and overlap of various inhibitory signals to continue fluid ingestion following initiation of drinking in response to a fluid deficit. London: Springer-Verlag.)

Mechanisms of Thirst Regulation

The sensation of thirst is regulated separately by both the osmotic pressure and the volume of the body fluids and as such is closely related to the control mechanisms that are responsible for the secretion of the fluid balance hormones, which affect water and solute reabsorption in the kidneys and play a role in blood pressure control. These hormones—arginine vasopressin, atrial natriuretic peptide, oxytocin, and the renin–angiotensin–aldosterone system—are central to the regulation of thirst. The hypothalamus and forebrain appear to be the main areas involved in the control of thirst and antidiuresis, and collectively these parts of the brain have been termed the

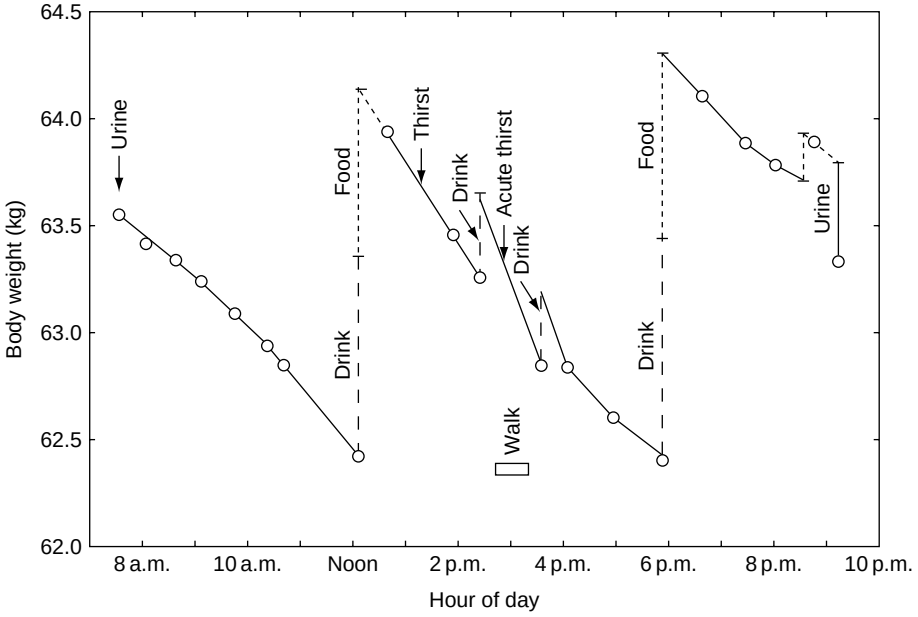

Figure 6 Changes in body weight during 13 h in the desert. The majority of the volume of drink ingested was associated with food intake. Sweat loss varied from 150 to 700 ml/h, and total fluid intake was 3.05 l. At the end of the period body mass was essentially the same at the beginning and end of the day; therefore, water intake and output were equal. (From Adolph ED, *Physiology of Man in the Desert*. thirst control centres. Neurons that are responsive to changes in osmolality, intravascular volume (volemia), and blood pressure are found within these areas of the brain, as are other receptors that are responsive to many of the fluid balance hormones. Neural pathways from the thirst control centers and the kidneys may allow some direct integration between the control of thirst and excretion, whereas within the brain all of the major fluid balance hormones are present as neurohormones. Afferent input from systemic receptors monitoring osmolality, circulating sodium concentration, and changes in intravascular volume and pressure also have roles in controlling the feeling of thirst. Therefore, there appears to be a complex integrated system for both monitoring the status of the body water pools and controlling intake and excretion (**Figures 3** and **4**). Many of the regulatory mechanisms controlling water balance appear to overlap, with several stimuli appearing to subserve the same response; however, it is assumed that this effect is required in order to ensure that the blocking of one type of stimulus will not prevent homeostatic control.

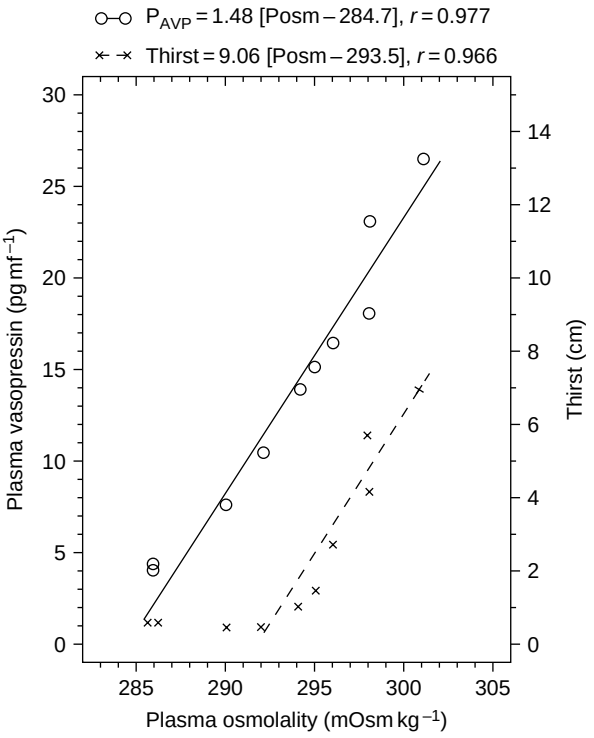

Figure 7 The relationship of plasma vasopressin (o) and thirst (×) to plasma osmolality in a volunteer during infusion of 5% saline. (Redrawn with permission from Robertson GL (1984) Abnormalities of thirst regulation (Nephrology forum). *Kidney International* **25**: 460–469.)

Osmotic Regulation of Thirst

The osmolality of circulating plasma is normally maintained within a very narrow limit between 270 and 295 mosmol/kg, with the circulating levels of the antidiuretic hormone arginine vasopressin playing a major role in its homeostatic regulation. An increase of as little as 2 or 3% in plasma osmolality is sufficient to produce a strong sensation of thirst and a significant increase in circulating arginine vasopressin concentration (**Figure 7**). The osmoreceptors that monitor the tonicity of the body pools appear to reside mainly in an area of the brain that lacks a blood–brain barrier; therefore, they appear to respond mainly to changes that occur in the osmolality of the blood rather than in the cerebral interstitium. Although the changes in the circulating levels of arginine vasopressin and the perception of thirst appear to parallel one another, it is unlikely that the same receptors are responsible for both responses. It is likely that there are different neurons that react to the same stimulus. However, there may be some neurohormonal interaction between the osmotically activated thirst centers and the 'vasopressin-releasing center' in the brain, and arginine vasopressin-responsive neurons have been detected within the thirst centers (**Figure 3**).

The current theory of the osmotic control of thirst suggests that there is constant output of both inhibitory and excitatory neural activity from the respective osmoreceptors to the thirst centers and the arginine vasopressin-releasing centers. Within the normal range for plasma osmolality, the inhibitory and excitatory activities in the thirst centers effectively cancel out one another and there is neither a sensation of thirst or satiety. However, at this level of activity there is release of a basal level of arginine vasopressin that is sufficient to maintain a state of half-maximum antidiuresis. A rise in plasma osmolality above the normal level stimulates greater excitatory output causing an increase in the feeling of thirst and higher levels of circulating arginine vasopressin. Raised levels of arginine vasopressin increase the concentrating ability of the kidneys. A decrease in plasma osmolality below the normal range increases the inhibitory output producing a feeling of satiety, and arginine vasopressin release is suppressed allowing urinary dilution (**Figure 3**).

Cells and fibers within the brain have been shown to contain several hormones, including angiotensin and vasopressin, within the same cell. Although neurons associated with the thirst centers can be activated *in vitro* by vasopressin, it is not clear whether peripheral- or neural-generated arginine vasopressin levels influence the perception of thirst.

Volemic Regulation of Thirst

The receptors that initiate hypovolemic thirst are generally thought to be the cardiovascular baroreceptors, which respond to underfilling of the circulation by reducing their inhibitory nerve impulse activity to the thirst centers. However, in areas of the brain associated with the thirst centers there are neurons that are separately responsive to volemic, pressure, and osmotic changes. This suggests that at least part of the response to changes in blood volume originates in the brain. It is thought that changes in blood pressure and osmolality are monitored mainly within the brain, whereas variations in blood volume are principally sensed by the peripheral baroreceptors, with a degree of overlap between the different receptors. The mechanisms that respond to changes in intravascular volume and pressure appear to be not as sensitive as those responsive to osmotic changes; for example, a decrease of approximately 10% of the plasma volume is required to initiate hypovolemic thirst. Because fairly large variations in blood volume and pressure occur during normal daily activity, such as postural changes and physical activity, this apparent lack of sensitivity presumably prevents overactivity of the volemic control mechanisms. As with osmotic thirst, the control of volemic thirst is thought to be a balance between continuous inhibitory and excitatory neural activity, although in this system the basal level appears to be essentially inhibitory. Another difference in the basic control mechanism between the two systems is due to the requirement for both solute, mainly sodium, and water to restore the extracellular volume. Therefore, extracellular dehydration causes an initial thirst and a delayed increase in sodium appetite.

Reduction in the intravascular volume sufficient to lower cardiac output and arterial blood pressure decreases afferent activity from the low- and high-pressure cardiovascular baroreceptors to the thirst centers and increases sympathetic activity to the kidneys. Because afferent input from the baroreceptors to the thirst centers is inhibitory, a decrease in activity produces a reflex increase in the perception of thirst and also appears to directly stimulate arginine vasopressin release. The increase in sympathetic activity to the kidneys directly promotes greater renal renin release. In addition, reduction in blood pressure lowers the renal perfusion pressure, which stimulates renin release both as a direct pressure effect and by decreasing the delivery of sodium to the kidneys.

Increased activation of the renin–angiotensin–aldosterone system also helps regulate hypovolemic thirst. While circulating levels of both vasopressin and aldosterone affect water and sodium reabsorption in the kidneys and thereby control water and solute loss, angiotensin acts directly on the thirst and sodium appetite centers to stimulate their respective responses. Neurons that are stimulated by angiotensin are found in areas of the brain that lack a blood–brain barrier; therefore, circulating angiotensin has direct access to both centres. In addition, the release of neurally generated angiotensin is promoted by suitable neuron activity responding to sensory stimuli (**Figure 4**).

There are a variety of neural and hormonal responses that interact to modulate and control both thirst and urine excretion. A number of other hormones, including oxytocin, atrial natriuretic peptide, tachykinins, neuropeptide Y, thyroid hormones, corticotrophin-releasing factor, and steroid hormones, have also been shown experimentally to affect the drinking response. Under normal conditions of water and solute loss, both osmotic and volemic dehydration occur; therefore, stimuli from receptors for both systems are usually involved in the sensation of thirst. Increases in extracellular osmolality appear to be more effective than hypovolemia in promoting the thirst and hence drinking response. More than 70% of the stimulus to drink appears to be generated by increased osmolality.

Sensory Regulation of Thirst

The sensations of a dry mouth or desire for a specific taste or effect also generate the desire to drink when there may be no physiological requirement to drink. A dry mouth promotes changes in neural activity in the parahippocampus, amygdala, thalamus, cingulate, insula, allocortex, and transitional cortex of the brain. This finding has strengthened the hypothesis that the perception of thirst is a primitive vegetative function that appeared long before vertebrates evolved.

Drinking water activates areas of the anterior insular and frontal opercular cortex that are also involved in the perception of taste. Areas of the orbitofrontal cortex are also activated by the ingestion of water or sweet or salty tastes, but activation is greatest when subjects are thirsty and it diminishes when subjects have drunk water to satiety. This has been interpreted as functionally separate areas of the brain, one of which responds to taste stimuli that are not diminished following drinking to satiety, whereas the other is highly active during drinking when water is physiologically required but reduces as the need for water is met.

Mechanisms for Terminating the Sensation of Thirst

Although undoubtedly decreasing osmolality and increasing extracellular volume promote a reduction in the perception of thirst by reactivating inhibitory neuron activity, usually there is a decrease in the perception of thirst and termination of drinking before circulating osmolality, volume, and hormonal levels have returned to predehydration levels. Although it could be argued that receptors in the brain may be responsible for the early cessation of the perception of thirst, the majority of the evidence suggests that it is receptors in the upper gastrointestinal tract that promote the early termination of drinking. Although the nature and neural connections of these proposed receptors have not been fully characterized, most appear to have an inhibitory response. It has been suggested that because much of the thirst and drinking response is behavioral, an individual learns what volume of drink is required to restore a given water deficit. Termination of drinking therefore could be a learned response that anticipates a future fluid deficit or matches a known current level of dehydration. The stimuli for gauging the current level of dehydration may be the same as that which initiates the sensation of thirst.

The mere presence of liquid, particularly cold liquid, in the mouth reduces the perception of thirst. Receptors in the mouth and oesophagus responding to different chemical, tactile, pressure, and temperature stimuli are thought to be part of the mechanism that influences the relative intensity of the perception of thirst. The neural activity involved in swallowing and perhaps oropharyngeal and gastric receptors are thought to be effective in sensing or metering the volume of liquid ingested. Distension of the stomach tends to inhibit drinking due to increased gastric stretch receptor activity, although this response does not always reduce the perception of thirst. Taste and other psychological factors can have a stimulatory effect on consumption of a drink that is considered to be palatable.

The continuation and termination of the acute sensation of thirst are regulated by a series of stimuli that operate before all of the drink consumed has been absorbed and before disturbances in the body water pools have been corrected. A variety of receptors located from the mouth to the upper part of the small intestine, and probably neural control from the higher centers of the brain, appear to monitor and regulate the initial volume consumed. After absorption, if restoration of body water pools does not occur the sensation of thirst is once again initiated, presumably by the same homeostatic stimuli that initially evoked the feeling of thirst, and drinking restarts. The integration of the pre- and postabsorptive stimuli modulates the sensation of thirst and finally the volume of drink consumed.

Fluid Requirements

Renal reabsorption can reduce the volume of water and solute loss and hence slow the rate of progress of a fluid deficit, but it cannot stop its development. Intake of fluid either as food or as drink is required to restore a fluid deficit. Daily fluid intake is highly variable between individuals and the rate of loss is dependent on factors such as environmental temperature, physical activity, sweating rate, antidiuretic function, and dietary solute load. A representative normal daily water turnover in a sedentary individual living in a temperate climate and eating a typical Western diet is approximately 2 or 3 l, and a minimum daily fluid intake of approximately 1.7 l is necessary to conserve fluid balance. The water content of the typical Western diet approximates to about 1 l and metabolically derived water produces in the order of approximately 300 ml, which together almost offset the daily obligatory water loss. Therefore, in many situations the requirement for fluid intake can actually be very low.

There are conditions in which water loss is greater than that indicated previously and replacement obviously requires a compensatory increase in daily fluid intake (**Figure 6**). Urine volume is related to the solute content of the diet, with a minimum volume of approximately 500 ml being necessary to eliminate the daily solute load. Diets rich in protein or foods with high sodium content require a greater obligatory urine output for excretion. The renal concentrating ability at maximum antidiuresis determines the minimum urinary water loss for a given dietary solute load. Normally, there is a wide range of urinary osmolality such that the same solute load can be excreted in 500 ml of urine with an osmolality of 1400 mosmol/kg or in 23 l of urine with an osmolality of 30 mosmol/kg. This feature of renal excretion allows body water balance to be maintained while fluid intake volume is varied.

Prolonged relatively intense muscular activity, elevated ambient temperature, and fever all increase the rate of evaporative sweat loss. Individual sweat rates are highly variable, but daily losses of between 10 and 15 l have been recorded. Daily faecal losses associated with a Western diet are usually between 100 and 200 ml; however diarrhea, particularly infectious diarrhea, can produce prodigious fecal water losses that are potentially fatal.

Inappropriate fluid intake can be produced following lesions or development of tumors in regions of the brain associated with the thirst centers. Diabetes insipidus promotes an increase in the volume of fluid ingested, which is caused by a lowering of the basal threshold set point for osmotic thirst. A similar, although less pronounced, lowering of the osmotic thirst threshold occurs during pregnancy. In both the young and the elderly, the thirst response can be blunted and inappropriate drinking habits may occur. Psychogenic disturbances in the sensation of thirst and hence fluid intake have also been reported for a variety of clinical conditions.

Published by Elsevier Ltd.

The oral traditions of medicine and public health state that malnutrition is an important risk factor for the development of tuberculosis (TB). Malnutrition profoundly affects cell-mediated immunity (CMI), and CMI is the principal host defense against TB. It makes biological sense. Although most health professionals readily accept this principle, much of this belief is based on uncontrolled observations such as disaster situations or on backwards logic from the cachexia common among TB patients. In fact, the evidence in humans is surprisingly thin from the perspective of scientific rigor. Also, few data, if any, quantify the extent of the relative or attributable risk of TB due to malnutrition. Moreover, data from experimental animals, until recently, were based on animal models that largely were not relevant to human TB infection and disease. Malnutrition may account for a greater population-attributable risk of TB than HIV infection, and certainly a much more correctable one.

Malnourished individuals have an increased likelihood of primary or latent infection progressing to active disease. In populations with substantial latent TB infection, the occurrence of malnutrition may be an important determinant of the incidence of TB. The potential public health impact of malnutrition on the global incidence of TB was summarized in the US Surgeon General's 1988 *Report on Nutrition and Health*, which emphasized that malnutrition was the leading cause of acquired, correctable immune system dysfunction throughout the world. The United Nations Food and Agriculture Organization (FAO) estimated that 841 million people in developing countries, or 20% of the world's 1990–1992 population, were undernourished. Modest decreases in resistance affecting such large numbers of people may result in substantial increases in TB incidence at a population level. Population groups at highest risk for poor nutrition are also at high risk for TB, with poverty being the common denominator.

In general, there are three streams of evidence relating the risk of TB to malnutrition: observations in humans, experimental work in animal models, and inferences from related work in microbiology and immunology. In humans, direct evidence for the risk of TB due to malnutrition is sparse, and the data have not been reviewed critically in more than three decades. *In vitro* studies have generated a substantial body of evidence documenting the negative effects of malnutrition on cell-mediated immune function and on the immunology of TB. Although one can reason from the *in vitro* evidence, it cannot replace *in vivo* data. This article summarizes the evidence from observations in human populations and from experimental animal models with relevance to human TB.

TB risk is of two kinds: the risk of becoming infected with *Mycobacterium tuberculosis* and the risk of the infection progressing to TB disease. This article focuses on the risk of infection progressing to disease because that is where CMI comes into play. There is no evidence of a direct relationship between malnutrition and the risk of initial infection. Although both TB and malnutrition are linked with poverty, the data reviewed here suggest no independent association between malnutrition and primary or latent TB infection.

Human Data

Ecological Studies

Ecological studies present fairly convincing evidence that nutrition, isolated to some extent from other historical circumstances, has played a direct role in TB morbidity and mortality. In 1938, Faber reported on TB epidemiology in Denmark during World War I. For most of the war, neutral Denmark exported the bulk of its meat, fish, poultry, and dairy products to the extent that the local diet lacked these protein-, vitamin-, and mineral-rich foods. TB rates increased

as in the warring countries. The German blockade of Denmark in 1918, however, created a surfeit of these foods and TB rates plummeted. In contrast, TB rates in the neighboring warring countries continued to increase unabated.

The second study involves the Trondheim, Norway, Naval Training School, where the high rate of TB among recruits in the early twentieth century was ascribed to crowded, poor housing and unhygienic conditions. In 1954, Leitch reported that TB rates did not decrease after improved housing and hygiene were provided. Subsequently, the diet was fortified with milk, margarine, cod liver oil, whole wheat bread, and fresh fruits and vegetables. TB morbidity promptly declined to the prevailing level for young adults of that area.

The third important contribution to the early literature was Leyton's study of TB morbidity among British and Russian prisoners of war (POW) held in German POW camps during World War II. The prisoners shared the same diet, but the British received Red Cross food supplements amounting to 30 g protein and 1000 kcal per day. In a subsequent radiographic survey, the TB rate among the British was only 1.2% and their plasma proteins were higher than those of the Russians, who had a TB rate of 15–19%. Both groups shared the same living and working conditions and had the same chance for infection. In the malnourished prisoners, TB was more severe, the onset was more rapid, and patients died rapidly with large pulmonary cavities and massive tissue breakdown. Granuloma formation was poor in the malnourished prisoners, supporting the idea that there was a deficit of CMI in this group.

Lastly, McKeown's seminal work in the 1950s and 1960s elaborated on the concept that the decline in TB mortality in England and Wales from 1770 to 1900 was most likely due to improving standards of living in general and to the nutritional status of the population in particular. Through extensive critical reasoning, McKeown excluded the alternative explanations: (i) advances in medicine and medical effort or (ii) natural selection. What remained, according to McKeown, was that the environment and thereby the resistance of the host improved. The death rate from TB at the beginning of the nineteenth century was approximately 40/1000 person-years. It declined to 14/1000 person-years by the end of the century and accounted for nearly half of the overall decline in mortality in the nineteenth century. McKeown concludes, "Having confidently excluded therapy and genetic selection, with reservations, we are left with changes in the environment as the most acceptable reason for the trend of mortality from tuberculosis." Of the features of the environment to be considered, "the evidence in respect of diet seems ... highly suggestive."

Case Series

Nutrition, immune function, and infection interact in complex and dynamic patterns. Protein–energy malnutrition compromises CMI and increases susceptibility to or severity of infections. Conversely, infection can rapidly lead to nutritional stress and weight loss, thereby worsening nutritional status and immunologic function. Therefore, understanding the temporal relationship between the onset of malnutrition and the development of the infectious disease is crucial in order to correctly assess any possible cause–effect relationship.

Since 1968, several case series of postsurgical patients undergoing intestinal bypass surgery for morbid obesity have provided observational data in which nutritional status and incident cases of TB were observed in the same individuals in the correct temporal sequence. These patients experience rapid weight loss and malabsorption due to their short-circuited bowels. In several series, the incidence rate of TB was 1–4% among postoperative patients throughout various durations of follow-up. This range was much higher than expected based on historical or population comparisons. Similarly, partial gastrectomy for ulcer disease was shown to predispose men to TB, but the association was 14 times more likely for men whose weight was $<85\%$ of ideal than for men whose weight was normal for their height. Although the patients in these series do not represent persons at risk for TB in general, and there are no contemporaneous controls, the observations are worth noting due to the sharply increased incidence of TB following nutritional insult.

Cross-Sectional and Case–Control Studies

Cross-sectional and case–control studies generally suffer from the same inherent fatal flaw: Patients with and without TB disease are compared in terms of their concurrent nutritional status. However, TB causes wasting, depression of the immune system, and other changes resembling malnutrition. Therefore, the intrinsic uncertainty regarding the sequence of cause and effect in case–control and cross-sectional study designs becomes intractable. Although these studies demonstrate substantial macro- and micronutrient deficits in TB patients, one cannot infer a causal role for nutritional deficiency in the development of disease from these data because the chronological sequence is unclear and TB plays a role in the development of the nutritional deficits.

Two cross-sectional studies on vitamin D metabolism in relation to TB focused on the molecular and cellular mechanisms of the interaction rather than on the direction of causality. These studies examined the dynamics of $1,25(OH)_2$ vitamin D_3 in lymphocytes and macrophages from patients with TB compared to patients without TB. Investigators determined that lymphocytes obtained by bronchoalveolar lavage from patients with TB expressed specific receptors for $1,25(OH)_2$ vitamin D_3 but not 25(OH)D3. These were primarily $CD4^+$ T lymphocytes. Peripheral blood lymphocytes did not express these receptors. Furthermore, uncultured cells recovered by bronchoalveolar lavage and blood mononuclear cells from normocalcemic patients with TB both produced $1,25(OH)_2$D3. The amount correlated with the number of $CD8^+$ T lymphocytes present but not other cell types. Purified T lymphocytes from all patients with TB produced $1,25(OH)_2$D3, which correlated closely with that produced by unseparated lavage cells. Since $1,25(OH)_2$D3 can improve the capacity of macrophages to kill mycobacteria, these results support the conclusion that cellular interactions mediated in part by $1,25(OH)_2$D3 may be important in the antituberculosis immune response. These data are consistent with those for experimental animals noted later.

Cohort Studies

Very few follow-up studies have been performed with the explicit purpose of understanding the relationship between nutrition and the incidence of TB. The unique strength of cohort studies is that nutritional status is measured prior to the onset of TB.

Only two cohort studies have examined the relationship between micronutrients and TB incidence; both of these included vitamin C. In the 1940s, Getz and coworkers followed 1100 men who were free of TB at baseline, by clinical and radiographic criteria, for up to 5 years with serial clinical, radiographic, and laboratory examinations. Among 16 men who developed TB, blood levels of vitamins A and C were consistently lower than those of men who remained free of TB. Plasma vitamin A levels were low in 13 of 16 men who developed TB compared to 30% (318/1058) of those who did not. Similarly, plasma vitamin C levels were low in all of the subjects who developed active TB compared to only 11% (117/1013) of those who did not. Exposure to TB did not differ between the men who developed TB and those who did not.

Investigators in Finland randomized 26 975 healthy male smokers aged 50–69 years to supplementation with tocopherol, β-carotene, both, or neither. The subjects were followed for a mean of 6.7 years for diagnoses of cancer identified through a registry of all hospital discharges and the associated diagnoses in the region. Hemilä and coworkers analyzed the dietary data in this cohort for vitamin C and vitamin C-rich foods and the discharge registry for diagnoses of TB. In more than 173 000 person-years of follow-up, 167 cases of TB were detected. Higher intake of fruits and vegetables was associated with lower risk of TB. Among those with increased intakes of vitamin C and fruits and vegetables, the adjusted relative risk of TB decreased to 0.4 (95% confidence interval, 0.24–0.69). This study is noteworthy for its size and quality of data. However, detecting TB through hospital discharges selects TB patients who were sick enough to require hospital admission. Lower intakes of fruits and vegetables and of vitamin C may be associated with higher rates of hospitalization rather than higher rates of TB.

Regarding macro indicators of nutritional status, as part of the long-term follow-up of participants in the large-scale BCG vaccine trials in Georgia and Alabama, Comstock and Palmer reported that the incidence of TB was 2.2 times higher in children with 0–4 mm subcutaneous fat than in those with 10 mm subcutaneous fat. Cegielski examined the relationship between undernutrition and the incidence of TB based on data from the first National Health and Nutrition Examination Survey (NHANES-1) and the NHANES-1 Epidemiological Follow-Up Study (NHEFS). NHANES-1 was a cross-sectional survey of a representative sample of the US population from 1971 to 1975. In the NHEFS, the adult subjects of NHANES-1, aged 25–74 years at baseline, were followed up longitudinally with serial waves of questionnaires and examinations. Follow-up exceeded 95%. Through 1987, 64 cases of TB were detected. In proportional hazards analysis, having body mass index, average skin-fold thickness, or upper arm muscle area in the lowest decile of the population increased the adjusted hazard of TB from 6- to 10-fold, controlling for other known risk factors for TB.

Palmer's group studied the relationship of TB incidence to naturally acquired delayed-type tuberculin sensitivity among US Navy recruits. Nearly all Navy recruits from 1949 to 1951 were skin tested and followed longitudinally. Of 68 754 subjects with follow-up data, tuberculin sensitivity was recorded as >0 mm for 8704 (12.7%). During 4 years of follow-up, 109 developed TB: $28/10^5$ among those with 0 mm skin test reactions, $29/10^5$ among those with 1–9 mm reactions, and $157/10^5$ among those with 10 mm or greater reactions. Later, these investigators related the risk of

TB to 'body build' by obtaining height and weight data from the entrance medical examination on a stratified random sample of 1138 subjects. A weight–height index was constructed based on deviation of weight from the median weight-for-height of the study sample. There were no significant differences in tuberculin sensitivity by weight, height, or weight–height index. In contrast, the weight–height index was strongly associated with TB incidence: TB incidence was $75/10^5$ for those 15% or more below the median weight for their height and decreased to $19/10^5$ for those at least 5% overweight for their height ($p < 0.01$ for both purified protein derivative (PPD) groups). The trends were the same regardless of the degree of tuberculin sensitivity, although incidence rates were higher among those with 10 mm PPD reactions. Edwards extended Palmer's study to more than 823 000 Navy recruits and found that TB developed three times more often in young men 10% or more below their ideal body weight than in those 10% or more above it.

Curiously, these authors avoid any reference to inadequate nutrition in the recruits. Instead, they conclude that the results demonstrate an association between body build and TB disease, that some unknown factor associated with body build is an important determinant of host susceptibility to TB disease but not to primary infection. A small but consistent body of literature has accumulated on the relationship of body build to TB and was reviewed by Snider in 1987. One study stands out. The country of Norway attempted to screen all people older than age 14 years for TB with compulsory mass miniature radiography from 1963 to 1975. This screening program covered 42–85% of the population, varying by age group. Height and weight were measured accurately for approximately 80% of those screened. From these data, Tverdal reported results from more than 1.7 million Norwegians, with follow-up via the national notification system through 1982 (i.e., 8–19 years of follow-up; mean, 12.1 years). A total of 2531 incident cases of TB were identified. The incidence of pulmonary TB, both sputum smear positive and smear negative, declined logarithmically with increasing body mass index (BMI) for both sexes, all age groups, and at all durations of follow-up: The age-adjusted incidence of new pulmonary TB was five times higher in the lowest BMI category than in the highest. This relationship was not observed for extrapulmonary TB. Tverdal argued that the association could not be explained by preexisting nutritional status or TB. As with the US Navy studies, he argues that this relationship is a function of body build and, aside from this single mention, does not discuss nutrition. Comstock suggested that body build may influence susceptibility to TB because of differences in pulmonary mechanics, but no studies have attempted to address this hypothesis.

Interpreting the findings of these large studies in terms of body build rather than nutritional status disregards the well-established concept that body weight is a function of the balance over time between caloric intake and energy expenditure. Clearly, increased or decreased intake can transform a thin individual into an overweight one or an obese person into an underweight one. With physical training and appropriate intake, a person with either body type may become muscular and fit. Therefore, the concept of body build as a fixed phenotype that, by itself, predisposes to or protects against TB may be inadequate. Reinterpreting the findings of these studies in terms of nutritional status would be useful. A more inclusive view may be that body habitus as a function of genetic and early environmental influences and nutritional status as a function of ongoing nutrient intake and physical activity each affect the incidence of TB. Sorting out the mechanisms and relative contribution of each remains a challenge for future research.

Intervention Trial

Micronutrient deficiencies in relation to TB are difficult to study in isolation in human beings. In this respect, a unique study of the effect of micronutrient supplementation on TB incidence was reported by Downes in 1949. In a controlled trial among the families of black TB patients in Harlem, New York City, 194 of 218 families under public health supervision in 1941 were examined and divided into two groups matched for family size. The families were allocated alternately to receive vitamin and mineral supplements versus no supplements, along with the health department's standard health education program. The education program included intensive nutrition education. The two groups were similar in terms of prior attack rates and mortality from TB, prevalence of primary and reinfection TB at the start of the study, sputum smear positivity among the index cases, and relation of the index case to the rest of the family. In addition, the groups were similar in terms of their income, the proportion receiving welfare, the degree of crowding within the home, and their food habits. After 5 years of follow-up, using an intention-to-treat analysis, the risk of TB in the control group was 2.8 times the risk of TB in the vitamin group. However, there was substantial noncompliance with the supplements. The relative risk of TB among the controls (1096 person-years of follow-up) compared to those who actually took the vitamin

supplements for the entire follow-up period (644 person-years of follow-up) was 5.9. The relative risk among contacts compared to those who did not take the supplements despite being allocated to that group (27% of the supplement group) or who only took them for some of the follow-up period (33% of the supplement group) (total of 598 person-years of follow-up) was only 1.82. Therefore, vitamin supplementation substantially reduced the risk of TB among family contacts of active TB cases.

This study probably underestimates the efficacy of micronutrient supplements for two reasons related to an underlying secular trend: The economic status and food habits of both groups improved substantially during the period of the study. Both these secular trends would diminish the apparent effect of vitamin and mineral supplements. A third consideration, unrelated to secular trends, was that noncompliance with the supplements by more than half the individuals in the supplemented group would further bias the measure of effect toward the null. With these three factors working against the experimental intervention, it is likely that the effect may be greater than the findings demonstrated.

Nutrition and the Immune Response to BCG Vaccine in Humans

One study design permits prospective evaluation of the effects of malnutrition on the immune response to mycobacterial proteins closely related to *M. tuberculosis*, namely delayed-type hypersensitivity (DTH) responses following BCG vaccination. Satyanarayana *et al*. showed that milder grades of malnutrition did not affect the skin test response to PPD 6 months after immunization with BCG, but that children with kwashiorkor were skin test negative. Chandra and Newberne demonstrated that the DTH skin test response to tuberculin and to numerous other antigens is reduced in protein–energy malnutrition in children and adults. Among TB patients, PPD skin test reactivity was directly proportional to serum transferrin level, a sensitive indicator of protein malnutrition. Similarly, malnourished individuals do not develop skin test responses to tuberculin as often or as large after BCG vaccination as do well-nourished children. Importantly, this effect has been demonstrated even in modest protein–energy malnutrition.

Nutrition–Immunity–Tuberculosis: Limitations of Human Data

Although the Surgeon General's report summarizes data on the interaction of nutrition and infection, it cautions that few reliable data have been obtained in human subjects on the influence of individual essential nutrients or of protein–energy nutrition on specific immune system functions and their interactions. Nutrition, immune function, and infection interact in complex and dynamic patterns. Many intervening and unknown variables affect the relationship. Protein–energy malnutrition (PEM) impairs CMI and worsens infections. Conversely, infection can lead rapidly to weight loss, malnutrition, and immunologic dysfunction. Indeed, PEM is only partly due to food deprivation. Common infectious diseases, such as diarrheal diseases and respiratory and parasitic infections, are major contributing and precipitating factors in PEM. However, in patients with TB it is nearly impossible to determine accurately their nutritional status prior to the onset of TB and, therefore, determine whether malnutrition led to TB or whether TB led to malnutrition. This problem naturally leads to the use of experimental animal models to elucidate the causal links between nutritional deficiencies, immune system function, and TB.

Experimental Animal Data

Guinea Pig Model of Pulmonary Tuberculosis

In the past 30 years, a modest literature has accumulated regarding the link between diet, antimycobacterial immunity, and disease resistance in TB. The vast majority of this work has been conducted in a highly relevant guinea pig model of low-dose pulmonary TB. The pathogenesis of TB in this model mimics essentially all of the important aspects of TB in humans.

Early studies established that moderate, chronic deficiencies of protein and other nutrients (e.g., zinc) could be induced in guinea pigs, and that the resulting nutritional states had many of the metabolic hallmarks of human dietary deficiencies. In general, the design of these experiments called for giving BCG vaccine to one group of guinea pigs among a larger group receiving different diet treatments and measuring a number of antigen-specific immune responses *in vitro* and *in vivo* several weeks later. Groups of vaccinated and nonvaccinated animals from each diet group were then challenged with an aerosol containing a low dose of virulent *M. tuberculosis*. The ability of the guinea pigs to control the infection was assessed quantitatively by culture of viable mycobacteria from the lungs and spleens.

Protein

Most of the work involving this model has been carried out with moderate, chronic protein deficiency.

Feeding a 10% ovalbumin-based diet over several weeks resulted in a dramatic loss of T cell functions in BCG-vaccinated guinea pigs. Thus, protein-deprived animals had much smaller PPD skin tests and their lymphocytes proliferated poorly to mitogenic and antigenic stimuli *in vitro*. PPD-stimulated T cells from low-protein animals produced significantly less interleukin (IL)-2 and interferon (IFN), and macrophage–lymphocyte cocultures from malnourished animals produced less tumor necrosis factor-α (TNF-α) in response to infection of the macrophages with virulent *M. tuberculosis*. Following virulent pulmonary challenge, protein-deficient guinea pigs were unable to form mature, well-circumscribed granulomas in the lung, and they expressed significantly less BCG-induced resistance in the lung and spleen. Not only was BCG-induced protection diminished by protein deficiency but also the response to exogenous reinfection was impaired. Furthermore, although immune cells from normally nourished guinea pigs adoptively protected syngeneic, protein-deficient guinea pigs against aerosol infection, the reverse was not true. That is, immune lymphocytes from low-protein animals did not protect naive, normally nourished recipients.

Protein malnutrition altered the absolute and relative numbers of total T lymphocytes and various subpopulations, including $CD2^+$, $CD4^+$, $CD8^+$, and Fc receptor-bearing T cell subsets in the circulation and lymphoid organs (e.g., spleen and bronchotracheal lymph nodes draining the infected lung). Taken together, these results imply that protein deficiency is accompanied by alterations in the ability of guinea pigs to regulate the normal recirculation and trafficking of T lymphocytes that would be required for the formation of protective granulomas. These phenomena could be explained by diet-induced changes in the production or function of chemokines, which have been observed to be altered in TB, or by perturbations in the expression of adhesion molecules on T cells or endothelial cells.

Finally, macrophages from TB patients are known to produce suppressive factors for T cells, including transforming growth factor-β (TGF-β). Alveolar macrophages are particularly effective at downregulating T cell proliferation in many species, including humans. Although protein deficiency was not associated with loss of some macrophage functions in the guinea pig model, alveolar macrophages suppress the mitogen-induced proliferation of autologous splenic lymphocytes at macrophage-to-lymphocyte ratios of 1:4 or greater. More important, the intrinsic suppression of alveolar macrophages was enhanced 10-fold in this system when the cells were derived from protein-deficient guinea pigs. In a separate series of experiments, it was demonstrated that TGF-β was produced in higher amounts by cells from protein-deprived guinea pigs, and that recombinant human TGF-β injected daily into guinea pigs infected with virulent *M. tuberculosis* suppressed T cell functions and impaired bacillary control in the lungs and spleens of treated animals. Thus, macrophages from protein-deprived guinea pigs appear to be more suppressive for T lymphocyte functions, and this suppression may be mediated, in part, by overproduction of TGF-β.

It should be noted that the profound loss of T cell-mediated resistance that accompanies chronic dietary protein deprivation in this model is substantially and rapidly reversible. BCG-vaccinated guinea pigs maintained on a low-protein diet during the entire 6-week period postvaccination, but given a normal diet beginning on the day of virulent pulmonary challenge, displayed PPD skin test reactivity and vaccine-induced control of bacillary loads in the lungs and spleens 2–4 weeks later. These reactions were indistinguishable from those in BCG-vaccinated animals that had never been protein deficient. One possible interpretation of these observations is that protein deficiency interferes with the expression, but not the development, of T cell-mediated protective mechanisms in TB.

These basic observations were confirmed and extended by studies performed in protein-malnourished mice. Using a high-dose, intravenous challenge model, Chan and colleagues observed many of the same T cell defects that have been reported in low-protein guinea pigs, including loss of control of the virulent infection and impaired granuloma formation and also recovery of resistance following refeeding with an adequate diet. They concluded that loss of resistance to TB in their model was a result of diminished nitric oxide (NO) production by activated macrophages, which occurred secondary to an IFN-γ defect in malnourished animals. These are important studies because they confirm the fundamental nature of the effects of protein deprivation in TB even when such crucial variables as host species and infection dose and route are altered.

Micronutrients

Zinc Chronic dietary zinc deficiency was found to exert a profound suppressive effect on T lymphocyte functions in BCG-vaccinated guinea pigs. Thus, there was significant anergy in response to PPD skin tests in zinc-deficient animals and dramatic loss of PPD-induced lymphoproliferation *in vitro*. The activity of a cytokine, macrophage migration

inhibitory factor, was also impaired by zinc deficiency. Taken together, these data implied that zinc deficiency interfered with the ability of BCG vaccine to induce protection against virulent, pulmonary challenge. However, no differences were observed between the bacillary loads of zinc-deficient and normally nourished guinea pigs 4 weeks following aerosol infection, and BCG exerted the same protective effect regardless of zinc status in this model.

Vitamin D Calcitriol [1,25(OH)$_2$ vitamin D$_3$] is a potent coactivator of macrophages. Several *in vitro* studies demonstrated that the addition of calcitriol to cultured human macrophages enhanced the ability of the cells to control the intracellular replication of virulent *M. tuberculosis* over several days in culture. The role of dietary vitamin D deficiency was examined in the guinea pig model of pulmonary TB. Feeding a diet completely devoid of vitamin D for several weeks resulted in marked depletion of serum levels of the calcitriol precursor, 25(OH) vitamin D$_3$, and resulted in significant loss of some T cell functions in BCG-vaccinated guinea pigs. However, vitamin D deficiency did not alter the course of TB disease in nonvaccinated guinea pigs, nor did it impair the protective efficacy of BCG vaccination in this model.

Conclusions from Experimental Animal Studies

The previously discussed studies confirm that protein deficiency, in particular, can have devastating consequences on both innate and vaccine-induced resistance against TB in animal models. Certain micronutrient deficiencies, although not as well studied, also appear to affect the immune response to *M. tuberculosis*, but the effect on the course of the disease is less clear. The precise mechanisms by which diet exerts these effects remain to be elucidated. However, the results of the experiments summarized previously point to defects in T cell trafficking and antigen-induced proliferation, the inability to form mature granulomas, diminished production of 'protective' cytokines (e.g., IL-2, IFN-γ, and TNF-α) and antimycobacterial effector molecules (e.g., NO in mice), and increased suppression by adherent cells, perhaps secondary to increased TGF-β production.

Summary

This article critiques known studies in human populations and in relevant animal models to cover the *in vivo* evidence concerning the risk of TB due to malnutrition. Although TB is clearly related to malnutrition, the risk relative to specific levels and types of PEM and micronutrient deficiencies remain to be defined. Analysis of the NHANES-1 Epidemiological Follow-Up Study provides plausible estimates of the relative risk in a representative nationwide sample of adults. The 6- to 10-fold increase in relative risk includes mild to moderate as well as severe undernutrition. Severe PEM may increase the relative risk more than mild or moderate malnutrition, but severe malnutrition occurs in a small fraction of the population, even in low-income countries, except, for example, in famine, war, or disaster situations. Mild to moderate PEM or micronutrient deficiencies affect larger fractions of the population at risk for TB, so prevention efforts may not be successful if they target only severely undernourished groups.

The questions we would like answered include not only how much of the TB burden in a population is due to malnutrition but how is TB due to malnutrition? As suggested by work in the aerosol-infected guinea pig model, protein undernutrition in particular impairs host defense against TB and the impairment is rapidly reversed with nutritional rehabilitation. Changes in the movement and proliferation of T lymphocyte subpopulations in response to specific antigens, in the production of key cytokines, in the formation of organized granulomas, and in macrophage activation have been identified as important components of the process.

Nutritional Status at the Time of Diagnosis

Compared to people without tuberculosis (TB), TB patients have significantly lower body mass index (BMI), skinfold thicknesses, mid-upper arm circumference, and overall proportion of body fat. In the United States, weight loss was present at diagnosis in 45% of patients. In Tanzania, among 200 consecutive adult patients with sputum smear-positive pulmonary TB, 77% of males and 58% of females had a BMI $<18.5\,kg/m^2$, whereas slightly more than 20% had a BMI $<16\,kg/m^2$. In Malawi, TB patients' muscle strength was substantially weaker than the control group as measured by hand-grip dynamometry (mean, 29.9 kg versus 36.5 kg in males; mean, 23.3 kg versus 32.1 kg in females), suggesting less somatic protein. TB patients in Malawi had 35% lower fat mass and 19% lower lean body mass than controls. BMI in both countries was lower in patients with a long symptom history and with extensive disease than in the complementary groups. In countries with a relatively high prevalence of both TB and HIV, one-third to two-thirds of TB patients have HIV infection. Patients with concurrent HIV infection tend to be even more malnourished. In the United Kingdom, TB patients had significantly lower serum albumin levels than controls (mean, 37 g/l versus 46 g/l), suggesting the possibility of protein undernutrition. Among Asians living in the United Kingdom, BMI among TB patients ($19.3\,kg/m^2$) was 13% lower than that of controls ($22.2\,kg/m^2$), skinfold thickness was 13% lower, and arm muscle circumference was 20% lower.

The relationship between concurrent TB and malnutrition is complex. Even though malnutrition is an important risk factor for TB, TB in turn results in cachexia, anorexia, and asthenia. As in other infectious diseases, resting energy expenditure is increased and intake is decreased. Weight loss and muscle wasting may in part be related to tumor necrosis factor-α (TNF-α) and other proinflammatory cytokines that participate in the immune response against TB. On the one hand, TNF-α plays a critical protective role against *Mycobacterium tuberculosis*. On the other hand, TNF-α results in wasting and anorexia. One of the first research teams to identify TNF called it 'cachectin' because the team identified it as the chemical mediator of weight loss in cancer and chronic inflammatory diseases. In experimental mycobacterial infections, TNF-α is required for the control of bacillary growth and the protective granulomatous response. Patients receiving anti-TNF-α monoclonal antibodies for the treatment of rheumatoid arthritis developed reactivation TB at much higher rates than rheumatoid arthritis patients not receiving TNF blockers. One school of thought believes that TNF and other cytokines released from the population of activated macrophages responding to *M. tuberculosis* account for much of the weight loss and tissue damage that characterize this disease. Other experts disagree, however, and consider the matter unresolved. Protein utilization may be altered by the cytokine milieu. Anabolic pathways may be functionally blocked due to preferential oxidation of ingested amino acids for energy rather than for protein synthesis.

Protein–energy malnutrition (PEM) rarely occurs without micronutrient deficiencies as well. TB patients have been found to be deficient in vitamins A, B_6, and D as well as zinc, copper, and iron. Of these, vitamins A

and D, zinc, and copper play roles in cell-mediated immune responses. The D vitamins, for example, are important macrophage activators. One study found that in addition to serum albumin, blood hemoglobin, plasma retinol, and plasma zinc were significantly lower in malnourished TB patients than in well-nourished TB patients, well-nourished healthy controls, and undernourished but otherwise healthy controls.

Comorbidity and Nutrition in Tuberculosis Patients

TB often occurs in association with other diseases or conditions that have nutritional implications. HIV infection is a strong risk factor for the progression of primary or latent infection with *M. tuberculosis* to active TB disease. Tuberculin skin test (TST)-positive, HIV-infected people develop active TB at the rate of 7–10% per year. TST-positive individuals without HIV infection develop active TB at the rate of 5–10% over their lifetime. HIV infection, of course, has profound implications for nutritional status and nutrient requirements. Diabetes mellitus also increases the risk of progressive primary or reactivation TB. Nutrition is a central consideration in the pathogenesis and management of diabetes mellitus. TB is more frequent in alcoholic individuals. Alcoholism is associated with profound alterations in nutrition that affect production of red blood cells, intermediary metabolism, and mucous epithelial tissue such as the lining of the gastrointestinal system. These include deficiencies of thiamine, all fat-soluble vitamins (A, D, E, and K), folic acid, pyridoxine, ascorbic acid, cobalamin, and zinc. Therefore, nutritional management of TB patients frequently must take these and other comorbidities into account.

Effect of Malnutrition on the Course of Tuberculosis

To the extent that cellular immune function affects recovery from TB, one might expect malnutrition to retard or impair the response to treatment. The adverse consequences of malnutrition on the course and outcome of TB disease have been well documented. Malnutrition increases the risk of death in TB patients nearly twofold. Among approximately 1200 patients with TB followed prospectively, 10.9% of patients with moderate to severe malnutrition died in the first 4 weeks compared to 6.5% of patients with normal nutritional status or mild malnutrition. Another study found that TB patients with a BMI $<17.0\,kg/m^2$ were at increased risk of early death. These findings cannot be interpreted to mean malnutrition *per se* causes the increased mortality risk. For example, the duration or extent of disease or drug resistance may be the primary cause(s) of death. At the same time, these disease characteristics would lead to even worse malnutrition. In children, weight for age is an important indicator of the prognosis. In general, the severity of malnutrition is an important indicator of the progress of the disease, and normalization of body weight in response to treatment is a positive sign.

In addition, anemia and hypoalbuminemia are associated with severity of the clinical course of TB. Severe anemia has been negatively correlated with the response to treatment and is associated with early mortality from TB. Anemia in TB patients may be normocytic and normochromic, or it may be microcytic and hypochromic, suggesting a relationship to iron homeostasis in some cases. Iron metabolism is disrupted in active TB. *Mycobacterium tuberculosis* requires iron to grow and avidly scavenges iron from its environment. One aspect of the host response to TB is intense sequestration of iron that restricts microbial growth. Whether iron supplementation or iron chelation may play a role in the treatment of TB remains speculative.

Nutritional Management of Tuberculosis Patients

The extent to which optimal nutrient intake improves the body's ability to heal during (and after) TB treatment is not well established. Fortunately, the immunological deficits associated with PEM and various micronutrient deficiencies are reversed rapidly with nutritional rehabilitation. One would expect this to improve recovery. The scientific literature is limited, however, with regard to the effect of nutrition on the outcomes of treatment. Only one randomized, double-blind trial is known, comparing vitamin A and zinc supplementation with placebo in 80 patients with pulmonary TB in Jakarta, Indonesia. BMI was $<18.5\,kg/m^2$ in 64% of TB patients, plasma retinol was $<0.70\,\mu mol/l$ in 32%, and plasma zinc was $<10.7\,\mu mol/l$ in 30%. After treatment, plasma zinc was similar in the two groups, and plasma retinol was significantly higher in the supplement group. Sputum conversion and resolution of the radiographic extent of lung disease were slightly more rapid in the supplement group. One other prospective study compared 6 weeks of high-energy nutritional supplements plus education to education alone among TB patients starting treatment, but the outcome was nutritional status, not TB disease status. At 6 weeks, the supplement group had gained substantially more body

weight (2.6 versus 0.8 kg) and total lean body mass (1.2 versus 0.0 kg) significantly more in the trunk than limbs. By 24 weeks, however, the relative difference in weight gain between the two groups was smaller (4.4 versus 2.7 kg), and the difference was mostly in fat mass, especially in the limbs. The patients' treatment outcomes were not compared, but at both time points, the supplement group performed better in tests of muscle strength or endurance.

It is clear that TB patients gain weight during treatment, and weight gain is one of the traditional metrics for treatment effectiveness. The extent to which diet influences the course and outcome of treatment is less clear. A large study in Madras in the 1950s compared the nutritional aspects of sanatorium versus home treatment for pulmonary TB and found no difference in the outcome after 12 months of treatment. In the sanatorium patients, however, sputum was converted to negative faster, and fewer patients relapsed. Both diet and food intake were substantially better in the sanatorium patients, and these patients gained more weight. However, adherence to treatment may have been better also. In addition, strict bed rest in the sanatorium may have affected energy balance and nutrient utilization. In the Malawian study noted previously, weight, arm muscle area, arm fat area, and hand grip strength increased significantly by 4 weeks and continued to increase at 8 weeks. However, among the Asian population in the United Kingdom described previously, after 12 months of treatment arm muscle circumference and serum albumin were still lower than those of controls, suggesting that full recovery may take even longer. The dynamics of nutritional status in relation to TB treatment in a very low-income population were described in the Tanzanian study of 200 patients noted previously. Patients gained weight irrespective of their clinical response, and weight gain continued for up to 6 months—the duration of treatment. The mean weight gain was 10 kg. Weight gain was most closely correlated with the duration of hospitalization. After treatment was completed and patients were released from the hospital, the mean weight of cured patients declined by 2.5 kg, but it declined 7.3 kg among patients who relapsed. Apparently, the hospital diet was substantially better than what was normally available to these patients.

In the treatment of TB patients, the nutritional goals are to supply adequate nutrients (i) to fuel the elevated resting energy expenditure and catabolic state and (ii) to support the extensive cellular proliferation, metabolic pathways, and protein synthesis required to repair damaged tissues and replenish somatic reserves. A deficit of 10 kg, evenly divided between lean and fat mass, represents 60 000 kcal that needs to be replaced in addition to daily nutrient requirements. A rough guideline includes at least 2 g of high-quality protein and 50 kcal of energy per kilogram body weight per day, with caloric intake distributed as 40–50% from carbohydrates, 30–40% protein, and not more than 20% to 30% fat, including essential fatty acids. Micronutrients should be supplemented to at least the recommended daily allowance, although some experts may increase the intake of vitamins and minerals needed for cellular immune function and tissue regeneration, especially vitamins A, B_6, and D and the minerals copper, iron, and zinc. Calcitriol, for example, plays an important role in macrophage activation and has been shown to contribute to the control of intracellular growth of *M. tuberculosis*.

Nutritional Issues with Antituberculosis Drug Toxicity

The standard treatment for all newly diagnosed patients with active TB lasts at least 6 months and includes isoniazid, rifampicin, pyrazinamide, and ethambutol for 2 months followed by isoniazid and rifampicin for 4 months. Isoniazid interferes with vitamin B_6 metabolism. The term vitamin B_6 refers to a group of vitamins including pyridoxine, pyridoxal, and pyridoxamine. Isoniazid combines with pyridoxal or pyridoxal phosphate to form hydrazones, which are potent inhibitors of pyridoxal kinase. Thus, isoniazid blocks the formation of the coenzyme form of the vitamin. Normally, pyridoxal phosphate participates in metabolic transformations of several amino acids.

In the absence of vitamin B_6 supplements, approximately 2% of patients treated with 5 mg/kg will develop peripheral neuritis, increasing up to 20% at higher doses or in high-risk patients such as diabetics or alcoholics. Daily administration of 25 mg of vitamin B_6 prevents peripheral neuritis and nearly all nervous system side effects of isoniazid. A similar situation exists for the second-line anti-TB drug, D-cycloserine, which has useful antibiotic properties but inhibits a wide range of pyridoxal phosphate-requiring enzymes. Cycloserine is used only for patients with drug-resistant TB, but in such patients doses of 200–300 mg of vitamin B_6 have been recommended.

Although vitamin B_6 occurs in many foods, if intake is limited to types of food with low B_6 content, deficiency can occur, especially in TB patients

whose intake is compromised by anorexia and metabolism accelerated by chronic inflammation. Foods such as peas, beans, and cereals contain adequate amounts. Meat and eggs are not good sources, however, and high protein intake increases vitamin B_6 requirements. Deficiencies of vitamin B_6, like other nutrients, can increase because of significant intestinal malabsorption or loss by gastrointestinal dysfunction.

Treatment of TB may induce other problems that affect nutritional status and nutrient intake. Three of the first-line drugs—isoniazid, rifampicin, and pyrazinamide—all carry a small risk of chemical hepatitis, ranging from the asymptomatic elevation of hepatic transaminases to severe and potentially fatal hepatitis. Although nutritional factors do not contribute to the cause, hepatitis has many important consequences affecting nutritional status and nutrient intake. Other anti-TB drugs that affect nutrition include *para*-aminosalicylic acid and ethionamide, which commonly cause moderate to severe gastrointestinal disturbances such as abdominal pain, nausea, vomiting, and anorexia.

Barriers to Nutritional Rehabilitation

Many barriers to successful nutritional rehabilitation do not include the disturbed metabolism or pathological processes of the disease. The following cognitive and behavioral factors may play important roles in promoting or impeding nutritional rehabilitation:

- *Education for health care workers:* It is necessary to promote education related to the nutrition of TB patients to health care workers in virtually every country, but especially in regions with a high TB incidence. These workers will be responsible for planning and implementing the nutritional program, and their participation is critical.
- *Information/education for patients:* Information and education for patients about the principles of good nutrition and dietary strategies is also lacking. We found no published data on TB patients' knowledge about nutrition/nutritional status or the role of nutrition in treating TB.
- *Resources:* TB mainly occurs among the poorest people in both industrialized and developing countries. A primary problem is the lack of resources for treatment other than the essential anti-TB drugs. The resource deficiency exceeds the capacity of international donor groups. In addition, the resource deficiency includes the unavailability of food, a common problem for people in low- and middle-income countries.
- *Cultural and individual food preferences:* Specific food preferences in different regions and among different people strongly affect willingness to eat and drink. Traditions regarding food are among the strongest ties with one's culture. This is particularly relevant to immigrants, refugees, displaced people, and other migrating populations that comprise important risk groups for TB. In addition to primary factors (e.g., availability of food), secondary factors may be responsible for the apparent lack or misuse of food. One may determine which secondary factors in the person's environment have been responsible for inadequate nutrient consumption and rectify them to the extent possible.

Nutritional support is an important component of the comprehensive care of people with TB. In theory, a nutritionist–dietician can tailor a specific dietary prescription for each TB patient based on a careful nutritional assessment and the patient's clinical status, including any comorbidities. In low- and middle-income countries, however, this degree of effort may not be possible and it may not be necessary, given the sparse data reviewed in this article. Virtually all TB patients should be given nutritional support and recommendations, but a generally healthful standardized diet with adequate protein, energy, essential fats, and micronutrients may suffice for the large majority of patients to achieve the potential benefits. A deeper understanding of the essential role of nutrition in TB pathogenesis and resolution may help improve treatment practices and improve outcomes of TB patients.

The extent of nutritional deficits among TB patients is reason enough for intensified nutritional support. The association of malnutrition with worse clinical outcomes and the possibility of favorably influencing the course of treatment add to the impetus for further work to be carried out to identify the optimal strategies for nutritional intervention.

U

ULTRATRACE ELEMENTS

F Nielsen, Grand Forks Human Nutrition Research Center, Grand Forks, ND, USA

This article is reproduced from the first edition, pp. 1884–1897, © 1999, Elsevier Ltd., with revisions made by the Editor.

Definition

In the earlier part of this century, scientists could qualitatively detect small amounts of several mineral elements in living organisms. In reports, these elements were described as being present in 'traces' or 'trace amounts.' It is not surprising that these elements soon became known as trace elements. Today, sophisticated analytical techniques have permitted the accurate measurement of the amount of many mineral elements, some at very low concentrations, in biological material. The trace elements found in living organisms may be essential, that is, indispensable for growth and health, or they may be nonessential, fortuitous reminders of our geochemical origins or indicators of environmental exposure. Some of the nonessential trace elements can be beneficial to health through pharmacological action. All of the trace elements are toxic when intake is excessive.

Trace elements are those elements of the periodic table that occur in animals or humans in amounts measured in mg per kg of body weight or less. The trace elements essential for health are usually required by humans in amounts measured in mg per day; these elements include copper, iron, manganese, and zinc. The individual trace elements are discussed elsewhere in the encyclopedia. Since 1980, the term 'ultratrace element' has appeared in the nutritional literature. Ultratrace elements have been defined as those elements with estimated dietary requirements usually less than $1\,mg\,kg^{-1}$, and often less than $50\,\mu g\,kg^{-1}$ of diet for laboratory animals. For humans, the term often is used to indicate an element with an established, estimated, or suspected requirement of less than 1 mg per day or generally indicated by μg per day. At least 18 elements could be considered ultratrace elements: aluminum, arsenic, boron, bromine, cadmium, chromium, fluorine, germanium, iodine, lead, lithium, molybdenum, nickel, rubidium, selenium, silicon, tin, and vanadium. Emerging evidence indicates that silicon should be categorized as a trace element instead of an ultratrace element. However, knowledge about the practical importance or beneficial actions of silicon is in a state similar to that for most of the ultratrace elements; thus, it is considered as one of them here. Cobalt perhaps also belongs in the ultratrace category; however, it is required only in the form of vitamin B_{12} and thus is usually discussed as a vitamin.

The quality of the experimental evidence for nutritional essentiality varies widely for the ultratrace elements. The evidence for the essentiality of three elements, iodine, molybdenum and selenium, is substantial and noncontroversial; specific biochemical functions have been defined for these elements. The nutritional importance of iodine and selenium are such that they have separate entries in this encyclopedia. Molybdenum, however, is given very little nutritional attention, apparently because a deficiency of this element has not been unequivocally identified in humans other than individuals nourished by total parenteral nutrition or with genetic defects causing disturbances in metabolic pathways involving this element. Specific biochemical functions have not been defined for the other 15 ultratrace elements listed above. Thus, their essentiality is based on circumstantial evidence, which most often is that a dietary deprivation in an animal model results in a suboptimal biological function that is preventable or reversible by an intake of physiological amounts of the element in question. Often the circumstantial evidence includes an identified essential function in a lower form of life, and biochemical actions consistent with a biological role or beneficial action in humans. The circumstantial evidence for essentiality is substantial for arsenic, boron, chromium, nickel, silicon, and vanadium. The evidence for essentiality for the

other elements is generally limited to a few gross observations in one or two species by one or two research groups. However, it should be noted that two of these ultratrace elements have beneficial actions when ingested in high (pharmacological) amounts: they are fluorine, which prevents tooth caries, and lithium, which is used to treat manic-depressive disorders.

Although aluminum has a separate article, and the elements cadmium, lead, and nickel are discussed in the entry the focus in those entries is toxicity; thus, these elements will be included in the following discussion. Chromium, however, which also has a separate entry, will not be included.

Absorption, Transport, and Storage

Homeostasis (maintenance of a steady optimal concentration of an element in the body) regulation involves the processes of absorption, storage, and excretion. The relative importance of these three processes varies among the ultratrace elements. The amount absorbed from the gastrointestinal tract is often the controlling mechanism for positively charged ultratrace elements such as aluminum, nickel, and tin. With these trace elements, if the body content is low, or if intake is low, the percentage of the element absorbed from the gastrointestinal tract is increased, and vice versa. Elements that exist mainly as negatively charged ions or oxyanions, such as arsenic, boron, and fluoride, are usually absorbed quite freely and completely from the gastrointestinal tract. Excretion through the urine, bile, swear, and breath is, therefore, the major mechanism for controlling the amount of these ultratrace elements in an organism. By being stored at inactive sites or in an inactive form, some ultratrace elements are prevented from causing adverse reactions when present in high quantities. An example of this homeostatic process is the binding of cadmium by the cysteine-rich protein called metallothionein. Release of an ultratrace element from storage forms also can be important in preventing deficiency.

Absorption of ultratrace elements from the intestinal lumen can occur in three ways. These are described below.

1. Passive diffusion – passive transport driven by a difference in concentration of the element between the two sides of the luminal membrane and the mucosa. Transmembrane movement of ions occurs through pores or channels within the membrane and is an energy-independent process. A significant amount of passive transport across the intestinal mucosa may occur through a paracellular pathway, or the transport between cells across intercellular right junctions.
2. Facilitated diffusion – the transfer of an element across the membrane by carrier proteins embedded in the membrane. Facilitated transport resembles simple diffusion because it is not energy dependent and is driven by a difference in the ion concentration between two sides of a membrane. Facilitated transport occurs much more rapidly than simple diffusion and is saturable because of a finite number of carrier proteins.
3. Active transport – the accumulation within, or the extrusion from, a cell of an element in opposition to a concentration gradient. Active transport is saturable, is energy dependent and involves a carrier protein that usually is quite specific for an element. The mechanisms of absorption for the various ultratrace elements are given in **Table 1**; this table also lists the known transport and storage vehicles for these elements.

Metabolism and Excretion

Knowledge about chemical changes that must occur before excretion for most of the ultratrace elements is quite limited. Perhaps the best characterized is inorganic arsenic, which is methylated into monomethylarsonic acid and dimethylarsinic acid, and organic arsenic, which is converted into, or remains mostly as, arsenobetaine before being excreted in the urine. Other ultratrace elements that are known to be incorporated into biochemical metabolites for transport and/or excretion include aluminum bound to transferrin, cadmium incorporated into metallo-thionein, nickel as the α-2-macroglobulin nickeloplasmin or bound to albumin and L-histidine, and vanadium converted into vanadyl-transferrin and vanadyl-ferritin (see **Table 1**). A known important metabolite of molybdenum is a small nonprotein cofactor containing a pterin nucleus that is present at the active site of molybdoenzymes. More than 40% of molybdenum not attached to an enzyme in liver also exists as this cofactor bound to the mitochondrial outer membrane. This form can be transferred to an apoenzyme of xanthine oxidase or sulfite oxidase, which transforms it into an active enzyme molecule. Molecules of biological importance for the ultratrace elements are shown in **Table 2**. The ultratrace elements are excreted from the body mainly via the feces and urine. Fecal excretion of absorbed ultratrace elements

Table 1 Absorption, transport, and storage characteristics of the ultratrace elements

Element	*Major machanism(s) for homeostasis*	*Means of absorption*	*Percentage of ingested absorbed*	*Transport and storage vehicles*
Aluminum	Absorption	Uncertain; some evidence far passive diffusion through the paracellular pathway; also, evidence for active absorption through processes shared with active processes of calcium; probably occurs in proximal duodenum; citrate combined with aluminum enhances absorption	Less than 1%	Transferrin carries aluminum in plasma; bone a possible storage site
Arsenic	Urinary excretion: Inorganic arsenic as mostly dimethylarsinic acid and organic arsenic as mostly arsenobetaine	Inorganic arsenate becomes sequestered in or on mucosal tissue, then absorption involves a simple movement down a concentration gradient; organic arsenic absorbed mainly by simple diffusion through lipid regions of the intestinal boundary	Soluble inorganic forms, >90%; slightly soluble inorganic forms, 20–30%; inorganic forms with foods, 60–75%; methylated forms, 45–90%	Before excretion inorganic arsenic is converted into monomethyl arsonic acid and dimethylarsinic acid; arsenobetaine not biotransformed; arsenocholine transformed to arsenobetaine
Boron	Urinary excretion	Ingested boron is converted into $B(OH)_3$ and absorbed in this form, probably by passive diffusion	Greater than 90%	Boron transported through the body as undissociated $B(OH)_3$; bone a possible storage site
Bromine	Urinary excretion	Probably passive diffusion because no apparent saturable component	75–90%	None identified
Cadmium	Absorption	May share a common absorption mechanism with other metals (e.g., zinc) but mechanism is less efficient for cadmium	5%	Incorporated into metallothionein, which probably is both a storage and transport vehicle
Fluorine	50% daily intake excreted in urine; about 50% daily intake stored in bone and developing teeth	Absorption by passive diffusion and inversely related to pH. Significant portion absorbed as hydrogen fluoride from stomach; absorption of fluoride also occurs throughout the small intestine	76–90%	Exists as fluoride ion in plasma; hydrogen fluoride is the form in diffusion equilibration across cell membranes. Stored in bone
Germanium	Urinary excretion	Has not been conclusively determined but most likely is by passive diffusion	Greater than 90%	None identified

Continued

Table 1 Continued

Element	*Major machanism(s) for homeostasis*	*Means of absorption*	*Percentage of ingested absorbed*	*Transport and storage vehicles*
Lead	Absorption	Uncertain; thought to be by passive diffusion in small intestine, but evidence has been presented for an active transport, perhaps involving the system for calcium	Adults 5–15% Children 40–50%	Bone is a repository for lead
Lithium	Urinary excretion	Passive diffusion by paracellular transport via the tight junctions and pericellular spaces	Lithium chloride highly absorbed – greater than 90%	Bone can serve as a store for lithium
Molybdenum	Urinary and biliary excretion	Uncertain, possible that molybdate is moved both by diffusion and by active transport, but at high concentrations active transport is a small portion of flux; absorption occurs rapidly in stomach and continues throughout the small intestine	50–93%	Molybdate in blood loosely attached to erythrocytes and tends to bind α_2-macroglobulin. Liver and kidney retain highest amount of molybdate
Nickel	Both absorption and urinary excretion	Uncertain, evidence both for passive diffusion (perhaps as an amino acid or other low molecular weight complex) and for energy driven transport; occurs in the small intestine	$<$10% with food	Transported in blood principally bound to serum albumin with small amounts bound to L-histidine and α_2-macroglobulin; no organ accumulates physiological amounts of nickel
Rubidium	Excretion through kidney and intestine	Resembles potassium in its pattern of absorption; rubidium and potassium thought to share a transport system	Highly absorbed	None identified
Silicon	Both absorption and urinary excretion	Mechanisms involved in intestinal absorption have not been described	Food silicon near 50%; insoluble or poorly soluble silicates $=1\%$	Silicon in plasma believed to exist as undisassociated monomeric silicic acid
Tin	Absorption	Mechanisms involved in intestinal absorption have not been described	About 3%. Percentage increases when very low amounts are ingested	None identified. Bone might be a repository
Vanadium	Absorption	Vanadate has been suggested to be absorbed through phosphate or other anion transport systems; vanadyl has been suggested to use iron transport systems. Absorption occurs in the duodenum	$<$10%	Converted into vanadyl-transferrin and vanadyl-ferritin; whether transferrin is the transport vehicle and ferritin is the storage vehicle for vanadium remains to be determined. Bone is a respository for excess vanadium

Table 2 Excretion, retention, and possible biological roles of the ultratrace elements

Element	*Organs of high content (typical concentration)*	*Major excretory route after Ingestion*	*Molecules of biological importance*	*Possible biological role*
Aluminum	Bone (1–12 $\mu g\,g^{-1}$) Lung (35 $\mu g\,g^{-1}$)	Urine; also significant amounts in bile	Aluminum binds to proteins, nucleotides, and phospholipids; aluminum-bound transferrin apparently is a transport molecule	Enzyme activator
Arsenic	Hair (0.65 $\mu g\,g^{-1}$) Nails (0.35 $\mu g\,g^{-1}$) Skin (0.10 $\mu g\,g^{-1}$)	Urine	Methylation of Inorganic oxyarsenic anions occurs in organisms ranging from microbial to mammalian; methylated and products include arsenocholine, arsenobetaine, dimethylarsinic acid, and methylarsonic acid; arsenite methyltransferase and monomethylarsonic acid methyltransferase use *S*-adenosylmethionine for the methyl donor	Metabolism of methionine, or involved in labile methyl metabolism; regulation of gene expression
Boron	Bone (1.6 $\mu g\,g^{-1}$) Fingernails (15 $\mu g\,g^{-1}$) Hair (1 $\mu g\,g^{-1}$) Teeth (5 $\mu g\,g^{-1}$)	Urine	Boron biochemistry essentially that of boric acid, which forms ester complexes with hydroxyl groups, preferably those adjacent and *cis*, in organic compounds. Five naturally occurring boron esters (all antibiotics) synthesized by various bacteria have been characterized	Cell membrane function or stability such that it influences the response to hormone action, transmembrane signaling or transmembrane movement of regulatory cations or anlons
Bromine	Hair (3.0 $\mu g\,g^{-1}$) Liver (4.0 $\mu g\,g^{-1}$) Lung (6.0 $\mu g\,g^{-1}$) Testis (5.0 $\mu g\,g^{-1}$)	Urine	Exists as Br Ion *in vivo*, binds to proteins and amino acids	Electrolyte balance
Cadmium	Kidney (14 $\mu g\,g^{-1}$) Liver (4 $\mu g\,g^{-1}$)	Urine and gastrointestinal tract	Metallothionein, a high sulfhydryl-containing protein involved in regulating cadmium distribution	Involved in metallathionein metabolism and utilization
Fluorine	Bones (1–5 $mg\,g^{-1}$) Teeth (500 $\mu g\,g^{-1}$)	Urine	Exists as fluoride ion or hydrogen fluoride in body fluids; about 99% of body fluorine found in mineralized tissues as fluoroapatite	Role in biological mineralization
Germanium	Bone (9 $\mu g\,g^{-1}$) Liver (0.3 $\mu g\,g^{-1}$) Pancreas (0.2 $\mu g\,g^{-1}$) Testis (0.5 $\mu g\,g^{-1}$)	Urine	None identified	Role in immune function
Lead	Aorta (1–2 $\mu g\,g^{-1}$) Bone (25 $\mu g\,g^{-1}$) Kidney (1–2 $\mu g\,g^{-1}$) Liver (1–2 $\mu g\,g^{-1}$)	Urine; also significant amounts in bile	Plasma lead mostly bound to albumin; blood lead binds mostly to hemoglobin but some binds a low molecular weight protein in arythrocytes	Facilitates iron absorption and/or utilization

Continued

Table 2 Continued

Element	*Organs of high content (typical concentration)*	*Major excretory route after Ingestion*	*Molecules of biological importance*	*Possible biological role*
Lithium	Adrenal gland ($60\,ng\,g^{-1}$) Bone ($100\,ng\,g^{-1}$) Lymph nodes ($200\,ng\,g^{-1}$) Pituitary gland ($135\,ng\,g^{-1}$)	Urine	None Identified	Regulation of some endocrine function
Molybdenum	Kidney ($0.4\,\mu g\,g^{-1}$) Liver ($0.6\,\mu g\,g^{-1}$)	Urine; also significant amounts in bile	Molybdoenzymes of aldehyde oxidase, xanthine oxidase/ dehydrogenase and sulfite oxidase in which molyldenum exists as a small nonprotein factor containing a pterin nucleus; molybdate ion (MoO_4^{2+}), the form that exists in blood and urine	Molybdoenzymes oxidize and detoxify various pyrimidines, purines, and pteridines; catalyze the transformation of hypoxanthine to xanthine and xanthine to uric acid; and catalyze the conversion of sulfite to sulfate
Nickel	Adrenal glands ($25\,ng\,g^{-1}$) Bone ($33\,ng\,g^{-1}$) Kidney ($10\,ng\,g^{-1}$) Thyroid ($30\,ng\,g^{-1}$)	Urine as low molecular weight complexes	Binding of Ni^{2-} by various ligands including amino acids (especially histidine and cysteine), proteins (especially albumin), and a macroglobulin called nickeloplasmin important in transport and excretion. Ni^{2+} component of urease; Ni^{3-} essential for enzymatic hydrogenation, desulfurization, and carboxylation reactions in mostly anaerobic microorganisms	Cofactor or structural component in specific metalloenzymes; role in a metabolic pathway involving vitamin B_{12} and folic acid. Role similar to potassium; neurophysiological function
Rubidium	Brain ($4\,\mu g\,g^{-1}$) Kidney ($5\,\mu g\,g^{-1}$) Liver ($6.5\,\mu g\,g^{-1}$) Testis ($20\,\mu g\,g^{-1}$)	Urine: also significant amounts excreted through intestinal tract	None identified	Role similar to potassium; neurophysiological function
Silicon	Aorta ($16\,\mu g\,g^{-1}$) Bone ($18\,\mu g\,g^{-1}$) Skin ($4\,\mu g\,g^{-1}$) Tendon ($12\,\mu g\,g^{-1}$)	Urine	Silicic acid ($SiOH_4$) is the form believed to exist in plasma; magnesium orthosilicate is probably the form in urine. The bound form of silicon has never been rigorously identified	Structural role in some mucopolysaccharide or collagen; role in the initiation of calcification and in collagen formation
Tin	Bone ($0.8\,\mu g\,g^{-1}$) Kidney ($0.2\,\mu g\,g^{-1}$) Liver ($0.4\,\mu g\,g^{-1}$)	Urine; also significant amounts in bile	Sn^{2+} is absorbed and excreted more readily than Sn^{4+}	Role in some redox reaction
Vanadium	Bone ($120\,ng\,g^{-1}$) Kidney ($120\,ng\,g^{-1}$) Liver ($120\,ng\,g^{-1}$) Spleen ($120\,ng\,g^{-1}$) Testis ($200\,ng\,g^{-1}$)	Urine; also significant amount in bile	Vanadyl (VO^{2+}), vanadate ($H_2VO_4^-$ or VO_3^-) and peroxovanadyl [V–OO]; VO^{2+} complexes with proteins, especially those associated with iron (e.g., transferrin, hemoglobin)	Lower forms of life have haloperoxidases that require vanadium for activity; a similar role might exist in higher forms of life

None of the suggested biological functions or roles of any of the ultratrace elements have been conclusively or unequivocally identified in higher forms of life except for those of molybdenum.

usually results from biliary excretion, but may be of nonbiliary origin (e.g., through the pancreas or intestine). Ultratrace elements may also be excreted through sweat and breath. Ultratrace elements also are removed from the body through the loss of blood (e.g., menses), skin, hair, semen, saliva, and nails. **Table 2** gives the major routes of excretion for the ultratrace elements.

Requirements and High Intakes

As already mentioned, the ultratrace elements other than selenium and iodine are a disparate group in terms of their possible requirement or nutritional importance for human health and well-being. Although molybdenum has known essential functions, it has no unequivocally identified practical nutritional importance. The other 14 ultratrace elements discussed here have been suggested to be essential based on circumstantial evidence. This evidence is presented below along with some indication of possible requirement (extrapolated from the deficient animal intakes shown in **Table 3**), and some indication as to what constitutes a high intake.

Aluminum

A dietary deficiency of aluminum in goats reportedly results in increased abortions, depressed growth, incoordination and weakness in hind legs, and decreased life expectancy. Aluminum deficiency has also been reported to depress growth in chicks. Other biochemical actions that suggest aluminum could possibly act in an essential role include the *in vitro* findings that it activates the enzyme adenylate cyclase, enhances calmodulin activity, stimulates DNA synthesis in cell cultures, and stimulates osteoblasts to form bone through activating a purative G, protein-coupled cation sensing system.

If humans have a requirement for aluminum, for which there is currently no evidence, it probably is much less than $1.0\,mg\,day^{-1}$. Aluminum toxicity apparently is not a concern for healthy individuals. Cooking foods in aluminum cook-ware does not lead to detrimental intakes of aluminum. High dietary ingestion of aluminum probably is not a cause of Alzheimer's disease. However, high intakes of aluminum through such sources as buffered analgesics and antacids by susceptible individuals (e.g., those with impaired kidney function including the elderly and low-birthweight infants) may lead to pathological consequences and thus should be avoided. For most healthy individuals, an aluminum intake of $125\,mg\,day^{-1}$ should not lead to toxicological consequences.

Arsenic

Arsenic deprivation has been induced in chickens, hamsters, goats, pigs, and rats. In the goat, pig, and rat, the most consistent signs of deprivation were depressed growth and abnormal reproduction characterized by impaired fertility and elevated perinatal mortality. Other notable signs of deprivation in goats were depressed serum triacylglycerol concentrations and death during lactation. Myocardial damage was also present in lactating goats. Other signs of arsenic deprivation have been reported, including changes in mineral concentrations in various organs. However, listing all signs reported to be caused by arsenic deficiency may be misleading because studies with chicks, rats, and hamsters have revealed that the nature and severity of the signs are affected by a number of dietary and other factors. For example, female rats fed a diet that is conducive to kidney calcification have more severe calcification when dietary arsenic is low; kidney iron was also elevated. Male rats fed the same diet do not show these changes.

Other factors that affect the response to arsenic deprivation include methionine, arginine, choline, taurine, and guanidoacetic acid. In other words, the signs of arsenic deprivation were changed and generally enhanced by nutritional stressors that affected sulfur amino acid or labile methyl-group metabolism; this suggests that arsenic has a biochemical function that affects these substances. Further evidence for this suggestion is the finding that arsenic deprivation slightly increases liver S-adenosylhomo-cysteine (SAH) and decreases liver S-adenosyl-methionine (SAM) concentrations in animal models, thus resulting in a decreased SAM/SAH ratio; SAM and SAH are involved in methyl transfer. Additionally, arsenite can induce the isolated cell production of certain proteins known as heat shock proteins. The control of production of these proteins in response to arsenite apparently is at the transcriptional level, and involves changes in the methylation of core histones. It also has been shown that arsenic can increase the methylation of the *p53* promoter, or DNA, in human lung cells.

It has been suggested, based upon animal data, that a possible arsenic requirement for humans eating 8.37 MJ (2000 kcal) would be $12–25\,\mu g\,day^{-1}$; this is near the typical daily intake shown in **Table 3**. Because of mechanisms for the homeostatic regulation of arsenic (including methylation,

Table 3 Human body content, and deficient, typical, and rich sources of intakes of ultratrace elements

Element	*Apparent deficient intake (species)*	*Human body content*	*Typical human daily dietary intake*	*Rich sources*
Aluminum	160 μg kg^{-1} (goat)	30–50 mg	2–10 mg	Baked goods prepared with chemical leavening agents (e.g., baking powder), processed cheese, grains, vegetables, herbs, tea, antacids, buffered analgesics
Arsenic	<25 μg kg^{-1} (chicks) <35 μg kg^{-1} (goat) <15 μg kg^{-1} (hamster) <30 μg kg^{-1} (rat)	1–2 mg	12–60 μg	Shellfish, fish, grain, cereal products
Boron	<0.3 mg kg^{-1} (chick) 0.25–0.35 mg per day (human) <0.3 mg kg^{-1} (rat)	10–20 mg	0.5–3.5 mg	Food and drink of plant origin, especially noncitrus fruits, leafy vegetables, nuts, pulses, avocados, legumes, wine, cider, beer, peanut butter
Bromine	0.8 mg kg^{-1} (goat)	200–350 mg	2–8 mg	Grain, nuts, fish
Cadmium	<5 μg kg^{-1} (goat) <4 μg kg^{-1} (rat)	5–20 mg	10–20 μg	Shellfish, grains – especially those grown on high-cadmium soils, leafy vegetables
Fluorine	<0.3 mg kg^{-1} (goat) <0.45 mg kg^{-1} (rat)	3 g	Fluoridated areas, 1–3 mg Nonfluoridated areas, 0.3–0.6 mg	Fish, tea, fluoridated water
Germanium	0.7 mg kg^{-1} (rat)	3 mg	0.4–3.4 mg	Wheat bran, vegetables, leguminous seeds
Lead	<32 μg kg^{-1} (pig) <45 μg kg^{-1} (rat)	Children less than age 10 years, 2 mg Adults, 120 mg	15–100 μg	Seafood, plant foodstuffs grown under high-lead conditions
Lithium	<1.5 mg kg^{-1} (goat) <15 μg kg^{-1} (rat)	350 μg	200–600 μg	Eggs, meat, processed meat, fish, milk, milk products, potatoes, vegetables (content varies with geological origin)
Molybdenum	< 25 μg kg^{-1} (goat) <25 μg day^{-1} (human) <30 μg kg^{-1} (rat)	10 mg	50–100 μg	Milk and milk products, dried legumes, pulses, organ meats (liver and kidney), cereals, and baked goods
Nickel	<100 μg kg^{-1} (goat) <20 μg kg^{-1} (rat)	1–2 mg	70–260 μg	Chocolate, nuts, dried beans and peas, grains
Rubidium	180 μg kg^{-1} (goat)	360 mg	1–5 mg	Coffee, black tea, fruits and vegetables (especially asparague), poultry, fish
Silicon	<2.0 mg kg^{-1} (chick) <4.5 mg kg^{-1} (rat)	2–3 g	20–50 mg	Unrefined grains of high fiber content, cereal products, beer, coffee
Tin	<20 μg kg^{-1} (rat)	7–14 mg	1–40 mg	Canned foods
Vanadium	<10 μg kg^{-1} (goat)	100 μg	10–30 μg	Shellfish, mushrooms, parsley, dill seed, black pepper, some prepared foods, grains, beer, wine

then excretion in urine), its toxicity through oral intake is relatively low; it is actually less toxic than selenium, an ultratrace element with a well-established nutritional value. Toxic quantities of inorganic arsenic generally are reported in milligrams. For example, reported estimated fatal acute doses of arsenic for humans range from 70 to 300 mg or about 1.0 to 4.0 mg per kg body weight.

Some forms of organic arsenic are virtually nontoxic; a 10 g per kg body weight dose of arsenobetaine depressed spontaneous motility and respiration in male mice, but these symptoms disappeared within 1 h. Results of numerous epidemiological studies have suggested an association between chronic overexposure to arsenic and the incidence of some forms of cancer; however, the role of arsenic in carcinogenesis remains controversial. Arsenic does not seem to act as a primary carcinogen, and is either an inactive or extremely weak mitogen. In the USA, a standard known as a reference dose (RfD; lifetime exposure that is unlikely to cause adverse health effects) of 0.3 μg per kg body weight per day, or 21 μg day^{-1} for a 70 kg human, has been suggested for inorganic arsenic. Because of safety factors in the determination, the RfD for arsenic conflicts with the possible arsenic requirement; this conflict is similar to that for some other mineral elements including zinc. These conflicts are currently being addressed by nutritionists and toxicologists.

Boron

Listing the signs of boron deficiency for animal models is difficult because most studies have used stressors to enhance the response to changes in dietary boron. Thus, the response to boron deprivation varied as the diet changed in its content of nutrients such as calcium, phosphorus, magnesium, potassium, and vitamin D. Although the nature and severity of the changes varied with dietary composition, many of the findings indicated that boron deprivation impairs calcium metabolism, brain function, and energy metabolism. Studies also suggest that boron deprivation impairs immune function and exacerbates adjuvant-induced arthritis in rats. Feeding low boron to humans (<0.3 mg day^{-1}) altered the metabolism of macrominerals, electrolytes, and nitrogen, as well as oxidative metabolism, and produces changes in erythropoiesis and hematopoiesis. Boron deprivation also altered electroencephalograms to suggest depressed behavioral activation and mental alertness, depressed psychomotor skills and cognitive processes of attention and memory, and enhanced some effects of estrogen therapy such as increases in concentrations of serum 17β-estradiol and plasma copper. Other findings suggest that boron may have an essential function. *In vitro* it competitively inhibits oxidoreductase enzymes, which require pyridine or flavin nucleotides, and enzymes such as serine proteases, which form transition state analogs with boronic acid or borate derivatives. Boron has an essential function in plants, in which it influences redox actions involved in cellular membrane transport. This latter finding supports the hypothesis that boron has a role in cell membrane function or stability such that it influences the response to hormone action, transmembrane signaling, or transmembrane movement of regulatory cations or anions. Another finding in support of this hypothesis is that boron influences the transport of extracellular calcium into and the release of intracellular calcium in rat platelets activated by thrombin.

An analysis of both human and animal data has resulted in the suggestion by a World Health Organization (WHO) publication that an acceptable safe range of population mean intakes of boron for adults could well be 1.0–13 mg day^{-1}. In other words, 1.0 mg probably covers any requirement and 13 mg will not lead to any toxicological consequences. However, the US and Canada concluded in 2002 that there was still insufficient evidence to establish a clear biological function for boron in humans, so no recommended dietary intake was set for those countries. Boron has a low order of toxicity when administered orally. Toxicity signs in animals generally occur only after dietary boron exceeds 100 μg g^{-1}. The low order of toxicity of boron for humans is shown by the use of boron as a food preservative between 1870 and 1920 without apparent harm. It was reported in 1904 that when doses equivalent to more than 0.5 g of boric acid were consumed daily, disturbances in appetite, digestion, and health occurred. It was concluded in this report that this quantity of boron per day was too much for an average person to receive regularly. The upper limit (UL) for the US and Canada has been set at 20 mg day^{-1} based on extrapolation from animal studies.

Bromine

It has been reported that a dietary deficiency of bromide results in depression of growth, fertility, hematocrit, hemoglobin, and life expectancy, and increases in milk fat and spontaneous abortions in goats. Other biological actions that suggest bromine could possibly act in an essential role include the findings that bromide alleviates growth retardation caused by hyperthyroidism in mice and chicks, and insomnia exhibited by many hemodialysis patients has been associated with bromide deficit.

If humans have a requirement for bromide, which has not yet been shown to be the case, based on deficient intakes for animals it is probably no more

than 1.0 mg day^{-1}. Bromine ingested as the bromide ion has a low order of toxicity; thus bromine is not of toxicological concern in nutrition.

Cadmium

Deficiency of cadmium reportedly depresses growth of rats and goats. Other *in vitro* biochemical actions that suggest cadmium could possibly act as an essential element include the finding that it has transforming growth factor activity and stimulates growth of cells in soft agar.

If humans have a requirement for cadmium, which is still uncertain, based on deficient intakes for animals it is probably less than 5 μg day^{-1}. Although cadmium may be an essential element at these extremely low amounts, it is of more concern because of its toxicological properties. Cadmium has a long half-life in the body and thus high intakes can lead to accumulation, resulting in damage to some organs, especially the kidney. The toxicological aspects of cadmium have been discussed earlier (*See:* xx).

Fluorine

Reported unequivocal or specific signs of fluoride deficiency are almost nonexistent. A study with goats indicated that a fluoride deficiency decreases life expectancy and caused pathological hisrology in the kidney and endocrine organs. Most of the evidence accepted as showing a need for fluoride comes from studies in which it was orally administered in pharmacological doses. Pharmacological doses of fluoride have been shown to prevent tooth caries, improve fertility, hematopoiesis and growth in iron-deficient mice and rats, prevent phosphorus-induced nephro-calcinosis, and perhaps prevent bone loss leading to osteoporosis.

Although fluoride is not generally considered an essential element in the classical sense for humans, it still is considered a beneficial element. Because of this, in the US-Canada, the AI has been set, on the basis of reducing dental caries without adverse effects, at: 0.01 mg day^{-1} for infants 0–6 months; 0.5 mg for 6–12 months; 0.7 mg for 1–3 years; 1 mg for 4–8 years; 2 mg for 9–13 years; 3 mg for 14–18 years; 3 mg for women and 4 mg for men. These intakes provide amounts of fluoride that will give protection against dental caries and generally not result in any consequential mottling of teeth; they should not be considered intakes that are needed to prevent a nutritional deficiency of fluoride. Chronic fluoride toxicity through excessive intake mainly through water supplies and industrial exposure has been reported in many parts of the world. Chronic toxicity resulting from the ingestion of water and food providing in excess of 2.0 mg day^{-1} is manifested by dental fluorosis or mottled enamel ranging from barely discernible with intakes not much above 2.0 mg day^{-1} to stained and pitted enamel with much higher amounts. Crippling skeletal fluorosis apparently occurs in people who ingest 10–25 mg day^{-1} for 7–20 years. The UL (mg per day) is 0.7 mg for 0–6 months, 0.9 mg for 7–12 months, 1.3 mg for 1–3 years, and 2.2 mg for 4–8 years, and 10 mg for all older age groups including pregnant and lactating women.

Germanium

A low germanium intake has been found to alter bone and liver mineral composition and decrease tibial DNA in rats. Germanium also reverses changes in rats caused by silicon deprivation, and is touted as having anticancer properties because some organic complexes of germanium can inhibit tumor formation in animal models.

If humans have a requirement for germanium, based on animal deprivation studies, it is probably less than 0.5 mg day^{-1}. The toxicity of germanium depends upon its form. Some organic forms of germanium are less toxic than inorganic forms. Inorganic germanium toxicity results in kidney damage. Some individuals consuming high amounts of organic germanium supplements contaminated with inorganic germanium have died from kidney failure. Although germanium has long been believed to have a low order of toxicity because of its diffusible state and rapid elimination from the body, until more knowledge is obtained about the intakes at which germanium becomes toxic, they probably should not greatly exceed those found in a typical diet. An intake of no more than 5.0 mg day^{-1} would meet any possible need for germanium and most likely will be below the level found to have toxicological consequences.

Lead

A large number of findings have come from one source that suggests that a low dietary intake of lead is disadvantageous to pigs and rats. Apparent deficiency signs found include: depressed growth; anemia; elevated serum cholesterol, phospholipids and bile acids; disturbed iron metabolism; decreased liver glucose, triacylglycerols, LDL-cholesterol and phospholipids; increased liver cholesterol; and altered blood and liver enzymes. A beneficial action of lead (2 μg g^{-1} versus 30 ng g^{-1} diet) is that it alleviates iron deficiency signs in young rats.

If humans have a requirement for lead, which has not yet been demonstrated to be the case, it is probably less than 30 μg day^{-1} based on animal deprivation studies. Although lead may have beneficial effects at low intakes, lead toxicity is of more concern than lead deficiency. Lead is considered one of the major environmental pollutants because of the past use of lead-based paints and the combustion of fuels containing lead additives. The toxicological aspects of lead are discussed elsewhere (*See:* xx).

Lithium

Lithium deficiency reportedly results in depressed fertility, birthweight, and life span, and altered activity of liver and blood enzymes in goats. In rats, lithium deficiency apparently depresses fertility, birthweight, litter size, and weaning weight. Other *in vitro* biochemical actions suggesting that lithium could possibly act as an essential element include the stimulation of growth of some cultured cells, and having insulinomimetic action. Lithium is best known for its pharmacological properties; it is used to treat manic-depressive psychosis. Its ability to affect mental function perhaps explains the report that incidence of violent crimes is lower in areas with high-lithium drinking water.

If humans have a requirement for lithium, based on animal deprivation studies it is probably less than 25 μg day^{-1}, which is much less than the usual dietary intake (see **Table 3**). Lithium is not a particularly toxic element, but the principal disadvantage in the use of lithium for psychiatric disorders is the narrow safety margin between therapeutic and toxic doses. About 500 mg lithium per day is needed to raise serum concentrations to be effective in these disorders; this is close to the concentration where mild toxicity signs of gastrointestinal disturbances, muscular weakness, tremor, drowsiness, and a dazed feeling begin to appear. Severe toxicity results in coma, muscle tremor, convulsions, and even death.

Molybdenum

The evidence for the essentiality of molybdenum is substantial and conclusive. Molybdenum functions as a cofactor in enzymes that catalyze the hydroxylation of various substrates. Aldehyde oxidase oxidizes and detoxifies various pyrimidines, purines, pteridines, and related compounds. Xanthine oxidase/dehydrogenase catalyzes the transformation of hypoxanthine to xanthine, and xanthine to uric acid. Sulfite oxidase catalyzes the transformation of sulfite to sulfate. Attempts to produce molybdenum deficiency signs in rats, chickens, and humans have resulted in only limited success, and no success in healthy humans. Deficiency signs in animals are best obtained when the diet is supplemented with massive amounts of tungsten, an antagonist of molybdenum metabolism. Nonetheless, reported deficiency signs for goats and pigs are depressed food consumption and growth, impaired reproduction characterized by increased mortality in both mothers and offspring, and elevated copper concentrations in liver and brain. A molybdenum-responsive syndrome found in hatching chicks is characterized by a high incidence of late embryonic mortality, mandibular distortion, anophthalmia, and defects in leg bone and feather development. The incidence of this syndrome was particularly high in commercial flocks reared on diets containing high concentrations of copper, another molybdenum metabolism antagonist.

Examples of nutritional standards that have been set for molybdenum are the current US-Canada recommendations, which are the following: Adequate Intake for infants aged 0–0.5 years, 2 μg and aged 0.5–1 years, 3 μg; RDA for children 1–3 years, 17 μg; 4–8 years, 22 μg; 9–13 years, 34 μg; 14–18 years, 43 μg; women from 19–>70 years, 34 μg; and men aged 19–>70 years, 45 μg. The recommended intake is 50 μg day^{-1} in pregnancy and lactation. These values were set using balance data in adults with extrapolation to the other groups. Usual dietary intakes are substantially higher than these recommendations. Large oral doses are necessary to overcome the homeostatic control of molybdenum; thus, it is a relatively nontoxic nutrient. The UL for children 1–3 years is 300 μg, for 4–8 years, 600 μg, and 9–13 years, 1100 μg. For adolescents the UL is 1700 μg, and for adults, 2000 μg, including pregnant and lactating women, based on doses that caused reproductive damage in animals.

Nickel

Based on recent studies with rats and goats, nickel deprivation depresses growth, reproductive performance and plasma glucose, and alters the distribution of other elements in the body, including calcium, iron, and zinc. As with other ultratrace elements, the nature and severity of signs of nickel deprivation are affected by diet composition. For example, vitamin B_{12} status affects signs of nickel deprivation in rats, and the effects suggest that vitamin B_{12} must be present for optimal nickel function. The nickel function also may involve folic acid because an interaction between these two affected the vitamin B_{12} and folic acid-dependent pathway of methionine synthesis from homocysteine. Nickel might function as a cofactor or structural component in specific metalloenzymes in higher organisms

because such enzymes have been identified in bacteria, fungi, plants, and invertebrates. These nickel-containing enzymes include urease, hydrogenase, methylcoenzyme M reductase, and carbon monoxide dehydrogenase. Moreover, nickel can activate numerous enzymes *in vitro*.

Based on a lack of human studies, no recommended intake levels have been set for humans. Life-threatening toxicity of nickel through oral intake is unlikely. Because of excellent homeostatic regulation, nickel salts exert their toxic action mainly by gastrointestinal irritation and not by inherent toxicity. Based on extrapolation from animal studies, the UL has been set for the US and Canada at the following doses of soluble nickel salts: 1–3 years, 0.2 mg; 4–8 years, 0.3 mg; 9–13 years, 0.6 mg; and all adolescents and adults, 1 mg.

Rubidium

Rubidium deficiency in goats reportedly results in depressed food intake and life expectancy, and increased spontaneous abortions. If rubidium is required by humans, the requirement probably would be no more than a few hundred micrograms per day, based on animal data. Rubidium is a relatively nontoxic element and thus is not of toxicological concern from the nutritional point of view.

Silicon

Most of the signs of silicon deficiency in chickens and rats indicate aberrant metabolism of connective tissue and bone. For example, chicks fed a silicon-deficient diet exhibit structural abnormalities of the skull, depressed collagen content in bone, and long-bone abnormalities characterized by small, poorly formed joints and defective endochondral bone growth. Silicon deprivation can affect the response to other dietary manipulations. For example, rats fed a diet low in calcium and high in aluminum accumulated high amounts of aluminum in the brain; silicon supplements prevented the accumulation. Also, high dietary aluminum depressed brain zinc concentrations in thyroidectomized rats fed low dietary silicon; silicon supplements prevented the depression. This effect was not seen in nonthyroidectomized rats. Other biochemical actions suggest that silicon is an essential element. Silicon is consistently found in collagen, and in bone tissue culture has been found to be needed for maximal bone prolylhydroxylase activity. Silicon deficiency decreases ornithine aminotransferase, an enzyme in the collagen formation pathway, in rats. Finally, silicon is essential for some lower forms of life in which silica serves a structural role and possibly affects gene expression.

Much of the silicon found in most diets probably occurs as aluminosilicates and silica from which silicon is not readily available. Owing to lack of evidence for a biological role for silicon in humans, no recommended intakes have been set. Silicon is essentially nontoxic when taken orally. Magnesium trisilicate, an over-the-counter antacid, has been used by humans for more than 40 years without obvious deleterious effects. Other silicates are food additives used as anticaking or antifoaming agents.

Tin

A dietary deficiency of tin has been reported to depress growth, response to sound, and feed efficiency, alter the mineral composition of several organs, and cause hair loss in rats. Additionally, tin has been shown to influence heme oxygenase activity and has been associated with thymus immune and homeostatic functions.

Owing to lack of data no recommended intakes have been set for tin. Inorganic tin is relatively nontoxic. However, the routine consumption of foods packed in unlacquered tin-plated cans may result in excessive exposure to tin, which could adversely affect the metabolism of other essential trace elements including zinc and copper. Because $50\,\mathrm{mg\,day^{-1}}$ of tin was found to affect zinc and copper metabolism, routine intakes near this amount probably should be avoided.

Vanadium

Vanadium-deprived goats were found to exhibit an increased abortion rate and depressed milk production. About 40% of kids from vanadium-deprived goats died between days 7 and 91 of life with some deaths preceded by convulsions; only 8% of kids from vanadium-supplemented goats died during the same time. Also, skeletal deformations were seen in the forelegs, and forefoot tarsal joints were thickened. In rats, vanadium deprivation increases thyroid weight and decreases growth. Other biochemical actions support the suggestion that vanadium could possibly act in an essential role. *In vitro* studies with cells and pharmacological studies with animals have shown that vanadium has: insulin-mimetic properties; numerous stimulatory effects on cell proliferation and differentiation; effects on cell phosphorylation-dephosphorylation; effects on glucose and ion transport across the plasma membrane: and effects on oxidation-reduction processes. Some algae, lichens, fungi, and bacteria contain enzymes that require vanadium for activity. The enzymes include nitrogenase in bacteria, and bromoperoxidase, iodoperoxidase, and chloroperoxidase in algae, lichens, and fungi, respectively. The

haloperoxidases, catalyze the oxidation of halide ions by hydrogen peroxide, thus facilitating the formation of a carbon–halogen bond. The best known haloperoxidase in animals is thyroid peroxidase. Vanadium deprivation in rats affects the response of thyroid peroxidase to changing dietary iodine concentrations. Since a functional role for vanadium has not been determined in humans no recommended intakes have been set.

Vanadium can be a relatively toxic element. Green tongue, cramps and diarrhea, and neurological effects have occurred in humans ingesting vanadium salts. Based on renal damage in animals, the UL for adults is 1.8 mg vanadium salts per day, with insufficient data to set a UL for other age groups.

Dietary Sources

The requirements for the ultratrace elements will be met if a person consumes a diet based on the dietary guidelines recommended by. For some areas of the world, especially in developing countries where traditional, monotonous diets are based primarily on a cereal (particularly rice) or tuber staple, the intake of several ultratrace elements (e.g., boron, molybdenum) could possibly be low. Reported typical dietary intakes (mostly for industrialized countries) and rich sources of the ultratrace elements are shown in **Table 3**.

UNITED NATIONS CHILDREN'S FUND

J P Greaves, London, UK
R Shrimpton, Institute of Child Health, London, UK

The United Nations Children's Fund (UNICEF) is that part of the United Nations (UN) system that has a special mandate to improve the welfare of children and women. Beginning with a restricted mandate for a limited period, the organization now has a permanent concern for the whole child (rights to health, education, protection, etc.) throughout the world. This article describes the history of the organization, with special reference to how its approach to nutrition has evolved over the years. The article also describes its role, structure, and funding.

History

UNICEF was established for a limited period by the General Assembly of the UN in December 1946 as the United Nations International Children's Emergency Fund to provide assistance to children in Europe and China suffering from the devastations of World War II. In 1950, its life was extended for an additional 3 years, with a mandate covering all developing countries, and in 1953 the General

Assembly gave it permanent status in recognition of the chronic and continuing needs of children. Its name was changed to that by which it is known today: 'International' was dropped as being redundant and 'Emergency' as too restrictive, but the familiar acronym was retained.

Early Days

In its early days, UNICEF gave priority to relief and rehabilitation and the provision of material assistance, laying the foundations for its reputation as an efficient supply agency. UNICEF needed people 'in the field' to ensure supplies reached those for whom they were intended; this was the origin of UNICEF's network of country offices. The 'specialized agencies'—the Food and Agriculture Organization of the United Nation (FAO) and the World Health Organization (WHO)—provided technical advice from a regional or headquarters base.

In the year after it was created, UNICEF requested FAO and the WHO Interim Commission (WHO itself not formally having been established) for technical advice on child nutrition. A joint committee of specialists in nutrition and pediatrics was established, and its advisory report provided basic information on such matters as the energy and protein needs of different age groups, the importance of breast feeding, the negative effects of infections on nutritional status, and the consequences of deficiencies of micronutrients such as iodine, iron, and vitamin A. These remain major issues in public nutrition, although understanding has increased of how to address them successfully. UNICEF has developed its own technical capacity and has become recognized as primarily a developmental rather than a humanitarian organization, dealing in ideas as well as supplies.

During its early years, UNICEF's work on nutrition concentrated on support to direct child feeding through schools, especially through provision of dried skim milk, which was in plentiful supply. This was sometimes coupled with the development of local dairy industries. Fortification of milk powder with vitamin A was an issue—and sometimes still is today. Later, following the common scientific perception of the day, and guided by the Protein Advisory Group (PAG) of the UN system, UNICEF shifted attention from school to preschool feeding and to commercial production of low-cost, high-protein supplementary foods for children. However, costs could not be kept so low that those for whom they were chiefly designed could afford them, and although a frequent condition for UNICEF provision of plant was that the government should subsidize the product for the poor, this commitment could not be maintained.

Applied Nutrition and Nutrition Planning

During the 1960s, UNICEF provided support, with FAO technical inputs, to so-called applied nutrition programs (ANPs), which were essentially educational programs at the local level encouraging the production and consumption of 'nutritious foods.' Emphasis was placed on horticulture and raising of small animals; kitchen, school, and community gardens; and use of appropriate technology to store, preserve, and prepare foods and conserve fuel. Nutrition education was always a component and such programs were often linked to provision of health services, such as immunization, potable water, and environmental sanitation. Although some of these programs attempted to be responsive to local needs and to mobilize local resources, insufficient attention was given in practice to these critical matters, and ANPs tended to be regarded as of peripheral significance. Nevertheless, in some countries they were acknowledged to have laid the groundwork for national nutrition policies, to have provided the first practical experience of intersectoral cooperation at various levels, and to have increased recognition of the need to involve local people in community programs.

The 1970s saw attempts to introduce nutrition strategies into regional and national development planning. In 1971, the UNICEF executive board declared that "the best action was through the establishment of national food and nutrition policies." Governments were asked to consider specific measures designed to improve nutritional conditions of mothers and children of low-income families. However, these were primarily food based, and the insight of the Mixed Committee of the League of Nations, with its call in 1937 for multisectoral approaches to problems of hunger and malnutrition with a "marriage of agriculture and medicine," seemed to have been lost. Many found it difficult to accept that malnutrition could result either from infection or from an inadequate diet, or often from some combination of the two. Meanwhile, UNICEF continued to try to deal with poor child nutrition through interventions of various complementary kinds, including public health, small-scale agriculture, and the promotion of women's groups.

During this period, experience of program delivery and coverage and better understanding of the development process led to the formulation of concepts that have had a profound effect on the operational approach to improving nutrition. One of these

was the basic services concept, first presented by UNICEF to the World Food Conference in 1974 but accepted as policy by the executive board and endorsed by the General Assembly of the UN in 1976. The essence of this holistic approach lies in promoting and responding to community initiatives, the involvement of local community or village-level workers, appropriate technology, and effective support, technical supervision, and referral services. The objective is to foster self-reliance. Similar principles are behind the primary health care (PHC) approach, endorsed by the WHO/UNICEF jointly sponsored international conference on PHC in Alma Ata in 1978. The PHC strategy involves shifting the focus of attention to the primary level of health care, involving the community in its establishment and management, and recognizing the many different sectoral activities that contribute to improved health, among which the Declaration of Alma Ata included the "promotion of food supply and proper nutrition." Experience of these approaches has demonstrated the difficulty of generating community participation and the generally inadequate attention given to training and support of village-level workers. More fundamentally, problems have been encountered in the comprehension and acceptance of the philosophy of the approaches, indicating the importance of effective communication. Often, nongovernmental organizations (NGOs) are able to overcome these handicaps: The challenge then is to expand their local successes into the national scene.

Child Survival and Development

In 1982, UNICEF launched a new initiative, known as the Child Survival and Development Revolution, which focused on the young child and emphasized low-cost actions appropriate for the family but suitable for national application. This was characterized by some as selective PHC. Key components (all reflecting the synergism between nutrition and infection) were the protection and promotion of breastfeeding, immunization against the six EPI (WHO's Expanded Programme of Immunization) diseases, oral rehydration therapy in the control of diarrhea, and regular growth monitoring of the child primarily to help the mother promote optimal growth. Sometimes referred to as the GOBI strategy, it relied heavily on mass communication and social mobilization. The component that received most support was immunization, and in 1991 the UN recognized the attainment of the 1990 goal toward universal child immunization (UCI): 80% of all infants immunized against tuberculosis, polio, diphtheria, pertussis, tetanus, and measles.

UNICEF had become concerned by the erosion of breast-feeding consequent on urbanization and encouraged by aggressive marketing of breast milk substitutes, and it was actively involved with WHO and NGOs in steps that led to the adoption in 1981 by the World Health Assembly of the International Code of Marketing of Breast-Milk Substitutes. In 1990, UNICEF convened with WHO, with the cosponsorship of the US Agency for International Development and the Swedish International Development Authority, an international conference on the protection, promotion, and support of breast-feeding. This conference issued the Innocenti Declaration (named for its venue at the historic Spedale degli Innocenti in Florence, home of UNICEF's International Child Development Centre), which called for the reinforcement of a 'breast-feeding culture' and its vigorous defence against incursions of a 'bottle-feeding culture.'

Growth monitoring was perceived as a useful tool for promoting satisfactory growth of children, which itself represented the outcome of influences of diet and disease. Furthermore, child growth was held to be a sensitive and reliable indicator of overall development, and UNICEF advocated that nutritional status should be considered along with more conventional economic indicators in assessing situations and determining policy, in the context of its advocacy of 'structural adjustment with a human face.' Growth charts and weighing scales were widely distributed, but the approach came into some disrepute when it was recognized that too often it was perceived as an end in itself, a sort of technological fix, with little attention to how monitoring should be done and how the results should be used.

Aware of the importance of communication and concerned about identifying simple messages about survival and development of universal validity, although often requiring local adaptation or addition of specificity, UNICEF in 1989 published with WHO and the United Nations Educational, Scientific and Cultural Organization *Facts for Life: What Every Family and Community Has a Right to Know*. More than 15 million copies are in use in 215 languages. The third edition, published in 2002 by UNICEF and seven other UN agencies including the World Bank, covers 13 topics, including safe motherhood, breast feeding, nutrition and growth, diarrhea, and HIV/AIDS.

Nutrition Strategy and the World Summit for Children Goals

In 1990, the UNICEF executive board approved a new strategy for improving nutrition of children

and women in developing countries. The strategy stemmed from the Convention on the Rights of the Child: freedom from hunger and malnutrition are recognized as basic human rights, and continued malnutrition is unacceptable. The strategy proposed a methodology for the identification of appropriate actions through situation assessment and analysis rather than through a predetermined set of technical interventions. This so-called triple A cycle (assessment, analysis, and action, followed by reassessment, etc.) is applicable at household, district, and national levels.

Nutrition status is seen as an outcome. Immediate determinants are dietary intake and infectious disease. Underlying influences can be grouped into three major clusters: household food security, health services coupled with a healthy environment, and care for children and women. The degree to which the three conditions necessary for good nutrition are fulfilled depends on the availability and control of human, economic, and organizational resources at different levels of society: household, community, national, and international. Education has an important role, against a background of political, economic, cultural, and ideological factors. The conceptual framework advocated by the strategy for analyzing the nutrition situation is shown in **Figure 1**.

The strategy proposed a number of nutrition goals for the 1990s, shared with WHO. As endorsed by heads of government at the World Summit for Children in 1990, the goals were

- reduction of severe and moderate malnutrition among under-fives by half of 1990 levels;
- reduction of the rate of low birth weight (less than 2.5 kg) to less than 10%;
- virtual elimination of iodine deficiency disorders (IDD);
- virtual elimination of vitamin A deficiency (VAD) and its consequences, including blindness;
- reduction of iron deficiency anemia (IDA) in women by one-third of 1990 levels; and
- empowerment of all women to exclusively breastfeed their children for 4–6 months (later changed to 6 months) and to continue breast feeding with complementary food for up to 2 years of age or beyond.

The summit endorsed a number of other goals related to women's health and education, child health and sanitation, and basic education, all of which are relevant to the attainment of the goals for nutrition. Governments committed themselves to prepare and execute national plans of action to implement the summit goals. In 1992, the FAO/WHO International Conference on Nutrition in Rome included in its World Declaration and Plan of Action for Nutrition a commitment to the nutritional goals of the World Summit for Children.

In 1991, the first meeting on a global scale to pursue summit goals was held in Montreal,

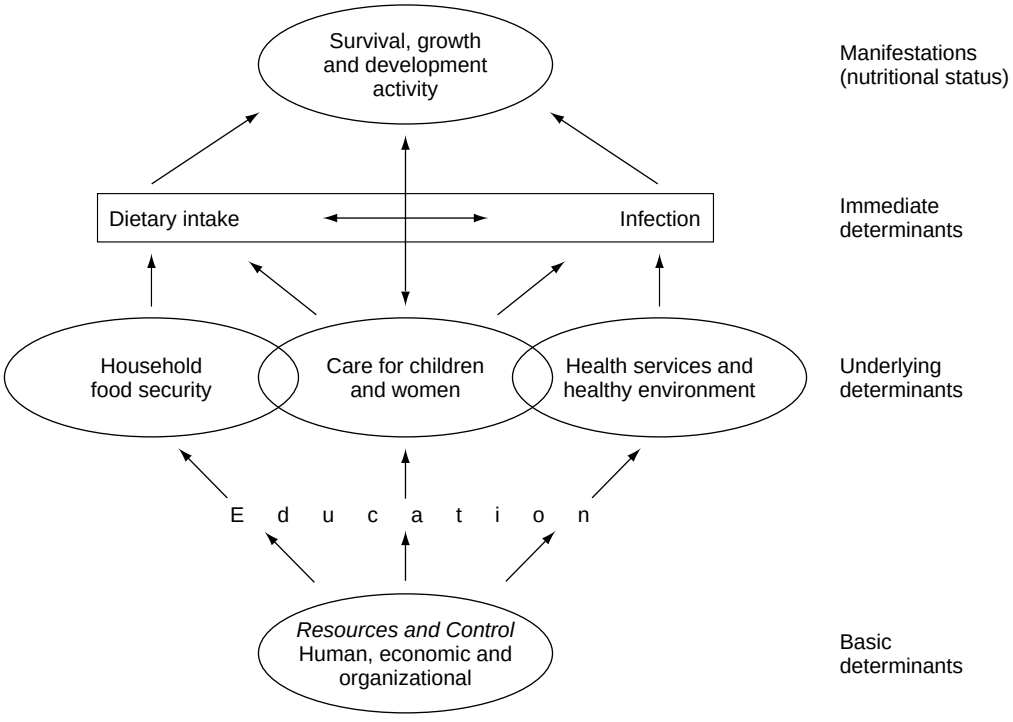

Figure 1 Determinants of child survival and development and nutritional status.

Canada: it was a policy conference on overcoming micronutrient malnutrition titled Ending Hidden Hunger. The strategy to control the three micronutrient deficiencies was to involve a country-specific combination of short-term and long-term measures, including dietary diversification, food fortification, and nutrient supplementation. In 1991, UNICEF also launched with WHO the Baby-Friendly Hospital Initiative, which formally recognizes maternity facilities that follow specified practices that enable mothers to make an informed choice about how to feed their babies and that helps them to establish and maintain lactation.

By 1993, UNICEF and WHO adopted mid-decade goals, which included goals for IDD, VAD, and breast-feeding, as a way to ensure early progress toward achieving the end-decade goals. The mid-decade goals were the more doable 'top down' goals that could be verified by coverage surveys. For IDD, it was Universal Salt Iodisation (USI), to be verified by the coverage of iodized salt at the household level. For VAD, it was the coverage of children aged 6–59 months consuming high-dose vitamin A capsules in the previous 6 months, and for breast-feeding it was the extent of exclusive breast-feeding at 4 months and the coverage of baby-friendly hospitals. The mid-decade push and prioritization ensured real progress toward these goals by the end of the decade.

By 2000, most children in more than 40 countries were receiving at least one high-dose vitamin A capsule yearly. Between 1998 and 2000, an estimated 1 million child deaths were prevented by vitamin A supplementation. USI was also a great success. Whereas in 1990 less than 20% of households were consuming iodized salt, by 2000 this was 90% or more in 24 countries, with a further 21 achieving 70–90%. The exclusive breast-feeding rates also increased by 10% during the decade, and by 2001 more than 15,000 hospitals in 136 countries had been certified as baby-friendly. These large increases in coverage of iodized salt, and also of vitamin A capsule distribution, and exclusive breast-feeding, can be translated into millions of child lives saved, and child disabilities prevented, and improvement in children's development improved.

Nutrition in the World Fit for Children

At the Special Session on Children held at the UN General Assembly in May 2002, the nations of the world committed to building a world fit for children and adopted a resolution that includes the World Fit for Children (WFFC) goals for 2010. Among the WFFC goals are the reduction of child malnutrition among children younger than 5 years of age by at least one-third, with special attention to children younger than 2 years of age, and reduction of the rate of low birth weight by at least one-third.

UNICEF has adopted in its medium-term strategic plan for 2002–2005 five priorities that derive from emphasis on the rights of the child: integrated early childhood development (IECD); immunization 'plus' (signifying services that can utilize the same delivery system, for example, vitamin A supplementation); girls' education; improved protection of children from violence, abuse, exploitation and discrimination; and fighting HIV/AIDS.

The IECD approach is a holistic one that looks at the whole child and starts from before birth to preschool age, with the emphasis on children younger than 3 years of age. IECD is where nutrition now resides in terms of UNICEF programs. Reduction of protein energy malnutrition (PEM) through implementation of the nutrition strategy requires what have been called diagonal approaches—those that respect both vertical goal orientation and horizontal community process capacity building. IECD should facilitate the tackling of PEM since it is about understanding how to deliver a set of integrated services to children in their community. UNICEF's capacity to do this alone is limited, and partnerships are sought with others, including the World Bank.

With regard to emergencies, UNICEF continues to be responsive to natural and man-made disasters within the constraints of its mandate and resources, and in close cooperation with other parts of the UN system. Thus, UNICEF would not normally provide food aid, this being the province of the World Food Programme (WFP), but may provide supplementary or therapeutic foods for children, health supplies, blankets and tents, fuel for heating, water purifiers, cash assistance, and logistical support.

Role

UNICEF's role can be appropriately summarized by the following quotations from its mission statement, adopted by its executive board in January 1996:

> UNICEF is mandated by the United Nations General Assembly to advocate for the protection of children's rights, to help meet their basic needs and to expand their opportunities to reach their full potential. ... UNICEF aims, through its country programmes, to promote the equal rights of women and girls and to support their full participation in the political, social and economic development of their communities.

UNICEF pursues its advocacy and educational role at all levels and in all possible fora. The World

Summit for Children at the UN in New York in September 1990 attracted 71 heads of state and government and also ministers or other senior officials from 88 other countries—at the time the largest gathering of world leaders in history. In May 2002, the UN General Assembly held a special session on children, which was notable for the unique and active participation of approximately 400 children from more than 150 countries. UNICEF had facilitated the collection in these countries of key information about children's rights and well-being to assess progress made for children since the 1990 World Summit. Nutrition (and other) indicators for each country in the world are published in the annual *State of the World's Children* reports.

UNICEF's programming role is essentially a country activity, conducted by the UNICEF representatives and their staff in close collaboration with officials of concerned government departments (e.g., of planning, health, education, and social affairs ministries) and in consultation with representatives of other UN agencies and NGOs. The country programming process, which begins with a situation analysis (describing the situation of women and children in the country and reviewing past programs of cooperation and potential areas of future cooperation), is intended to ensure that the UNICEF country program relates to the needs of children and women in the country, is fully integrated into the government program, reflects government policy and programs as well as policies established for UNICEF by its board, and is complementary to assistance provided by other multilateral and bilateral agencies. The process involves balancing a global ethic with country priorities, but there need be no inconsistency between setting international and national goals and targets and at the same time working to empower local partners to participate in progress toward improved nutrition. 'Bottom-up' advance need not be an alternative to 'top-down' advocacy and policy development.

UNICEF operates one of the largest supply networks in the UN system. In 2001, it procured $596 million worth of supplies relating to health, education, water and sanitation, and nutrition products, including 40% of global vaccine doses for children.

UNICEF works closely with other UN agencies concerned with nutrition, particularly WHO, FAO, WFP, and the World Bank. A long-standing mechanism for harmonization of policies with WHO exists in the form of a Joint Committee on Health Policy (now including UNFPA). UNICEF is a major supporter of the United Nations System Standing Committee on Nutrition (SCN). The SCN (which evolved from the earlier PAG) currently has 19 UN members and also representatives of other agencies, bilateral donors, and NGOs; it is the focal point for promoting harmonized nutrition policies and strategies throughout the UN system and for strengthening collaboration with other partners.

Structure

Within the UN system, UNICEF's comparative advantage relates to its field-based structure. At the end of 2002, 86% of UNICEF's 8083 staff members were located in its 199 field offices, supported by 7 regional offices. UNICEF's headquarters is in New York. In 2002, professional staff numbered 3458, representing 165 different nationalities: 68% were from developing countries, and 45% were female.

UNICEF is governed by an executive board consisting of representatives of 36 countries who serve on a rotational basis. The board is responsible for overall policy and for authorizing receipt and expenditure of funds. The executive director is appointed by the secretary-general of the UN in consultation with the board. The executive director appoints all other staff.

UNICEF has established a unique structure of supporting bodies in most industrialized countries. Known as National Committees for UNICEF, in 2001 there were 37 largely autonomous organizations with an important role of advocacy and fund-raising. They each have a formal relationship with UNICEF and are responsible for fund-raising operations in their own countries, public information and development education, and promotion of UNICEF concerns, including the Convention on the Rights of the Child and follow-up of the Children's Summit. Much of their work is supported through voluntary action.

Funding

UNICEF is funded entirely through voluntary donations, chiefly from governments but also from private institutions and individuals. In 2001, the total income was $1225 million, of which $990 million was for regular programs (unrestricted plus earmarked resources) and $235 million raised for emergencies (**Table 1**). Of the total, governments and

Table 1 UNICEF Income, 1999–2001 (in millions of US$)

	1999	*2000*	*2001*
Regular resources	589	563	551
Other (regular)	332	377	439
Other (emergencies)	197	199	235
TOTAL	1118	1139	1225

intergovernmental organizations contributed 64%, and the National Committees contributed nearly 30%.

Although 152 countries made some contribution to UNICEF in 2001, only 9 contributed more than $40 million from both the governmental and private sectors. The three governments that contributed most in total funds were the United States, Japan, and the United Kingdom. In terms of total funds per head of population, Norway, Sweden, and Denmark contributed most.

UNICEF has developed supportive relationships with international service organizations such as Rotary International, which has contributed more than $462 million for the global eradication of polio (with $167 million directly through UNICEF), and Kiwanis International, which raises funds for the elimination of IDD. Canada and Sweden are also major contributors for such activities.

Regular resources are available for cooperation in country programs approved by the executive board, as well as for programme support and administrative expenditures. Allocations are made to country programs according to three criteria: annual number of deaths of children younger than 5 years per 1000 live births, income level (GNP per caput), and the size of the child population. Thus, most money is allocated to the larger, and poorer, countries. Representatives have the responsibility to negotiate with governments programs of cooperation within these allocations. Such programs may be expanded if other resources become available.

Total expenditure in 2001 was $1246 million—93% for country programs of cooperation and 6% for management and administration of the organization.

URBAN NUTRITION

N Solomons, Center for Studies of Sensory Impairment, Aging and Metabolism (CeSSIAM), Guatemala City, Guatemala

Introduction

For most readers of this encyclopedia, the notion of urban living and life style would be considered the demographic norm or a 'ground state.' In fact, the history of human biological and cultural evolution was written in rural areas. Currently, 53% of the population of developing countries is still living in the rural countryside as agrarian peasants or hunters; this proportion has fallen rapidly from 83% in 1950. The context for the topic of urban nutrition includes: the manner in which wealth and income are distributed among the urban populations; the agricultural efforts within and without the cities to supply food to the urban masses; trends and fashions in marketing and consumption of foods; and the ecological and environmental influences generated in the agrarian countryside and in the urbs themselves.

Urbanization

For 90% of the duration of *Homo sapiens*' evolution, all human endeavor was related to obtaining

food, reproducing and rearing young, or defense and survival. During that period, humans were part of nomadic tribal groups roving over the hunting and foraging ranges that provided their food, the pelts or fiber for their clothing, and other necessities. More recently, some 40 000 years ago, mankind witnessed the advent of the pastoralist lifstyle, with pursuit of grazing livestock across available pasture areas constituting a new form of livelihood.

Only with the domestication of plants and the emergence of the agrarian life style, some 10 000 years ago, did settling of specific terrains become a human attribute. For the first time in human history, a rural family's effort could produce enough food to feed more than just a single family. Agriculture was the precondition for human 'civilization,' as it freed some of the time, for some of the population, from an obligation to gather food as the sole human pursuit. Thus, classes of artisans, traders, clergy, politicians, and warriors could enter the society, supported and fed by the livestock, crops, and produce supplied by farmers. These classes did not live in dispersed terrains but rather created communities that were larger and more complex than a tribal village. The first towns represent either the seats of rulers or the temple complexes of religious elites. As trade expanded, towns and cities developed along the routes of commerce. These were often situated along waterways and at coastal harbors, or scattered along caravan routes. With the rise of warrior classes, protective walls and fortifications began to surround such communities. The Mediterranean and Asia Minor were the sites of the cities of antiquity such as Babylon, Athens and Sparta, Alexandria, Rome, and Carthage.

The evolution of mercantile trade in Europe became a motive for constructing even larger cities, as exemplified by the city-states of Renaissance Italy. Finally, the Industrial Age gave a whole new charge and dimension to cities. The change of production from artisan guilds to workers in factories altered the character of urban life. Crowded teeming cities with tenements, as described by Dickens, came into being in Europe at the beginning of the nineteenth century. These early modern metropolises were smoky, grimy, smelly, unsanitary places, ripe for the occurrence of occupational mishaps and the transmission of contagious diseases. Although the caloric supply might have been sufficient, only the most stably preserved of foodstuffs could be used to feed urban populations before the era of refrigeration and food technology. Fresh fruits and vegetables were available largely to those still living on countryside lands.

It is important to realize that until very recently in world history, the proportion of humanity living in cities remained very small. Most were living in tribal settings, as nomadic pastoralists, or as rural peasants. The United Nation defines an 'urban center' as a concentrated population of at least 20 000 inhabitants. By this definition, only 5% of the world's population was urbanized at the turn of the nineteenth century, 13% at the turn of the twentieth century, and 47% by the year 2000. In 1950, the urban population of developing countries was 17%; by the year 2000, it had reached 44%. The degree of urbanization varies from region to region. In the Americas, 75% of the population is now urban, whereas on the African continent, urbanization hovers around 40%.

The massive megapolises, cities of over 10 million inhabitants, are a recent phenomenon. Initially, the biggest metropolitan areas, such a New York and Tokyo-Yokohama, were in industrialized countries. In 1975, there were only five cities with more than 10 million inhabitants; this rose to 19 in 2000, and is projected to reach 23 by the year 2015. The top-ten of megapolises 10 years hence are projected to be: (1) Tokyo-Yokohama; (2) Bombay; (3) Lagos; (4) Dhaka; (5) Sao Paulo; (6) Karachi; (7) Mexico City; (8) New York; (9) Jakarta; and (10) Calcutta. Only two of these are in currently industrialized nations.

Urbanization and Nutrition Transition

Whatever the era in the evolution of cities, from antiquity to the present, it is likely that the cuisine and dietary fare of urban populations has always differed from that in tribal, nomadic, or agrarian settings of the same countries. On the one hand, if the town were a coastal port or fishing village, consumption of fish and seafood would be higher than in the interior countryside, while populations of trading centers would have more access to exotic, imported items such as Oriental spices and teas or Caribbean rums and molasses. On the other hand, food is produced in the countryside. The agrarian producers have first access to the crops and foodstuffs produced, whereas the cities can only gain that which is transported to the urbs and offered for sale. Generally, then, the basic staples in the cities are those that are traditional to the farmers that serve them.

Despite a history of poorly mechanized industry in urban factories that required heavy physical labor, an even greater daily energy output was required for rural agricultural pursuits. Hence, the amount of dietary energy needed for child growth

or to maintain energy balance is generally lower for urban populations. Until recently, the variety of foods, especially produce,- was more limited in urban markets than on farms and plantations. The meat in urban centers was more likely to be dried and salted than fresh, and one or two staples, grains or tubers, would provide the bulk of dietary energy.

Electricity, food technology, and concentration of wealth in urban areas have changed this panorama in recent years as a process of 'nutrition transition,' a term introduced by Barry Popkin, has come to dominate particularly the urban populations of today's developing nations. More, rather than less, variety of food is the reality of modern cities. Sweetened and flavored processed foods have higher appeal than coarse staple roots and cereals. The 20th century saw a meteoric rise in the demand for and production of cooking oils and fat-based spreads, while refrigeration meant that fluid milk did not have to come from the udder of a dairy animal on one's doorstep to be safe and available. Processed foods – bottled, canned, and frozen – entered the market with the rise of the food sciences and food technology, and sweets and desserts became a larger component of daily fare. Inexpensive vegetable oils from corn, soy, safflower, cottonseed, etc., entered international commerce for cooking, or were hydrogenated and solidified into margarines and shortening. These dietary changes are not restricted to the affluent elite of developed countries, but are part of the change affecting the urban middle and lower classes in developing countries to an ever-increasing extent. However, at the same time, those living in abject poverty in both urban unemployment and rural landlessness could be unable to participate in any of this varied and energy-dense fare. This is the setting for 'nutrition transition' defined by Popkin as 'the rapid shift in the structure of diet in low-income countries and the coexisting problems of under- and overnutrition.' With respect to the overnutrition aspect, developing country residents are participating in the dietary patterns associated with increased risk of chronic diseases.

Contemporary Food Supplies and Diets for the Cities

In terms of availability, factors such as transport, refrigeration, sewage treatment and disposal, etc., have allowed the modern city the option to overcome some of the barriers to having the food supply safe for the urban populace. Westernization of the dietary patterns of cities is an interesting consequence and a reinforcing cycle of supply and demand. Not only domestic production, but also the importation of commodities, becomes an alternative for supplying food to urban populations. The transport infrastructure to get foods to cities from regional farms or across routes for foreign imports has improved with the advent of refrigeration and high-speed transportation. More perishable foods can reach urban tables, not only from the interior of countries but from overseas. Currently, issues of food supplies are generally more an issue of accessibility at the household level than availability in the urban marketplace.

Electrification and refrigeration are factors in household diets, as well. Although most cities have electricity, not all urban homes have their own refrigerators; but the food consumed in these homes will have been refrigerated in its processing, storage, and while on sale in the store. The factor of access to refrigeration has been associated with a major decrease in the use of traditional conservation methods such as salting, pickling, and smoke-curing of food for preservation, as well as improved microbiological quality. In this respect, urbanization may be a factor in reducing the incidence of carcinogenesis associated with mycotoxins, salt, and organic byproducts, as well as the incidence of episodes of some food-borne diseases.

Accessibility (the ability to obtain items actually on the market) is more important in determining what gets onto the tables of urban households. Inequality of resources and wealth within the urban populations gives rise to food insecurity within households in the urban area. Often a pattern of geographical distribution demarcates the zones with the highest risk of insecure and inadequate household food supplies. Generally, the greater diversity of items that one is able to include in one's diet, the lower is one's risk of experiencing food insecurity.

Urban Agriculture

Urban agriculture, using marginal lands within the confines of the metropolitan area, can save up to 20% on outlays of cash for food for poor families at the expense of 1–2 days of labor per week. Urban gardening is seen as a means to improve public health not only through improving economic and food security, but also in providing exercise, psychological, and community well-being, and environmental stewardship. The type of plants that are grown in urban settings are largely foods that contribute micronutrients, and are much less likely to be the

staples that provide the bulk of energy and protein. For reasons of sanitation and zoonotic diseases, as well as waste disposal, domestic livestock in the cities are a much more remote option, although aquaculture with treated waste waters could provide for fish, crustaceans, and mollusks toward meeting the protein needs of urban populations.

Street Foods

Roads and highways may be a phenomenon of rural communication but the street is an urban entity. Street foods are defined by the Food and Agricultural Organization as "ready to eat foods and beverages prepared and/or sold by vendors, especially in streets and others similar public places." With urban life has come both the opportunity, and at times the necessity, to consume one or more daily meals away from one's home. For the affluent and middle-class, cafeterias and restaurants serve the clientele looking for a meal outside of the household. For low-income populations, street foods fill this dietary niche. One-quarter or more of daily calories are often consumed outside of poor urban homes by adult workers and high school children.

The main concerns about street foods have been issues of sanitation and microbiology. The dietetics, anthropology, and economics have remained more obscure. As Sarah Atkinson has said with respect to street foods: "safety has to be assessed not by middle class standards but in relation to other food sources and the environmental conditions in the homes of those buying these foods." Positive aspects are the accessibility of these foods to the poor and the economic empowerment that street foods represent for the vendors. Scrutiny of street food from municipal authorities may come from the fact that it is an unregulated informal activity from which taxes or licensure revenues cannot be collected. Street food is a convenient scapegoat for politicians and bureaucrats when explaining local epidemics that may relate to other failings of the municipal investment in infrastructure.

Nutrition and Health in the Urban World

The way in which people eat is a major determinant of their nutritional stores and status, but issues of life style, health and pollution modify and influence the nutriture of individuals and populations. Each of these factors contributes to the distribution of the simultaneous under- and overnutrition states that characterize nutrition transition.

Labor market shocks impact on maternal pursuits, child work, and schooling. Rural children have traditionally worked on both household and farm chores as part of an integrated family-production pattern. In urban areas, mere economic survival often obligates families to send children to work in factories at low wages, exposing them to occupational risk and interfering with their formal education. To the extent that urban mothers seek income-generating activities outside of the home, monetary resources may be bolstered by child-rearing and child-caring and meal provision can be disrupted. Breast-feeding is one form of meal provision, i.e., that for the infant, that can be influenced adversely by maternal work obligations. In general, less exclusive breast-feeding and shorter total lactation are seen in urban mothers as compared to their counterparts in the countryside.

Urban poverty and undernutrition are growing, in part because of the influx of migrants. Spatial distribution of the pockets of poverty can often be identified on a map of the city. The unempowered and abjectly poor tend to congregate in the least desirable and most precarious areas of the urban landscape. It has been established that such groups have scarce municipal services and low incomes. The relative social power of women in such households is vastly inferior to that of the men. True food insecurity is a legitimate concern in these zones of urban poverty.

Finally, pollution, some of which has its negative effect on the population by contaminating the food supply, cannot be ignored. In Jakarta, where leaded gasoline is still the norm, individuals spending time on the streets became contaminated. Poor air quality (smog) can provoke respiratory distress with a cascade effect on appetite, regular eating, and nutrient retention.

Nutritional Deficiencies of Urban Populations

At a physiological level, nutritional status is a function of the intake, absorption, and retention of nutrients. Any of the micronutrient deficiencies common to human populations can be seen in residents of towns and cities. Household food insecurity or poor caring practices can explain low intakes of total macronutrients or diets with poor micronutrient density and bioavailability. To the extent that sanitation may be better in the urban setting, disease-related wastage of nutrients may contribute less to the process of general undernutrition reflected in poorer growth and higher prevalences of stunting and wasting.

Iron deficiency is prevalent in infants, young children, fertile women, and pregnant and lactating women, independent of social class or setting. If

lead exposure is present in the cities, this can aggravate iron status, especially of the young. In the broadest generality, micronutrient deficiencies are less frequent among urban populations, but a residual prevalence of poor status with respect to riboflavin, zinc, folic acid, and vitamin B_{12} is common in low-income segments of urban populations. Intervention programs are logistically more accessible to urban populations, but relief agencies often direct and target their assistance to the countryside, bypassing the problem that may exist around their headquarters in Third World capitals.

Social determinants related to poverty in urban communities and households constitute the underlying reasons for impaired growth and poorer anthropometric indices. Discrepancies in women's status, that is their social and economic power relative to men in the same households and societies, has a profound influence on the status of their children and the risk of the latter to suffer stunting and wasting. Greater equality between the sexes generally results in overall improved prenatal, obstetrical, and child care, better complementary feeding and treatment of illness, and higher immunization rates. Urban settings would generally tend to foster less traditional social views and provide women with more options for self-realization. Moreover, campaigns and programs for empowering women through education and entry into the work-force would be logistically easier to maintain in towns and cities. Hence, both the better general nutritional status of children in cities may be a consequence of trends toward a greater equality of women and improved decision-making power in favor of their children's nutritional evolution.

Survival through and beyond infancy and preschool years with generally more favorable nutritional status than one's rural counterparts is likely to be reflected in continued better nutriture into childhood and adolescence. A phenomenon of family disintegration, more commonly seen in urban communities, has led to the proliferation of street children who live in the street or of the street. Several aspects of the stereotypical portrait of their life style, including abuse of glue and illicit drugs and participation in child prostitution, would point to increased risks of organic damage and sexually transmitted disease, including HIV/AIDS. On the other hand, through the various modalities of obtaining income from legitimate sales and tasks, to extorsion, theft, and prostitution on the illegitimate side, street children have more disposable income than other urban children from equally humble origins but dependent on meager household means. Little research into comparative nutritional status of street children in the urban setting has been conducted, but fragmentary findings suggest that their income and ingenuity provides them with a more diverse diet than their homebound peers.

The urban elderly are another generational group of concern in terms of their risk to suffer nutritional deficiencies. To the extent that their age, *per se*, makes them more susceptible to undernutrition and social isolation, with the weakening of extended family traditions, and afflicts more urban than rural elders, their situation in the urban context can be more nutritionally precarious.

HIV/AIDS can be more of an urban or a rural health problem depending upon the country in question, its patterns of transmission, and the specific differences of urban and rural culture. Wherever it occurs, for HIV-infected individuals their disease represents a double burden for their nutrition. On the one hand, the ravages of the infection interfere with appetite, disrupt metabolism and deplete nutrient reserves; on the other hand, lost income and the cost of treating the illness jeopardizes individual food budgets and poses the risk of household food security.

Nutritional Excess in Urban Populations

The most important nutritional excesses to consider are those of overweight. This is officially defined as a body mass index (BMI) of $>25\,kg/m^2$. For children, overweight begins at the 85th percentile of normative curves and obesity at the 95th percentile, as defined on the 2000 BMI charts of the US Center for Disease Control and Prevention.

Physical activity patterns are altered from the traditional rural focus role of food production. Even construction and manufacturing work requires increasingly less physical effort. Household chores are favored by electrical labor-saving devices and home delivery of goods and services such as fuel and water. For both adults and children, sports and active recreational pursuits are being replaced by television watching and computer entertainment, including internet, in urban settings. Much of the increase in the number of overweight individuals in cities is ascribed to sedentariness. A new and troubling association of stunted child-overweight mother pairs has been identified, but it is not restricted to urban families. However, low stature seems to be a risk factor for overnutrition as confirmed in China, Singapore, Brazil, and Mexico, especially in their urban areas.

The tendency not only to eat away from home but also omit specific meals is an innovation of modern urban life; family integrity at mealtimes is more

traditionally observed in rural areas Not consuming breakfast is a habit surging in urban households and with it comes proven deficits in attention span and school and work performance. Paradoxically, breakfast-skipping behavior is found to be associated with generally less physical activity and more sedentary life styles and is also linked to excess weight gain. Moreover, higher usage of alcohol and tobacco are found in those who regularly skip the breakfast meal.

Vitamin or mineral excess as a public health problem is rare. It generally occurs as the result of excessive consumption of micronutrient supplements, and this would be more likely to take place in the urban setting.

Diet, Nutrition, and Quality of Life

It is probably safe to conclude that suffering nutritional deficiency and dying a premature death from infectious illness is more likely to occur among the rural agrarian peasantry than among the urban masses. But for rural individuals who survive accidental and infectious deaths, their plant-based diets and rigorous lifelong physical activity patterns makes the goal of 'dying healthy in old age' a stronger possibility. With extended life expectancy among urban populations, ensuring the quality of life in later life is important as both a humanistic and economic consideration. Cardiovascular and malignant diseases produce lingering debility and dependency, robbing individuals of well-being and placing a burden of healthcare on relatives and governmental resources. Global and sustainable interventions to reduce sedentariness and pathogenic dietary practices in the growing segment of the world's population living in cities are an imperative for social and economic stability going forward.

Conclusions

Through the progressive evolution from rural residence in nomadic tribes and pastoral pursuits to settling of farms and plantations, the conditions for creation of towns, cities, and metropolises have emerged. Public health nutrition and the epidemiology of nutrition must focus more on what has been termed 'urban nutrition' as the world's population shifts from rural to urban residency. The essential complexity of providing for human needs in densely populated settings has repercussions for the resulting nutriture of the urban populations and for the nature of their environments. Street foods, street children, urban pollution, and diet and life styles can foster or be associated with undernutrition and reduced productive capacity in some circumstances while contributing to overnutrition and excess noncommunicable disease in others. Rather than use the 'lessons' from the rural experience in developing countries, it is important to direct one's reading, one's research, or both to the study of the urban milieu in order to gain insights for addressing the challenges of urban nutrition. **Table 1** outlines a framework of opportunities for urban nutrition research that derive from the considerations in this review.

Table 1 Opportunities in urban nutrition research

- Basic description of diet and nutrition in selected townships and metropoli
- Rural-urban comparisons
- Role of family and household relationships
- Influence of rural-to-urban migration on nutritional status and dietary status
- Universality and generalizability of dietary factors for degenerative diseases
- Contributions of urban agriculture to the urban food supply
- Influence of urban pollution on the food supply and nutritional status
- Nutritional and health status of street children
- Containing the epidemic of obesity and metabolic syndrome in urban populations

VEGETARIAN DIETS

J Dwyer, Tufts University, Boston, MA, USA

Published by Elsevier Ltd.

Introduction

Vegetarian eating patterns are the norm in many parts of the world, while in Western countries they are the exception. Currently, about 2.5% of adults in the US and 4% of adults in Canada follow some sort of self-described vegetarian diet. This article examines the nutritional adequacy of vegetarian diets and some eating patterns and practices that affect it, focusing on Western countries.

Definitions are important in discussing vegetarian diets and nutritional adequacy since both of these terms cover a multitude of disparate characteristics.

Vegetarianism

For most vegetarians today, their investment in vegetarian eating as an all-encompassing philosophical system for organizing all of life is minimal. Food preferences, habit, and flavor take precedence over philosophy in dictating their eating choices. That is, these individuals have vegetarian eating styles but they do not subscribe to vegetarianism.

There is a smaller group of vegetarians whose eating patterns serve as badges of honor for a deeper and more encompassing set of beliefs that includes and is reflected in but is not limited to their eating patterns. This belief system is referred to as vegetarianism. Vegetarianism is a philosophy and belief system rather than simply an eating pattern. Those who subscribe to vegetarianism hold strong convictions about the moral, metaphysical, ethical, or political appropriateness of their eating choices. Often more restrictive animal food and other dietary avoidances are accompanied by the most deeply held views. In fact, it is a minority of all of those who consume vegetarian diets who subscribe to vegetarianism. Advocates of vegetarianism have become more militant in recent years. With some vegans, it remains an ethical, philosophical, or predominantly religious conviction, or a deeply rooted health concern that is privately held and the diet is practiced with great conviction. Other vegans are strongly committed to enlisting additional followers and appear to have become more militant in recent years. Some have adopted broader agendas, including that of animal rights, while others do not. In the US, animal rights organizations such as People for the Ethical Treatment of Animals (PETA), the PETA foundation, the Animal Liberation Front, and the Physicians' Committee for Responsible Medicine (PCRM) in the US are all very vocal. They finance advertizing, journal articles, and educational efforts to encourage adoption of their views. Extensive efforts are directed toward youth. Similar groups are also active in other countries.

Vegetarian Eating Patterns

The term vegetarian diet does not fully describe the variety in nutrient intakes and health status of those

Table 1 Common types of vegetarian dietary patterns categorized by animal food use

Pattern	*Comments*
Meat avoiders	Limit or avoid red meat and other flesh foods; may also restrict poultry, fish, and seafood. Diets are similar in most respects to nonvegetarian diets
Lacto-ovo vegetarians	Avoidances include all meat, poultry, and often fish, but consume milk products and eggs. Iron may be limiting and it can be obtained from iron-fortified cereals. Low-fat dairy products are preferred to keep intakes of saturated fat and total fat moderate
Lacto vegetarians	Avoid all meat, fish, poultry, and eggs. Nutrient considerations same as above
Macrobiotics	Numerous restrictions generally including avoidance of all meat, poultry, milk and eggs, but may consume fish in small amounts. Also avoid sugar and other refined sweeteners, foods that are members of the nightshade family (peppers, egg plant, tomatoes, and potatoes) and tropical fruits. Current variations of the diet are less restrictive than the versions of 30 years ago, but deficiencies of energy, iron, calcium, vitamin B_{12}, vitamin D, and other nutrients may still arise in weanlings, pregnant women, and young children if diets are nutritionally unplanned
Vegans	Avoidances include all animal products including meat, fish, poultry, eggs, and dairy products. Some vegans may also refuse to use any animal products in daily life. Without careful planning, energy, vitamins B_{12} and D, and bioavailable sources of iron may be low. Concentrated sources of energy-dense foods such as sugars and fats are helpful in increasing energy intakes. Vitamins B_{12} and D and calcium can be supplied from fortified soy milk, fortified cereals, and/or dietary supplements of these nutrients. Usually protein is adequate if a variety of protein sources is consumed
Other patterns	Raw food eaters and 'living food' eaters avoid animal foods and eat raw plant foods, including fruits, vegetables and cereals with special health foods such as wheatgrass or carrot juice. Fruitarians consume diets mostly of fruits, nuts, honey, and olive oil. Rastafarians eat a near-vegan diet and avoid alcohol, salt-preserved foods and additives. Yogic groups vary in their eating patterns but are often lacto vegetarian

who follow such eating patterns. There are many different types of vegetarian eating patterns (see **Table 1**). The impact of these patterns on nutritional status and health requires more complete characterization of diet and other aspects of lifestyle than such a simple descriptor.

The terms vegetarian, lactovegetarian, and vegan focus on foods that are left after others have been omitted from the diet. From the nutritional standpoint the animal food groups (e.g., meat fish, fowl, eggs, milk, and milk products) are nutrient-dense foods. In traditional diets of usual foods, they were often rich sources of certain nutrients. Depending on the particular animal food group under consideration, these nutrients may include protein of high biological value, highly bioavailable iron, zinc, calcium, vitamins A, D, B_{12} and B_6, riboflavin, omega 3 fatty acids, and iodine. When these food groups are eliminated entirely from the diet, intakes of the nutrients these groups are rich in may fall short.

Although dietary diversity in the number of food groups consumed is less among vegetarians, diversity within food groups is often considerable and is sufficient to provide adequate amounts of nutrients. Variety within food groups may even be increased on vegetarian diets. For example, among those consuming vegan diets the amount and type of legumes as well as other vegetables and fruits is often increased.

Eating patterns appear to be more closely associated with health outcomes than are nutrient intakes alone. Therefore, it is important to also consider other phytochemicals and zoochemicals in vegetarian diets that may have health effects.

Vegetarians' intakes of some of the bioactive constituents that are rich in fruits and vegetables such as the flavonoids, antioxidants, and dietary fiber may be much higher than those of omnivores. If these substances prove to have beneficial effects on health, such increased intakes may be important.

From the nutritional standpoint there are beneficial trade-offs from vegetarians' limited animal food intakes. Animal foods are major sources of dietary constituents that are in excess in Western diets, such as high amounts of calories, fat, saturated fat, cholesterol, and low amounts of dietary fiber. Consumption of fewer animal foods, especially if it leads to lesser intakes of these constituents may have positive effects on overall nutritional status. Thus, there are both nutritional benefits and risks to limiting animal foods. The exact effects on nutritional status will vary depending on the food group avoided, the degree of limitation, substitutions of other rich food sources, use of fortified foods and dietary supplements, and other changes in dietary intake that occur at the same time. The nutritional goal is to maximize the benefits and minimize the risks by a judicious choice of the type and amount of animal foods or other sources of the nutrients they contain.

Nutritional Adequacy

In English-speaking North America, dietary reference intakes (DRI) have been issued by the Food and Nutrition Board, Institute of Medicine,

National Academy of Sciences. Nutritional adequacy is defined as meeting nutrient needs such as the recommended dietary allowances (RDAs) or the adequate intakes (AI), while avoiding excess and staying below the tolerable upper levels of intakes (UL) and keeping within the macronutrient ranges specified by expert groups. Similar reference standards are available in other countries.

It is useful to screen out those vegetarians who are likely to be at high risk of dietary inadequacy by using some simple characteristics of their diets and lifestyles to determine if further dietary assessment is likely to be needed. The entire pattern of intake (including avoidances, substitutions and additions of foods, and use of dietary supplements) describes the individual vegetarian's profile of nutrient adequacy or inadequacy.

Because dietary practices among vegetarians are so variable, individual assessment of their dietary intakes is recommended. Those at special risk are those in the nutritionally vulnerable groups due to age, life stage (pregnancy, lactation) or illness, especially if they eschew many animal food groups (vegans), have numerous other food avoidances, or hold beliefs that otherwise limit their dietary intakes.

Adequate Vegetarian Diet Patterns

There are many individuals who have little or no risk of dietary inadequacy from their vegetarian eating patterns; for example, an adult male who regards himself as a vegetarian (also referred to as a meat avoider, or semi-vegetarian) but has a dietary pattern that consists solely of occasionally avoiding red meat about half of the time with no other dietary alterations. Such an individual is unlikely to need further dietary assessment.

Some characteristics of sound, adequate vegetarian diet patterns include the following:

- Use of a nutritionally sound food guide of diet planning; vegan and vegetarian food guides that conform to the latest recommendations of expert groups may help to ensure that nutrient needs will be met with balance and without excessive intakes.
- If diet alone does not meet the RDAs, regular use of appropriate vitamin mineral supplements plus use of a nutritionally sound food guide.
- Vegans and some other vegetarians sometimes have multiple food avoidances; intakes of nutrients likely to be deficient can be increased by use of rich sources of whole foods, foods fortified with the nutrients falling short, and/or vitamin or mineral supplements.
- Consumption of a wide variety of food groups and foods within each group.
- Membership of a family with a long history of adherence to healthy vegetarian eating styles.
- Avoidances are limited to a few foods or are sporadic in nature.

Signs of Possibly Inadequate Vegetarian Diet Patterns

The more of the following characteristics that apply, the higher the potential risk of inadequacy and the greater the need for further assessment.

Diet First it is important to examine what food groups, foods, or products are avoided or de-emphasized on vegetarian diets, and then some additional characteristics of dietary patterns, personal characteristics, and belief systems that further increase risk of dietary inadequacy and other health problems:

- **Many types and extensive avoidance of animal food groups**. Assessment of the nutritional adequacy of vegetarian eating patterns begins by examining animal food groups (red meat, poultry, fish and seafood, milk and milk products, eggs) and specific foods within these that are avoided entirely or eaten only in minimal amounts. Unless other foods or food groups rich in these nutrients or nutrient-containing dietary supplements are used, problems may arise.
- **Many types and extensive avoidance of fortified foods, nutrient-containing dietary supplements, and processed foods**. Some vegetarians believe that fortified foods (highly fortified cereals, calcium fortified soy milk and/or juices, B_{12} fortified yeast), processed foods (frozen, canned, and in extreme cases cooked foods for raw food eaters), and nutrient-containing dietary supplements (vitamins, minerals, fatty acids) should be avoided for various philosophical, ideological, or religious reasons, and refuse to use them. Usage needs to be assessed since such avoidances limit options for nutrition intervention strategies.
- **Few acceptable foods and supplements**. Foods and groups that are stressed and emphasized on the vegetarian diet should be noted. If very few foods or food groups are acceptable for one reason or another, or if only special foods are permitted (organic, nonprocessed, etc.) this may further limit intakes. Some vegetarians are willing to use both fortified foods and nutrient-containing dietary supplements. Use of these may have implications for health and should be recorded. Nutrient intervention strategies for increasing intakes of nutrients falling short in diets may be limited

since such individuals may refuse to use fortified foods and/or dietary supplements.
- **Many practices such as fasting, altered diet during illness, and use of special foods for medicinal purposes**. These practices may further increase risks of nutritional inadequacy. If medical care or treatment is avoided, additional risks may accrue.

Other practices Other practices must also be considered:

- **Other lifestyle practices with beneficial potential health impacts**. Vegetarians have other health habits and lifestyles that alter risks for chronic diseases for the better, such as nonsmoking, abstinence from alcohol, and high levels of physical activity. Therefore, differences in their health outcomes are probably due to a range of factors, and not solely to differences in their diets.
- **Lack of ongoing health surveillance by a physician**. Lack of medical supervision increases the chances that preventable or treatable health problems will be dealt with expeditiously.

Personal characteristics Among these are the following:

- **Nutritionally vulnerable because of age or physiological condition**. The very young, the old, the rapidly growing, pregnant and lactating women, pubertal children, the elderly, and the ill and frail all fall into this group. Individuals at especially high risk are those with chronic diseases and conditions that alter nutritional needs who also have inadequate dietary intakes.
- **Low weight for height**. If weight for height, as measured by body mass index, is below 18.5 or if unintentional weight loss has totaled more than about 5–7 kg (10–15 pounds), there is reason for concern.
- **Rapid weight loss**. Unintentional loss of more than 5% of weight in a month is a cause for concern.

Beliefs Ideology is also important:

- **Deeply held beliefs in alternative philosophical or religious systems that govern food choice**. Some individuals feel bound to make their diets conform to their ethical, philosophical, or religious systems. This can further constrain choice and nutrient intakes.
- **Membership of a quasi-philosophical or religious group that includes vegetarian diets that are not planned in line with nutritional recommendations by experts**. Some groups, e.g., the Seventh-Day Adventists or certain other lacto-ovo vegetarian groups, make a conscious effort to incorporate the recommendations of expert groups, such as those of the Food and Nutrition Board/Institute of Medicine and Health Canada in English-speaking North America into the regimens they recommend. In such cases, the group support provided may be of positive benefit and help to ensure nutritional adequacy. However, at times in the past other groups have insisted on regimens that did not incorporate such recommendations. For those who are active in such groups, the group's support may reinforce negative attitudes toward meeting such expert recommendations.

Using the characteristics above, it is usually possible to sort out those consuming vegetarian diets who are at low or no risk of inadequacy from those who may potentially have problems and need further assessment and counseling.

Key Nutritional Concerns for Vegetarians

Of particular concern with respect to risk of inadequacy for vegetarians are energy, vitamins B_{12} and D, riboflavin, omega 3 fatty acids, calcium, iron, zinc, and iodine. Intakes of these tend to be lower on vegan diets, and may also be low on other diets that include extensive avoidances. Vegetarians of all types can easily meet current recommendations for all nutrients if they are willing to use fortified foods and supplements. However, some vegetarians are unwilling to use these options, increasing risks of deficiency and making dietary planning more difficult.

Vegetarian and particularly vegan diets tend to be low in energy, total fat, saturated fat, cholesterol, dietary fiber, and sodium. If processed foods are avoided added sugars are also low. Current recommendations for acceptable macronutrient distribution ranges (AMDR) in the US are for fat 20–55% of calories and for protein 10–35% of calories, with added sugars no more than 25% of calories, and the remainder from other carbohydrates.

Key Nutrients for Vegetarians over the Life Cycle

Well-planned vegan and vegetarian diets can meet nutritional needs at all stages of the life cycle including pregnancy, lactation, infancy, childhood, and adolescence. There are very few longitudinal studies of those on the more restrictive vegetarian diets; an exception is a Dutch cohort of macrobiotic vegetarians who have been followed from birth to adolescence, and who continue to have some health problems. More studies are needed so that long-lasting effects of diet early in life can be better ascertained.

Some vegetarian parents feed their children diets that are inadequate. The problem is not that nutritionally adequate diets cannot be planned, but that the eater's or cook's ideologies and concerns may get in the way. Thus, actual diets, as eaten, may not conform to the recommendations of expert nutritional bodies. Under such circumstances health problems have arisen and continue to do so, especially among infants and children on vegan diets that are limited in other foods as well.

Vegan diets present more problems of micronutrient adequacy than do other vegetarian diets across the life cycle and particularly in infants and children because more food groups are eliminated, sources of vitamins B_{12} and D may be lacking and the caloric density of the diet is lower and bulk higher than that of vegetarians or omnivorous infants. They may also have diets that are limited in other foods, and thus in nutrients such as calcium and iron.

Vegetarian infants are usually breast-fed. They generally thrive until 4–6 months of age, and continue to do so if they are weaned to diets containing cows' milk-based or soy formulas and sufficient food energy. In countries where infant formulas do not provide adequate amounts of micronutrients, dietary supplements may be needed. Today, many more fortified vegan foods are widely available than in the past. They are helpful in meeting the nutrient needs of weanlings and toddlers. Also, dietary supplements are available, and for some vegans these are acceptable alternatives. Good sources of vitamin B_{12} need to be identified and also of vitamin D if exposures to sunlight are not adequate. Sources of other nutrients such as linolenic acid, the omega 3 fatty acid, should be included so that docosahexanenoic acid (DHA) intakes are satisfactory. Vegan diets may also be low in calcium, iron, and zinc, and the forms in which iron and zinc are present may not be highly bioavailable. A source of riboflavin also needs to be identified.

Vegetarian diets need to be carefully monitored when they are fed to young children. Soy milk is not appropriate under 1 year of age. When soy milk is used later in childhood, especially if the child is a vegan, it should be fortified with vitamins D and B_{12} and calcium.

For pubertal children, energy, calcium, iron, vitamins D and B_{12}, as well as iron are of particular concern with respect to dietary adequacy, but these can usually be dealt with by dietary planning.

Current Vegetarian Eating Patterns and Practices

Until about 40 years ago, in Western countries virtually all of the common vegetarian eating patterns involved avoidance of animal flesh (meat and poultry); categorization of vegetarian patterns was relatively straightforward and consisted simply of differentiating between those who ate no animal foods at all (vegan vegetarians), those who also consumed milk and milk products (lacto vegetarians), and those who ate eggs as well (lacto-ovo vegetarians). This simple categorization scheme broke down in the 1960s and 1970s as a result of greater exposure to the cuisines of other cultures, new Eastern religions and philosophical systems with a vegetarian tradition, and other influences, which led to the emergence of new patterns of vegetarianism.

Today, myriad vegetarian eating patterns exist, and they cannot be easily described by focusing on a single dimension, such as animal food intake.

Meatless and vegetarian eating patterns and life styles are growing in popularity today. They continue to be fostered by a greater availability and variety of meat alternatives and analogs for animal products. There is also a good deal of favorable publicity about phytochemicals with supposedly beneficial health effects. At the same time, concerns about the healthfulness of animal foods have been triggered by publicity on the bovine spongiform encephalopathy (BSE) epidemic in the UK, a later epidemic of hoof and mouth disease in cattle, and most recently an epidemic of SARS spread from animals to people. Worries about saturated fat/trans fat coronary artery disease links, dietary fat and cancers, food safety, and other factors probably also contributed to the increased prevalence of vegetarian eating.

At the same time, vegetarian eating patterns are much more heterogeneous today than in the past. The availability and variety of plant foods, as well as commercially available and tasty meat analogs has greatly increased. Fortified foods today include soy milks fortified with vitamins B_{12} and D and a highly bioavailable form of calcium, and highly fortified breakfast cereals. These foods and nutrient-containing dietary supplements make it easier for vegans and vegetarians to obtain nutrients that would otherwise be low or lacking.

Conformity to Nutritional Recommendations

Well-planned vegetarian diets have nutritional profiles that are in line with recent expert recommendations. A well-planned vegetarian diet pattern, if sustained throughout adulthood, may reduce risks of coronary artery and other chronic degenerative diseases associated with excessive weight. Generally, vegetarian diets tend to be low in saturated fat and

cholesterol and high in complex carbohydrates, dietary fiber, magnesium, potassium, folic acid, and antioxidant nutrients such as vitamins C and E. They also tend to be relatively low in energy. Thus, the diet-related risks for a number of chronic degenerative diseases associated with intakes of these nutrients may be decreased on vegetarian diets. Some risks are clearly lower; for example, vegetarians generally tend to have lower weight for height than do nonvegetarians. Constipation tends to be less of a problem in this group, perhaps due in part to the higher intake of dietary fiber.

Conclusions

Vegetarian diets should be planned in accordance with expert nutritional recommendations. When this is followed, such diets are healthful and nutritionally adequate. When they are not planned, the nutrients that are likely to fall short usually differ somewhat from those on nonvegetarian diets. In some cases these deficits can be remedied by dietary counseling. In others differences between ideologies about diet and nutrient needs are such that acceptable dietary strategies cannot be found.

Nutrition scientists and practitioners can help vegetarians who seek their advice by monitoring the nutritional status of high-risk individuals, by identifying food sources of specific nutrients, and by suggesting dietary modifications that may be necessary to meet individual needs when intakes fall short.

Physiology

A C Ross, The Pennsylvania State University, University Park, PA, USA

Introduction

Vitamin A is a fat-soluble micronutrient that is required by all vertebrates to maintain vision, epithelial tissues, immune functions, reproduction, and for life itself. It was discovered in 1913 as a minor component in eggs, butter, whole milk, and fish liver oils. It soon became apparent that vitamin A exists in two chemically distinct yet structurally related forms. The first form to be characterized was retinol, a lipid alcohol that is present only in foods of animal origin. Retinol is also known as 'preformed vitamin A' because it can be metabolized directly into compounds that exert the biological effects of vitamin A. A second form of vitamin A, present in deep-yellow vegetables, was characterized as β-carotene, which is synthesized only by plants but can be converted to retinol during absorption in the small intestines. These carotenoids are sometimes referred to as 'provitamin A.' The nutritional requirement for vitamin A can be met by preformed retinol, provitamin A carotenoids, or a mixture, and therefore it is possible to obtain a sufficient intake of vitamin A from carnivorous, herbivorous, or omnivorous diets.

Neither retinol nor the provitamin A carotenoids are directly bioactive. Retinol must be activated in a series of oxidative reactions, while the provitamin A carotenoids must first be cleaved to produce retinol. Of numerous metabolites of vitamin A, two are well recognized as crucial to its physiological functions. 11-*cis*-retinaldehyde (retinal) is a component of the visual pigment required for vision, rhodopsin. Retinoic acid, an acidic derivative, is required for the regulation of gene expression in essentially all tissues.

Besides the natural forms of vitamin A, a large number of structurally related analogs of vitamin A have been synthesized as potential therapeutic agents. The term 'retinoid' applies to both natural dietary forms of vitamin A, its metabolites, and those synthetic analogs that possess some, but usually not all, of the biological activities of vitamin A.

Chemistry

Vitamin A and its metabolites comprise a group of more than a dozen molecules that differ in isomeric form, oxidation state, and whether they are unesterified (free), esterified with a fatty acid, or conjugated.

All-*trans*-Retinol (Vitamin A Alcohol)

Retinol, the parent molecule of the vitamin A family, is a fat-soluble lipid alcohol ($C_{20}H_{30}0$, molecular mass 286.4) composed of a methyl substituted cyclohexenyl (β-ionone) ring, an 11-carbon conjugated tetraene side chain, and a terminal hydroxyl group (**Figure 1A**, R_1). Most of the double bonds can exist in either *trans* or *cis* conformation. All-*trans*-retinol is the most stable and most prevalent form in foods and tissues, but small amounts of other geometric isomers such as 9-*cis*- and 13-*cis*-retinol are found in some cells. The terminal hydroxyl group of retinol can be free or esterified with a fatty acid. Esterification reduces the susceptibility of retinol to oxidation and changes its physical state from a crystalline lipid to an oil. Fatty acid esters of retinol (**Figure 1A**, R_2) are the predominant form of vitamin A in most tissues. In some pharmaceutical products, retinol is present as retinyl acetate. Variant forms of vitamin A are present in some foods and human tissues. For example, vitamin A_2, (3,4-didehydroretinol) is present in freshwater fish, and is also a product of retinol metabolism in human skin.

Oxidized Metabolites of Retinol

Figure 2 illustrates key steps in the metabolism of vitamin A. Retinol is oxidized within cells to generate retinal (**Figure 1A**, R_3) and retinoic acid (**Figure 1A**, R_4). 11-*cis*-Retinal, the isomer of retinal

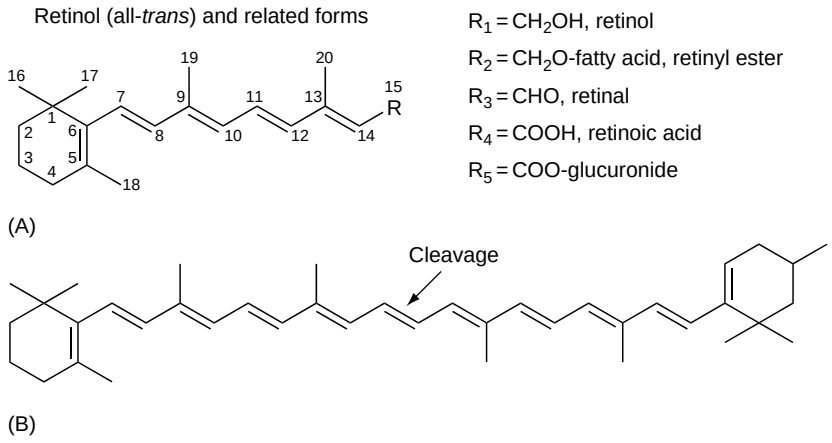

Figure 1 (A) Structure of all-*trans*-retinol and several related forms. (B) Beta-carotene (all-*trans*) showing the position of 15,15′ double bond that through cleavage yields retinal, which can be reduced to form retinal, giving rise to all of the structures indicated in **Figure 1A**.

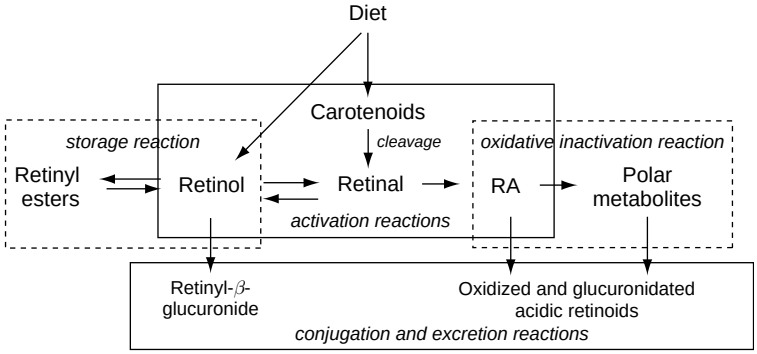

Figure 2 Schematic of principal reactions of vitamin A metabolism.

critical for vision, absorbs light maximally at ~365 nm when in organic solvent, but when coupled with a protein, such as opsin, its peak absorptivity is shifted into the visible range of the electromagnetic spectrum (see 'Vision'). In its all-*trans* isomeric form, retinal is a transient intermediate in the bioconversion of retinol to retinoic acid. Retinoic acid exists in several isomeric forms, two of which (all-*trans*-retinoic acid and 9-*cis*-retinoic acid) interact specifically with nuclear receptor proteins.

Numerous metabolites of retinol or retinoic acid are more polar than retinol or retinoic acid due to additional oxidation of the cyclohexenyl ring, often on carbon 4. Some retinoids, particularly retinoic acid and 4-keto-retinoic acid, may be conjugated with glucuronic acid, forming retinyl- or retinoyl-β-glucuronide (R_5); these metabolites are water-soluble and therefore readily excreted. While some polar and water-soluble retinoids possess bioactivity, most show reduced, or no, activity compared to their precursors.

Carotenoids

Carotenoids are produced only by plants and a few microalgae. In plants, they function as accessory light-gathering pigments that enhance the efficiency of photosynthesis. Of the 600 or so carotenoids found in nature, only β-carotene, α-carotene, and β-cryptoxanthin have the structural features necessary for vitamin A activity. Beta-carotene is a hydrocarbon ($C_{40}H_{56}$, molecular mass 536) with two β-ionone rings, a polyene chain, and structural symmetry around the central 15,15′ double bond (**Figure 1B**). The oxidative cleavage of this bond releases two molecules of retinal, which can be reduced to form vitamin A (retinol). Other isomers of β-carotene with potential nutritional activity include 9-*cis*-β-carotene produced by certain microalgae. Other common carotenoids found in fruits and vegetables, such as lycopene, lutein, and zeaxanthin, are absorbable but they lack structural features essential for vitamin A activity.

Dietary Sources and Nutritional Equivalency

Preformed vitamin A is present at highest concentration in liver and fish oils, and at lower concentrations in nonorgan meats. Food sources of preformed vitamin A and provitamin A are provided in **Table 1**. In 1990, 39% of the vitamin A (including carotenes) in the diets of Americans came from fruits and vegetables. Meats and dairy products each supplied about 20% of the vitamin A consumed. Foods that contain small amounts of vitamin A can still contribute significant amounts of vitamin A to an individual's diet if they are consumed often or in large amounts.

Table 1 Food sources of vitamin A

Food	*%DV**
Animal sources of preformed vitamin A	
Liver, beef, cooked, 3 oz	610
Liver, chicken, cooked, 3 oz	280
Fat-free milk, fortified with vitamin A, 1 cup	10
Cheese pizza, 1/8 of a 12-inch diameter pie	8
Milk, whole (3.25% fat;), 1 cup	6
Cheddar cheese, 1 oz	6
Whole egg, 1 medium	6
Plant sources of β -carotene and other provitamin A carotenoids	
Carrot, 1 raw (7.5 inches long)	410
Carrots, boiled, 1/2 cup, slices	380
Carrot juice, canned, 1/2 cup	260
Sweet potatoes, canned, drained solids, 1/2 cup	140
Spinach, frozen, boiled, 1/2 cup	150
Mango, raw, 1 cup, sliced	130
Vegetable soup, canned, chunky, ready-to-serve, 1 cup	115
Cantaloupe, raw, 1 cup	100
Kale, frozen, boiled, 1/2 cup	80
Spinach, raw, 1 cup	40
Apricot nectar, canned, 1/2 cup	35
Oatmeal, instant, fortified, plain, water, 1 packet	30
Tomato juice, canned, 6 oz	20
Apricots, with skin, juice pack, 2 halves	10
Pepper, sweet, red, raw, 1 ring, 3-inch diam. 1/4-inch thick	10
Peas, frozen, boiled, 1/2 cup	10
Peach, raw, 1 medium	10
Peaches, canned, water pack, 1/2 cup halves or sliced	10
Papaya, raw, 1 cup, cubes	8

*% DV = Daily Value. %DVs are reference numbers based on the Recommended Dietary Allowance (RDA), Percent DVs are based on a 2000 calorie diet. They were developed to help consumers determine if a food contains a lot or a little of a specific nutrient. The DV for vitamin A is 5 000 IU (1 500 micrograms retinol which is 1500 μg RAE). Most food labels do not list a food's vitamin A content. The %DV listed in **Table 1** refer to the vitamin A provided in one serving. Data from Clinical Nutritional Service (2003) *Facts about Dietry Supplements*. Maryland, USA: Warren Grant Magnuson Clinical Center.

Units of Nutritional Activity

Owing to the multiple forms of vitamin A in most diets and the lower efficiency of utilization of carotenoids compared to preformed vitamin A, the total amount of vitamin A (bioactivity) in foods or in the total diet must be expressed in equivalents. Over the years, several equivalency units and conversion factors have been adopted. Most recently, the retinol activity equivalent was adopted by the Institute of Medicine (IOM) in 2001 to replace older units of bioactivity because new information indicated that the conversion of carotenoids is less efficient than previously thought. One microgram of retinol activity equivalent (RAE) is equivalent in terms of activity to 1 μg of all-*trans*-retinol or 2 μg of β-carotene in oily solution. One microgram of RAE is also equivalent to higher amounts of other provitamin A carotenoids in foods because they are less bioavailable than β-carotene in oil. On average, carotenoids must be ingested in the following amounts to provide the equivalent nutritional value of 1 μg of all-*trans*-retinol:

- 2 μg of supplemental β-carotene (in an oily, easily absorbed solution);
- 12 μg of β-carotene in fruits and vegetables (due to association with food matrices); and
- 24 μg of α-carotene or β-cryptoxanthin (due to food matrices and structure of compounds).

Prior to 2001, the retinol equivalent (RE) was used and this unit is still found in most food composition tables. While similar in theory to the RAE, the RE is based on older conversion factors for carotenoids in foods. Using RAE, the vitamin A activity of the provitamin A carotenoids in foods is half that using RE. An older unit, the international unit (IU or USP), which should eventually be replaced by these newer units, is still used in food tables and on some supplement labels. One IU is equal to 0.3 μg of all-*trans*-retinol. Finally, another indicator of nutritional value, % daily value (%DV), is a less quantitative but more convenient means for consumers to compare foods and select those with a substantial portion of a given nutrient. The %DV does not require extensive knowledge of nutritional units; this value appears on food package labels in the US. Besides its application in food labeling, the %DV is a useful value for quickly comparing the vitamin A contents of various common foods.

Transport and Metabolism

Few retinoids are appreciably soluble in water or aqueous body fluids. They gain solubility through association with specific proteins.

Retinol-Binding Protein

Plasma retinol is transported by a specific 21-kDa transport protein, retinal binding protein (RBP). Most RBP is produced in the liver, but some extrahepatic organs also synthesize it. Each molecule of RBP binds one molecule of all-*trans*-retinol noncovalently. In plasma, the retinol-RBP complex (holo-RBP) forms a larger complex with a cotransport protein, transthyretin (TTR), which also binds the hormone thyroxine.

Cellular Retinoid-Binding Proteins

Cellular retinoid-binding proteins (CRBP) are present in the cytoplasm of many types of cells. These proteins are similar in structure and size (~14.6 kDa), and each contains a single binding site that preferentially binds a particular form of retinoid (retinol, retinal, or retinoic acid), often preferring a specific isomer. Four cellular retinol-binding proteins (CRBP-I, -II, -III, and -IV) and two cellular retinoic acid-binding proteins (CRABP-I and -II) are expressed in many cells, yet each has a different tissue distribution. These proteins function as chaperones that confer aqueous solubility on otherwise insoluble retinoids while directing them to specific enzymes that then catalyze their further metabolism. These binding proteins may also play a role, although it is not yet well defined, in the delivery of retinoids (RA) to the nucleus for binding to nuclear retinoid receptors, which are discussed later.

Intestinal Metabolism

Dietary retinyl esters must be hydrolyzed in the lumen of the small intestine before retinol is absorbed, while carotenoids must be absorbed into the intestinal mucosa before being cleaved intracellularly. Several enzymes with retinyl ester hydrolase (REH) activity are present in pancreatic juice or on the brush border of duodenal and jujenal enterocytes (**Figure 3**). Retinol and carotenoids must be solubilized in the lumen in mixed micelles composed of bile acids and products of lipid digestion prior to their uptake into enterocytes. These processes require the release of an adequate amount of bile salts and a minimal quantity of dietary fat (approximately 5%), which must be consumed concomitantly. The retinol thus liberated diffuses into the enterocyte, is bound by CRBP-II, and is then esterified. The newly formed retinyl esters are incorporated into the lipid core of chylomicra, lipoproteins that transport dietary fat into the lymphatic system for absorption. The overall efficiency of retinol absorption is quite high, about 70–90%, and is not significantly downregulated as vitamin A consumption increases.

The efficiency of absorption of β-carotene is considerably lower (9–22%) and more variable than that of retinol. In fact, in controlled studies some subjects have absorbed little, if any, of a test dose of β-carotene. In individuals who do absorb dietary carotenoids, the efficiency of absorption tends to fall as intake increases. The type of carotenoid and its physical form in the ingested foodstuff also affect the efficiency of carotene absorption. Pure β-carotene in an oily solution or supplements is absorbed more efficiently than an equivalent amount of β-carotene in foods. Much of the carotenoid present in foods is bound within a matrix of

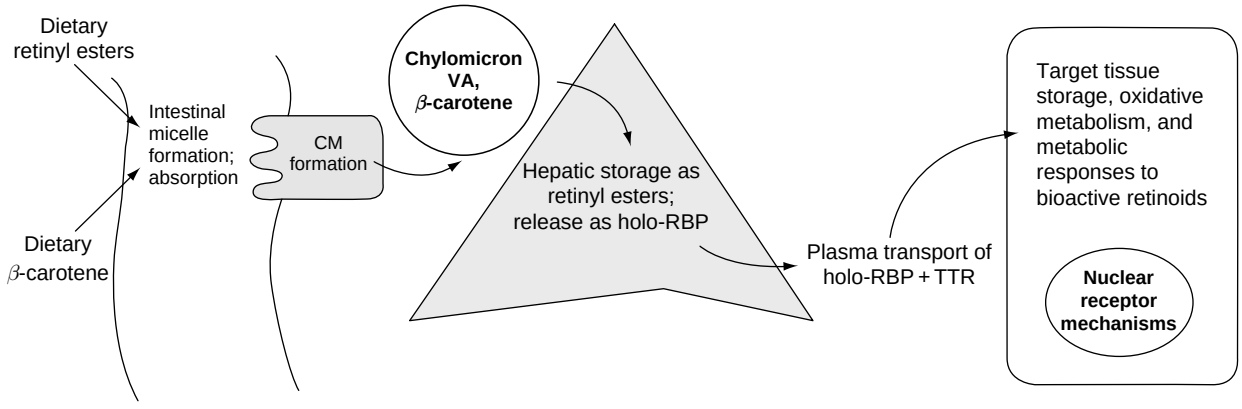

Figure 3 Absorption of dietary vitamin A (VA) via chylomicrons (CM), vitamin A storage in liver, and the release of retinal to plasma as holo-retinol-binding protein (RBP), which combines with transthyretin (TTR), to deliver retinal to organs that produce retinal (eyes) or retinoic acid (essentially all tissues) for the biological functions attributed to vitamin A.

polysaccharides, fibers, and phenolic compounds that is incompletely digested. Although the absorption of provitamin A carotenoids from fruits is generally better than from fibrous vegetables, it is still low as compared to β-carotene in oil (see section on Units).

Once in the enterocyte, provitamin A carotenoids are cleaved by one or more carotene monooxygenases, and the product (initially retinal) is metabolized to form retinol and, subsequently, retinyl esters (see **Figure 2**). In humans about one-third of ingested β-carotene escapes cleavage and, instead, is incorporated intact into chylomicrons.

A small fraction of intestinal β-carotene is oxidized to retinoic acid and absorbed into portal blood. It is speculated that the cleavage of dietary 9-*cis*-β-carotene and its subsequent oxidative metabolism may be a significant source of 9-*cis*-retinoic acid.

Hepatic Vitamin A Uptake, Storage and Release

Once chylomicra enter lymph and plasma, chylomicron remnants are formed rapidly by lipolysis. The majority of chylomicron remnants, still containing vitamin A, are quickly cleared into liver parenchymal cells (hepatocytes) by receptor-mediated endocytosis. Adipose and other tissues, including the mammary glands during lactation, also take up small amounts of newly absorbed vitamin A during the lipolysis of chylomicra. Within a few hours of chylomicron remnant clearance by hepatocytes, most of these newly absorbed retinyl esters are hydrolyzed and the retinol component is re-esterified, forming new retinyl esters. Newly formed retinyl palmitate and stearate are deposited in lipid droplets in vitamin A-storing stellate cells. In the vitamin A adequate state, more than 90% of total body vitamin A is stored in liver stellate cells. Small numbers of similar stellate cells have been described in extrahepatic tissues, suggesting the presence of a network of vitamin A-storing cells throughout the body.

As retinol is needed, stellate cell retinyl esters are hydrolyzed by one or more REHs and retinol is transferred back to hepatocytes for combination with newly synthesized RBP. The holo-RBP complex then passes through the Golgi secretory apparatus and binds noncovalently with a tetramer of TTR. The larger size of this transport complex (~75 kDa) compared to holo-RBP alone (~21 kDa) helps to prevent the rapid loss of retinol and RBP during renal glomerular filtration.

Plasma Concentrations

In normal plasma in the fasting state, more than 95% of retinol is bound to RBP. Retinyl esters also are present during the absorption of vitamin A-rich meals, but they are bound to plasma lipoproteins.

Although there is a significant relationship between plasma retinol and liver vitamin A storage (considered a 'gold standard' for assessing vitamin A status), the relationship is by no means linear. In fact, plasma retinol is nearly constant over a rather wide range of liver vitamin A concentrations, all consistent with vitamin A adequacy. The constancy of plasma retinol reflects its close homeostatic regulation. Plasma retinol levels in normal adults show only minor day-to-day variations, staying close to ~2 and 1.7 $\mu mol\,l^{-1}$ in males and females, respectively. The molar concentration of RBP (1.9–2.4 $\mu mol\,l^{-1}$) is slightly higher and thus RBP is normally 80–90% saturated. A small proportion of circulating RBP is apo-RBP (RBP without retinol). Owing to its reduced affinity for TTR, apo-RBP is readily filtered in the kidneys and catabolized.

When liver vitamin A reserves fall below about 20–30 μg retinol g liver, the secretion of holo-RBP is compromised due to inadequate retinol. Plasma retinol levels begin to fall and, if liver vitamin A continues to decline, plasma levels will fall into the deficient range and will be inadequate to supply retinol to tissues. Essentially all of the vitamin A in liver can be mobilized when it is needed to meet the needs of peripheral tissues. But ultimately, vitamin A intake must increase to bring plasma retinol levels back to the normal range.

Conversely, when vitamin A is consumed in excess of needs, its concentration in liver can increase markedly. When the concentration rises above about 300 $\mu g\,g^{-1}$, as occurs in hypervitaminosis A (see later section), the levels of plasma retinol and RBP remain almost normal but total vitamin A increases due to retinyl esters bound to plasma lipoproteins.

Plasma Vitamin A Kinetics

Both RBP and TTR have a relatively short half-life (~0.5 and 2–3 days, respectively) and, therefore, they must be synthesized continuously to maintain normal plasma levels. Plasma retinol, RBP, and TTR are reduced in states of impaired protein synthesis, which may be due to an inadequate intake of protein or energy or to impairments in metabolism. Plasma RBP and TTR are sometimes used as clinical indicators of visceral protein synthesis. During infection and/or inflammation, plasma retinol, RBP, and TTR fall transiently, even though liver vitamin A reserves

are adequate, due to altered protein synthesis during the acute-phase response. Because multiple nutritional and metabolic disturbances can lead to a similar decrease in plasma retinol, RBP, and TTR, laboratory values must be interpreted with caution.

Studies using computer-based compartmental modeling to analyze plasma retinol kinetics have shown that each molecule of retinol circulates through the plasma compartment several times before it is irreversibly degraded (see 'Tissue Retinoid Metabolism'). In a young man who consumed 105 μmol of retinyl palmitate in a test meal, 50 μmol of retinol passed through his plasma per day, while only 4 μmol day^{-1} was degraded. Unlike retinol, RBP is not recycled, implying that RBP is synthesized in extrahepatic tissues for the release and continued recycling of retinol. Some extrahepatic tissues, such as kidney and adipose, contain RBP mRNA at a level ~5–10% of that in liver. The kidneys evidently play a very significant role in the recycling and conservation of retinol after the glomerular filtration of holo-RBP. Cell culture studies have shown that holo-RBP can bind to renal epithelial cells and cross the epithelium by transcytosis, suggesting a mechanism for the recovery of retinol lost by filtration.

Overall, the body is efficient at conserving retinol, but relatively inefficient in degrading and eliminating excess retinoids. These differences seem to explain the propensity for retinyl esters to accumulate in tissues when vitamin A is consumed in amounts that substantially exceed requirements.

Carotenoids

Carotenoids circulate in plasma in association with low-density and high-density lipoproteins. The level of β-carotene reflects its recent intake, but it also is higher when plasma lipoprotein levels are elevated. Beta-carotene is stored at relatively low concentrations in liver and fatty tissues. A prolonged slow rate of postabsorptive conversion to retinol has been observed in volunteers in isotope kinetic studies.

Tissue Retinoid Metabolism

Tissues obtain retinol from holo-RBP throughout the day, and retinyl esters from chylomicrons and chylomicron remnants after consumption of vitamin A-containing meals. Although the majority of the body's vitamin A is stored in the liver, many organs contain small reserves of retinyl esters. These small local supplies are believed to be critical for the generation of bioactive retinoids, formed through oxidative metabolism (**Figure 2**). Retinol that is liberated by the hydrolysis of retinyl esters is oxidized to retinoic acid in a two-step process in which retinal is an obligate intermediate. The oxidation of retinol to retinal has been attributed to several enzymes of the alcohol dehydrogenase and the short-chain dehydrogenase/reductase gene families. Both of these types of enzymes also oxidize other substrates and the specifics of retinol oxidation in various tissues have been difficult to define. It is likely that the CRBP proteins function as chaperones for retinol during its oxidative metabolism. Since retinal can be reduced to form retinol, the retinal that is generated from the metabolism of carotenoids can give rise to retinyl esters and all of the other metabolites of retinol (see **Figure 2**). In the second oxidative step, which is irreversible, retinal is converted to retinoic acid. This step also may be catalyzed by several enzymes. Retinoic acid is present, sometimes in several isomeric forms, at nanomolar concentrations in many tissues. Its half-life is very short, a few hours or less, which implies that it is produced continuously to maintain tissue retinoic acid levels.

The β-ionone ring of retinol and retinoic acid also can be oxidized, usually at carbon 4 to form 4-hydroxy and 4-oxo metabolites. The metabolism of retinoic acid is, in part, autoregulated due to the ability of retinoic acid to induce the expression of cytochrome P450 enzymes that form 4-oxo derivatives of retinoic acid. At this time, although limited evidence suggests that ring-oxidized retinoids still possess bioactivity, most evidence supports the thinking that they are metabolites in a catabolic pathway, destined for excretion. Ring-oxidized metabolites, which are normally present in plasma in low concentrations, are readily removed by the liver and conjugated with glucuronic acid, which makes them soluble in water. Glucuronides comprise a substantial fraction of the total retinoid excreted in bile and eliminated by the fecal route.

Production and oxidation both serve to maintain normal tissue retinoid levels. Nonetheless, these physiological processes can be overwhelmed by an excess of dietary vitamin A, resulting in excessive vitamin A in tissues and plasma, or by the use of synthetic retinoids that lead to substantial elevations in tissue bioactive retinoids (see the article section 'Hypervitaminosis A and Vitamin A Toxicity').

Physiological Actions

Vision

The retinal pigment epithelium cells (RPE) of the retina form an epithelial cell layer that takes up retinol from choroid capillaries and stores it as

retinyl esters, to be used as substrate for the generation of 11-*cis*-retinal. In the layer of rod and cone photoreceptor cells adjacent to the RPE, 11-*cis*-retinal combines covalently with the protein opsin to generate the visual pigment rhodopsin in rods and, similarly, iodopsin in cones. Each rod outer segment is densely packed with some 10^8 molecules of rhodopsin per cell. The small quantity of vitamin A stored in the retina would be inadequate to maintain vision were it not for the visual cycle, a process in which 11-*cis*-retinal is regenerated after photobleaching. The absorption of light by rhodopsin catalyzes the photoisomerization of the 11-*cis*-retinal moiety of rhodopsin to all-*trans*-retinal (resulting in bleaching), which induces the release of all-*trans*-retinal from opsin. The change in retinal's isomeric configuration is crucial for initiating a signal transduction cascade from the rods to nearby retinal ganglion cells, and thereafter to the optic nerve for transmission to the brain's visual cortex. For vision to continue, 11-*cis*-retinal must be regenerated. This is accomplished in a series of biochemical reactions constituting the visual cycle, some of which take place in the rod cell outer segment and others in the RPE. The regeneration of 11-*cis*-retinal (dark adaptation) is slow (on the order of minutes) compared to the photoisomerization (fractions of a second). However, normal vision continues without a period of blindness as long as retinol can be drawn from retinyl esters stored in the RPE, rapidly isomerized to 11-*cis*-retinol, re-oxidized to 11-*cis*-retinal, and passed to the rod cell outer membrane where rhodopsin is regenerated. When the supply of retinyl esters in the RPE is not adequate, there is significant slowing of the visual cycle, resulting in the condition known as night blindness, a loss of the ability to quickly dark adapt after exposure to bright light. Night blindness is often the first-detected clinical sign of vitamin A deficiency (see the article section 'Hypervitaminosis A and Vitamin A Toxicity').

Cornea The cornea, an avascular tissue, requires retinoic acid for the normal differentiation of the corneal and conjunctival epithelium. Holo-RBP, which is present in the lacrimal glands and tears, is likely to provide the substrate for the local biogenesis of retinoic acid. Retinoid deficiency results first in a loss of goblet secretory cells, which can be detected histologically. Corneal xerosis and Bitôt's spots (foamy deposits) are strong signs of prolonged vitamin A deficiency (see 'Hypervitaminosis A and Vitamin A Toxicity'). Vitamin A must be administered immediately to prevent the progression of corneal xerosis to corneal ulceration, which causes life-long blindness.

Cell Morphology and Differentiation

Soon after the discovery of vitamin A, a light microscopic investigation of the tissues of vitamin A-deficient rats revealed marked abnormalities in many epithelial tissues. It is now recognized that essentially all organ systems require retinoids. Some epithelial tissues (skin, respiratory tract, the immune system, the reproductive organs, etc.) are especially sensitive to a lack, as well as an excess, of vitamin A. The systemic effects of vitamin A deficiency include dryness of the skin (follicular hyperkarotosis), loss of mucus-secreting goblet cells in the trachea and respiratory tract, and a generalized flattening of epithelia (squamous metaplasia, sometimes with keratinization) throughout the body. The hematopoietic system is also affected, as are reproductive organs. In the testes, spermatogenesis is inhibited by vitamin A deficiency. Although a lack or an excess of retinoids is recognized to affect many organ systems, the developing embryo and the functions of the immune system have been studied most intensively. Essentially all of the functions of vitamin A other than those involving the retina are mediated by its active metabolite, RA, in conjunction with nuclear retinoid receptors.

Nuclear Retinoid Receptors

The nuclear retinoid receptor proteins are synthesized in the cytoplasm but reside in the nucleus where they form dimers capable of binding to specific sequences of DNA in target genes (retinoid response elements, RAREs). The family consists of six retinoid receptors (RARα, β and □, and RXR□□ and □) that belong to the superfamily of steroid hormone receptors. The RAR and RXR function as ligand-activated transcription factors to either activate or repress the transcription of hormone-responsive genes. Two isomers of retinoic acid, all-*trans*-retinoic acid and 9-*cis*-retinoic acid, function as the major ligands for the RAR and RXR subfamilies, respectively. The binding of all-*trans*-retinoic acid to the RAR induces a conformational change in the receptor dimer pair, bound to its response elements (RARE) in the regulatory region of the DNA of target genes. This conformational change, in turn, promotes the interaction of the retinoid receptor dimer with other transcriptional regulators. Ligand binding may promote the dissociation of corepressor molecules and the binding of coactivator molecules, leading to gene activation when the basal transcriptional complex is recruited. This multiprotein complex then functions enzymatically to transcribe the DNA template into messenger RNA. Additionally, some receptor functions appear

to be ligand independent. Similarly to all-*trans*-retinoic acid, 9-*cis*-retinoic acid has been shown to bind to nuclear receptors of the RXR family. However, the physiological role of 9-*cis*-retinoic acid *in vivo* is currently unclear and, moreover, other ligands besides 9-*cis*-RA (such as polyunsaturated fatty acids) may also activate the RXR. Besides forming dimers with the RAR, the RXR bind in a similar manner with the nuclear receptors for vitamin D, thyroid hormone, and several other lipophilic hormones and xenobiotic agents.

Embryonic Development

Vitamin A is essential in appropriate amounts for normal embryogenesis. Retinoids are required from the early, postgastrulation stage of embryonic development. The requirement for retinoids has been deduced from molecular developmental studies in mice, and other species. These studies have consistently shown a highly regulated pattern of expression of the genes for nuclear retinoid receptors, retinoid-binding proteins, and enzymes of retinoid production and catabolism. It is likely, based on the expression of retinoid biosynthetic enzymes, that maternally derived retinol is metabolized by the embryo to produce retinoic acid at specific times in specific cells, and that retinoic acid is also catabolized in a highly regulated, tissue-specific manner. Retinoic acid has been proposed to be an essential morphogen whose concentration, or concentration gradient, is a key determinant of the expression of one or more families of genes, particularly the *Hox* gene family. This gene family is crucial in determining the formation of the anterior-posterior body axis. Some of these key genes contain a RARE.

In animals, both vitamin A deficiency and an excess of dietary vitamin A or retinoid analogs, at specific critical periods of development, can result in severe developmental defects, and may be lethal to the embryo. The differentiation of cells in the neural crest and the development of the head and sensory organs, nervous system, heart, limbs, and skeletomuscular system are often affected. Birth defects of a similar nature have occurred in women exposed to excessive dietary vitamin A, or to pharmacologic retinoids for treatment of skin diseases, in early pregnancy.

Immunity

Impaired immunity was one of the earliest effects described for vitamin A deficiency. Numerous abnormalities have been described. A dysregulation of T cell functions has been implicated in many abnormal immune responses, as vitamin A-deficient animals often have reduced T cell counts and an altered pattern of differentiation markers on T cell subsets. The response of T cells to antigens and mitogens tends to be low. Similarly, the functional capacity of cytotoxic cells, such as cytotoxic T cells and natural killer cells, and macrophages is often low. Numerous alterations have been documented in the production of cytokines that regulate T cell immunity and antibody production by B cells. Because the immune response elicited by pathogens, vaccines, or other experimental treatments can differ significantly depending on the type of stimuli, it is not surprising that the effect of vitamin A status has also varied depending on the type of natural infection or experimental challenge. Consistently, however, the administration of vitamin A, or therapeutic doses of retinoic acid, has restored a more normal pattern of T cell-dependent immune responses, often quite rapidly, to previously vitamin A-deficient hosts.

In children at risk of vitamin A deficiency, vitamin A supplementation, given prophylactically or as therapy during illness, has significantly reduced the severity of measles and measles-related mortality (see 'Hypervitaminosis A and Vitamin A Toxicity').

Recommended Dietary Allowances and Tolerable Upper Intake Levels for Vitamin A

Recommended dietary allowances (RDA) for the US and Canada were recently revised by the Institute of Medicine (IOM). Owing to the serious, potentially irreversible, effects caused by an excess of vitamin A, guidelines were also established for a tolerable upper intake level (UL), defined as the highest intake of a nutrient that is likely to pose no risk of adverse health effects in nearly all healthy individuals. The 2001 RDA and UL for vitamin A for various life stages are listed in **Table 2**.

Infancy and Childhood

Recommendations for an adequate intake (AI) of vitamin A for children 0–6 and 7–12 months of age are based on the vitamin A content of human breast milk and on usual milk intakes for these age groups. The vitamin A content of breast milk from well-nourished women was estimated to be $1.7\,\mu mol\,l^{-1}$; therefore, it provides approximately $400\,\mu g$ RAE day^{-1} to 0- to 6-month-old infants. This value was used by the IOM as the AI for infants in this age group. The AI is $500\,\mu g$ RAE day^{-1} for 7- to

Table 2 Recommended dietary allowances (RDA) for vitamin A in micrograms (μg), retinol activity equivalents (RAE) and international units (IU), and tolerable upper intake levels (UL, μg retinol day^{-1}) for children and adults

Age (years)	*Children*	*Men*	*Women*	*Pregnancy*	*Lactation*
RDA (μg RAE day^{-1})					
1–3	300 μg or 1000 IU				
4–8	400 μg or 1333 IU				
9–13	600 μg or 2000 IU				
14–18		900 μg or 3000 IU	700 μg or 2330 IU	750 μg or 2500 IU	1200 μg or 4000 IU
19+		900 μg or 3000 IU	700 μg or 2330 IU	770 μg or 2565 IU	1300 μg or 4335 IU
UL (μg retinol day^{-1})					
1–3	600 μg				
4–8	900 μg				
9–13	1700 μg				
14–18		3000 μg	2800 μg	2800 μg	2800 μg
19+		3000 μg	3000 μg	3000 μg	3000 μg

12-month-old infants, who are assumed to also consume complementary foods.

Physiological studies have shown that the placental transfer of vitamin A is limited in most mammals. Thus, it is normal for the liver and plasma vitamin A levels of newborns to be much lower than those in adults. In humans, premature infants often have lower plasma retinol levels than full-term infants. The period of breastfeeding is important for the accrual of vitamin A reserves as shown by animal studies in which liver vitamin A stores have increased rapidly in the suckling young of well-nourished healthy mothers. The importance of the neonatal period for establishing vitamin A reserves in young children is well recognized, and programs to promote maternal nutrition and breast feeding have become an integral component of public health programs to improve the vitamin A status of women and children worldwide.

For infants born prematurely, vitamin A (provided in enteral feeds or intramuscularly) is now recognized as an important component of medical care, and as a significant factor in reducing the risk of bronchopulmonary dysplasia and chronic lung disease.

Childhood and Adolescence

Little information specific to this age group is available, and recommendations are based on adult values, scaled down based on body weight.

Adulthood

Adults require a maintenance level of vitamin A. The RDA is based on maintaining an adequate level of vitamin A in liver while meeting normal tissue demands. In animals fed a normal vitamin A adequate diet, retinyl esters tend to accumulate as the animal ages, such that it becomes very difficult to induce vitamin A deficiency in adult animals, even by feeding them a diet free of vitamin A. These data imply that tissue reserves readily make up for lapses in the day-to-day intake of vitamin A. As is evident from **Table 1**, some foods contain an amount of vitamin A well in excess of 100% of the daily value (%DV).

Pregnancy and Lactation

The requirement for vitamin A is increased during pregnancy and lactation, but only to the extent needed for growth of maternal and fetal tissues. Nearly all of the vitamin A in breast milk is in the form of retinyl esters. Milk vitamin A concentration is influenced by recent maternal vitamin A intake. Physiological studies have shown that the lactating mammary glands derive retinol from holo-RBP and from the metabolism of chylomicra. As chylomicron vitamin A increases, milk vitamin A also increases. The RDA for lactation (**Table 2**) is calculated to provide sufficient vitamin A for the mother's needs and for the secretion of vitamin A in breast milk.

Upper Levels

There are three major adverse effects of hypervitaminosis A:

- birth defects;
- liver abnormalities; and
- reduced bone mineral density, which may result in osteoporosis.

The critical adverse effects used to establish the upper level (UL) were risk of teratogenicity for women of reproductive age, and liver abnormalities for all other life stage groups. For vitamin A, the UL applies specifically to chronic intakes of preformed vitamin A (not carotenoids) obtained from foods, fortified foods, and supplements. The UL is not meant to apply to individuals taking vitamin A under medical

supervision. For several life stage groups, the UL are less than three times the RDA (**Table 2**). Based on epidemiological studies of vitamin A intakes and birth outcomes in pregnant women, and on the well-documented teratogenic effects of excessive vitamin A in experimental animals, the UL for women of reproductive age is 2800–3000 $\mu g\,day^{-1}$. The UL based on risk of damage to the liver, although calculated in a different way to that for teratogenicity, has the same value of 2800–3000 $\mu g\,day^{-1}$. Like the RDA, the UL for younger age groups was scaled down based on body weight.

Risk of reduced bone mineral density was also considered in setting the UL, but dose-response data were insufficient to estimate a UL based on this effect. Nonetheless, there is increasing concern that bone health may be adversely affected by intakes of vitamin A not very much higher than the RDA. Epidemiological studies in Swedish men and women, and similar studies in the US, have provided evidence that a chronic intake of preformed vitamin A on the order of 2–3 times the recommended levels (near the UL) may increase the loss of bone mineral density and incidence of hip fracture. Although more research is needed, an upper intake of 2800–3000 μg preformed vitamin A per day also appears to be a prudent guideline for maintaining bone health.

Users of supplements that contain retinol or a retinyl ester should evaluate their average combined intake from diet (especially liver, milk, dairy products), fortified foods (including breakfast cereals), and all dietary supplements to ensure that it does not exceed the UL. Children's vitamin supplements should be checked to make sure that the amount of vitamin A is suitable for the child's age.

Hypervitaminosis A and Vitamin A Toxicity

Hypervitaminosis A is a rare but serious, sometimes fatal, condition. Hypervitaminosis A refers to high storage levels of vitamin A in the body that can lead to toxic symptoms. Toxic symptoms can arise after consuming very large amounts of preformed vitamin A over a short period of time, or they may develop slowly (chronic toxicity), depending on the duration and dose of vitamin A (retinol) consumed. Case reports of vitamin A toxicity include cases of excessive intakes of foods high in retinol such as liver (see **Table 1**), but most cases of vitamin A toxicity result from an excess intake of vitamin A in supplements. Symptoms resembling hypervitaminosis A have been reported in a few patients taking prescription retinoids for therapy. The clinical hallmarks of vitamin A toxicity include nausea and vomiting, headache, dizziness, blurred vision, muscular uncoordination, abnormal liver functions, and pain in weight-bearing bones and joints.

Besides eliminating intake of vitamin A, or retinoids, there is little that can be done, and no antidote, to treat hypervitaminosis A. Tissue retinoid levels fall gradually, but due to the body's tendency to conserve vitamin A, the loss is very slow. Thus, care should be exercised to avoid overconsumption or supplementation with preformed vitamin A (see 'Upper Levels', **Table 2**).

Excessive Consumption of β-Carotene

Beta-carotene and other carotenoids in foods, even when consumed at high levels, are believed to be nontoxic, and therefore no UL was established for β-carotene. Nonetheless, a 'safe range' of intracellular β-carotene has yet to be determined. Individuals who have consumed large amounts of carotenoid-rich foods, juices, or extracts containing a large amount of β-carotene over a prolonged period of time may show signs of carotene accumulation in fatty tissues, to the point where yellowing of the skin (carotenodermia) is apparent. This condition is not known to be harmful and the color subsides over time after carotene intake is reduced to normal levels. Nonetheless, epidemiological evidence suggests that the use of high-dose β-carotene as a dietary supplement should not be regarded as safe because the current knowledge of the metabolism of high doses is inadequate, and some epidemiological studies have indicated that high doses of β-carotene, at least in smokers, may be detrimental (see 00045).

Biochemistry and Physiological Role

J L Napoli, University of California, Berkeley, CA, USA

In 1913, E.V. McCollum isolated a yellow, fat-soluble substance from egg yolks that was critical for animal growth. He called it fat-soluble A, indicating the first isolated of several dietary microconstituents emerging as obligatory for vertebrate life and health. Later, fat-soluble A was renamed vitamin A, derived from the terminology 'vital amine,' coined by Casmir Funk to describe these obligatory micronutrients.

Currently, the term vitamin A refers to the specific organic compound all-*trans*-retinol (atROH). atROH, however, does not have biological activity in its own right. Rather, it serves as a circulating substrate for metabolism into the compounds that fulfill the biological functions attributed to vitamin A. These metabolites include, but may not be limited to, 11-*cis*-retinal (11cROH) and all-*trans*-retinoic acid (atRA). The term 'retinoids' describes all compounds that support vitamin A activity, both naturally occurring and synthetic, including atROH. **Figure 1** illustrates the structures of key carotenoids and retinoids.

Daily Recommended Dietary Allowance of Vitamin A

The Food and Nutrition Board of the Institute of Medicine revised the Recommended Dietary Allowance (RDA) of vitamin A in 2001 as 900 retinol activity equivalents (RAE) for men and 700 RAE for women. The RAE was introduced to avoid the ambiguity of international units (IU), which arises because 1 IU of vitamin A (0.3 μg) and 1 IU of the vitamin A precursor (provitamin A) all-*trans*-β-carotene (0.6 μg) do not have the same biological activity. Rather, 6 IU of β-carotene and 12 IU of mixed carotenoids provide the biological activity of 1 IU of vitamin A. The RAE refers to the amounts necessary for the same degree of biological activity: 1 μg atROH = 12 μg β-carotene = 24 μg mixed carotenoids = 1 RAE.

Liver, dairy products, and saltwater fish, including herring, sardines, and tuna, serve as dietary sources of vitamin A and its esters. Cod and halibut liver oil provide especially rich sources of vitamin A, as does the liver of the polar bear, which benefits from occupying the top of the marine food chain. Carrots, yellow squash, corn, and dark-green leafy vegetables serve as dietary sources of provitamin A carotenoids. Because less than 10% of the 600 naturally occurring carotenoids generate vitamin A, vegetable color does not necessarily indicate vitamin A value. In the United States and Europe, retinol and its esters serve as the chief sources of dietary vitamin A, but elsewhere carotenoids serve as the primary source. According to the World Health

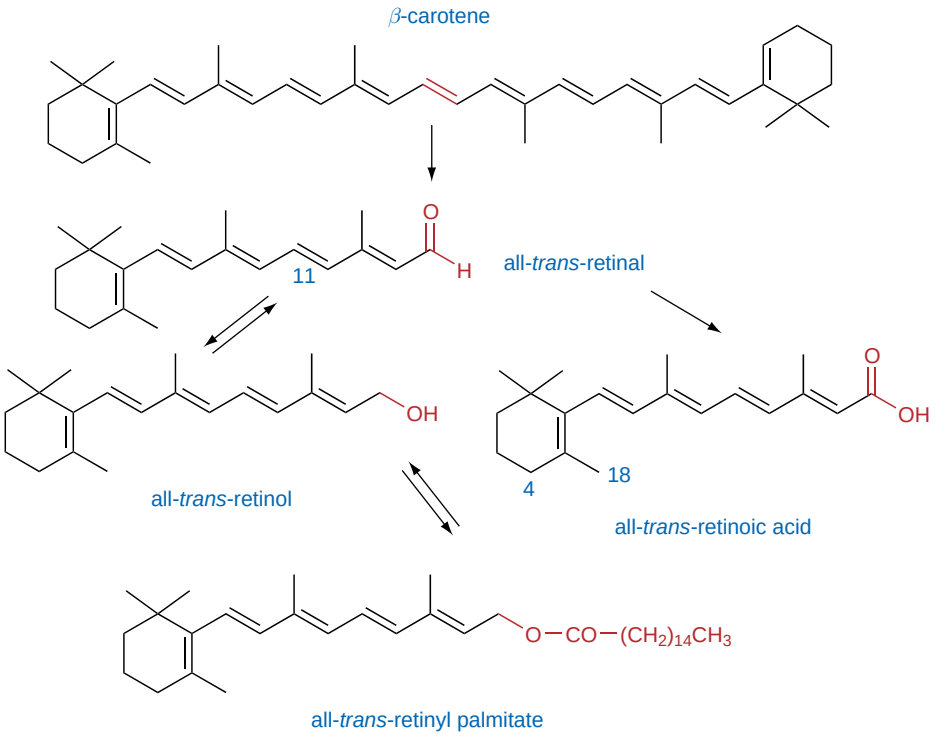

Figure 1 Structures of β-carotene and common endogenous retinoids. The numbers indicate the position of *trans* to *cis* isomerization of atRCHO (C11) and the positions of hydroxylation of atRA (C4 and C18).

Organization (WHO), the major inadequacies of dietary micronutrients involve vitamin A, iron, and iodine. Although vitamin A intake seems adequate in most populations in the United States, Canada, and Europe, this appears evolutionarily aberrant. The recurrent vitamin A-deficiency problem in Third World populations indicates that human diets in nonindustrialized countries are limited in vitamin A.

Vitamin A Status

atROH represents the quantitatively major circulating plasma retinoid in serum, but serum atROH does not reflect vitamin A status unless low (<0.35 μmol/l or 10 μg/dl) or unequivocally adequate (>1.1 μmol/l in children and >1.4 μmol/l in adults). Humans show a range of normal serum atROH values, with unknown factors contributing to the individual's normal value, and fever, infection, and/or inadequate intake of other nutrients (e.g., zinc and protein) can depress serum retinol. Liver reserves provide the most reliable measure of human vitamin A status. Noninvasive assessments of liver vitamin A reserves (the relative dose–response and modified relative dose–response tests) measure the amount of dose in serum relative to the original plasma atROH after a small oral dose of marker vitamin A. The larger the proportion of dose that appears in serum, the lower the liver reserves.

Binding Proteins

Several high-affinity (low K_d), soluble binding proteins seem crucial to vitamin A homeostasis and/or function. Two are widely distributed throughout many tissues and cell types, whereas others have limited expression loci (**Table 1**). These binding proteins occur in all vertebrates, have highly conserved amino acid sequences among orthologs, and show high specificity for distinct retinoids. Where measured, their concentrations exceed the concentrations of their ligands. Indeed, CRBP(II) accounts for ~1% of the soluble intestinal enterocyte proteins. These qualities and experimental data indicate that retinoids exist *in vivo* bound to specific proteins. For example, purification of CRBP(I) from tissues produces predominantly holoprotein, despite the capacity of membranes to sequester more atROH than occurs physiologically and the time-consuming isolation techniques originally used to isolate these proteins (including tissue homogenization, centrifugation, and several types of column chromatography). The locus of atROH at equilibrium would depend on both affinity for potential acceptors and acceptor capacity. Nature

Table 1 Examples of retinoid binding proteins

Retinoid binding protein	*Ligand(s)*	K_d *(nM)*	*Adult distribution*
CRBP (cellular retinol binding protein, type I)	atROH	~0.1	Nearly ubiquitous (low in intestine)
	atRCHO	10–50	
CRBP(II)	atROH	10–50	Intestine
	atRCHO	10–50	
CRABP (cellular retinoic acid binding protein, type I)	atRA	0.4	Widespread
CRABP(II)	atRA	2	Limited (e.g., skin, uterus, ovary)
CRALBP (cellular retinal binding protein)	11cROH	—	Eye, especially retinal pigment epithelium
	11cRCHO		
SRBP (serum retinol binding protein)	atROH	—	Serum

(*in vivo*) and the scientist (*in vitro*) provide plenty of opportunities for retinol to equilibrate between CRBP(I) and potential acceptors (membranes, lipid droplets, etc.). Evidently, the large capacity of membranes and other potential acceptors does not overcome the comparatively limited capacity of CRBP(I) to sequester retinol, consistent with tight binding.

CRBP (types I and II) and CRABP (types I and II) have molecular weights of ~15 kDa and belong to the intracellular lipid binding protein (iLBP) gene family, which includes the various fatty acid binding proteins. The family members have similar three-dimensional structures, despite low primary amino acid conservation among nonorthologous members. These proteins form globular but flattened structures of 10 antiparallel strands of β-sheets, 5 orthogonal to and above the other 5, referred to as a β-clam (**Figure 2**). The polar head group of atROH (i.e., the functional group that undergoes esterification or dehydrogenation) lies buried deep within CRBP, protected from the milieu of oxidants, nucleophiles, and enzymes.

CRBP(I) null mice are phenotypically normal until retinol depletion, but they eliminate retinol and its esters sixfold faster than wild-type mice, presumably through enhanced catabolism via enzymes that normally have limited access. In contrast, CRBP(II) null mice pups suffer 100% mortality by 24 h after birth when born to dams fed a vitamin A-marginal diet. Retinoid binding proteins apparently confer selective advantage to vertebrates by promoted sequestering, transport, and storage of vitamin A and limiting its catabolism. CRBP(III) has been detected in mouse heart and skeletal muscle, which express little or no CRBP(I) or CRBP(II), but not in other retinoid target tissues, such as liver, kidney, and brain. CRBP(III) seems to bind about equally well with atROH, 9cROH, and 13cROH (K_d ~80–110 nM). Humans express yet another CRBP, originally referred to as CRBP(III), but distinct from mouse

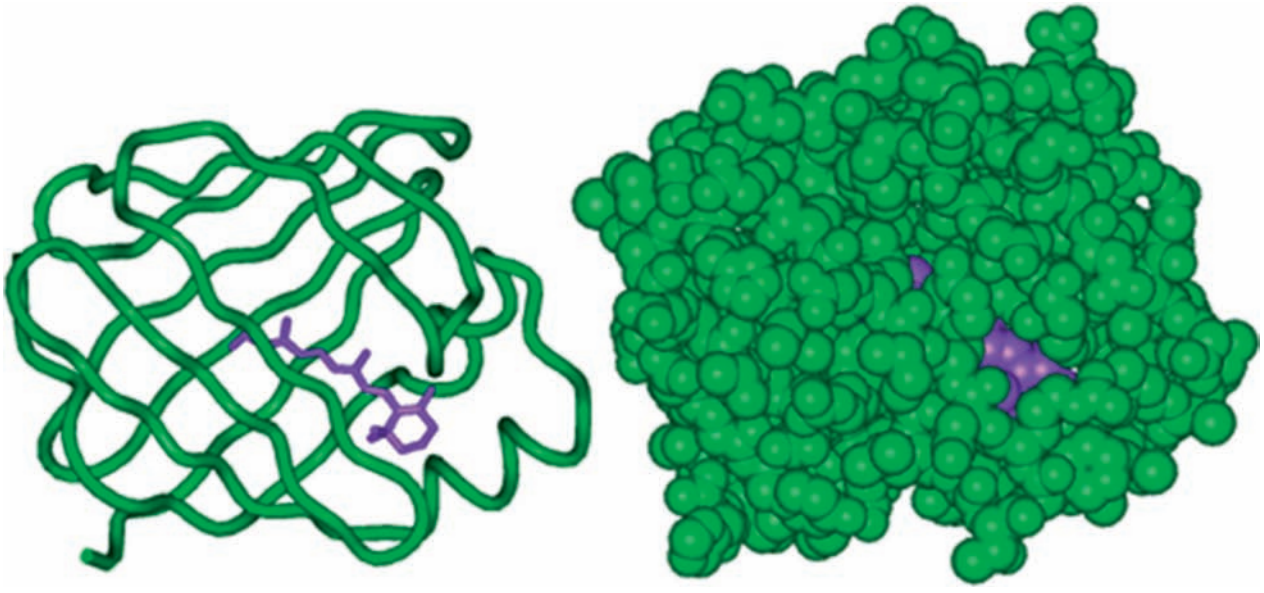

Figure 2 Ribbon (left) and space-filling (right) models of CRBP(I). (Courtesy of Marcia Newcomer (1995) Retinoid-binding proteins: Structural determinants important for function. *FASEB Journal* **9**: 229–239, Louisiana State University.)

CRBP(III) and therefore really CRBP(IV). CRBP(IV) mRNA is much more abundant in human liver and intestine than CRBP(I) mRNA, but the mouse does not encode a complete CRBP(IV) gene. CRBP(IV) binds atROH with a K_d of ~60 nM but does not bind *cis*-isomers. The precise functions of CRBP(III) and CRBP(IV) have not been clarified: Presumably, they moderate retinol metabolism, similar to CRBP(I) and CRBP(II).

CRABP(I) and -(II) do not have well-defined physiological functions. Mice doubly null in CRABP(I) and -(II) have an approximately fourfold higher rate of death from unknown causes by 6 weeks after birth than wild-type mice, but the survivors appear essentially normal, with one exception. The doubly null mouse as well as the CRABP(II)-only null mouse respectively show 83 and 45% incidence of a small outgrowth anomaly on the postaxial side of digit five, predominantly in the forelimbs. The double mutants do not exhibit enhanced sensitivity to atRA, suggesting that CRABP do not serve primarily to protect against atRA toxicity or teratogenicity.

CRALBP (~36 kDa) belongs to a gene family that includes the α-tocopherol transfer protein (TTP). *In vitro*, CRALBP sequesters 11cROH in the retinal pigment epithelium (RPE) of the rods, driving forward the *trans* to *cis* isomerization, and also facilitates dehydrogenation of 11cROH into 11cRCHO. Mutations in human CRALBP cause night blindness and photoreceptor degeneration.

SRBP (~20 kDa) belongs to the lipocalin family, which includes apolipoprotein D, β-lactoglobulin, odorant binding protein, and androgen-dependent secretory protein. SRBP has a globular structure formed by eight antiparallel β-sheets in two orthogonal sheets that mold a β-barrel. The β-ionone ring of atROH lies deep within SRBP, whereas the hydroxyl group lies closest to the opening. atROH in serum remains bound with SRBP, despite high concentrations of a potential alternative high-capacity carrier, albumin. This illustrates the affinity of SRBP for atROH and the importance of sequestering retinoids within specific proteins. Liver is the major site of SRBP synthesis: Accordingly, liver expresses SRBP mRNA most abundantly. Extrahepatic tissues, however, also express SRBP mRNA, including adipose and kidney, but the functions of SRBP produced extrahepatically remain unknown. Knocking out the SRBP gene produces a phenotypically normal mouse, except for impaired vision after weaning. Vision can be restored after months of feeding a vitamin A-adequate diet. Thus, the eye, which consumes (but does not store) the vast majority of vitamin A, normally relies on SRBP for retinol delivery. Retinol delivered by albumin and lipoproteins apparently supports the nonvisual functions of vitamin A, at least in the SRBP null mouse kept under laboratory conditions.

Vitamin A and the Visual Cycle

Figure 3 depicts a model of the functions of multiple proteins and forms of vitamin A that constitute the visual cycle. SRBP delivers atROH to the RPE, possibly through a plasma membrane SRBP receptor. No SRBP receptor has been isolated, however, and molecular characterization remains elusive. As in other tissues, CRBP(I) sequesters atROH and allows its esterification by the 25-kDa endoplasmic reticulum (ER) enzyme lecithin:retinol acyltransferase (LRAT). In fact, the amount of CRBP(I) may represent the controlling event in the rate of atROH uptake, and uptake may be coupled to retinyl ester (RE) formation. RPE65, an ~65-kDa RPE protein, binds the highly hydrophobic atRE with a K_d of ~20 pM. This accelerates mobilization of atRE and delivery to the next step, isomerization by an isomerohydrolase (IMH). The RPE65 null mouse cannot produce 11-*cis*-retinoids, attesting to its importance in mobilizing atRE in the quantity and rate necessary to support the visual cycle. The IMH both hydrolyzes atRE and isomerizes the double bond at C11 to produce 11cROH. Unfortunately, little is known about the IMH: It has not been isolated or cloned. The cytosolic protein CRALBP sequesters 11cROH and also 11cRCHO produced by the ER enzyme 11-*cis*-retinol dehydrogenase (11cRDH), and it seems to enhance isomerization. The 11cRDH of the RPE belongs to the SDR (short-chain dehydrogenase/reductase) gene family: RDH4 and RDH5 encode the murine and human 11cRDH genes, respectively. 11cRDH also has been referred to as 9cRDH (9-*cis*-RDH) or cRDH, but the eye expresses 11cRDH mRNA far more intensely than other tissues, and more efficient potential 9cRDHs have been cloned and characterized, namely the SDR isozymes CRAD1 and -3 (*cis*-retinol/androgen dehydrogenase). Mutations in RDH5 cause the rare autosomal recessive disorder fundus albipunctatus, which is a form of night blindness characterized by delayed regeneration of photopigments in rods and cones. Enzymes in addition to RDH4/5 probably contribute to dehydrogenation of 11cROH in the RPE, which explains why the RDH5 mutation does not cause blindness.

Interphotoreceptor retinoid binding protein (IRBP) occupies the space between the RPE and the rod outer segment (ROS), the interphotoreceptor matrix, and binds both 11cROH and 11cRCHO.

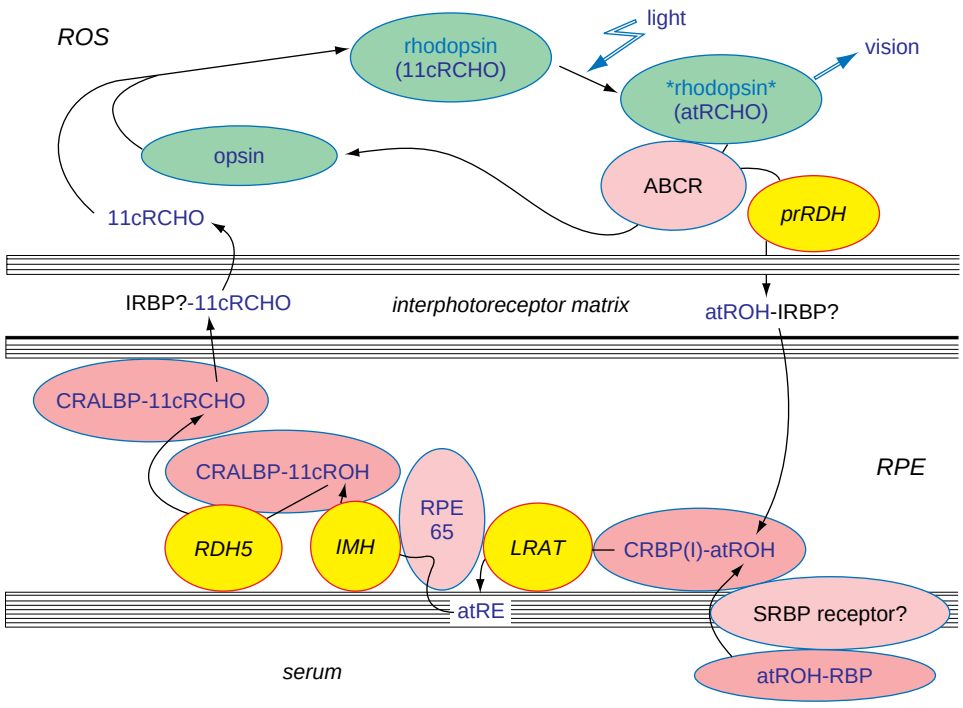

Figure 3 Model of the mammalian visual cycle. ABCR, ATP-binding cassette; atRCHO, all-*trans*-retinal; atROH, all-*trans*-retinol; atRE, all-*trans*-retinyl esters; 11cRCHO, 11-*cis*-retinal; 11cROH, 11-*cis*-retinol; CRALBP, cellular retinal binding protein; CRBP(I), cellular retinol binding protein, type I; IRBP, interphotoreceptor retinoid binding protein; IMH, isomerohydrolase; LRAT, lecithin:retinol acyltransferase; ROS, rod outer segment; RPE, retinal pigment epithelium; RPE65, RPE protein 65; SRBP, serum retinol binding protein.

Retinoids do not require IRBP for transfer between the two membranes, however, because IRBP null mice show no gross abnormalities of the visual cycle, even though they have severe retinal abnormalities. Although retinoids have very limited solubility in the aqueous phase, membranes of the RPE and ROS transfer retinoids between them in the absence of IRBP.

In the ROS, 11cRCHO forms a Schiff's base adduct with a lysine residue in the protein opsin to create rhodopsin. Light isomerizes the 11cRCHO of rhodopsin into atRCHO. The isomerization straightens the retinoid side chain, changing the conformation of rhodopsin. This conformation change initiates a nerve impulse through G proteins and releases atRCHO, regenerating opsin. An ATP transporter ABCR facilitates leaching of atRCHO from rhodopsin, and an ER enzyme, prRDH (photoreceptor retinol dehydrogenase), also an SDR, reduces atRCHO into atROH. atROH cycles back to the RPE and binds with CRBP(I).

Vitamin A Homeostasis and Activation into atRA

Intestinal absorptive cells absorb dietary carotenoids and retinol during the bile–acid-mediated process of lipid absorption. Within the enterocyte, central cleavage by a soluble 63-kDa carotene 15,15′-monooxygenase catalyzes the principal route of carotenoid metabolism (**Figure 4**). Carotene 15,15′-monooxygenase belongs to the same gene family as RPE65 (the mouse proteins have only 37% amino acid identity, however), suggesting a family of proteins/enzymes dedicated to transport/metabolism of highly hydrophobic substances. Intestine expresses the carotene 15,15′-monooxygenase mRNA, but kidney and liver show much more intense expression, and the testis curiously shows most intense expression, consistent with the ability of tissues other than the intestine to cleave carotenoids. Carotene 15,15′-monooxygenase also metabolizes carotenoids without provitamin A activity, such as lycopene, although with lower efficiency.

CRBP(II) sequesters atRCHO generated from carotenoids and allows its reduction into atROH, catalyzed by an ER retinal reductase (uncharacterized). In contrast to CRBP(I), CRBP(II) does not allow oxidation/dehydrogenation of its ligands. LRAT accesses the CRBP(II)–atROH complex and produces atRE for incorporation into chylomicrons. During conversion into remnants by lipoprotein lipase in adipose, chylomicrons retain most of their RE, as they do cholesterol esters.

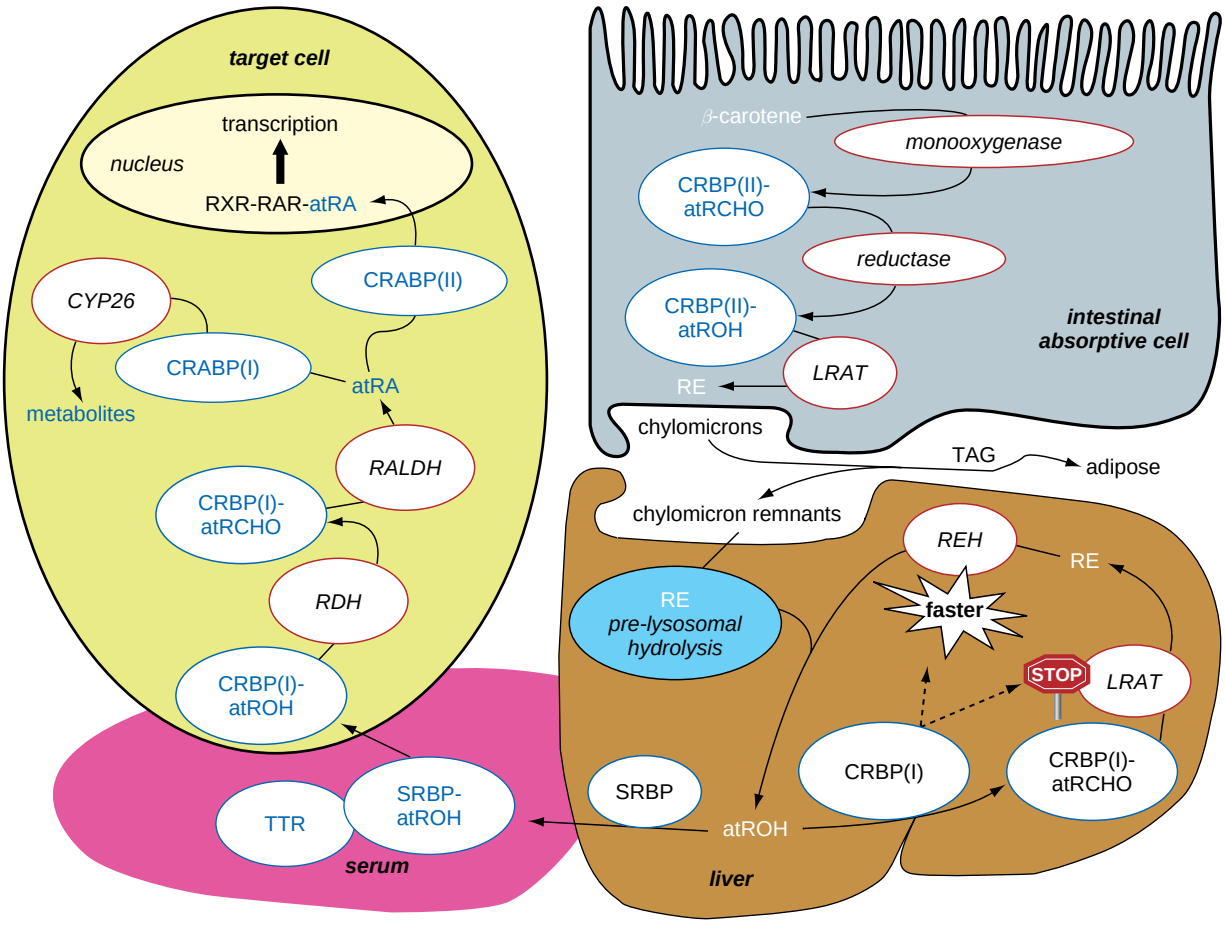

Figure 4 Model of atRA biogeneration in mammals. REH, retinyl ester hydrolase (e.g., ES4 and ES10); TTR, transthyretin; RAR-RXR, the heterodimer of retinoic acid receptors with retinoid X receptors; atRCHO, all-*trans*-retinal; atROH, all-*trans*-retinol; CRBP(I), cellular retinol binding protein, type I; LRAT, lecithin:retinol acyltransferase; SRBP, serum retinol binding protein. CRBP(I), CRABP(I), and CRABP(II) have been placed in the same cell for simplicity. This does not necessarily occur *in vivo*.

Hepatocytes sequester RE and cholesteryl esters by receptor-mediated endocytosis of chylomicron remnants. Substantial RE hydrolysis apparently occurs before engulfing of the remnants by lysosomes. CRBP(I) sequesters the atROH released and allows esterification by LRAT but protects from esterification via other acyltransferases, just like CRBP(II) functions in the intestine. Ultimately, liver stellate cells accumulate most of the RE. CRBP(I) seems necessary for retinoid transfer from hepatocytes to stellate cells because the CRBP(I) null mouse does not accumulate RE in stellate cells. The mechanism of transfer, however, has not been established.

Liver senses local and extrahepatic need for atRA biosynthesis by an unknown signal (possibly atRA) and need for atROH in the visual cycle, and it responds by mobilizing RE to maintain serum retinol levels. ES-10 and ES-4, two neutral ER-localized, bile salt-independent carboxyesterases, provide at least 94% of the RE hydrolysis activity in liver. Kidney also expresses ES-4, and kidney, testis, lung, and skin express ES-10. Either SRBP or CRBP(I) sequesters the atROH released. SRBP delivers atROH to serum, whereas CRBP(I), unlike CRBP(II), allows dehydrogenation into atRCHO to support atRA biosynthesis. (**Figure 4** shows atRA biogeneration only in target cells, but it also occurs in liver; likewise, RE storage also occurs in target cells in animals exposed to higher dietary atROH, suggesting that the liver does not initially sequester all dietary retinoids.) What keeps the CRBP(I)-bound atROH from undergoing futile cycling back to atRE? Apo-CRBP(I) stimulates endogenous microsomal RE hydrolysis and inhibits LRAT (**Figure 5**). Note that apo-CRBP(I) exerts potent effects at concentrations of ~2.5 μM—well within the range of the CRBP(I) expressed in liver. Thus, the ratio apo-CRBP/holo-CRBP signals atROH status and directs atROH flux into or out of atRE.

SRBP–atROH circulates as a complex with transthyretin (TTR) that protects it from degradation. The mechanism of atROH delivery from SRBP into

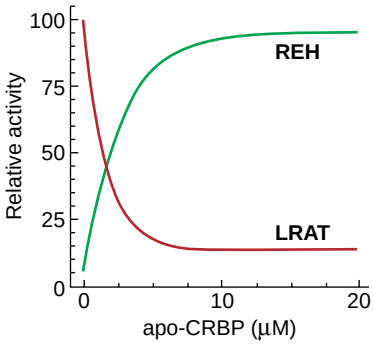

Figure 5 The effect of apo-CRBP(I) on the rates of retinol esterification (lecithin:retinol acyltransferase (LRAT)) and retinyl ester hydrolysis (REH).

cells has not been established. Some data suggest a specific SRBP membrane receptor, whereas other data indicate that CRBP(I) pulls atROH transfer from SRBP through the membrane. A third hypothesis is that an SRBP receptor is mainly in the eye, the quantitatively major site of atROH consumption.

Extrahepatic cell atROH supports atRA biosynthesis but also undergoes esterification if delivered in sufficient quantities. CRBP(I) allows dehydrogenation of atROH by an ~35-kDa ER retinol dehydrogenase (RDH) but protects atROH from dehydrogenation via other dehydrogenases. RDH (*Rdh1*) belongs to the SDR gene family. The SDR gene family consists of ~50 mammalian members that catalyze intermediary metabolism, and the metabolism of steroids and prostaglandins, in addition to retinoids.

The mechanism of atROH transfer from CRBP(I) or -(II) to RDH and LRAT has not been elucidated. Specific cross-linking of holo-CRBP(I) with both RDH1 and LRAT, however, indicates close proximity of CRBP(I) to the two enzymes. Notably, apo-CRBP(I) at concentrations of 1 μM prevents cytosolic dehydrogenation of atROH, even by soluble enzymes that access the CRBP(I)–atROH complex, while not impacting ER SDR until reaching much higher concentrations. This suggests the importance of membrane RDH, rather than soluble dehydrogenases, to atRA biosynthesis. Obviously, atRA biosynthesis *in vivo* occurs in the absence of CRBP(I), as indicated by lack of morphological pathology in the CRBP(I) null mouse. This was predicted by *in vitro* experiments that showed that neither RDH nor LRAT require presentation of atROH by CRBP(I). Rather, CRBP(I) operates as a molecular chaperone that restricts metabolism to enzymes that can access its atROH.

In the early 1950s, cytosolic alcohol dehydrogenases (ADHs) were suggested to metabolize atROH. This was an attempt to explain atRCHO generation and the controversial and poorly understood putative occurrence (at the time) of atRA in tissues, when other families of dehydrogenases remained anonymous. ADHs do recognize atROH *in vitro*, albeit only when presented free of CRBP(I) and with comparatively low efficiencies. However, enzymes have poor substrate discrimination *in vitro* and do not metabolize many of the same substrates *in vivo* because of intracellular constraints. Mice null in both ADH class I (*Adh1*) and ADH class IV (*Adh4*) show no vitamin A-deficiency phenotype, nor do mice null in ADH class III (*Adh3*). *Adh1* null mice show a decreased rate of metabolism of 50–100 mg/kg atROH, but this demonstrates only that extraordinary high exposure can defeat physiological controls imposed by retinoid binding proteins. Vitamin A excess has not been a problem throughout evolution (mice do not usually eat polar bear or marine fish liver): No pressure forced evolution of protective mechanisms against such exposure. Natural selection exerted the opposite pressure (i.e., evolution of retinoid binding proteins to conserve vitamin A).

Retinal dehydrogenases (RALDHs) catalyze the irreversible conversion of atRCHO into atRA and can do so in the presence of CRBP(I) using atRCHO generated *in situ* from CRBP(I)–atROH and RDH. These ~54-kDa soluble enzymes belong to the ADLH gene family. RALDH1 (*Aldh1a1*), -2 (*Aldh1a2*), and -3 (*Aldh1a3*) contribute most to atRA generation, whereas RALDH4 has much more efficient activity with 9-*cis*-retinal. The RALDH1 null mouse remains fertile and healthy but may have decreased ability to produce atRA in the liver. The RALDH2 null mouse dies *in utero* by midgestation, demonstrating its unique contribution to atRA synthesis during embryogenesis. The situation may differ in the adult. RALDH1–3 show overlapping expression patterns in the adult, with RALDH1 expressed most intensely. Interestingly, atRA regulates mRNA levels of RALDH1 differently in different tissues. For example, vitamin A sufficiency increases kidney and liver RALDH1 mRNA, whereas vitamin A insufficiency increases testis RALDH1 mRNA. This may represent a mechanism to divert atROH from liver to testis for atRA production during vitamin A scarcity.

Other Active Retinoids

Discrete loci synthesize 3,4-didehydro-atRA, such as skin. 3,4-Didehydro-atRA binds RAR with high affinity, similar to atRA. The purpose of creating a signaling molecule that functions similar to atRA

in specialized loci, which also biosynthesize atRA, has not been clarified.

Although 9-*cis*-RA was reported as a hormone *in vivo*, at best, its concentrations are much lower than atRA. Its putative function as a physiological ligand that controls RXR is controversial.

atRA Catabolism

atRA induces its own metabolism via cytochrome P450 (CYP) into a variety of initial catabolites, including 5,6-epoxy-atRA, 18-hydroxy-atRA, and 4-hydroxy-atRA. Metabolism of atRA limits its activity; conversely, inhibitors of atRA metabolism enhance atRA potency. CYP26A1 may catalyze the major degree of atRA catabolism, as evidenced by null mice dying in mid- to late gestation with serious morphological defects. Two other P450's, CYP26B1 and CYP26C1, also catabolize atRA, but null mice have not been reported. Several other CYPs reportedly catabolize atRA, but these candidates (CYP1A1/2, CYP2A6, CYP2C8/9, CYP2E1, and CYPP3A4/5) are not induced by atRA—in contrast to the well-established ability of atRA to induce its own metabolism as well as CYP26A1 transcription—and most have inefficient kinetics *in vitro* with atRA.

Presenting atRA to microsomes bound with CRABP(I) enhances kinetic efficiency of catabolism sevenfold. There seems to be little doubt that CRABP(I) sequesters atRA: Delivering the sequestered atRA for efficient catabolism seems to be a logical mechanism to discharge the ligand without releasing it back into the cell. Unfortunately, this insight does not reveal the primary purpose for CRABP(I) impounding atRA in the first place.

Regulation of Retinoid Homeostasis

atRA regulates retinoid homeostasis. It induces LRAT transcription ~100-fold and induces CRBP(I) transcription. These may be housekeeping functions that maintain retinol esterification and handling during vitamin A sufficiency. On the other hand, induction of CYP26A1 by atRA can be viewed both as a general mechanism of clearance and as a site-specific mechanism to maintain an environment during specific stages of development.

Several xenobiotics, including ethanol and polychlorinated biphenyls, reduce RE stores, possibly through enhancing atRA catabolism by inducing CYP. In addition, clofibrate, a ligand of PPARα (peroxisome proliferator activated receptor), causes a remarkably rapid depletion of liver retinoids and decreases TTR mRNA fourfold. In contrast, PPARγ, expressed in liver stellate cells among others, induces transcription of carotene 15,15′-monooxygenase. PPARγ also induces expression of CRBP(I), CRBP(II), LRAT, and RARβ. These actions of PPARα and -γ with retinoids reflect their effects on lipid metabolism: PPARα enhances fatty acid catabolism, whereas PPARγ enhances adipogenesis and fatty acid storage.

Mechanism of atRA Action

atRA induces transcription by binding with three ligand-activated transcription factors, RARs (retinoic acid receptors) α, β, and γ, each encoded by a distinct member of the nuclear hormone receptor gene superfamily. RARs function *in vivo* bound with three additional distinct members of the nuclear receptor gene family: RXR (retinoid X receptor) α, β, and γ. Forty-eight RXR–RAR combinations can occur because each receptor gene can express two to four protein isoforms, stemming from differential promoter use and alternative splicing. RXR in complex with RA acts 'silently' (i.e., it can function sans ligand). The RXR–RAR heterodimer recognizes several types of RARE (atRA response elements). The two most common consist of two direct repeats of (A/G)G(G/T)TCA separated by two (DR2) or five (DR5) nucleotides. This multiplicity of heterodimers and response elements suggests a mechanism for the pleiotropic functions of vitamin A.

atRA binding with RAR induces the receptor to convert from an open form to a more structured form that wraps the ligand. This conformation change leads to remodeling of coregulators bound to the RXR–RAR complex. Remodeling releases a complex array of co-corepressors and recruits a complex array of coactivators, accompanied by chromatin remodeling, histone acetylation, and recruitment of basal transcription factors, including TATA binding protein and RNA polymerase II. More than 500 genes have been reported as transcriptionally regulated by atRA either directly by this process or indirectly through events set into motion by this process.

RXR's influence extends beyond serving as an obligatory partner of RAR. RXR forms heterodimers with ~11 nuclear receptors, including the vitamin D receptor PPAR and the thyroid hormone receptors. 'The' RXR ligand, if not 9cRA, would have significant signaling impact.

CRABP(II), but not CRABP(I), delivers atRA to RAR and thereby induces transcription. The limited expression loci of CRABP(II), however, suggest that this action would be specialized rather than general.

Physiological Functions of atRA

All vertebrates require retinal for the visual cycle and atRA to support the systemic functions of vitamin A, including controlling the differentiation programs of epithelia cells and cells in nerve and bone and also the immune and reproductive systems. atRA frequently, but not always, induces terminal differentiation. atRA also regulates expression of genes in differentiated cells and genes crucial to spermatogenesis, hematopoiesis, estrus, placental development, embryogenesis, and apoptosis. atRA may also serve as a tumor suppressor.

The many RAR knockouts illustrate the physiological functions of vitamin A. Disruption of the RARα gene, the RAR with the most widespread, if not ubiquitous, expression in the embryo and adult, does not cause embryonic lethality but reduces the homozygous null population by 60% within 12–24 h after birth and by 90% within 2 months. The RARα null mice that survive 4 or 5 months have severe germinal epithelium degeneration and are sterile. RARβ gene null mice are fertile and viable and show no immediate signs of morphological abnormalities. Nevertheless, complementary data show that RARβ may mediate the antiproliferative function of atRA and as such may serve as a tumor suppressor. Moreover, RARβ null mice have virtually no hippocampal long-term potentiation or long-term depression, the forms of synaptic plasticity that provide a mechanism of short-term spatial learning and memory. This phenomenon can be reproduced by vitamin A depletion. RARγ null mice have an 86% incidence of skeletal abnormalities by embryonic day 18.5 but are born in Mendelian frequency. Postnatally, the homozygous null pups show retarded rates of growth, limiting them to 40–80% of the weight of wild-type pups. By 1–3 weeks old, 50% of RARγ null mice die; by 3 months, 80% die. Mature males also have squamous metaplasia of the seminal vesicles and prostate glands, similar to vitamin A deficiency, but other epithelia appear normal. These data reveal that even though RAR tend to express in site specific patterns in normal circumstances, they also exhibit a great degree of functional redundancy, enabling a mouse null in one receptor to (partially) compensate for the other two.

Numerous studies have correlated vitamin A insufficiency in laboratory animals with increased incidence of spontaneous and carcinogen-induced cancer. Chemopreventive trials in humans show some promise for retinoids in actinic keratoses, oral premalignant lesions, laryngeal leukoplakia, and cervical dysplasia. The US Food and Drug Administration has approved retinoids for acute promyelocytic leukemia and for non-life-threatening diseases, such as cystic acne and psoriasis. Retinoids also provide the active ingredients in agents to treat sun/age-damaged skin.

WHO recognizes vitamin A deficiency as a mortality factor for childhood measles. Two large doses (60,000 RAE each) of a water-soluble vitamin A formulation given to children on each of 2 days decrease the risk of death from measles 81% in areas of prevalent vitamin A deficiency.

Deficiency and Interventions

K P West Jr, Johns Hopkins University, Baltimore, MD, USA

Vitamin A (VA) deficiency is the leading cause of pediatric blindness, increases risk of severe infection, and is an underlying cause of child mortality in many developing countries. Night blindness, the mildest ocular manifestation of VA deficiency, has been recognized since antiquity, with the condition depicted in bas-relief on the Egyptian pyramid in Sakura, dating to the Middle Kingdom, and Hippocrates in the fourth century BC recognizing and treating the condition with animal liver. Corneal destruction and consequent blindness, as well as milder conjunctival lesions of xerophthalmia, were linked to dietary insufficiency in the eighteenth and nineteenth centuries, with cod liver oil emerging as recommended treatment for the various conditions of night blindness, Bitot's spots, and corneal necrosis (keratomalacia) more than a century ago. Discovery in the early twentieth century of 'fat-soluble A,' an ether-soluble factor in butter and egg yolk critical for sustaining growth, health, and vision in animals, accelerated recognition and treatment of xerophthalmia in children as well as decades of subsequent research that led to the synthesis of vitamin A and its analogues, an understanding of the vitamin's roles in the visual cycle, and discovery of the vitamin's involvement in maintaining epithelial, immune, hematopoietic, and osteoid function and multiple facets of human health.

Vitamin A Deficiency Disorders

Vitamin A is essential for maintaining normal retinal function and differentiation of rapidly dividing, bipotential cells. These regulatory roles give rise to specific manifestations of hypovitaminosis A, such as poor photoreceptor function leading to night blindness, metaplasia, and keratinization of mucosal epithelial surfaces leading to clinical abnormalities of conjunctival and corneal xerosis as well as epidermoid metaplasia and other epithelial defects throughout the respiratory, genitourinary, and gastrointestinal tracts and glandular ducts. Deficiency can also impair development or functioning of multiple arms of the immune system that can weaken host defenses against infection. Collectively, all pathophysiological consequences attributed in varying degrees to VA depletion are termed 'vitamin A deficiency disorders (VADD) (**Figure 1**).

Biochemical Depletion

Tissue depletion of vitamin A, although not a disorder per se, precedes the functional consequences of deficiency. In uncomplicated hypovitaminosis A, plasma retinol tends to be homoeostatically controlled until body (primarily liver) stores are low, after which plasma concentration declines. Plasma retinol may also decline during states of chronic inflammation and clinically significant infection, in parallel with raised circulating concentrations of acute phase proteins, likely reflecting increased tissue delivery, reduced hepatic mobilization via retinol binding protein, and increased urinary loss of vitamin A. Plasma retinol gradually normalizes during recovery from infection if there are adequate hepatic stores of the vitamin. If not, infection can leave the host more tissue depleted and at risk. Despite nondietary influences, plasma or serum retinol measurement remains the most common biochemical index of vitamin A status. Vitamin A deficiency is generally diagnosed at a serum retinol concentration below a cutoff of 0.70 μmol/l (20 μg/dl), below which 20 to >50% of concentrations occur in a VA-deficient population compared to <3% of well-nourished societies. A serum retinol concentration of <0.35 μmol/l is indicative of severe deficiency. Decrements in serum retinol concentration below these cutoffs are associated with marked increases in risk of xerophthalmia and infection. Other indices of tissue retinol depletion include the relative dose–response, a before–after test dose difference in serum retinol that indirectly reflects hepatic retinol adequacy, breast milk retinol concentration for assessing both maternal status

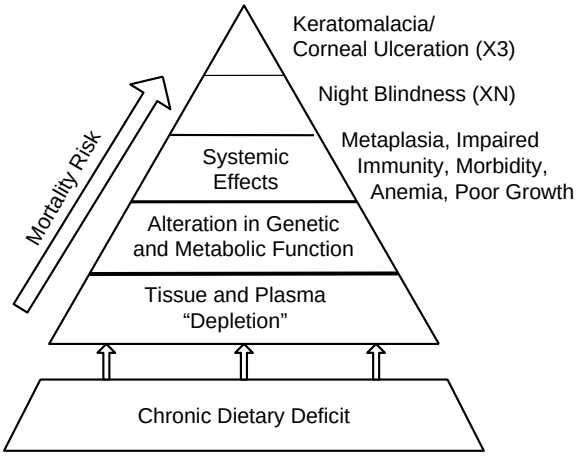

Figure 1 Concept of vitamin A deficiency disorders (VADD), due primarily to underlying chronic dietary deficit in preformed vitamin A and provitamin A carotenoids. From West KP Jr (2002) Extent of vitamin A deficiency among preschool children and women of reproductive age. *Journal of Nutrition* **132**: 2857S–2866S.

and intake adequacy of breast-fed infants, stable isotopic dilution to assess the total body vitamin A pool, impression cytology that detects early or mild metaplasia on the bulbar conjunctiva, and clinical stages of xerophthalmia.

Xerophthalmia

Conjunctival and corneal epithelium deprived of vitamin A undergoes keratinizing metaplasia. Columnar epithelial cells become squamous and mucus-producing goblet cells disappear, providing the histopathologic mechanisms for deficiency-induced xerotic (drying) changes to the ocular surfaces. VA deficiency is also required for rod vision in dim light. VA deficiency-induced night blindness often occurs with histopathologic changes on the ocular surface. Thus, night blindness and clinical eye signs are both listed under one xerophthalmia classification scheme (**Table 1**).

Night blindness Vitamin A, as retinaldehyde, is an essential cofactor in the generation of rhodopsin. This is a photosensitive pigment in rod photoreceptors of the retina that responds to light (it is 'bleached') by releasing vitamin A and initiating neural impulses to the brain that permit vision under conditions of low illumination. The utilization and recycling of vitamin A in this process is known as the 'visual cycle.' Hypovitaminosis A restricts rhodopsin production, which in turn raises the scotopic (low light) visual threshold. Gradually, a perceptive threshold is reached that leads to recognition of night blindness (XN), the earliest symptom of xerophthalmia. It is marked by an inability to move about in the dark. Children between 1 and 5 years of age and pregnant women appear to be at greatest risk of XN. Where endemic, there is often a local term for XN that translates into 'evening' or 'twilight' blindness or 'chicken eyes' (lacking rod cells, chickens cannot see at night), making the condition readily detectable by history. Typically, gestational night blindness resolves spontaneously with child birth and expulsion of the placenta, likely relieving maternal metabolic demands for vitamin A.

Table 1 WHO and IVACG classification and minimum prevalence criteria for xerophthalmia and vitamin A deficiency as a public health problem

Definition (code)	*Minimum prevalence (%)*	*Highest risk period*
Children 1–5 years of age		
Night blindness (XN)	1.0	2–6 years
Conjunctival xerosis (XIA)	—	—
Bitot's spots (X1B)	0.5	2–6 years
Cornea xerosis (X2)/corneal ulceration (X3A)/keratomalacia (X3B)	0.01	1–3 years
Xerophthalmic corneal scar (XS)	0.05	>1 year
Deficient serum retinol (<0.70 μmol/l)	15.0	<6 months; 1–5 years
Pregnant/lactating women		
Night blindness (XN) during most recent pregnancy	5.0	3rd trimester
Low serum retinol (<1.05 μmol/l)	20.0	

Adapted from Sommer A and Davidson FR (2002) Assessment and control of vitamin A deficiency: The Annecy Accords. *Journal of Nutrition*. **132**: 28455–28505.

Conjunctival xerosis and Bitot's spots Early xerosis of the conjunctiva can be detected subclinically by filter paper impression cytology, showing distorted, enlarged, and noncontiguous sheaths of epithelial cells and the disappearance of goblet cells. In advanced vitamin A deficiency, xerosis appears clinically as a dry, unwetable surface of the bulbar conjunctiva (X1A). The affected areas are usually overlaid with superficial white, cheesy, or foamy patches of triangular or oval shape that consist of desquamated keratin and bacteria (often the xerosis bacillus). These are known as Bitot's spots (X1B). They are nearly always bilateral, found temporal (and, in more advanced cases, also nasal) to the corneal limbus, and more reliably diagnosed than X1A. Bitot's spots are not blinding but are reflective of chronic moderate to severe systemic depletion of vitamin A.

Corneal xerophthalmia Corneal xerophthalmia is manifested in increasingly severe stages. The earliest corneal lesions appear as superficial punctate defects, evident with a slit lamp, that with advanced deficiency become more numerous and concentrated. The cornea is considered xerotic (X2) when punctate keratopathy covers large areas of the surface, rendering a hazy, nonwetable, lusterless, and irregular appearance on handlight examination. Stromal edema may be present. In more severe cases, thick, elevated xerotic plaques may form. Usually, both eyes are affected. Corneal ulcers (X3A) can be sharply demarcated, round or oval defects that are usually shallow but may also perforate the cornea. Healed ulcers form a leukoma (scar) or adherent leukoma if the iris has plugged the perforated ulcer. Most ulcers occur peripheral to the visual axis and thus may not threaten central vision if treated promptly. Keratomalacia (X3B) refers to a full-thickness softening and necrosis of the corneal stroma that can cause protruding, opaque, yellow to gray lesions to form (**Figure 2**). These tend to collapse or slough off, leaving a

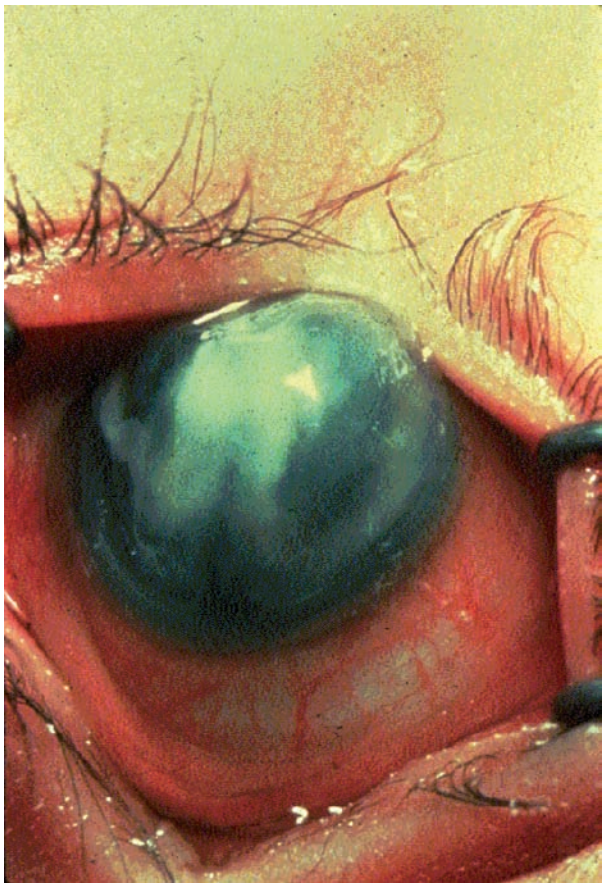

Figure 2 Keratomalacia. From Sommer A (1995) Vitamin A deficiency and its consequences. A Field Guild to detection and control. 3rd ed. Geneva, WHO.

descemetocele following VA treatment. Keratomalacia usually impairs vision in the involved eye, although the degree of visual loss depends on the location, thickness, and extent of corneal necrosis and resultant scar. Due to the generally malnourished and ill state of children with corneal xerophthalmia, the mortality rate of hospitalized cases is 4–25%.

Other VADD

Infection A bidirectional relationship exists between hypovitaminosis A and infection, each exacerbating the other, representing a classic 'vicious cycle.' Thus, infection may be considered both a cause of VA deficiency and, in terms of severity and sequellae, a 'disorder' as well. Cross-sectionally, xerophthalmia or severe hyporetinolemia has been consistently associated with higher frequencies of diarrhea, fever, and other infections, although directionality is difficult to parse from such evidence.

VA deficiency raises the risk of infection presumably due to compromised 'barrier' epithelial function and impaired innate, cell-mediated, and humoral immune mechanisms. VA-deficient Southeast Asian preschoolers (i.e., with mild xerophthalmia) were twice as likely to develop acute respiratory infection and (in Indonesia) three times more likely to develop diarrhea over subsequent 3- to 6-month periods. Deficient children are also more likely to die. This was so among Indonesian preschool children, whose risk of mortality increased with increased severity of mild eye signs (**Figure 3**). In Nepal, siblings of patients were more likely to develop the eye lesions but were also at a twofold higher risk of dying than children living in unaffected households, reflecting a clustering of child mortality risk within VA-deficient households.

Data from children and animals support the plausibility of these findings. VA-deficient children show increased bacterial adherence to respiratory epithelium, low lymphocyte counts and T helper to cytotoxic/suppressor cell ratios, and a weaker delayed-type hypersensitivity response compared to nonxerophthalmic children. In animals, VA deficiency produces keratinizing metaplasia of epithelial linings that may affect 'barrier' defenses. It also compromises acquired immunity, indicated by lymphoid atrophy, reduced numbers of circulating lymphocytes, impaired blast transformation responses to antigen, T cell-dependent antibody responses, and natural killer cell activity, and a greatly increased risk of infection and death.

Anemia and Poor Growth Children with xerophthalmia and night blind mothers tend to be anemic relative to peers without eye disease. VA-supplemented trials often show improvement in indicators of iron status, including reductions in anemia. Mechanisms involved in this interaction are not clear but may involve enhanced iron absorption, storage,

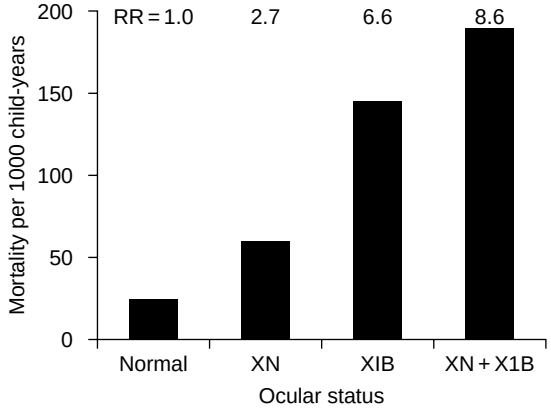

Figure 3 Risk of mortality among ~3500 Indonesian preschool children by ocular status at the outset of each 3-month interval. RR, relative risk of mortality. Adapted from Sommer A *et al.* (1983) Increased mortality in children with mild vitamin A deficiency. *Lancet* **2**: 585–588.

and transport as well as direct effects on hematopoiesis in the presence of adequate iron stores.

VA deficiency decelerates growth in animals and has been associated with both stunting and wasting malnutrition in children, possibly reflecting roles for the vitamin in osteogenesis and protein metabolism. Trials, however, have shown inconsistent effects of VA supplementation on child growth, possibly due to variations in the extent of infection, seasonality in dietary protein and energy adequacy, exclusion criteria, and levels of VA status among study children. It appears that VA supplementation can influence ponderal and linear growth, as well as body composition, in children for whom VA deficiency is a 'growth limiting' nutritional deficit.

Epidemiology

The epidemiology of VA deficiency provides a basis for quantifying its extent and health consequences; describing its demographic patterns, geocultural context, and dietary causes; and with which to target interventions for treatment and prophylaxis. It is mostly understood in relation to hyporetinolemia and xerophthalmia (**Table 1**), especially the noncorneal stages involving night blindness and Bitot's spots due to conjunctival xerosis. The latter eye signs are common, specific, and likely to exhibit risks relevant to more widespread hypovitaminosis A. Importantly, although both conditions represent 'mild' non-blinding xerophthalmia, they typically occur in moderate to severe systemic VA deficiency.

Magnitude

Current estimates suggest that VA deficiency (serum retinol $<0.70\,\mu$mol/l) afflicts 25% or 127 million preschool-aged children in the developing world, of whom 4–5 million have xerophthalmia. The number of potentially blinding corneal cases occurring annually is less well-known but, based on historic data, efficacy of VA interventions, and successes in controlling precipitating factors (such as measles), it is likely to be ~250,000 cases globally per year. The geographic distribution of VA deficiency, based on joint distributions of preschool xerophthalmia and hyporetinolemia, is presented in **Figure 4**. However,

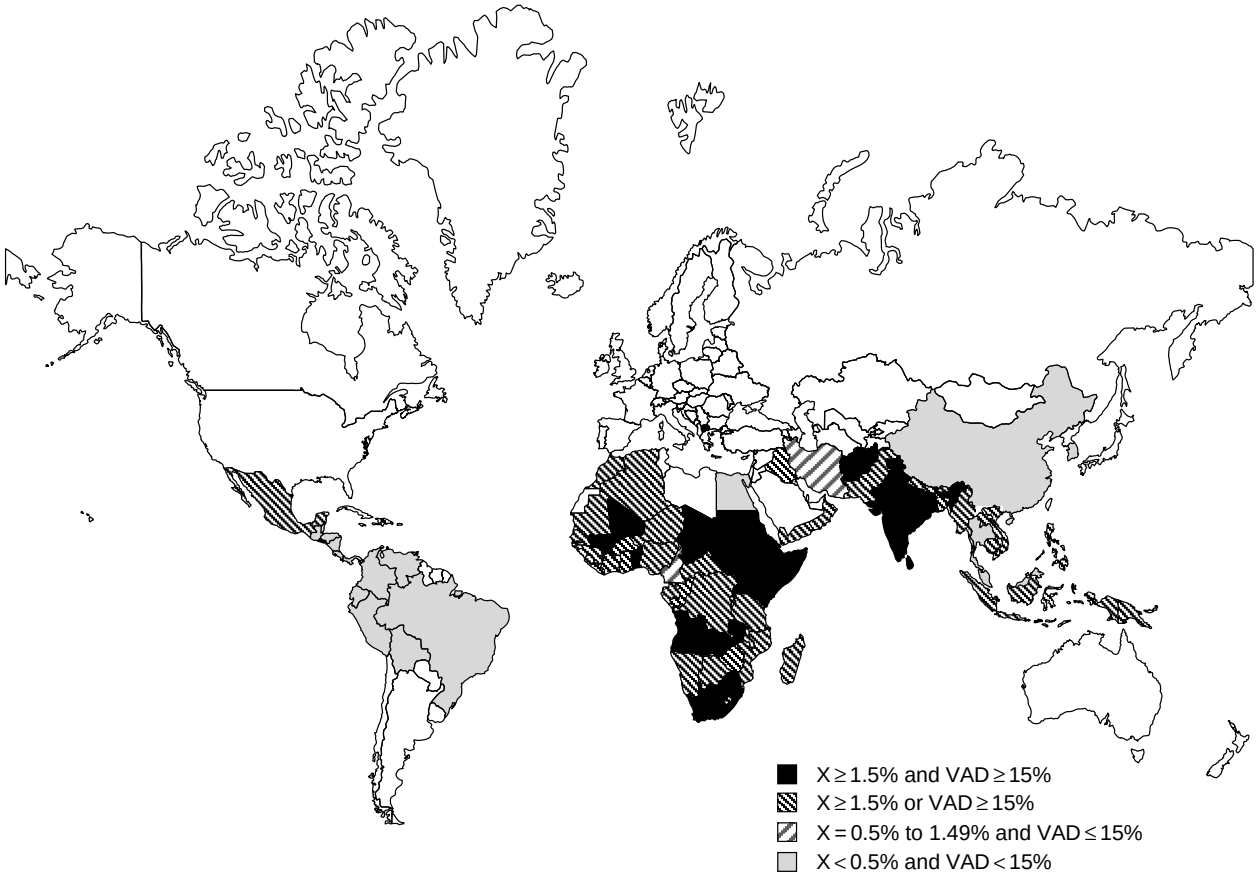

Figure 4 Global geographic distribution of xerophthalmia (X, all clinical stages) and vitamin A deficiency (VAD, serum retinol concentrations $<0.70\,\mu$mol/l) in preschool-aged children. From West KP Jr (2002) Extent of vitamin A deficiency among children and women of reproductive age. *Journal of Nutrition*.

increasing evidence shows that VA deficiency extends beyond the preschool years. For example, in Southeast Asia, >80 million children 5–15 years of age are thought to be hyporetinolemic, 9 million of whom have mild xerophthalmia. The burden of preadolescent school-aged VA deficiency in Africa and Latin America remains unestimated due to lack of population data. Adult VA deficiency is most notable in women living in undernourished conditions during and after pregnancy. Globally, approximately 20 million pregnant women have low vitamin A status (serum retinol concentration <1.05 μmol/l), of whom 7 million are thought to be deficient (serum retinol <0.70 μmol/l) and 6 million night blind, typically in the latter half of pregnancy. Regions of the world at greatest risk of VA deficiency are Southeast Asia and sub-Saharan Africa, where ~45 and 30% of all affected children and pregnant women reside, respectively.

High-Risk Groups

Preschool children and women during and following pregnancy are at highest risk for developing vitamin A deficiency and suffering its consequences. Infants in most poor populations are born with low VA status, which may predispose them to risk of blinding keratomalacia at <6 months of age. Without adequate VA from breast milk and complementary foods, VA stores can remain low to deficient throughout the first year of life and beyond. Risk of potentially blinding corneal xerophthalmia (**Figure 2**) peaks in the second through fourth years of life, typically following epidemics of acute infection such as severe measles, which can exacerbate a chronically wasted and vitamin A-deficient state. Milder stages of xerophthalmia, night blindness and Bitot's spots typically affect 1–5% of young children, with prevalence increasing from ~1 year of age through, in some cultures, the school-aged years. Boys tend to have higher rates of mild xerophthalmia than girls, possibly reflecting differences in dietary practices. In traditional societies, the increase follows weaning of children from VA-containing breast milk to a household diet chronically lacking preformed vitamin A or its carotenoid precursors.

VA deficiency persists through adolescence and into adulthood, as indicated by frequent reports of low serum retinol level (<0.70 μmol/l) in ~25% and night blindness in 5–20% of pregnant or lactating women in endemically deficient areas. Deficiency presumably results from heightened nutritional demand from late gestation through lactation superimposed on a chronic, poor dietary intake and preexisting low VA status of women. Although rarely blinding, maternal night blindness can identify high-risk women in populations in which it is associated with hyporetinolemia, anemia, wasting malnutrition, increased infant mortality, and markedly increased risks of maternal morbidity and mortality (**Figure 5**). In recent years, widespread maternal VA deficiency has been observed to coexist with HIV infection and AIDS throughout sub-Saharan Africa. However, modest, absent, or inconsistent effects of maternal VA supplementation on infant and maternal health, survival, or rates of transmission in trials suggest that VA deficiency may be more a consequence than a determinant of HIV-induced disease severity.

Geographic Clustering

Patterns of childhood hyporetinolemia or abnormal impression cytology plus xerophthalmia define the geographic risk of VA deficiency as a periequatorial nutritional problem throughout the world (**Figure 4**). Within regions, VA deficiency tends to cluster in parallel with indices of underdevelopment, low availability of food sources of vitamin A, and

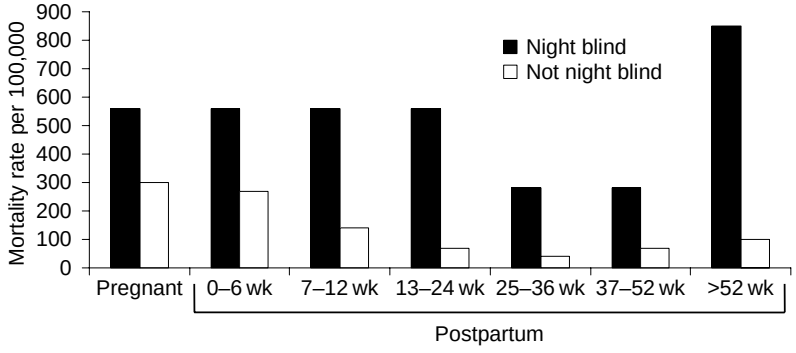

Figure 5 Mortality rates of rural Nepalese women (per 100,000 pregnancies) during and for up to 2 years following pregnancy according to whether mothers experienced night blindness ($n = 361$) or not ($n = 3052$) during pregnancy. Household head farms	57.3	55.5	53.4
Mother has <6 years of education	94.3	86.6	80.3[a]
History of child death	12.1	9.7	7.5[a]

[a]Significant linear trend in proportions ($p < 0.001$).
Adapted from Mele L *et al.* (1991) Nutritional and household risk factors for xerophthalmia in Aceh, Indonesia: A case-control study. *American Journal of Clinical Nutrition* **53**: 1460–1465.

disease patterns. In a large study in Aceh, Indonesia, villages in which cases of xerophthalmia were detected tended to be poorer than xerophthalmia-free communities and, within a village, cases arose more frequently from households of low socioeconomic standing than did children with normal eyes (controls) (**Table 2**). Also, in multiple surveys in Africa and Asia, preschool children incur an approximately twofold higher risk of having or developing xerophthalmia in villages in which at least one other child has been diagnosed compared to villages in which xerophthalmia has not been previously seen (**Table 3**). More striking is a 7- to 13-fold higher risk of xerophthalmia in siblings of cases compared to children in homes with no previous history of xerophthalmia. Maternal night blindness and childhood xerophthalmia tend to coexist at both household and community levels, reflecting the chronicity of dietary inadequacy in undernourished communities. Spatial clustering of deficiency risk seems to arise mostly from shared dietary practices in homes and villages rather than other exposures that lead to common infections. The exception to this observation is likely to be in households and communities afflicted by HIV/AIDS.

Periodicity

The occurrence of xerophthalmia can follow predictable, although not parallel, seasonal patterns in different areas of the world. Typically, a seasonal peak in VA deficiency emerges from a convergence of causal risk factors. In Southeast Asia, for example, a distinct peak in the incidence of mild xerophthalmia occurs during the late dry and early monsoon seasons (April–July). This peak follows a postharvest growth spurt in the cool dry season. It also coincides with a general scarcity of pro-vitamin A-rich vegetables and fruits and a seasonal increase in the incidence of diarrhea, respiratory infection, and measles. In this area of the world, the seasonal peak is often curbed abruptly midway through the 'mango season,' reflecting a likely impact of widespread consumption of this β-carotene-rich fruit. Periodicity, where it exists, can help identify causes and target prevention to specific times of the year.

Causes

Breast-feeding and diet Dietary risk in children refers to inadequate breast-feeding combined with low intakes of VA-rich foods from the household diet. A low dietary fat intake (e.g., $\leq$5% of calories) may restrict absorption of pro-vitamin A carotenoids from vegetables and fruits and thus also predispose children to deficiency.

Breast milk is the most important initial dietary source of vitamin A for an infant. Commonly, breast milk from marginally nourished mothers in developing countries contains ~500 μg of retinol activity equivalents (RAE) per liter, delivering 325 μg RAE per day to infants consuming a typical intake of ~650 ml per day. In the absence of a recommended dietary allowance for vitamin A, an 'adequate

intake' of 400–500 μg RAE has been set as a guide for infants in their first year, making infant VA intakes from breast milk marginal and, beyond infancy, marginally above an estimated deficient threshold thereafter (i.e., 210 μg RAE). Decrements in intake or concentration below this minimum increasingly place breast-fed children at risk, with greatest risk for those fully weaned and lacking a nutritious home diet. Studies in Asia and Africa show that breast-fed infants and toddlers are 65–90% less likely to have or develop xerophthalmia than non-breast-fed peers of the same age. Xerophthalmic children have been shown to begin weaning earlier (by ~1 month) and to be weaned ~6 months earlier than nonxerophthalmic children. Even when breast-fed, the more frequent the daily feeds, the greater the reduction in risk of xerophthalmia, reflecting the potential benefit achieved by promoting breast-feeding. However, the nutritional margin is still evident in the protective effects of vitamin A in reducing mortality in late infancy and early childhood, even where breast-feeding is ubiquitous for the first 2 or 3 years of life.

Complementary feeding affects childhood risk of VA deficiency. Indonesian preschoolers were at a two- to sixfold higher risk of xerophthalmia if food sources of vitamin A, such as dark green leaves, mango or papaya, egg, meat or fish with liver, and milk and other dairy products, were not routinely given during the first year of complementary feeding, instilling a pattern that may place children at risk throughout their first several years of life. Across undernourished regions of the world, studies reveal less frequent dietary intakes of foods rich in preformed vitamin A and carotenoid precursors by preschool-aged children with a history of xerophthalmia than children who remain free from the eye disease (**Figure 6**). Similar dietary differences are evident among women with versus those without a history of maternal night blindness.

Figure 6 Foods that protect against hypovitaminosis A (xerophthalmia), based on numerous studies. Dark line, strong evidence; dashed line, suggestive evidence. From Sommer A and West KP Jr (1996) Vitamin A Deficiency: Health, Survival and Vision. New York: Oxford University Press.

Infection As noted previously, a vicious cycle exists between VA deficiency and infection; thus, infection can be viewed as a cause of deficiency. Prospective studies show that severe infections, such as measles, chicken pox, diarrhea, and acute respiratory illness, decrease serum as well as apparent hepatic levels of retinol and increase the risk of xerophthalmia. In some settings, measles has been observed to increase the risk of children developing corneal xerophthalmia by >13-fold. In Indonesia, young children with diarrhea and acute respiratory infections were also twice as likely to develop mild xerophthalmia (XN or X1B) than apparently disease-free children. Similar patterns have been observed in undernourished populations of women, whereby maternal infection early in gestation raises the risk of becoming night blind later in pregnancy. Explanations for a role of infection as a cause of VA deficiency include decreased absorption of vitamin A, increased metabolic requirements, impaired retinol transport, greatly increased renal excretion during the acute phase response, and slow normalization of these mechanisms coupled with a chronically decreased dietary VA intake during extended recovery or repeated illness.

Impact of Interventions

VA deficiency can be prevented through direct supplementation, fortification of commonly eaten food items, or other food-based interventions that include home gardening, nutrition education, and agronomic approaches. Most evaluations have assessed the impact of direct supplementation and, occasionally, fortification on vitamin A status, xerophthalmia, survival, and other health outcomes. Data on the efficacy of dietary regimens are limited to change in vitamin A status.

Vitamin A Status

The impact of vitamin A prophylaxis on status varies by indicator, dosage and mode of delivery of the supplement, level of initial deficiency, and other risk factors. A single, high-potency supplement (210 μmol, 60 mg retinol activity equivalents or 200,000 IU) has been shown to elevate serum retinol in deficiency-prone populations for periods of 1–6 months, with most data suggesting protection from hyporetinolemia for only a few months. Continuous intake of 50–100% of the recommended allowance of vitamin A through fortified foods gradually improves and sustains adequate serum and breast milk retinol concentrations or, when assessed by indirect means, hepatic retinol

adequacy. Regular consumption of pro-vitamin A food sources (dark green leaves and yellow vegetables and fruits) has variable, although generally positive, effects on vitamin A status. Dietary carotenoid intake appears most efficacious in raising serum retinol from deficient concentrations to minimally adequate levels in children and women but often fails to optimize vitamin A status. Variations in food matrix, methods of storage and preparation, amounts of preformed vitamin A and fat in the diet, gut integrity and function, protein energy and VA status of the host, and other factors may affect dietary efficacy. Among these, food matrix factors may be most important in determining bioavailability of pro-vitamin A carotenoid for uptake, conversion, and absorption. The belief has long been held that β-carotene, the most ubiquitous pro-vitamin A carotenoid in the diet, can be converted from dietary sources to vitamin A in the body at a ratio of 6:1, but it is now recognized that conversion is far less efficient, conservatively set at 12:1 and 24:1 for other pro-vitamin A carotenoids (e.g., α-carotene and β-cryptoxanthin) for a mixed vegetarian diet. The change effectively reduces by half previous estimates of vitamin A activity in the developing world's nonanimal food supply and begins to address persistent questions of how VA deficiency can coexist amid at least a seasonal abundance of vegetables and fruits.

Xerophthalmia

Practically any intervention that delivers adequate amounts of VA will control VA deficiency. High-potency vitamin A delivered to preschool children every 4–6 months is ~90% efficacious in preventing both corneal and noncorneal xerophthalmia. Prophylactic failure (~10%) may reflect inadequacy of dosage for some children who are severely VA deficient or become ill. Xerophthalmia, on the other hand, virtually disappears in child populations consuming adequate amounts of vitamin A-fortified foods. There is less experience with regard to preventing night blindness in women, other than in large trials that suggest supplementation at recommended dietary levels may be insufficient to prevent all xerophthalmia, depending on background severity. Supervised dietary treatment has been reported to cure or improve noncorneal xerophthalmia; however, population trials to assess the impact of dietary change in preventing xerophthalmia have yet to be carried out.

Mortality

There has been extensive investigation into the effects of VA on mortality during the past two decades in preschool-aged children and, more recently, in young infants and women of reproductive age. The impact of vitamin A supplementation on preschool child mortality has been firmly established through eight controlled community trials performed in the 1980s and early 1990s involving ~160,000 children on three subcontinents (**Table 4**). In six trials, children 6 months to 6 years of age were supplemented every 4–6 months with an oral dose of vitamin A containing 60 mg retinol equivalents (RE) (or 200,000 IU). Half this dosage was provided to children <12 months of age. One study, in India, provided a small weekly dose to children and the other, in Indonesia, supplied half of a recommended allowance of vitamin A to children in treatment villages through a routinely marketed fortified mono-sodium glutamate product (a meal flavor enhancer). Rates of mortality in supplemented groups were compared to rates among children in concurrent control groups. Six of the eight trials showed reductions of 19–54% in preschool child mortality beyond either 6 or 12 months of age. Meta-analyses of data from these trials have estimated the reduction in mortality to range from 23 to 34%, with the latter value likely applicable to Southeast Asia. The estimates are remarkably consistent given differences in study designs and analytic approaches. Cumulative mortality curves from trials with positive results show a characteristic departure in mortality experience from control groups soon after initiation of vitamin A supplementation (**Figure 7**). Notably, the largest mortality impacts occurred in the two trials that mimicked a normal dietary intake of vitamin A compared to its periodic delivery as a bolus. Investigations of illnesses and events prior to death suggest that vitamin A reduced mortality associated with measles, diarrhea, and acute wasting malnutrition. A lack of apparent impact on mortality attributable to acute respiratory infection has been a perplexing, although consistent, finding across these and other trials. In contrast, administration of vitamin A, in the community prior to measles epidemics or on hospital admission as treatment for severe measles infection, has been shown to lower case fatality by ~50%.

High-potency VA (50,000–100,000 IU) may also substantially reduce early infant mortality, but this appears to depend almost entirely on the timing or age of supplement receipt. That is, in several trials involving infants of various ages through 6 months, during 4- to 6-monthly community dosing, or at the times of DPT vaccinations (typically at 6, 10, and 14 weeks of age), little or no effect in reducing mortality has been shown. However, two trials to date, in Indonesia and India, have reported 64 and 22% reductions, respectively, in mortality for infants <6 months of age when they were dosed at or soon

Table 4 Vitamin A mortality prevention trials

Location/target group	*Vitamin A dosage*[a]	*N*	*% change*[b]
Infants <1 month

after birth with 45,000–50,000 IU of VA (**Table 4**). In the trial reported from India, the effect was restricted to low-birth-weight infants (<2500 g), suggesting an impact on growth-restricted or preterm newborns. Explanations include plausible maturational effects on an immature immune system, gut, and airway that may enhance resistance to infection months later. Additional confirmatory trials are under way in Southeast Asia and sub-Saharan Africa.

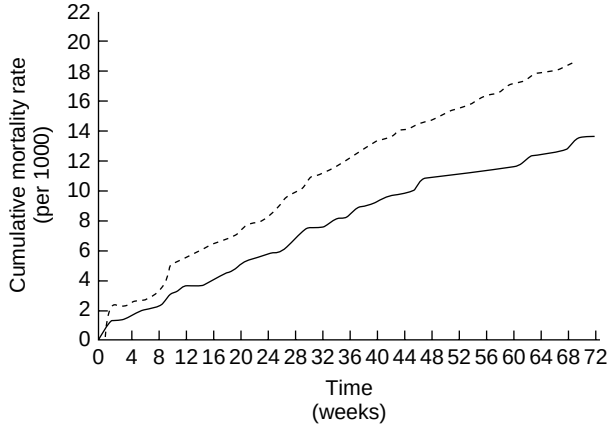

Figure 7 Cumulative mortality of children randomized to 4-monthly placebo control (dashed line) versus 200,000 IU of vitamin A (solid line) during a large community trial in Sarlahi District, rural Nepal. From Sommer A and West KP Jr (1996) Vitamin A Deficiency: Health, Survival and Vision. New York: Oxford University Press.

Finally, improving intake of VA, either preformed or as pro-vitamin A β-carotene in amounts approximating a recommended dietary intake, may reduce the risk of pregnancy-related death where maternal mortality is high and deficiency evident by widespread night blindness during pregnancy. In rural Nepal, supplementing women with VA lowered mortality related to pregnancy from 704 to 385 deaths per 100,000 pregnancies (44%), likely due to less severe infection, eclampsia, anemia, and possibly other obstetric causes. Malnourished women (e.g., those with night blindness) may likely benefit most from supplemental VA intake. Additional trials addressing this question are under way in Bangladesh and Ghana.

Morbidity

Direct effects of VA on morbidity have been difficult to establish, possibly due to variation in disease sensitivity to VA and inherent problems in measuring the incidence, duration, and severity of morbidity in community studies. Vitamin A interventions exert modest, if any, impact on the prevalence of common childhood morbidities typically obtained by history. In contrast,

VA appears to reduce the severity of potentially fatal infections, such as measles, persistent diarrhea, dysentery, and falciparum malaria, especially in the presence of wasting malnutrition. The protective effect becomes stronger with episode severity. Thus, febrile illnesses appear to be more responsive to vitamin A than nonfebrile events. Illnesses for which care is sought show a response to VA. In a large trial in Ghana, VA supplementation decreased childhood clinic visits for illness (RR = 0.88), hospitalization rates for severe disease (RR = 0.62), and severity of illness among children admitted for diarrhea compared to placebo recipients. In Brazil, prior VA receipt had no effect on children's diarrheal episodes of 1 or 2 days' duration (RR = 0.97) but was increasingly protective against episodes lasting $\geq$3 days with four or more stools per day (RR = 0.91) and episodes of $\geq$3 days with five or more stools per day (RR = 0.80). Vitamin A treatment of measles has led to fewer and less severe complications and enhanced immunologic and clinical recovery. However, multiple treatment trials report little effect of vitamin A on recovery from childhood pneumonia. This remains a paradox given decades of experimental animal evidence linking VA deficiency to extensive metaplasia and keratinization and, presumably, greater susceptibility to pathogen invasion and infection of the respiratory tract.

Management

Treatment

Children with xerophthalmia and measles should be treated immediately with oral, high-potency vitamin A (200,000 IU) according to WHO and IVACG guidelines (**Table 5**) and provided other supportive nutritional and medical therapy as indicated. Corneal lesions should be topically treated with a suitable antibiotic (e.g., tetracycline or chloramphenicol) to prevent bacterial infection. Corneal xerophthalmia typically improves with VA treatment within 1 week, with complete resolution within 4 weeks, depending on the size, thickness, and location of the lesion and nutritional and health status of the patient. Night blindness is typically cured within 24 h of VA treatment. Most Bitot's spots begin to respond within 2–5 days and disappear within 2 weeks, although some may persist, particularly in older children. High-potency vitamin A is indicated for women of reproductive age with corneal disease. For milder lesions, smaller daily (10,000 IU) or weekly (25,000 IU) doses are recommended for at least 3 months. Children presenting with severe wasting malnutrition should be given a single large oral dose (200,000 IU). It is also judicious to give cases of severe diarrhea, dysentery, respiratory infection, and exanthematous infections the same single, large oral dose of vitamin A.

Prevention

Hypovitaminosis A is prevented by increasing intakes of preformed vitamin A or pro-vitamin A carotenoids to levels that maintain adequate status. This can be done through direct supplementation of targeted risk groups, food fortification, or a number of dietary approaches that protect breast-feeding and improve the quality of the home diet.

Administration of high-potency, oral vitamin A (200,000 IU), adjusted for age (**Table 5**), on a 4- to 6-monthly basis is a common preventive approach in many developing countries. Half a dose is dispensed to infants 6–11 months and a quarter dose is given to younger infants to minimize risk of toxicity in high-risk areas. The intervention is based on the principle that a large dose of vitamin A is stored primarily in the liver, from where it is mobilized as needed. Beyond treatment, supplements can be provided during routine health care (e.g., for growth monitoring, immunization, other extension services) or more extensively and systematically in targeted populations on a regular basis (e.g., semiannual or every

Table 5 Vitamin A treatment and prevention schedules

Age	*Treatment at diagnosis*[a]	*Prevention*	
		Dosage (IU)	*Frequency*
<6 months	50,000 IU	50,000	With each of 3 doses of DPT/polio vaccine
6–11 months	100,000 IU	100,000	Every 4–6 months
12–59 months	200,000 IU	200,000	Every 4–6 months
Women	By severity of eye signs[b]	200,000	2 doses 24 h apart $\leq$6 weeks after delivery

[a]Treat all cases of xerophthalmia and measles on days 1 and 2; give an additional dose for xerophthalmia on day 14. For severe malnutrition give one dose on day 1.
[b]For women of reproductive age, give 200,000 IU only for corneal xerophthalmia on days 1, 2 and 14; for night blindness or Bitot's spots, give 10,000 IU per day or 25,000 IU per week for $\geq$3 months.
Based on Ross D (2002) Recommendations for vitamin A Supplementation. *Journal of Nutrition* **131**: 2902S–2906S.

4 months). Scaling up semiannual delivery of high-potency VA through national campaigns, such as National Immunization Days, and other mechanisms that have routinely achieved 80% or greater coverage has probably been decisive in reducing preventable, VA deficiency-induced child deaths annually from an estimated 1.7 million in 1991 to approximately 0.7 million in 2002. With accelerated immunization nearing completion, momentum established for periodic VA delivery has, in many countries, been transferred to campaigns such as National Child Health Days that, in early reports, are achieving comparable rates of coverage. Nearly four decades of distributing billions of high-potency VA supplements for population prophylaxis attests to the acceptance, effectiveness, and safety of this approach. However, it is essential to adequately inform the health and lay communities of potential benefits and risks, the latter including a 2–4% rate of (mild and self-limiting) bulging fontanel in young infants and ~5% rate of nausea, vomiting, irritability, or diarrhea following high-potency VA receipt.

Providing mothers two sequential doses of 200,000 IU each as soon after birth as possible, but always within 6 weeks to avoid excessive risk of periconceptional exposure, is a safe and effective way to improve vitamin A status of mothers and their breast-fed infants. Otherwise, supplements of up to 10,000 IU per day or 25,000 IU per week offer safe prophylactic regimens to women against VA deficiency during reproductive years.

Increasingly, developing countries are fortifying staple food items with a quarter to a full day's recommended allowance of VA to prevent deficiency in high-risk populations. Potential food vehicles should be technically fortifiable at required concentrations and consumed within a range that may be both effective in target groups and safe in the entire population. Fortification has been effectively carried out on a scaled-up basis with a limited number of products in a limited number of countries, including nonfat milk powder and vegetable oils in food assistance programs and sugar in Central America. Other food carriers have been successfully demonstrated, including monosodium glutamate (flavor enhancer) in Indonesia and the Philippines, nonrefrigerated margarine and wheat flour in the Philippines, and a powdered beverage in Tanzania. Additional foods are being fortified with VA each year. This trend will likely continue with increased use of processed foods and as the food industry becomes engaged in solving VA and other micronutrient deficiency problems.

Dietary diversification is widely held to be the most culturally appropriate and potentially sustainable approach to preventing VA deficiency. Although pilot trials show efficacy of a variety of dietary approaches for improving VA intake and status, data on the effectiveness and cost of population food-based interventions are generally lacking. Dietary intakes can be improved through home and school gardening initiatives, nutrition education, and social marketing of locally available food sources of vitamin A. However, effective dietary change requires a thorough understanding of local cultural, food system, and behavioral factors that increase the risk of VA deficiency.

VITAMIN B_6

D A Bender, University College London, London, UK

Vitamin B_6 has a central role in amino acid metabolism as the coenzyme for a variety of reactions, including transamination and decarboxylation. It is also the coenzyme of glycogen phosphorylase and acts to modulate the activity of steroid and other hormones (including retinoids and vitamin D) that act by regulation of gene expression.

Severe deficiency disease has only been reported in a single outbreak in infants fed overheated formula. However, a significant proportion of people in developed countries have marginal vitamin B_6 status, and this may be associated with enhanced responsiveness to steroid hormone action and may be a factor in the development of hormone-dependent cancer of the breast, uterus, and prostate. A number of drugs have antivitamin activity, and prolonged use may lead to secondary development of pellagra, as a result of impaired tryptophan metabolism.

Estrogens do not cause vitamin B_6 deficiency. However, there is evidence that high doses of vitamin B_6 may overcome some of the side effects of estrogenic steroids used in contraceptives and as menopausal hormone replacement therapy. At very high levels of intake, supplements may cause sensory nerve damage.

Absorption and Metabolism

The main form of vitamin B_6 in foods is pyridoxal phosphate, bound as a Schiff base to lysine in dietary proteins. There is also a small amount of pyridoxamine phosphate. In plant foods a significant amount of the vitamin is present as pyridoxine, and a number of plants contain pyridoxine glycosides, which have limited availability. Heating foods can lead to the formation of (phospho)pyridoxyllysine, which has antivitamin activity.

Pyridoxal phosphate bound to proteins is released on digestion of the protein. The phosphorylated vitamers are dephosphorylated by membrane-bound alkaline phosphatase in the intestinal mucosa; all three vitamers are absorbed by carrier-mediated diffusion, followed by oxidation and phosphorylation, so there is accumulation of pyridoxal phosphate, which does not cross cell membranes, by metabolic trapping.

Both pyridoxal and the phosphate circulate in the bloodstream; the phosphate is dephosphorylated by extracellular alkaline phosphatase, and tissues take up pyridoxal by carrier-mediated diffusion, followed by metabolic trapping as phosphate esters. Pyridoxine and pyridoxamine phosphates are oxidized to pyridoxal phosphate (**Figure 1**).

Tissue concentrations of pyridoxal phosphate are controlled by the balance between phosphorylation and dephosphorylation. The activity of the phosphatases is greater than that of the kinase in most tissues so that pyridoxal phosphate that is not bound to enzymes will be dephosphorylated. Free pyridoxal either leaves the cell or is oxidized to 4-pyridoxic acid by aldehyde dehydrogenase, which is present in all tissues, and also by hepatic and renal aldehyde oxidase. 4-Pyridoxic acid is the main excretory product.

Approximately 80% of total body vitamin B_6 is in muscle, associated with glycogen phosphorylase. This does not seem to function as a true reserve of the vitamin and is not released from muscle in times of deficiency.

Metabolic Functions of Vitamin B_6

The metabolically active vitamer is pyridoxal phosphate, which is involved in many reactions of amino acid metabolism, where the carbonyl group is the reactive moiety, in glycogen phosphorylase, where it is the phosphate group that is important in catalysis, and in the release of hormone receptors from tight

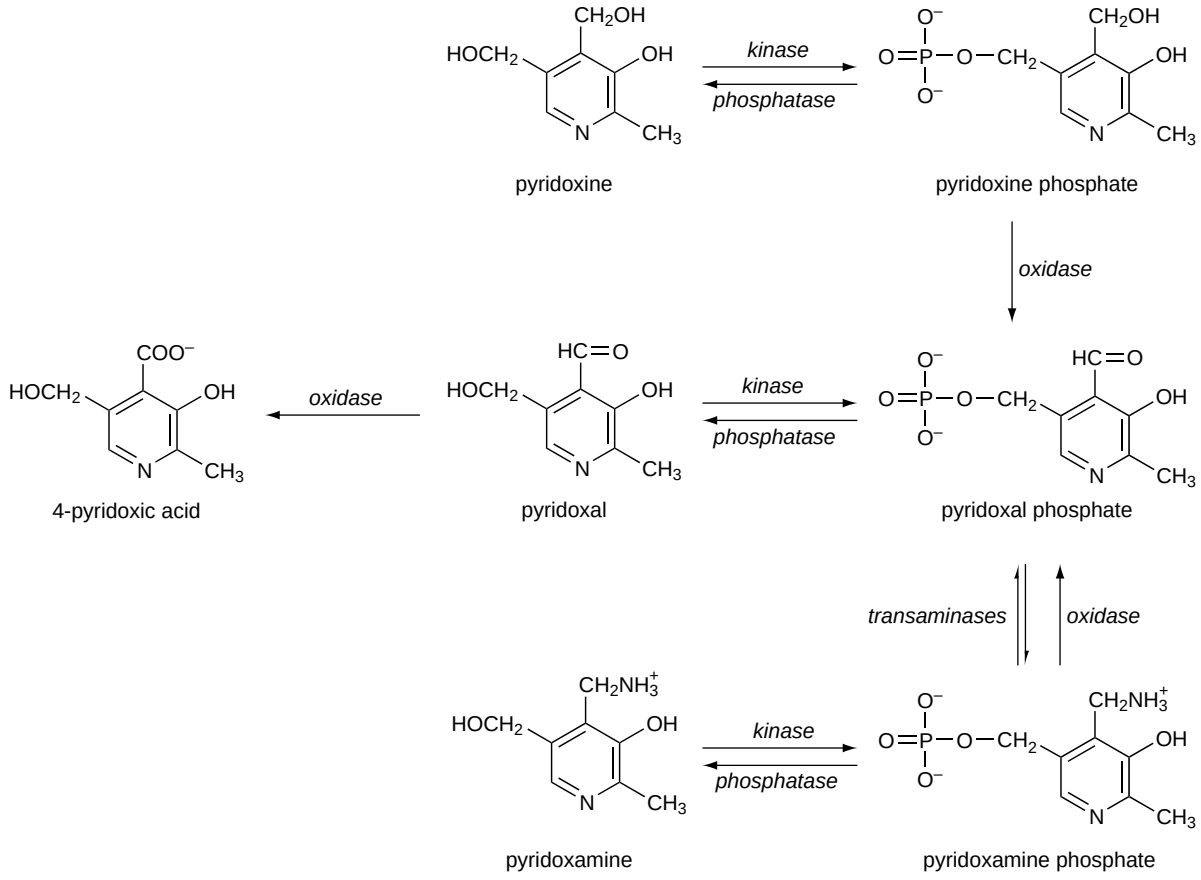

Figure 1 Metabolism of vitamin B_6.

nuclear binding, where again it is the carbonyl group that is important.

The Role of Pyridoxal Phosphate in Amino Acid Metabolism

The various reactions of pyridoxal phosphate in amino acid metabolism (**Figure 2**) all depend on the same chemical principle—the ability to stabilize amino acid carbanions, and hence to weaken bonds about the α-carbon of the substrate. This is achieved by reaction of the α-amino group with the carbonyl group of the coenzyme to form a Schiff base (aldimine).

Pyridoxal phosphate is bound to enzymes, in the absence of the substrate, by the formation of an internal Schiff base to the ϵ-amino group of a lysine residue at the active site. Thus the first reaction between the substrate and the coenzyme is transfer of the aldimine linkage from this ϵ-amino group to the α-amino group of the substrate.

The ring nitrogen of pyridoxal phosphate exerts a strong electron-withdrawing effect on the aldimine, and this leads to weakening of all three bonds about the α-carbon of the substrate. In nonenzymic model systems, all the possible pyridoxal-catalyzed reactions are observed: α-decarboxylation, aminotransfer, racemization, and side chain elimination and replacement reactions. By contrast, enzymes show specificity for the reaction pathway followed; which bond is cleaved will depend on the orientation of the Schiff base relative to reactive groups of the catalytic site.

α-Decarboxylation If the electron-withdrawing effect of the ring nitrogen is primarily centered on the α-carbon–carboxyl bond, the result is decarboxylation of the amino acid with the release of carbon dioxide. The resultant carbanion is then protonated, and the primary amine corresponding to the amino acid is displaced by the lysine residue at the active site, with reformation of the internal Schiff base.

A number of the products of the decarboxylation of amino acids are important as neurotransmitters and hormones—5-hydroxytryptamine, the catecholamines dopamine, noradrenaline, and adrenaline, and histamine and γ-aminobutyrate (GABA)—and as the diamines and polyamines involved in the regulation of DNA metabolism. The decarboxylation of phosphatidylserine to phosphatidylethanolamine is important in phospholipid metabolism.

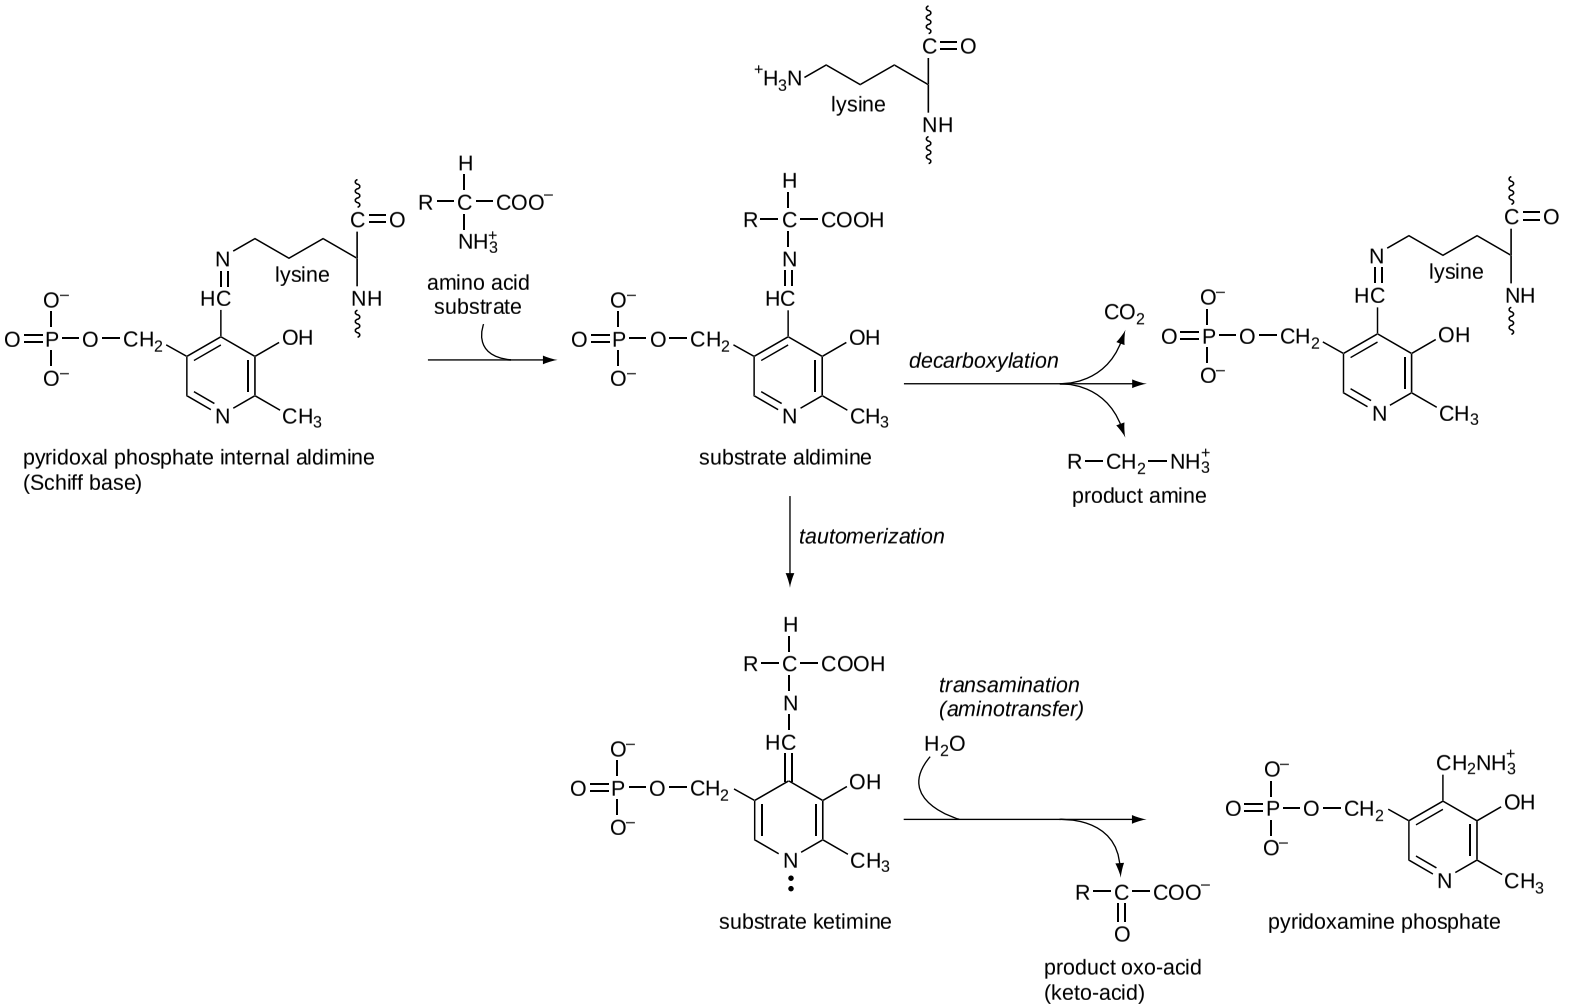

Figure 2 Roles of vitamin B_6 in amino acid metabolism.

Racemization of amino acids Deprotonation of the α-carbon of the amino acid leads to tautomerization of the Schiff base to yield a quinonoid ketimine. The simplest reaction that the ketimine can undergo is reprotonation at the now symmetrical α-carbon. Displacement of the substrate by the reactive lysine residue results in the racemic mixture of D- and L-amino acid.

Amino acid racemases have long been known to be important in bacterial metabolism since several D-amino acids are required for the synthesis of cell wall mucopolysaccharides. D-Serine is found in relatively large amounts in mammalian brain, where it acts as an agonist of the *N*-methyl-D-aspartate (NMDA) type of glutamate receptor. Serine racemase has been purified from rat brain and cloned from human brain.

Transamination Hydrolysis of the α-carbon–amino bond of the ketimine formed by deprotonation of the α-carbon of the amino acid results in the release of the 2-oxo-acid corresponding to the amino acid substrate and leaves pyridoxamine phosphate at the catalytic site of the enzyme. This is the half-reaction of transamination. The process is completed by reaction of pyridoxamine phosphate with a second oxo-acid substrate, forming an intermediate ketimine, followed by the reverse of the reaction sequence shown in **Figure 3**, releasing the amino acid corresponding to this second substrate after displacement from the aldimine by the reactive lysine residue to reform the internal Schiff base.

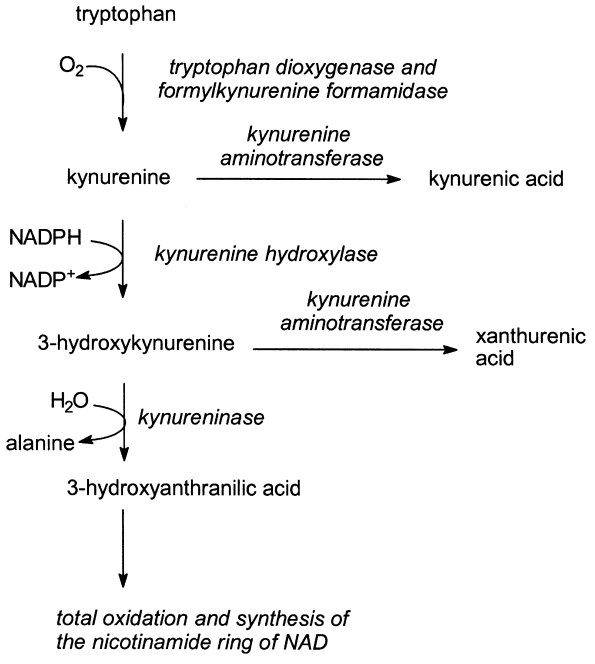

Figure 3 Tryptophan metabolism, the basis of the tryptophan load test for vitamin B_6 status.

Transamination is of central importance in amino acid metabolism, providing pathways for catabolism of most amino acids as well as the synthesis of those amino acids for which there is a source of the oxo-acid other than from the amino acid itself—the nonessential amino acids.

The Role of Pyridoxal Phosphate in Steroid Hormone Action

Pyridoxal phosphate has a role in controlling the action of hormones that act by binding to a nuclear receptor protein and modulating gene expression. Such hormones include androgens, estrogens, progesterone, glucocorticoids, calcitriol (the active metabolite of vitamin D), retinoic acid and other retinoids, and thyroid hormone. Pyridoxal phosphate reacts with a lysine residue in the receptor protein and displaces the hormone–receptor complex from DNA binding, so terminating the hormone action.

In experimental animals, vitamin B_6 deficiency results in increased and prolonged nuclear uptake and retention of steroid hormones in target tissues, and there is enhanced sensitivity to hormone action. In a variety of cells in culture that have been transfected with a glucocorticoid, estrogen or progesterone response element linked to a reporter gene, acute vitamin B_6 depletion (by incubation with 4-deoxypyridoxine) leads to a 2-fold increase in expression of the reporter gene in response to hormone action. Conversely, incubation of these cells with high concentrations of pyridoxal, leading to a high intracellular concentration of pyridoxal phosphate, results in a halving of the expression of the reporter gene in response to hormone stimulation.

Assessment of Vitamin B_6 Nutritional Status

The fasting plasma concentration of either total vitamin B_6 or, more specifically, pyridoxal phosphate is widely used as an index of vitamin B_6 nutritional status, as is the urinary excretion of 4-pyridoxic acid. The generally accepted criteria of adequacy are shown in **Table 1**.

Various pyridoxal phosphate dependent enzymes compete with each other for the available pool of coenzyme. Thus the extent to which an enzyme is saturated with its coenzyme provides a means of assessing the adequacy of the body pool of coenzyme. This can be determined by measuring the activity of the enzyme before and after the

Table 1 Indices of vitamin B_6 nutritional status

Index	*Adequate status*
Plasma total vitamin B_6	>40 nmol (10 μg)/l
Plasma pyridoxal phosphate	>30 nmol (7.5 μg)/l
Erythrocyte alanine aminotransferase activation coefficient	<1.25
Erythrocyte aspartate aminotransferase activation coefficient	<1.80
Erythrocyte aspartate aminotransferase	>0.13 units (8.4 μkat)/l
Urine 4-pyridoxic acid	>3.0 μmol/24 h >1.3 mmol/mol creatinine
Urine total vitamin B_6	>0.5 μmol/24 h >0.2 mmol/mol creatinine
Urine xanthurenic acid after 2 g tryptophan load	<65 μmol/24 h increase
Urine cystathionine after 3 g methionine load	<350 μmol/24 h increase

Data from Bitsch R (1993) Vitamin B_6. *International Journal of Vitamin and Nutrition Research* **63**: 278–282; Leklem JE (1990) Vitamin B-6: A status report. *Journal of Nutrition* **120**(supplement 11): 1503–1507; McChrisley B, Thye FW, McNair HM and Driskell JA (1988) Plasma B_6 vitamer and 4-pyridoxic acid concentrations of men fed controlled diets. *Journal of Chromatography* **428**: 35–42.

activation of any apoenzyme present in the sample by incubation with pyridoxal phosphate added *in vitro*. Erythrocyte aspartate and alanine transaminases are both commonly used; the results are usually expressed as an activation coefficient—the ratio of activity with added coenzyme to that without.

It seems to be normal for a proportion of pyridoxal phosphate-dependent enzymes to be present as inactive apoenzyme, without coenzyme. This may be a mechanism for metabolic regulation. It is possible that increasing the intake of vitamin B_6, so as to ensure complete saturation of pyridoxal phosphate-dependent enzymes, may not be desirable.

Tryptophan Load Test

The oxidative pathway of tryptophan metabolism is shown in **Figure 3**. Kynureninase is a pyridoxal phosphate-dependent enzyme, and in deficiency its activity is lower than that of tryptophan dioxygenase, so that there is an accumulation of hydroxykynurenine and kynurenine, resulting in greater metabolic flux through kynurenine transaminase and increased formation of kynurenic and xanthurenic acids. Kynureninase is exquisitely sensitive to vitamin B_6 deficiency because it undergoes a slow inactivation as a result of catalysing the half-reaction of transamination instead of its normal reaction. The resultant enzyme with pyridoxamine phosphate at the catalytic site is catalytically inactive and can only be reactivated if there is an adequate concentration of pyridoxal phosphate to displace the pyridoxamine phosphate.

The ability to metabolise a test dose of tryptophan has been widely adopted as a convenient and sensitive index of vitamin B_6 nutritional status. However, induction of tryptophan dioxygenase by glucocorticoid hormones will result in a greater rate of formation of kynurenine and hydroxykynurenine than the capacity of kynureninase, and will thus lead to increased formation of kynurenic and xanthurenic acids—an effect similar to that seen in vitamin B_6 deficiency. Such results may be erroneously interpreted as indicating vitamin B_6 deficiency in a variety of subjects whose problem is increased glucocorticoid secretion as a result of stress or illness, not vitamin B_6 deficiency.

Inhibition of kynureninase (e.g., by estrogen metabolites) also results in accumulation of kynurenine and hydroxykynurenine, and hence increased formation of kynurenic and xanthurenic acids, again giving results which falsely suggest vitamin B_6 deficiency. This has been widely, but incorrectly, interpreted as estrogen-induced vitamin B_6 deficiency: it is in fact simple competitive inhibition of the enzyme that is the basis of the tryptophan load test by estrogen metabolites.

While the tryptophan load test is a useful index of status in controlled depletion/repletion studies to determine vitamin B_6 requirements, it is not an appropriate index of status in population studies.

Methionine Loading Test

The metabolism of methionine, shown in **Figure 4**, includes two pyridoxal phosphate-dependent steps, catalysed by cystathionine synthetase and cystathionase. In vitamin B_6 deficiency there is an increase in the plasma concentration of homocysteine, and increased urinary excretion of cystathionine and homocysteine, both after a loading dose of methionine and under basal conditions. The ability to metabolize a test dose of methionine therefore provides an index of vitamin B_6 nutritional status.

Some 10–25% of the population have a genetic predisposition to hyperhomocysteinemia, which is a risk factor for atherosclerosis and coronary heart disease, as a result of polymorphisms in the gene for methylenetetrahydrofolate reductase. There is no evidence that supplements of vitamin B_6 reduce fasting plasma homocysteine in these subjects, and like the tryptophan load test, the methionine load test may be an appropriate index of status in

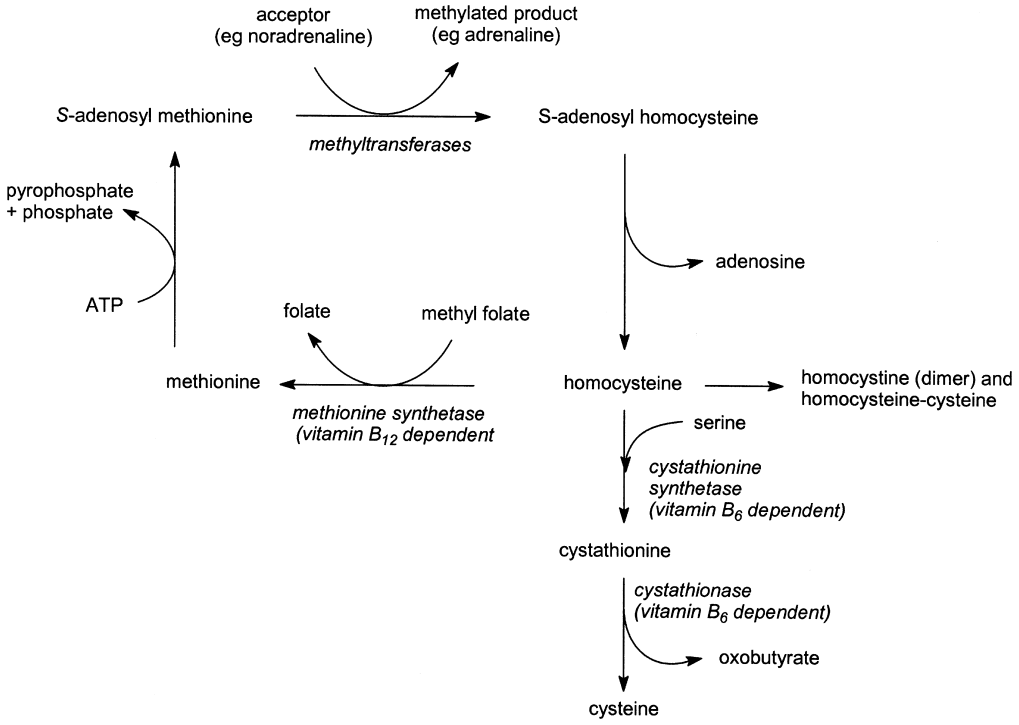

Figure 4 Methionine metabolism, the basis of the methionine load test for vitamin B_6 status.

controlled depletion/repletion studies to determine vitamin B_6 requirements, but not in population studies.

Requirements and Reference Intakes

The total body pool of vitamin B_6 is of the order of 15 μmol (3.7 mg) per kilogram body weight. Isotope tracer studies suggest there is turnover of about 0.13% per day, and hence a minimum requirement for replacement of 0.02 μmol (5 μg) per kilogram body weight—some 350 μg per day for a 70 kg adult. However, depletion/repletion studies suggest that requirements are higher than this.

Most studies of vitamin B_6 requirements have followed the development of abnormalities of tryptophan (and sometimes also methionine) metabolism during depletion and normalization during repletion with graded intakes of the vitamin.

Although some 80% of the total body pool of vitamin B_6 is associated with muscle glycogen phosphorylase, this pool turns over relatively slowly. The major metabolic role of the remaining 20% of total body vitamin B_6, which turns over considerably more rapidly, is in amino acid metabolism. Therefore, *a priori*, it seems likely that protein intake will affect vitamin B_6 requirements. People maintained on (experimental) vitamin B_6-deficient diets develop abnormalities of tryptophan and methionine metabolism faster, and their blood vitamin B_6 falls more rapidly, when their protein intake is high. Similarly, during repletion of deficient subjects, tryptophan and methionine metabolism and blood vitamin B_6 are normalized faster at low than at high levels of protein intake.

These studies suggest a mean requirement of 13 μg of vitamin B_6 per gram of dietary protein; reference intakes are based on 15–16 μg per gram of protein. At average intakes of about 100 g of protein per day, this gives an RDA of 1.4–1.6 mg of vitamin B_6. More recent depletion/repletion studies, using more sensitive indices of status, in which subjects were repleted with either a constant intake of vitamin B_6 and varying amounts of protein or a constant amount of protein and varying amounts of vitamin B_6, have shown average requirements of 15–16 μg/g of dietary protein, suggesting a reference intake of 18–20 μg/g protein.

In 1998 the reference intake in the United States and Canada was reduced from the previous RDA of 2 mg/day for men and 1.6 mg/day for women to 1.3 mg/day for both, compared with the UK RNI of 1.2 mg for women and 1.4 mg for men. The report cites six studies that demonstrated that this level of intake would maintain a plasma concentration of pyridoxal phosphate at least 20 nmol/l, although, as shown in **Table 1**, the more generally accepted criterion of adequacy is 30 nmol/l.

Possible Benefits of Higher Levels of Intake

The identification of hyperhomocysteinaemia as an independent risk factor in atherosclerosis and coronary heart disease has led to suggestions that higher intakes of vitamin B_6 may be beneficial. As shown in **Figure 4**, homocysteine may undergo either of two metabolic fates: remethylation to methionine (a reaction that is dependent on vitamin B_{12} and folate) or vitamin B_6-dependent trans-sulfuration to yield cysteine.

A number of studies have shown that while folate supplements lower fasting homocysteine in moderately hyperhomocysteinemic subjects, 10 mg/day vitamin B_6 has no effect, although they do reduce the peak plasma concentration of homocysteine following a test dose of methionine.

Vitamin B_6 Requirements of Infants

Estimation of the RDA for vitamin B_6 of infants presents a problem, and there is a clear need for further research to achieve a realistic estimate of infants' requirements. Human milk, which must be assumed to be adequate for infant nutrition, provides only some 40–100 μg per liter, or 3–8 μg of vitamin B_6 per gram of protein—very much lower than the apparent requirement for adults. There is no reason why infants should have a lower requirement than adults, and indeed since they must increase their total body pool of the vitamin as they grow, they might be expected to have a proportionally higher requirement than adults.

A first approximation of the vitamin B_6 needs of infants came from studies of those who convulsed as a result of gross deficiency caused by overheated infant milk formula in the 1950s. At intakes of 60 μg per day there was an incidence of convulsions of 0.3%. Provision of 260 μg per day prevented or cured convulsions, but 300 μg per day was required to normalize tryptophan metabolism. This is almost certainly a considerable overestimate of requirements since pyridoxyllysine, formed by heating the vitamin with proteins, has antivitamin activity, and would therefore result in a higher apparent requirement.

Based on the body content of 15 μmol (3.7 mg) of vitamin B_6 per kilogram body weight, and the rate of weight gain, the minimum requirement for infants over the first 6 months of life would appear to be 100 μg (417 nmol) per day to establish tissue reserves.

Pharmacological Uses and Toxicity of Vitamin B_6 Supplements

Supplements of vitamin B_6 ranging from 25 to 500 mg/day, and sometimes higher, have been recommended for treatment of a variety of conditions in which there is an underlying physiological or biochemical mechanism to justify the use of supplements, although in most cases there is little evidence of efficacy. Such conditions include postnatal depression, depression and other side effects associated with oral contraceptives, hyperemesis of pregnancy, and the premenstrual syndrome.

Supplements have also been used empirically, with little or no rational basis, and little or no evidence of efficacy, in the treatment of a variety of conditions, including acute alcohol intoxication, atopic dermatitis, autism, carpal tunnel syndrome, dental caries, diabetic neuropathy, Down's syndrome, Huntington's chorea, schizophrenia, and steroid-dependent asthma.

Doses of 50–200 mg per day have an antiemetic effect, and the vitamin is widely used, alone or in conjunction with other antiemetics, to minimize the nausea associated with radiotherapy and to treat pregnancy sickness. There is no evidence that vitamin B_6 has any beneficial effect in pregnancy sickness, nor that women who suffer from morning sickness have lower vitamin B_6 nutritional status than other pregnant women.

Vitamin B_6 and the Side Effects of Oral Contraceptives

Although oestrogens do not cause vitamin B_6 deficiency, the administration of vitamin B_6 supplements has beneficial effects on some of the side effects of both administered and endogenous oestrogens. The supplements act in two main areas: in normalizing glucose tolerance and as an antidepressant.

Impairment of glucose tolerance is common in pregnancy and may indeed be severe enough to be classified as gestational diabetes mellitus, which generally resolves at parturition, although in some subjects it may persist. High-estrogen oral contraceptives may also cause impaired glucose tolerance. This seems to be the result of increased tissue and blood concentrations of xanthurenic acid, because of the inhibition of kynureninase by estrogen metabolites. Xanthurenic acid forms a complex with insulin which has little or no hormonal activity. Vitamin B_6 supplements may have a beneficial effect by activating apokynureninase or kynureninase that has been inactivated by undergoing transamination.

One of the relatively common side effects of oestrogenic oral contraceptives is depression, affecting about 6% of women in some studies. This frequently responds well to the administration

of relatively large amounts of vitamin B_6 (generally in excess of 40 mg per day). Postnatal depression also responds to similar supplements in some studies.

Again, this does not seem to be due to correction of vitamin B_6 deficiency, but rather to a direct effect of pyridoxal phosphate on the metabolism of tryptophan. High concentrations of pyridoxal phosphate attenuate the response to glucocorticoid hormones; tryptophan dioxygenase is a glucocorticoid-induced enzyme, and thus its synthesis and activity will be reduced by high intakes of vitamin B_6. This reduces the oxidative metabolism of tryptophan and increases the amount available for synthesis of 5-hydroxytryptamine in the brain.

Vitamin B_6 in the Premenstrual Syndrome

The studies showing a beneficial action of vitamin B_6 in overcoming depression associated with oral contraceptives have led to the use of the vitamin in depression and other pathology associated with endogenous estrogens in the premenstrual syndrome. There is no evidence of poorer vitamin B_6 nutritional status in women who suffer from the premenstrual syndrome.

There are few well-controlled studies of the effects of vitamin B_6 in premenstrual syndrome. In general, those that have been properly controlled report little benefit from doses between 50 and 200 mg per day compared with placebo, although some studies do claim a beneficial effect. Interestingly, meta-analysis of controlled crossover trials shows that whichever treatment is used second, active vitamin or placebo, is (marginally) more effective. There is no obvious explanation for this observation.

Despite the lack of evidence of efficacy, vitamin B_6 is widely prescribed (and self-prescribed) for the treatment of premenstrual syndrome.

Vitamin B_6 for Prevention of the Complications of Diabetes Mellitus

A number of studies have suggested that vitamin B_6 (and specifically pyridoxamine) may be effective in preventing the adverse effects of poor glycemic control that lead to the development of the complications of diabetes mellitus, many of which are mediated by nonenzymic glycation of proteins. Pyridoxamine is a potent inhibitor of the rearrangement of the immediate product of protein glycation to the 'advanced glycation end-product.'

Toxicity of Vitamin B_6

Animal studies have demonstrated the development of signs of peripheral neuropathy, with ataxia, muscle weakness, and loss of balance, in dogs given 200 mg pyridoxine per kilogram body weight for 40–75 days, and the development of a swaying gait and ataxia within 9 days at a dose of 300 mg per kilogram body weight. At a dose of 50 mg per kilogram body weight, there are no clinical signs of toxicity, but histologically there is a loss of myelin in dorsal nerve roots. At higher doses there is more widespread neuronal damage, with loss of myelin and degeneration of sensory fibers in peripheral nerves, the dorsal columns of the spinal cord, and the descending spinal tract of the trigeminal nerve. The clinical signs of vitamin B_6 toxicity in animals regress after withdrawal of these massive doses, but sensory nerve conduction velocity, which decreases during the development of the neuropathy, does not recover fully. The mechanism of the neurotoxic action of vitamin B_6 is unknown.

The development of sensory neuropathy has been reported in patients taking 2–7 g of pyridoxine per day. Although there was residual damage in some patients, withdrawal of these extremely high doses resulted in a considerable recovery of sensory nerve function.

There is little evidence that intakes of up 200 mg vitamin B_6 per day for prolonged periods are associated with any adverse effects. The US Food and Nutrition Board set a tolerable upper level for adults of 100 mg/day; the EU Scientific Committee on Food set 25 mg/day.

Vitamin B_6 Deficiency

Gross clinical deficiency of vitamin B_6 is more or less unknown. The vitamin is widely distributed in foods, and intestinal flora synthesize relatively large amounts, at least some of which is believed to be absorbed.

In vitamin B_6-deficient experimental animals there are more or less specific skin lesions (e.g., acrodynia in the rat) and fissures or ulceration at the corners of the mouth and over the tongue, as well as a number of endocrine abnormalities, defects in the metabolism of tryptophan, methionine, and other amino acids, hypochromic microcytic anemia (the first step of heme biosynthesis is a pyridoxal phosphate-dependent reaction), changes in leucocyte count and activity, a tendency to epileptiform convulsions, and peripheral nervous system damage resulting in ataxia and sensory neuropathy.

Much of our knowledge of human vitamin B_6 deficiency is derived from an outbreak in the early 1950s, which resulted from an infant milk preparation which had undergone severe heating in manufacture. The probable result of this was the

formation of pyridoxyllysine by reaction between pyridoxal phosphate and the ϵ-amino groups of lysine in proteins. In addition to a number of metabolic abnormalities, many of the affected infants convulsed. They responded to the administration of vitamin B_6 supplements.

Investigation of the neurochemical basis of the convulsions in vitamin B_6 deficiency helped to elucidate the role of GABA as a neurotransmitter; GABA is synthesized by the decarboxylation of glutamate. More recent studies have suggested that the accumulation of hydroxykynurenine in the brain may be the critical factor precipitating convulsions in deficiency; GABA is depleted in the brains of deficient adult and neonate animals, while hydroxykynurenine accumulation is considerably more marked in neonates than adults—only neonates convulse in vitamin B_6 deficiency. GABA depletion may be a necessary but not sufficient condition for convulsions in vitamin B_6 deficiency.

Groups at Risk of Deficiency

A number of studies have shown that between 10 and 20% of the apparently healthy population have low plasma concentrations of pyridoxal phosphate or abnormal erythrocyte transaminase activation coefficient, suggesting vitamin B_6 inadequacy or deficiency. In most studies, only one of these indices of vitamin B_6 nutritional status has been assessed. Where both have been assessed, while each shows some 10% of the population apparently inadequately provided with vitamin B_6, few of the subjects show inadequacy by both criteria.

There is a decrease in the plasma concentration of vitamin B_6 with increasing age, and some studies have shown a high prevalence of abnormal transaminase activation coefficient in elderly subjects, suggesting that the elderly may be at risk of vitamin B_6 deficiency. It is not known whether this reflects an inadequate intake, a greater requirement, or changes in the tissue distribution and metabolism of the vitamin with increasing age.

Drug-Induced Vitamin B_6 Deficiency

A number of drugs that react with carbonyl compounds are capable of causing vitamin B_6 deficiency on prolonged use. These include the antituberculosis drug isoniazid (iso-nicotinic acid hydrazide), penicillamine, and the anti-Parkinsonian drugs, benserazide and carbidopa. In general, the main effect is impairment of tryptophan metabolism by inhibition of kynureninase, and hence the development of the niacin-deficiency disease, pellagra. The condition therefore responds to the administration of either vitamin B_6 or niacin.

VITAMIN D

Contents

Physiology, Dietary Sources and Requirements

M F Holick, Boston University Medical Center, Boston, MA, USA

Introduction

Vitamin D is a fat-soluble vitamin that is recognized for its importance for bone health. Vitamin D is neither a vitamin nor a nutrient because exposure to sunlight can provide the body's requirement for vitamin D. We take vitamin D for granted because it is casual exposure to sunlight that provides most humans with their vitamin D requirement. This recognition and the fortification of milk and other foods including some margarines, cereals, and orange juice with vitamin D has eradicated vitamin D deficiency rickets as a significant health problem for children in the US and countries that practice this fortification process. However, it is now recognized that both children and adults are at risk for developing vitamin D deficiency. The recommended adequate dietary intake for vitamin D is $200\,\text{IU}\,\text{day}^{-1}$ for children and adults <50 years old, $400\,\text{IU}\,\text{day}^{-1}$ for adults 51–70 years, and $600\,\text{IU}\,\text{day}^{-1}$ for those >70 years. However, without adequate sun exposure, $1000\,\text{IU}\,\text{day}^{-1}$ is needed. Once vitamin D is formed in the skin or ingested in the diet, it enters the bloodstream and travels to the liver and kidney where it is hydroxylated on carbons 25 and 1 to form 25-hydroxyvitamin D (25(OH)D) and 1,25-dihydroxyvitamin D (1,25(OH)D), respectively. 25-Hydroxyvitamin D is the major circulating form of the vitamin that is measured to determine the vitamin D status of patients. 1,25-Dihydroxyvitamin D is the biologically active form of vitamin D that is responsible for maintaining calcium homeostasis and bone health. It is now recognized that vitamin D deficiency increases the risk of many chronic diseases including cancers of the breast, prostate, and colon, type 1 diabetes mellitus, multiple sclerosis, rheumatoid arthritis, and heart disease.

Origin and Structure of Vitamin D

As the industrial revolution began to take hold in Northern Europe in the 17th century, it was quickly associated with a new disease that caused severe growth retardation and bony deformities in young children (**Figure 1**). This disease was commonly known as rickets or 'English disease' and plagued the children of the industrialized cities in Europe and North America for more than 250 years. Although Sniadecki in 1822 and Palm in 1890 both recognized that it was lack of exposure to sunlight that was the likely cause of rickets in children, Huldschinsky, in 1919, was the first to prove that exposure of the skin to ultraviolet radiation could cure rickets. Within 2 years, Hess and Unger reported that exposure of several rachitic children to sunlight was adequate for curing this bone-deforming disease.

Steenbock and Black and Hess independently recognized that exposure of animals and their food to ultraviolet radiation imparted antirachitic activity. This led to the recommendation for the ultraviolet irradiation of foods as a means of fortifying them with vitamin D. This resulted in the addition of provitamin D to milk followed by ultraviolet irradiation. As soon as it was possible to commercially synthesize vitamin D in large quantities, it was added directly to milk and other foods.

The first vitamin D was isolated from the irradiation of the yeast sterol ergosterol (**Figure 2**). This vitamin D was thought to be identical to that produced in the skin of animals and humans. However, studies revealed that when vitamin D produced from yeast was fed to chickens, they were unable to utilize it and developed rickets. When chickens were fed natural vitamin D from fish liver oil, rickets was prevented. This led to the conclusion that vitamin D originating from yeast was different from that in fish liver oil and animal and human skin. In 1937, this mystery was solved when the structure of provitamin D from pig skin was determined. A structural analysis revealed that provitamin D derived from ergosterol differed from that derived from pig skin. The provitamin D (ergosterol; provitamin D_2) that came from yeast had a double bond between carbons 22 and 23 and a methyl group on carbon 24.

Figure 1 This is a typical presentation of a child with rickets. The child is suffering from severe muscle weakness, has bony deformities including bowed legs, and knob-like projects in the middle of his ribcage called the rachitic rosary. (Reproduced with permission from Fraser D and Scriver CR (1979) Disorders associated with hereditary or acquired abnormalities of vitamin D function: hereditary disorders associated with vitamin D resistance or defective phosphate metabolism. In: De Groot LJ *et al.* (eds.) *Endocrinology*, pp. 797–808. New York: Grune and Stratton.)

The provitamin D in animal skin had a side-chain that was identical to cholesterol, i.e., it did not contain either a double bond or methyl group on carbons 22–23 and 24, respectively, and was identified as 7-dehydrocholesterol (provitamin D_3) (**Figure 2**). The vitamin Ds generated from ergosterol and 7-dehydrocholesterol were called ergocalciferol (vitamin D_2) and cholecalciferol (vitamin D_3), respectively.

Production of Vitamin D in the Skin

During exposure to sunlight, the ultraviolet B photons with energies between 290 and 315 nm are absorbed by provitamin D_3 (7-dehydrocholesterol) in the skin. This absorption results in a photolysis of the B-ring of provitamin D_3 resulting in the formation of previtamin D_3 (**Figure 3**). However, since previtamin D_3 is thermodynamically unstable, it quickly undergoes an isomerization (rearrangement) of its triple bond system to form vitamin D_3. This isomerization process is enhanced in skin cells because the previtamin D_3 is synthesized in the cell membrane, which restricts its movement thereby accelerating the transformation of previtamin D_3 to vitamin D_3. Once vitamin D_3 is formed in the skin cell membrane, it is no longer restricted in its movement and freely translocates into the extracellular space to find its way into the dermal capillary bloodstream where it is bound to a specific vitamin D-binding protein (**Figure 3**).

An increase in skin pigmentation and zenith angle of the sun (change in latitude, season, and time of day) and the topical application of a sunscreen can markedly diminish or even prevent the production of vitamin D_3 in the skin. Over the age of ~65 years, there is a three- to fourfold decline in the synthetic capacity of the skin to produce vitamin D_3. Excessive exposure to sunlight cannot cause vitamin D_3 intoxication because once previtamin D_3 and vitamin D_3 are made in the skin, excessive quantities are rapidly destroyed by sunlight (**Figure 3**).

Absorption, Metabolism, and Excretion of Vitamin D

Vitamin D (vitamin D without a subscript represents either vitamin D_2 or D_3) is fat soluble and, therefore, once ingested vitamin D_2 and vitamin D_3 are incorporated into the chylomicron fraction and absorbed in the small intestine into the lymphatic system. Both dietary vitamin D_2 and vitamin D_3, and cutaneous vitamin D_3 enter the circulation and are bound to a specific α_1-globulin known as the vitamin D-binding protein. It is believed that this protein acts as a buffering system whereby it helps maintain circulating concentrations of 25(OH)D so that the free unbound form of 25(OH)D can enter into the renal tubular cells to be metabolized.

Neither vitamin D_2 nor vitamin D_3 possess any intrinsic biologic activity on calcium metabolism. They both require a hydroxylation on carbon 25 to form 25(OH)D (**Figure 4**). 25(OH)D is the major circulating form of vitamin D and at physiologic concentrations it has little biologic activity on calcium metabolism. It must undergo a hydroxylation

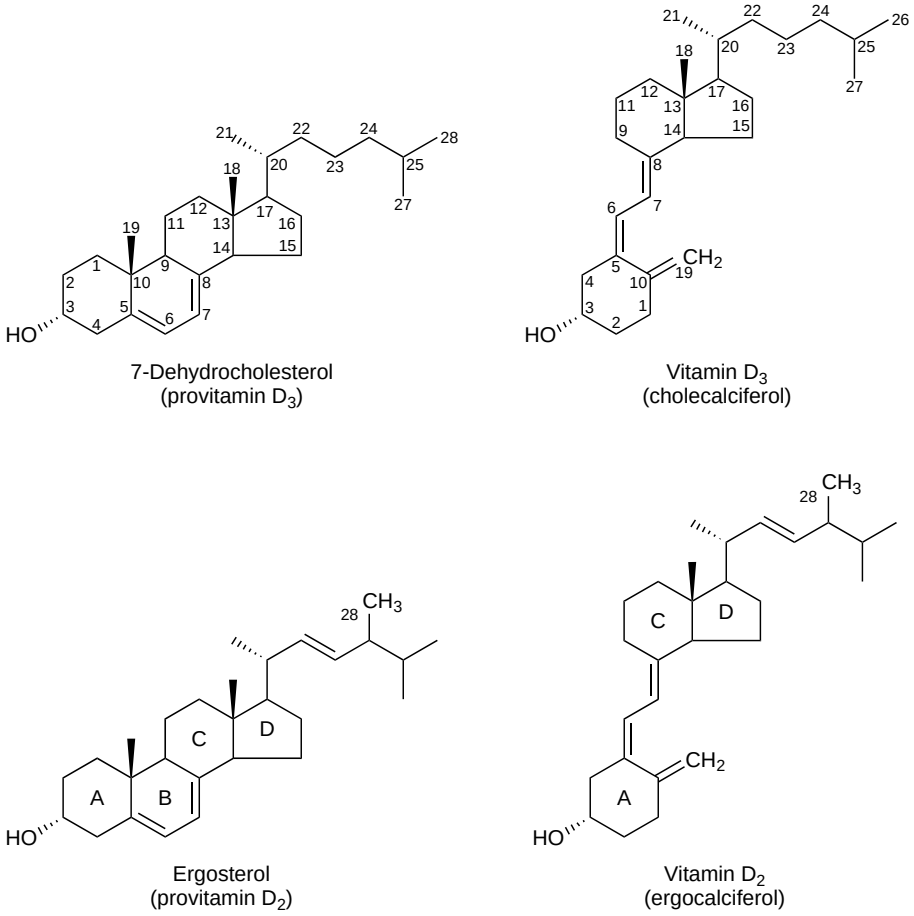

Figure 2 Structures for 7-dehydrocholesterol (provitamin D_3), ergosterol (provitamin D_2), vitamin D_3 (cholecalciferol), and vitamin D_2 (ergocalciferol). The carbons are numbered and the ring systems are labeled.

on carbon 1 in the kidney to form $1,25(OH)_2D$, the biologically active form of vitamin D (**Figure 4**). The metabolism of 25(OH)D to $1,25(OH)_2D$ is tightly regulated by parathyroid hormone (PTH) and serum phosphorus levels (**Figure 5**). PTH and low serum phosphorus levels increase the production of $1,25(OH)_2D$.

25(OH)D and $1,25(OH)_2D$ act as substrate for a 24-hydroxylase (an enzyme that attaches an hydroxyl on carbon-24), which is found in the kidney and other target tissues for $1,25(OH)_2D$. Once $1,25(OH)_2D$ is hydroxylated on carbon 24, this is the first step in its degradation to a water-soluble acid, calcitroic acid (**Figure 4**). Whereas, vitamin D is excreted in the bile, calcitroic acid is excreted by the kidney.

There continues to be speculation and controversy as to whether the 24-hydroxylation of 25(OH)D and $1,25(OH)_2D$ to 24, 25-dihydroxyvitamin D and 1,24,25-trihydroxyvitamin D, respectively, has important physiologic functions other than simply initiating the degradation of both metabolites.

Biologic Functions of Vitamin D on Calcium Metabolism

$1,25(OH)_2D$ interacts with a specific nuclear receptor that is commonly known as the vitamin D receptor (VDR) and is one of the many members of the super family of steroid hormone receptors that includes retinoic acid, thyroid hormone, glucocorticoids, and sex steroids. Once $1,25(OH)_2D$ interacts with the VDR, the complex forms a heterodimer with retinoic acid X receptor (RXR) (**Figure 6**). This new complex sits on specific segments of vitamin D responsive genes known as vitamin D responsive elements (VDREs) to either increase or decrease transcriptional activity of the vitamin D-sensitive genes such as osteocalcin, calcium binding protein (calbindin), PTH, and osteonectin (**Figure 6**).

In the intestine, $1,25(OH)_2D$ enhances the absorption of dietary calcium and phosphorus across the microvilli of the small intestinal absorptive cells (**Figure 5**). $1,25(OH)_2D$ also interacts with

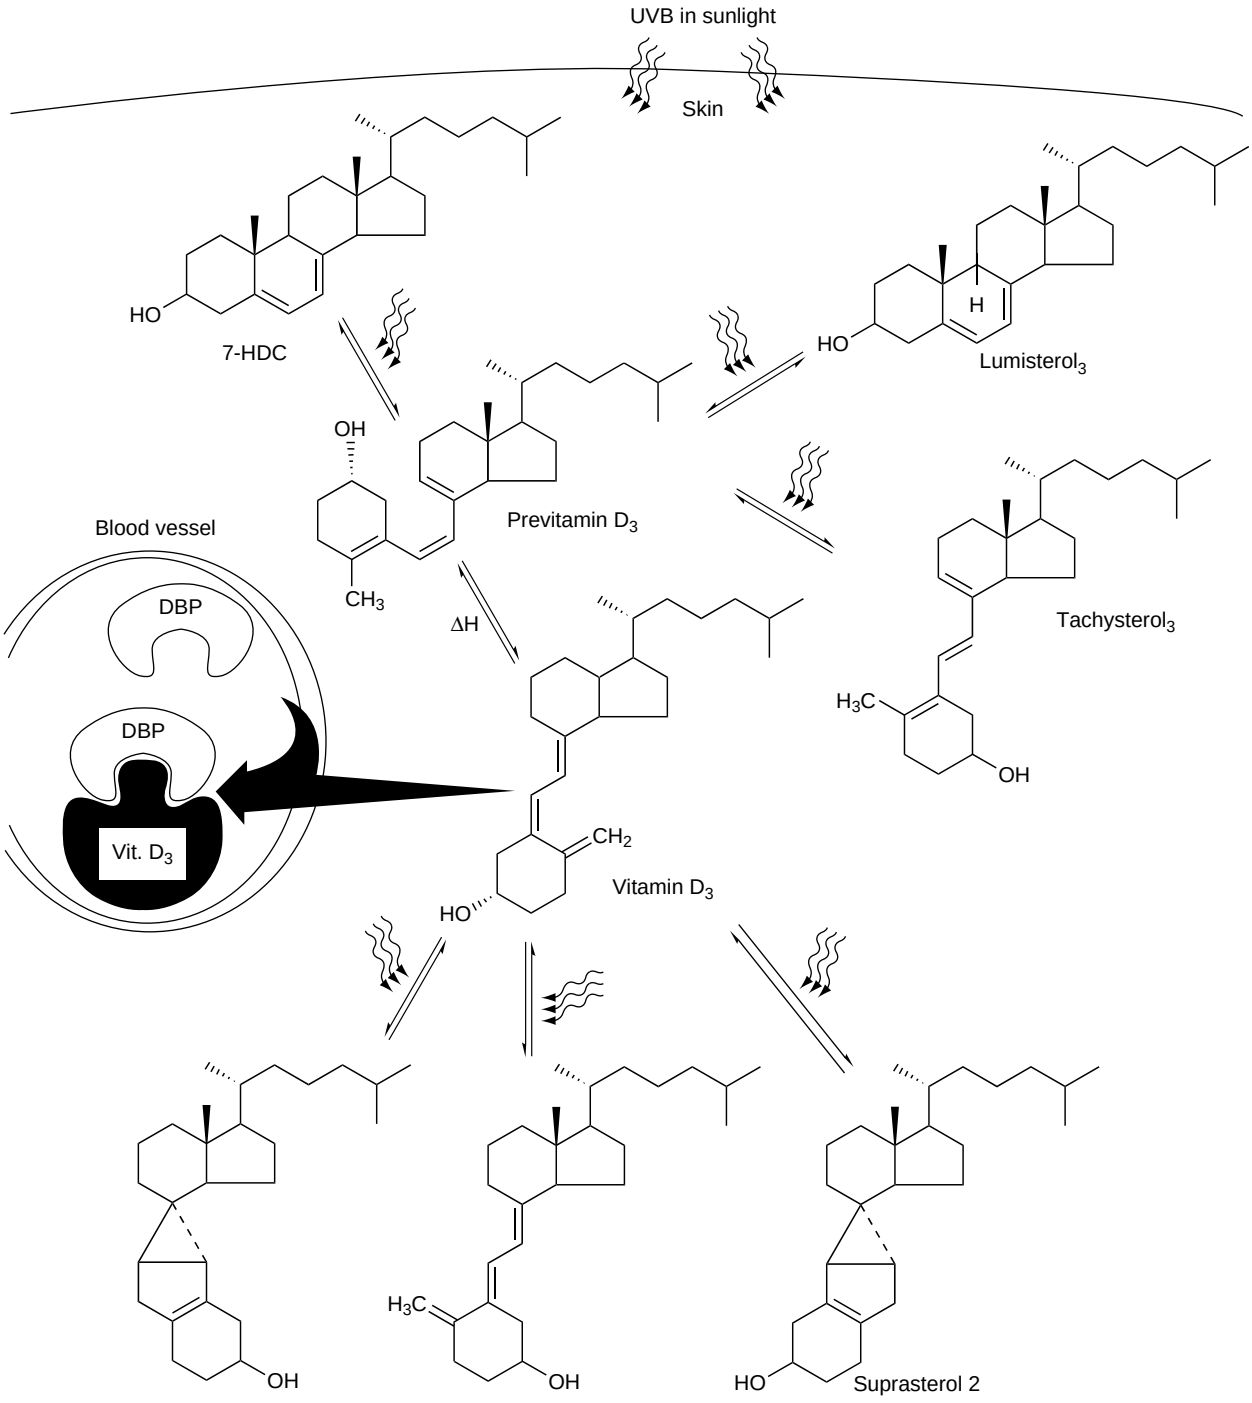

Figure 3 A schematic representation of the photochemical and thermal events that result in the synthesis of vitamin D_3 in the skin, and the photodegradation of previtamin D_3 and vitamin D_3 to biologically inert photoproducts. 7-Dehydrocholesterol (7-DHC) in the skin is converted to previtamin D_3 by the action of solar ultraviolet B radiation. Once formed, previtamin D_3 is transformed into vitamin D_3 by a heat-dependent (ΔH) process. Vitamin D_3 exits the skin into the dermal capillary blood system and is bound to a specific vitamin D-binding protein (DBP). When previtamin D_3 and vitamin D_3 are exposed to solar ultraviolet B radiation, they are converted to a variety of photoproducts that have little or no activity on calcium metabolism. (Reproduced with permission from Holick MF (1995) Vitamin D: Photobiology, Metabolism, and Clinical Applications. In: DeGroot LJ *et al.* (eds.) *Endocrinology*, 3rd edn, pp. 990–1013. Philadelphia: W.B. Saunders.)

monocytic stem cells in the bone marrow to initiate their transformation into mature osteoclasts (**Figure 5**). Thus, $1,25(OH)_2D_3$ regulates serum calcium levels by enhancing the efficiency of intestinal calcium absorption and stimulating resorption of calcium from the bone. It remains

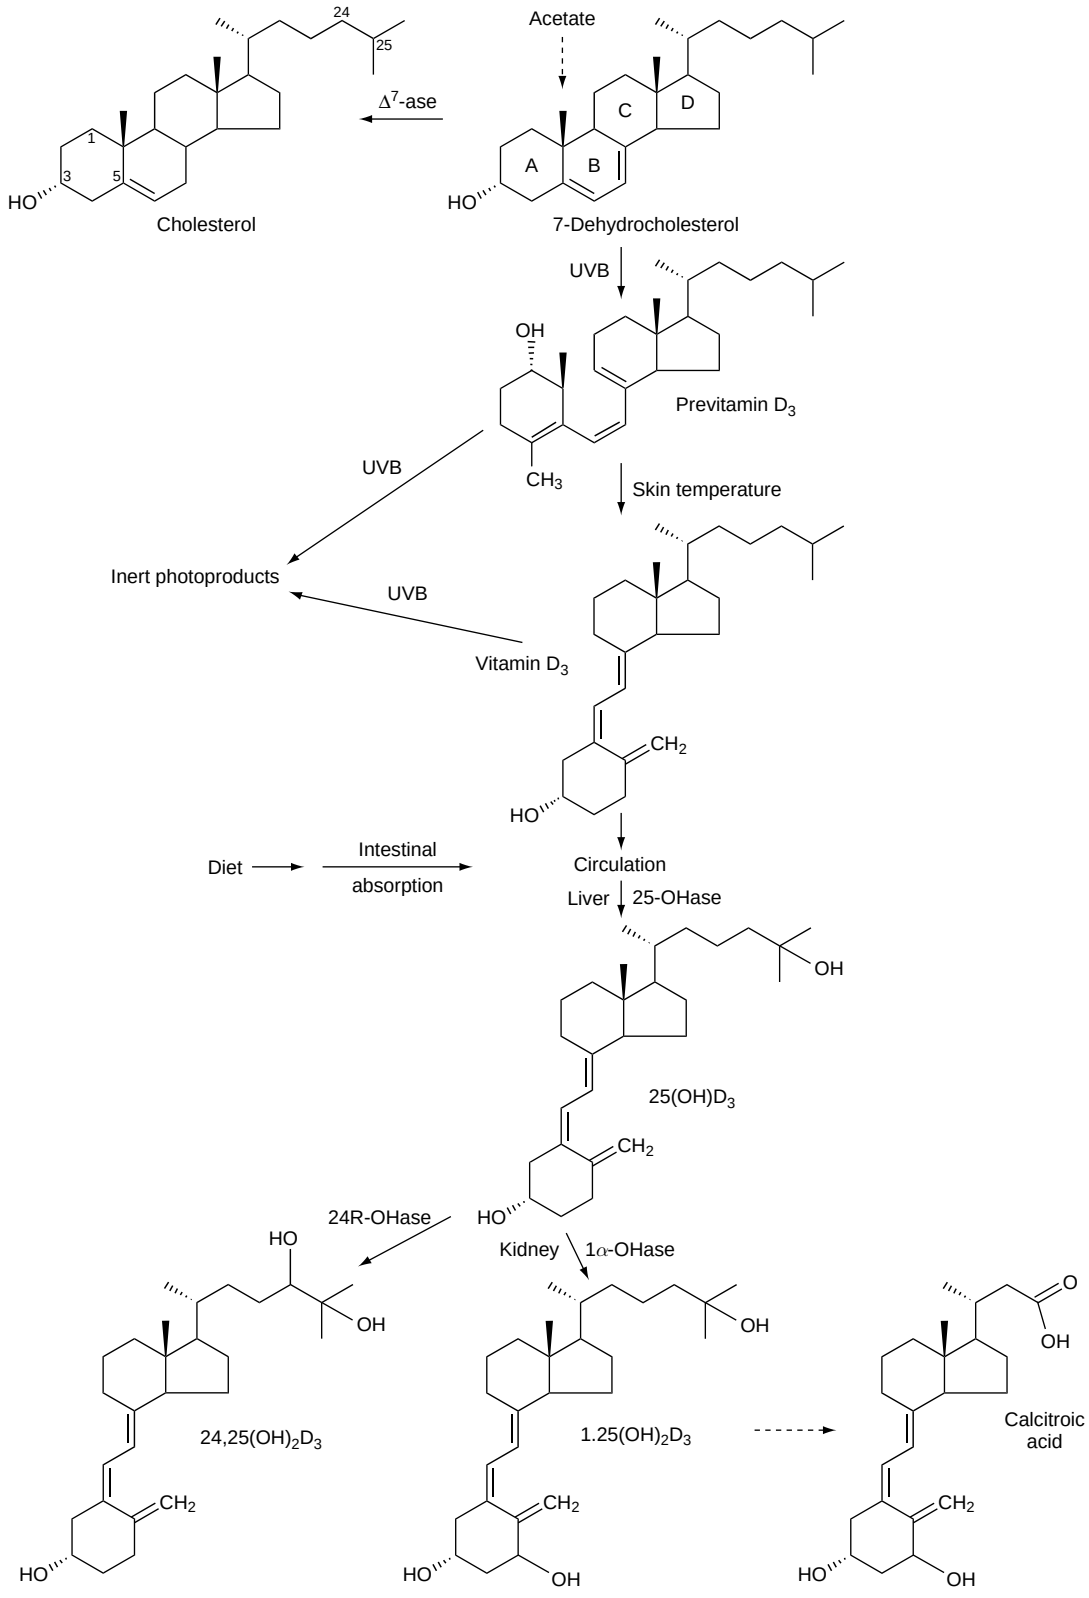

Figure 4 A schematic representation of the origin of vitamin D_3 and its metabolism in the liver by the hepatic vitamin D-25-hydroxylase. Once formed, the 25-hydroxyvitamin D_3 (25(OH)D_3) is metabolized by either a 25(OH)D-1α-hydroxylase or a 25(OH)D-24-hydroxylase. 1,25-Dihydroxyvitamin D_3 (1,25(OH)$_2D_3$) can either go to its target tissues to carry out its biologic function(s), or it can be metabolized in its side-chain and degraded to calcitroic acid. (Reproduced with permission from Holick MF (1995) Vitamin D: Photobiology, Metabolism, and Clinical Applications. In: DeGroot LJ *et al.* (eds.) *Endocrinology*, 3rd edn, pp. 990–1013. Philadelphia: W.B. Saunders.)

(Copyright Michael F Holick (2004) Vitamin D: Importance in the prevention of cancers, type 1 diabetes, heart disease, and osteoporosis. *American Journal of Clinical Nutrition* **79**: 362–371, used with permission.)

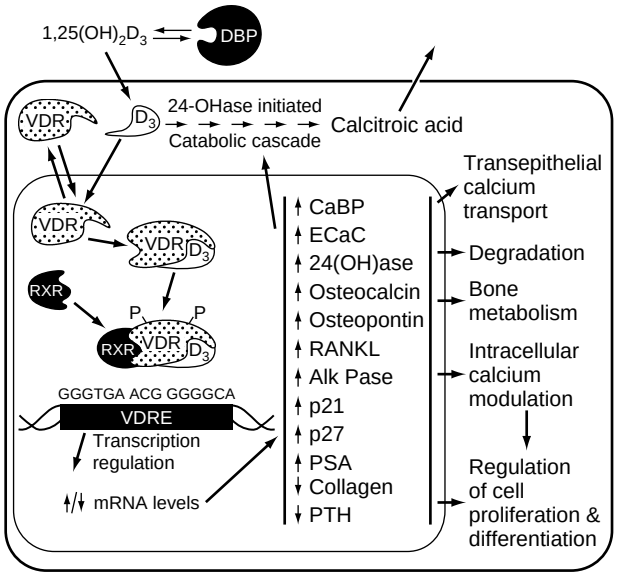

Figure 6 A schematic representation of the mechanism of action of $1,25(OH)_2D$ in various target cells resulting in a variety of biological responses. The free form of $1,25(OH)_2D_3$ enters the target cell and interacts with its nuclear vitamin D receptor (VDR), which is phosphorylated (Pi). The $1,25(OH)_2D$–VDR complex combines with the retinoic acid X receptor (RXR) to form a heterodimer, which, in turn, interacts with the vitamin D responsive element (VDRE), causing an enhancement or inhibition of transcription of vitamin D-responsive genes including calcium-binding protein (CaBP), ECaC, 24-OHase, RANKL, alkaline phosphatase (alk Pase), prostate-specific antigen (PSA), and PTH.

controversial as to whether $1,25(OH)_2D$ has any direct action on the renal handling of either calcium or phosphorus.

There are a variety of other tissues including the brain, gonads, pancreas, stomach, activated T and B lymphocytes, monocytes, and skin that have nuclear VDR. Although the exact physiologic function of $1,25(OH)_2D$'s interaction with these VDRs is not well understood, it is known that *in vivo* and *in vitro* $1,25(OH)_2D_3$ can inhibit proliferation and induce terminal differentiation of various normal and tumor cells including normal human keratinocytes. This is the reason why activated vitamin D compounds are now routinely used for the treatment of the hyperproliferative skin disorder psoriasis.

Evaluation for and Consequences of Vitamin D Deficiency

Vitamin D deficiency in young children causes rickets. As a child becomes vitamin D deficient, this results in a decrease in the efficiency of intestinal calcium absorption. There is a decline in blood-ionized calcium, which causes the parathyroid glands to produce and secrete more parathyroid hormone (PTH). PTH tries to conserve calcium by enhancing tubular reabsorption of calcium in the kidney. However, in the face of developing hypocalcemia, which could disturb neuromuscular function and a wide variety of metabolic and cellular processes, the body calls upon $1,25(OH)_2D$ and PTH to mobilize stem cells to become functional osteoclasts, which, in turn, mobilize calcium from the skeleton. In addition, PTH causes a loss of phosphorus into the urine causing hypophosphatemia. Thus, in early vitamin D deficiency the serum calcium is normal; it is the low serum phosphorus that causes the extracellular $CaXPO_4$ to be too low for normal mineralization of

bone matrix. This causes a disruption in the orderly sequence of events in the differentiation of hypertrophied chondrocytes in the epiphyseal plates resulting in their disorganization causing a widening of the epiphyseal plates (end of long bones), demineralization of the skeleton, and bony deformities (**Figure 1**).

Once the epiphyseal plates are closed later in adolescence, vitamin D deficiency can no longer cause bone deformities. Instead, there is an inability to mineralize newly deposited bone matrix leading to wide osteoid seams within the trabecular and cortical bone causing the bone disease commonly known as osteomalacia. In addition, the secondary hyperparathyroidism that results from vitamin D deficiency results in the mobilization of precious calcium stores from the bone thereby exacerbating bone loss and causing osteoporosis. This can increase a person's risk for fracture.

The hallmark for determining the vitamin D status is the measurement of the circulating concentration of 25(OH)D. The 25(OH)D is low or undetectable in vitamin D deficiency and markedly elevated in vitamin D intoxication. Measurement of $1,25(OH)_2D$ is of little value for determining the vitamin D nutritional status because its synthesis is tightly regulated. Indeed, as a person becomes vitamin D deficient, there is an increase in the secretion of PTH which, in turn, increases the production of $1,25(OH)_2D$. Thus, early in vitamin D deficiency one can see a normal fasting serum calcium, low-normal to low phosphorus, low 25(OH)D, and elevated PTH, $1,25(OH)_2D$ and alkaline phosphatase. In chronic vitamin D deficiency, all the above are seen with the exception that $1,25(OH)_2D$ is low-normal or low.

Nonskeletal Consequences of Vitamin D Deficiency

As early as 1941, it was appreciated that if you lived at higher latitudes in the US you were at higher risk of dying of cancer. A multitude of epidemiologic studies clearly show that if you live at higher latitudes and are more prone to vitamin D deficiency then you are at higher risk of dying of colon, prostate, breast, ovarian, and a variety of other cancers. It is also known that living at higher latitudes increases risk of having high blood pressure and heart disease as well as autoimmune diseases including multiple sclerosis and type I diabetes.

Essentially every cell and organ in the body requires vitamin D, i.e., they all have a VDR. It is also known that most tissues in the body can activate vitamin D. Thus, maintaining adequate levels of 25(OH)D in the circulation of at least $20\,ng\,ml^{-1}$ and preferably $30\,ng\,ml^{-1}$ is necessary for various organs including colon, breast, and prostate to convert it to $1,25(OH)_2D$, which in turn can help regulate various genes responsible for cell growth and differentiation. This could be the explanation for how vitamin D sufficiency is protective against most common cancers. The immune cells also recognize $1,25(OH)_2D_3$. This may explain why children who at 1 year of age had received 2000 IU of vitamin D a day decreased their risk of developing type I diabetes by 80%. Increasing intake of vitamin D and sun exposure has now been associated with decreased risk of developing multiple sclerosis, rheumatoid arthritis, and even Crohn's disease.

The relationship of vitamin D to cardiovascular disease is finally being understood. $1,25(OH)_2D$ inhibits the production of the blood pressure hormone renin. It also alters cardiomyocyte growth and modulates the inflammatory response of atherosclerosis (**Figure 7**).

Recommended Dietary Intake of Vitamin D

Vitamin D is very rare in foods naturally, with the exception of fatty fish and some fish liver oils. Although milk in the US is fortified with 400 IU of vitamin D/quart, several surveys during the past decade have demonstrated that approximately 80% of milk in the US contained less than 300 IU/quart. Fifty pecent of the milk samples contained less than 200 IU/quart and 15% had no detectable vitamin D. Some orange juice and other juice products are fortified with calcium and 100 IU of vitamin D_3/8 oz. Multivitamin preparations that contain vitamin D are a good source of vitamin D as are pharmaceutical preparations.

In 1997, the Institute of Medicine and the National Academy of Sciences reviewed the recommended dietary intake for several nutrients and vitamins including vitamin D. The recommended dietary allowance (RDA) was defined as the daily intake level that is sufficient to meet nutrient requirements for nearly all (97–98%) individuals in life-stage and gender group. The RDA was meant to apply to individuals and not groups. When sufficient scientific evidence was not available to calculate an estimated average requirement (EAR), i.e., a nutrient value that was estimated to meet the requirement defined by a specified indicator of adequacy in 50% of individuals in a life-stage and gender group, the Committee recommended using an adequate intake (AI). The AI is based on the observation of experimentally determined approximations of average nutrient intake by a defined population or subgroup that appears to sustain a defined nutritional state

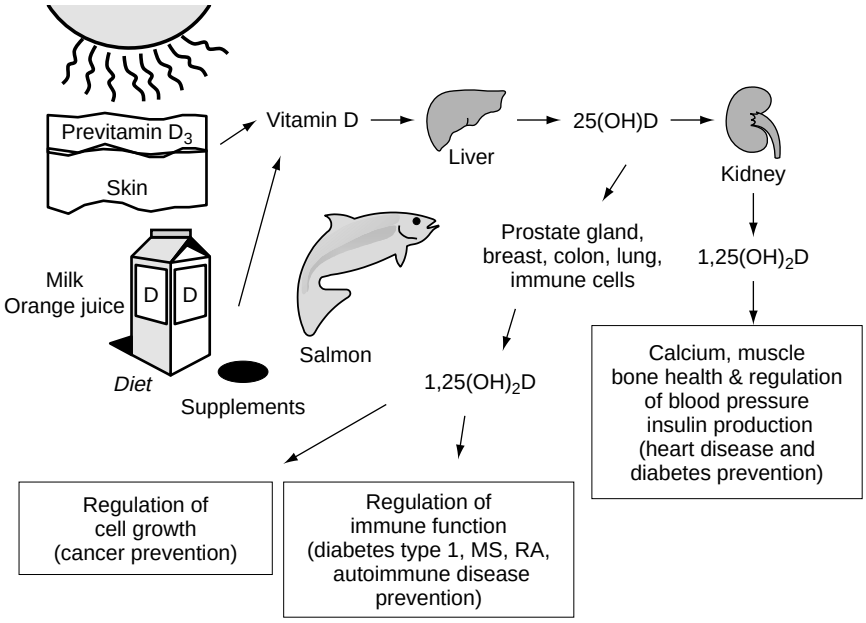

Figure 7 Photoproduction and sources of vitamin D. Vitamin D is metabolized in the liver to 25-hydroxyvitamin D [25(OH)D], which is responsible for maintaining calcium homeostasis. 25(OH)D is also converted to $1,25(OH)_2$ D in a variety of other cells and tissues for the purpose of regulating cell growth, immune function, as well as a variety of other physiologic processes that are important for the prevention of many chronic diseases. MS, multiple sclerosis; RA, rheumatoid arthritis. (Copyright Michael F Holick (2004) Vitamin D: Importance in the prevention of cancers, type 1 diabetes, heart disease, and osteoporosis. *American Journal of Clinical Nutrition* **79**: 362–371, used with permission.)

such as normal circulation nutrient values or growth. Because sunlight played such an important role in providing humans with their vitamin D requirement and, therefore, was a variable that was difficult to quantify in most studies that were reviewed by the Committee, it was concluded that an AI rather than an RDA should be used for vitamin D (**Table 1**).

Adequate Intake for Ages 0–6 Months

It is well documented that human and cows' milk has very little vitamin D naturally. Human milk contains on average between 10 and 50 IU l^{-1} (0.25–1.25 μg). This is dependent on the mother's exposure to sunlight and her vitamin D intake. Several studies have suggested that infant intakes of vitamin D of between 8.5 and 15 μg day^{-1} would provide the maximum effect on their linear growth. A study in infants from Northern China (40–47 °N) found that vitamin D supplements of 2.5, 5, or 10 μg day^{-1} resulted in 36, 29, and 2% of the infants being vitamin D deficient with 25(OH)D levels of less than 25 nmol l^{-1} (10 ng ml^{-1}). None of the infants, however, had manifestations of rickets. Chinese infants from two southern cities (22 °N and 30 °N) maintained normal vitamin D status on as little as 2.5 μg day^{-1} of vitamin D.

Table 1 Adequate Intake (AI) and Tolerable Upper Limit (UL) for Vitamin D

Age	*AI μg (IU)/d*	*UL μg (IU)/d*
0–6 m	5 (200 IU)	25 (1000 IU)
6 m–12 yr	5 (200 IU)	25 (1000 IU)
1 yr–18 yr	5 (200 IU)	50 (2000 IU)
19 yr–50 yr	5 (200 IU)	50 (2000 IU)
51 yr–70 yr	10 (400 IU)	50 (2000 IU)
71+ yr	15 (600 IU)	50 (2000 IU)

There was a seasonal variation of vitamin D status of infants when they were fed human milk only and did not receive vitamin D supplements; their 25(OH)D levels decreased in the winter due to less exposure to sunlight. However, this decrease did not occur in infants receiving a vitamin D supplement of 10 μg/day beginning at 3 weeks of age.

Therefore, based on the available literature, it was concluded that a minimum intake of 2.5 μg day^{-1} of vitamin D was adequate to prevent rickets. However, at this intake and in the absence of sunlight, infants are at risk for developing vitamin D insufficiency; therefore, it was recommended that an AI of 5 μg day^{-1} (200 IU) was prudent. 10 μg day^{-1} (400 IU), the current amount in 1 l of standard infant formula or one quart of commercial cows' milk, was not considered to be excessive.

Adequate Intake for Ages 6–12 Months

Infants between 6 and 12 months of age who were fed human milk and exposed to an average of 35 min day^{-1} of sunshine had similar 25(OH)D concentrations at 1 year of age whether the infants received 400 IU of vitamin D or no vitamin D supplementation. However, in Norway, in the winter, older infants who received an average of 5 μg day^{-1} of vitamin D had normal 25(OH)D levels that were intermediate between those of infants studied at the end of the summer and formula-fed infants.

Therefore, in the absence of any sunlight exposure, an AI of 5 μg day^{-1} was recommended. However, an intake of 10 μg day^{-1} was not considered to be excessive.

Adequate Intake for Ages 1–18 Years

There are no studies in the scientific literature that systematically evaluated the influence of different amounts of vitamin D on either serum 25(OH)D or bone mineral content in this age group. Sunlight exposure is very important for this age group to obtain its required vitamin D. In South Africa, children aged 1–8 years of mixed race showed no evidence of vitamin D deficiency. A longitudinal study in Norway, where sun exposure was presumed to vary widely over a year, an intake of vitamin D of about 2.5 μg day^{-1} from fortified margarine in children aged 8–18 years was adequate to prevent vitamin D deficiency.

During puberty, there is a need to increase the efficiency of dietary calcium absorption in order to satisfy the rapid growth of the skeleton. As a result, there is an increase in the metabolism of 25(OH)D to $1,25(OH)_2D$. Because the blood levels of $1,25(OH)_2D$ are approximately 1000 times less than 25(OH)D, this increase in metabolism does not appear to increase the requirement of vitamin D for either boys or girls between the ages of 8 and 18 years. An average daily intake of 2.5 μg day^{-1} prevented any evidence of vitamin D deficiency in Scandinavian children in this age group. However, intakes less than 2.5 μg day^{-1} in Turkish children aged 12–17 years resulted in a decrease in 25(OH)D levels consistent with vitamin D deficiency.

Therefore, based on the available literature, it appears that children between 1 and 18 years obtain most of their vitamin D from exposure to sunlight and do not normally need to ingest vitamin D. However, for children who live in far northern and southern latitudes, vitamin D supplementation may be necessary. An AI of 5 μg day^{-1} (200 IU) was recommended to maintain vitamin D sufficiency in this age group regardless of exposure to sunlight.

Adequate Intake for Ages 19–50 Years

There is only sparse literature regarding the role that sunlight and diet play in maintaining an adequate vitamin D status for men and women in this age group. This age group depends on sunlight for most of its vitamin D requirement. Regardless of exposure to sunlight, it was estimated that an AI of 5 μg day^{-1} is sufficient for preventing vitamin D deficiency in this age group.

Adequate Intake for Ages 51–70 Years

The Committee recommended a doubling of the dietary intake of vitamin D for this age group. This was based on several studies that demonstrated the importance of increasing dietary intakes of vitamin D to maximize bone health. An evaluation of 333 ambulatory Caucasian women (mean age 58 ± 6 years) found that serum PTH concentrations were elevated in the winter (between March and May) in women consuming less than 5.5 μg (220 IU) day^{-1} of vitamin D. There was no seasonal variation in serum PTH concentrations when vitamin D intakes were greater than 5.5 μg (220 IU) day^{-1}. When bone loss was evaluated between seasons in women (62 ± 0.5 years) who had a usual vitamin D intake of 2.5 μg day^{-1}, a dietary supplement of 10 μg day^{-1} decreased spinal and hip-bone density loss.

Thus, since this age group does not obtain as much of its vitamin D from exposure to sunlight, it is at more risk for developing vitamin D deficiency. Therefore, in the absence of exposure to sunlight, there appears to be an increased requirement for vitamin D in this age group and an AI of 10 μg (400 IU) day^{-1} was recommended. This is twice the previous RDA for this age group.

Adequate Intake for Ages Greater Than 70 Years

There was strong evidence-based literature that demonstrated a decrease in the circulating concentration of 25(OH)D, and an increase in the PTH level correlated with an increased risk of skeletal fractures in both the hip and spine in this age group. Studies in both men and women supplemented with 10–25 μg day^{-1} of vitamin D demonstrated reduced bone resorption, increased bone mineral content, and a decrease in vertebral and nonvertebral fractures. Therefore, because this age group is even less likely to receive an adequate amount of exposure to sunlight than adults aged 50–70 years and because they have a reduced capacity to

produce vitamin D in their skin, it was recommended that men and women in this age group, regardless of exposure to sunlight, have an AI of 15 μg (600 IU) day^{-1}, which is three times the previous RDA for vitamin D for this age group.

Adequate Intake for Pregnancy and Lactation

Although there is an increase in the metabolism of 25(OH)D to 1,25$(OH)_2$D during the last trimester of pregnancy and during lactation there is nothing in the evidence-based literature to suggest that there is an increased vitamin D requirement for pregnant and lactating women. Therefore, it was recommended that the AI of vitamin D for pregnancy and lactation follow that recommended for their age group, i.e., 5 μg (200 IU)/day^{-1}. However, the 400 IU of vitamin D found in prenatal supplements was not considered to be excessive.

Healthy Vitamin D Intakes

Since the publication of these recommendations there have been a multitude of studies that suggest that the AIs for vitamin D are inadequate if there is no exposure to sunlight. In the absence of sunlight, children above 1 year and all adults need 1000 IU of vitamin D to maintain a healthy level of 25(OH)D (above 20 ng ml^{-1}) in their circulation.

Tolerable Upper Intake Levels and Vitamin D Intoxication

An excessive intake of vitamin D can lead to vitamin D intoxication. This is characterized by a marked increase in serum 25(OH)D that is usually greater than 375 nmol l^{-1} (150 ng ml^{-1}), and is associated with hypercalciuria and hypercalcemia. This can lead to soft tissue calcification and increased risk of kidney stones. The safe upper limit for vitamin D, as recommended by the Committee, is found in **Table 1**.

Vitamin D intoxication usually occurs when a person ingests more than 5000 IU of vitamin D daily for several months. A person does not need to be concerned about becoming vitamin D intoxicated if they take a multivitamin that contains 400 IU of vitamin D, drink a quart of milk that contains 400 IU of vitamin D, and are exposed to sunlight.

Rickets and Osteomalacia

J J B Anderson, University of North Carolina, Chapel Hill, NC, USA

Introduction

Rickets and osteomalacia, diseases of impaired mineralization of bone tissue that occur among infants/young children or during adulthood, result from nutritional deficiencies of vitamin D (cholecalciferol) and/or calcium. Rickets has more severe deformities of bones because of the continued growth of the skeleton, but osteomalacia, especially less severe disease, commonly coexists with osteoporosis in many older adults. The latter comorbidities have been increasing, at least in part, as a result of both low dietary intakes of vitamin D and calcium and insufficient skin production of vitamin D because of limited skin exposure to ultraviolet (UV) light. This problem is likely to be more widespread than currently acknowledged because of behavioral changes in technologically advanced societies.

The last few years have witnessed a resurgence of rickets and osteomalacia in the US and possibly in other technologically advanced nations. The prevalence of rickets in the US has occurred primarily among young children of color, i.e., African-Americans and Hispanics, after cessation of breastfeeding and the failure to provide adequate amounts of vitamin D-fortified milk. The prevalence of osteomalacia has been suspected to be increasing because of low serum 25-hydroxycholecalciferol (25HCC) measurements in several studies of adults. In addition, new recommendations for healthy 25-hydroxyvitamin D ($25(OH)D_3$) concentrations have emerged from interpretation of the results of studies assessing the sufficiency of vitamin D to meet requirements across the life cycle.

The terminology of the vitamin D metabolites has not changed, and relatively little new resulted from basic research on vitamin D or cholecalciferol skin biosynthesis and subsequent biotransformations in the liver and kidney (**Figure 1**). Understandings of the role of the hormonal form of vitamin D, 1,25-dihydroxyvitamin D ($1,25(OH)_2D_3$), in intestinal absorbing cells have been expanded. In addition, new information suggests that the consumption of dietary calcium at adequate levels may reduce the critical need for vitamin D for the maintenance of serum calcium concentration. New information is also emerging on the role of vitamin D in patients with chronic renal failure and in the prevention of colon cancer.

This article reviews vitamin D status and highlights new research findings on vitamin D.

Dietary Vitamin D Intakes and Low Vitamin D Status in the US

Vitamin D intakes have not been assessed in national surveys and only rarely in research investigations involving smaller sample sizes. The few studies that have estimated vitamin D intakes typically find them to be below recommended amounts, especially among the elderly and, more recently, among adults. In the US, at least, most experts think that both intakes are too low and exposures of skin to sunlight are inadequate.

Role of the Diet in Providing Vitamin D

The few sources of vitamin D consumed in the diets of North Americans are fortified milks, fortified ready-to-eat breakfast cereals, and fish. For infants and young children who develop rickets, it has been established that they consume little milk and fish, but some cereals. No supplements containing calcium and vitamin D are ingested. For adults and the elderly, similar low consumption patterns of vitamin D-rich foods exist. Therefore, evidence strongly supports low intake of vitamin D as a major determinant of rickets and osteomalacia.

Role of Skin Biosynthesis of Vitamin D

The other major determinant is poor skin exposure to sunlight, mainly to UV-B that is responsible for the conversion of 7-dehydrocholesterol to $25(OH)D_3$ in the dermis layer of the skin. In the US, inadequate exposure has become a major contributor over the last few decades because of concerns about skin cancer and because of increased indoor activities, including television and computers. (This poor dietary consumption and poor skin production of vitamin D seems to be paralleling the increase in overweight.) Because it is even more difficult to assess skin exposure for vitamin D synthesis, it has been extremely difficult to estimate with accuracy the additional need for dietary vitamin D. Seasonal variations yield wide swings or oscillations in skin production, depending on the position of the sun. For example, in the northern hemisphere, the highest skin production rates occur in the late spring, summer, and early autumn months (May to October), whereas in the southern hemisphere, November to April are the months of the highest

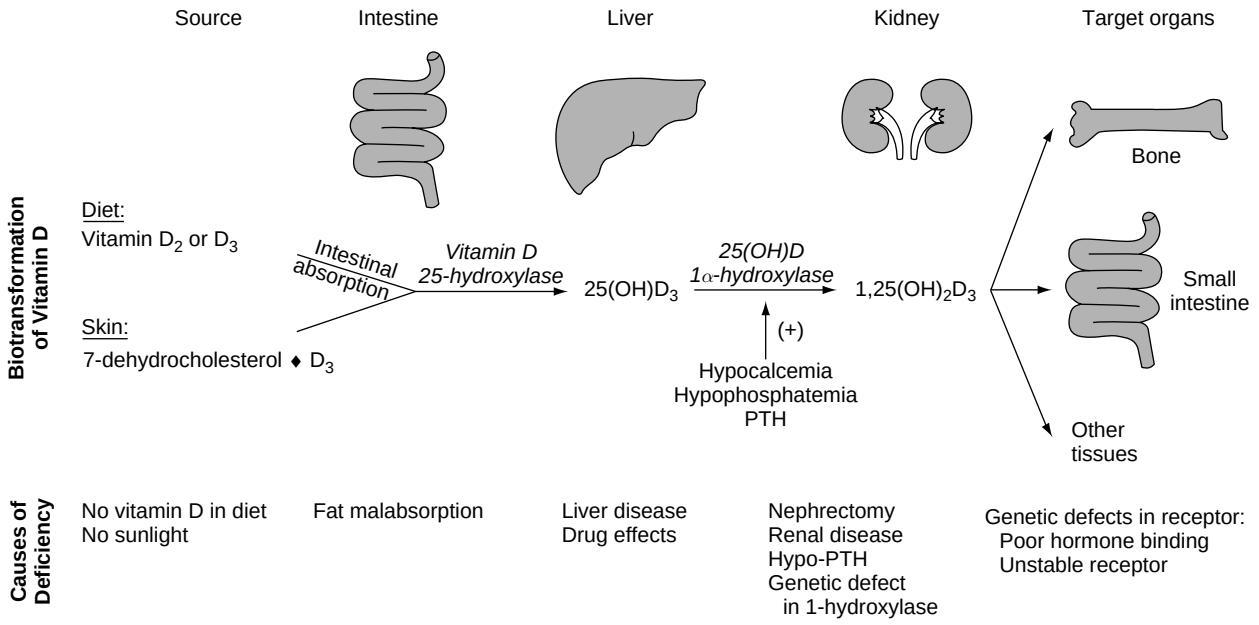

Figure 1 Causes of vitamin D deficiency. PTH, parathyroid hormone.

vitamin D production. Living near the equator extends these periods of optimal production. It is the winter months when low or even zero skin production occurs that are most problematic for the development of rickets or osteomalcia and, in the elderly, osteoporosis.

Vitamin D Recommendations

The current recommendations for consumption of vitamin D in the US are given in **Table 1**. The recommendations are defined as adequate intakes (AIs) rather than as recommended dietary allowances (RDAs) because insufficient data have been accumulated to determine estimated average requirements (EARs) across the life cycle. The AIs listed in **Table 1** are totally independent of skin production of vitamin D. Because of the uncertainty of knowing the amount of endogenous vitamin D, it is very difficult to determine, with accuracy, the amounts needed from the diet (see below).

Table 1 Recommended adequate intakes (AIs) of vitamin D in the US

Life stage group	*Age, years*	*AI, mcg/day*
Infants and Children	0–8	5
Males, Females	9–50	5
	51–70	10
	>70	15
Pregnancy	–	5
Lactation	–	5

From: Institute of Medicine, Food and Nutrition Board (1997) *Dietary Reference Intakes for Calcium, Phosphorus, Magnesium, Vitamin D, and Fluoride*. Washington, DC: National Academy Press.

Primary Causes and Abnormalities of Rickets and Osteomalacia

The primary cause of rickets and osteomalacia is vitamin D deficiency and the clinical characteristics of these diseases depend on age at onset. The biochemical patterns of too low a serum concentration of $25(OH)D_3$, however, remain quite similar (**Table 2**) even though the structural effects on the skeleton differ. One common microscopic feature of

Table 2 Characteristic clinical features and blood serum measurements in rickets and osteomalacia

Age	*Clinical features*	*Blood serum measurements*
Children	Skeletal deformations (rickets) Impaired growth Undermineralized bone	Hypocalcemia Hypophosphatemia Secondary hyperparathyroidism Low 25-hydroxyvitamin D Elevated alkaline phosphatase
Adults	Undermineralized bone (osteomalacia) Fractures	Hypocalcemia Hypophosphatemia Low 25-hydroxyvitamin D Elevated alkaline phosphatase Elevated osteocalcin[a]

[a]This finding has not been consistently reported.

the skeleton is that both rickets and osteomalacia have unmineralized bone matrix (osteoid), also known as widened osteoid seams.

In rare cases, e.g., in central Nigeria, rickets may occur despite elevated serum $25(OH)D_3$ concentrations. The rickets in these cases results from severely inadequate dietary calcium. It is likely that most cases of rickets result from a combination of insufficient skin biosynthesis and inadequate dietary intake of vitamin D.

Other biochemical changes include depressed serum concentrations of calcium and inorganic phosphate, largely because of insufficient intestinal absorption directly relating to too little of these ions in the usual diet. Serum alkaline phosphatase, especially bone-specific alkaline phosphatase, is elevated because of osteoblastic cell overproduction when these cells attempt to form new bone tissue.

Radiographic changes, the primary diagnostic evidence for many years, show widened growth plates of the long bones and reduced bone density (translucence) in rickets. In osteomalacia, unmineralization is evident and pseudofractures may be visible in nonweight-bearing bones.

Secondary Causes and Abnormalities of Rickets and Osteomalacia

The secondary causes of rickets and osteomalacia that result from vitamin D deficiency are illustrated in **Figure 1**. For example, in liver disease, serum concentrations of $25(OH)D_3$ are invariably too low, and in renal disease too little of the hormonal form of vitamin D, $1,25(OH)_2D_3$, is produced. Other causes relate to reduced cell receptor responsiveness to the hormone because of genetic mutations and, hence, inappropriate adaptations that normally contribute to conservation of calcium and/or phosphate ions.

Public Health Consequences of Vitamin D Deficiency

Despite the earlier belief that these classical defiency diseases had been eliminated, the surprising increase in incidence of rickets and osteomalacia places the burden on society to be ever more vigilant in assessing for vitamin D deficits. Two obvious explanations exist for the rise in vitamin D deficiency in the US: reduced consumption of vitamin D-fortified milks and reduced skin exposures to sunlight because of greater indoor activities. The deficit in vitamin D has possibly even greater consequences as the average age at death is extending in our populations. Low vitamin D intakes in later life, often coexisting with low dietary calcium, may increase the risk of osteoporotic fractures.

Supplements of vitamin D (400 IU or greater) are recommended for the elderly by health professionals in order to ensure adequate intakes, but even higher amounts are considered safe. The tolerable upper level of safety (UL) established in the US by the Institute of Medicine has been set at $50\,mg\,day^{-1}$ (equivalent to $2000\,IU\,day^{-1}$). Supplemental vitamin D becomes increasingly important as skin biosynthesis capability declines with age. Oral capsules of vitamin D containing up to 100 000 IU have been found to be safe and effective in reducing fractures. An alternative approach is injection of a depot of vitamin D ($\sim$200 000 IU) in the late autumn for slow release over the winter months when sunlight, especially UV-B, is limited or unavailable.

Rising Prevalence of Rickets

The increase in rickets in the US is occurring primarily in African-American and Hispanic children who have gone off breast-feeding and are not getting sufficient calcium and vitamin D in their diets. This problem has been more common in the southern US despite greater availability of sunlight. In large part, rickets is an educational issue that requires input from both medical and public health professionals.

Rising Prevalence of Osteomalacia

The increase in low serum $25(OH)D_3$ found in so-called ordinary adults in a hospital survey of surgical patients in Massachusetts opened the eyes of health authorities who did not expect to find such low blood concentrations, which indicate future osteomalacia and also osteoporosis. This evidence suggests that many adults in the US are not consuming adequate amounts of vitamin D and calcium in their usual patterns of food selection and that supplementation of these two nutrients is probably inadequate among adults. Low intakes among the elderly result from the same type of eating pattern, but typically with even lower caloric consumption (see below).

Life Cycle Changes in Vitamin D Production and Metabolism

Production of vitamin D by the skin typically declines during late adulthood or the early elderly period because of changes in the skin *per se*, i.e., reduction in thickness, reduction in circulating 7-dehydrocholesterol, and decline in the rate of conversion of 7-dehydrocholesterol to cholecalciferol. When these physiological decrements are combined

with less direct exposure to sun by the elderly, even in Florida, they have little opportunity to make the vitamin in their skin. Sun-screens and broad-brimmed hats and other protective clothing complete this scenario, which is aimed at preventing skin cancer.

Special Populations at Risk of Low Vitamin D Intakes and Low Status

Several at-risk subpopulations for poor vitamin D status have been identified. Except for migrant populations, these groups have already been mentioned previously.

The Elderly

Elderly individuals prefer to stay indoors and many are actually 'shut-ins' who have little opportunity for direct sun exposure (UV-B does not penetrate glass windows in rooms or solaria). The shut-ins are most likely to be deficient in vitamin D and calcium and at increased risk for fractures of the hip, especially with increasing age. They need supplementation on a daily basis with a calcium salt (~1000 mg of elemental calcium) plus vitamin D (400 IU or more) to counter not only hypovitaminosis D but also secondary hyperparathyroidism and possibly osteoporosis. Two large prospective trials have demonstrated efficacy of such therapy in reducing hip and other nonverteabral fractures.

Vegetarians

Vegans are at risk of low serum $25(OH)D_3$ and the pathologic changes mentioned above for the elderly unless they consume a supplement of vitamin D and calcium because plant foods are typically low in each nutrient. Fortification of plant foods, such as of soy milk, may overcome this concern.

Long-Term Breast-Fed Infants and Young Children of Dark Skin

Although breast-feeding is strongly recommended and lauded, the switching of infants from breast-milk to other beverages does not always include cows' milk or other calcium-rich drinks. In the southern US, this switching has led to a modest epidemic of rickets, which should not occur with our established knowledge about causation. Dark pigmentation reduces the efficiency of the skin to produce vitamin D and because many children with such skin coloration do not tolerate milk (lactose) well, they consume too little vitamin D and calcium. Supplementation and/or alternate food sources should easily correct these nutrient deficits.

Migrant Populations

Migration of dark-skinned people, especially Muslims, from the Middle East and other Asian nations to the UK and other Northern European nations has led to decreased skin production of vitamin D, especially in the winter months, and to reported cases of rickets and osteomalacia. Cultural practices, i.e., limited food selections and clothing that covers the bodies of women and children, contribute to the etiology of these diseases. Supplementation with calcium and vitamin D should prove effective in promoting bone health of affected individuals.

Excessive Consumption of Vitamin D and Toxic Effects

Because the hormonal form of vitamin D, 1,25DHCC, acts on the DNA in the genome, high intakes or excessive drug dosages of the vitamin lead to synthetic overexpression of proteins that contribute to toxic effects. In recent years, the amounts of vitamin D needed to cause toxic effects has been found to be considerably higher than previously thought; but caution is needed via monitoring of serum 25HCC to ensure that blood concentrations do not get too high. Concern is expressed here that excessive treatment of those with rickets or osteomalacia with high doses of vitamin D may result in toxicity.

Summary

The continuing discovery of low serum $25(OH)D_3$ concentrations among adults suggests that under-recognition of osteomalacia among adults and the elderly exists in the US and possibly in other technologically advanced nations. The hidden nature of the disease has resulted from poor diagnostic criteria; new criteria with lower cut-off points are under review. The surprising resurgence of rickets in the southern US has resulted from too little guidance by health professionals, poor nutrition knowledge of mothers, or other aspects, such as poverty. Correction of both rickets and osteomalacia can be simply achieved with vitamin D and calcium supplements and increased numbers of servings of calcium-rich foods. Public health agencies need to become more active in this regard.

Metabolism and Requirements

M G Traber, Oregon State University, Corvallis, OR, USA

Introduction

Vitamin E is the most potent fat-soluble antioxidant in human plasma. Although vitamin E was first discovered in 1922, its metabolic function remains an enigma. There are eight different molecular forms with vitamin E antioxidant activity, yet the body preferentially retains α-tocopherol. This preference for α-tocopherol has led the Food and Nutrition Board in its 2000 Dietary Reference Intakes (DRIs) for vitamin E to recommend that only α-tocopherol, not the other forms, meets human requirements for vitamin E. Moreover, only α-tocopherol is recognized by the hepatic α-tocopherol transfer protein (α-TTP). This protein regulates plasma α-tocopherol concentrations and genetic abnormalities in the protein (or its absence) leads to vitamin E deficiency in humans.

General Description and Scientific Name

Dietary components with vitamin E antioxidant activity include α-, β-, γ-, and δ-tocopherols and α-, β-, γ-, and δ-tocotrienols. These compounds all have a chromanol ring with a phytyl tail (tocopherols) or an unsaturated tail (tocotrienols) (**Figure 1**) and vary in the number of methyl groups on the chromanol ring: α-tocopherol or α-tocotrienol has three methyl groups, β- or γ- have two, and δ- tocopherol and δ-tocotrienol have one.

The naturally occurring form of α-tocopherol is called *RRR*-α-tocopherol; on labels it is called *d*-α-tocopherol and it is more formally known as 2,5,7,8-tetramethyl-2*R*-(4′*R*,8′*R*,12 trimethyltridecyl)-6-chromanol. At positions 2, 4′, and 8′of α-tocopherol are chiral carbon centers that are in the *R*-conformation in naturally occurring α-tocopherol, but theoretically can take on either the *R*- or the *S*-conformation. Position 2 is the most important for biologic activity. Therefore, the DRIs for vitamin E are given in milligrams of 2*R*-α-tocopherol (**Table 1** see below for discussion).

The chemical synthesis of α-tocopherol results in an equal mixture of eight different stereoisomers (*RRR, RSR, RRS, RSS, SRR, SSR, SRS, SSS*) or, more formally, 2,5,7,8-tetramethyl-2*RS*-(4′*RS*,8′*RS*,12 trimethyltridecyl)-6-chromanol. To indicate that synthetic α-tocopherol is a racemic mixture, it is called *all-rac*-α-tocopherol, or on labels, *dl*-α-tocopherol. The first letter of the three-letter combination is the 2 position; therefore, only half of the synthetic α-tocopherol is in the 'active' 2*R*-α-tocopherol conformation. **Table 2** lists the factors used to convert international units (IU) to milligrams. For example, if a vitamin E supplement is labeled 400 IU and it is *dl*-α-tocopheryl acetate, then 400 times 0.45 equals 180 mg 2*R*-α-tocopherol, but if it is labeled *d*-α-tocopheryl acetate, then 400 times 0.67 equals 268 mg 2*R*-α-tocopherol.

Vitamin E Supplements

Most vitamin E supplements and food fortificants contain *all rac*-α-tocopherol, but can contain mixtures of tocopherols or tocotrienols. Supplements often are sold as esters, which protect α-tocopherol from oxidation. These can be acetates, succinates, or nicotinates of α-tocopherol. Either the natural stereoisomer (*RRR*-α-tocopherol) or the synthetic (*all rac*-α-tocopherol) can be sold as an ester, e.g., *d*- or *dl*-α-tocopheryl acetate, respectively.

Dietary Vitamin E

Vitamin E can be readily obtained from food. Generally, the richest sources are vegetable oils. Wheat germ oil, safflower oil, and sunflower oil contain predominantly α-tocopherol, while soy and corn oils contain predominantly γ-tocopherol. All of these oils are polyunsaturated. Good sources of monounsaturated oils, such as olive or canola oils, also contain predominantly α-tocopherol. Whole grains and nuts are also good sources of vitamin E. Fruits and vegetables, although rich in water-soluble antioxidants, are not good sources of vitamin E.

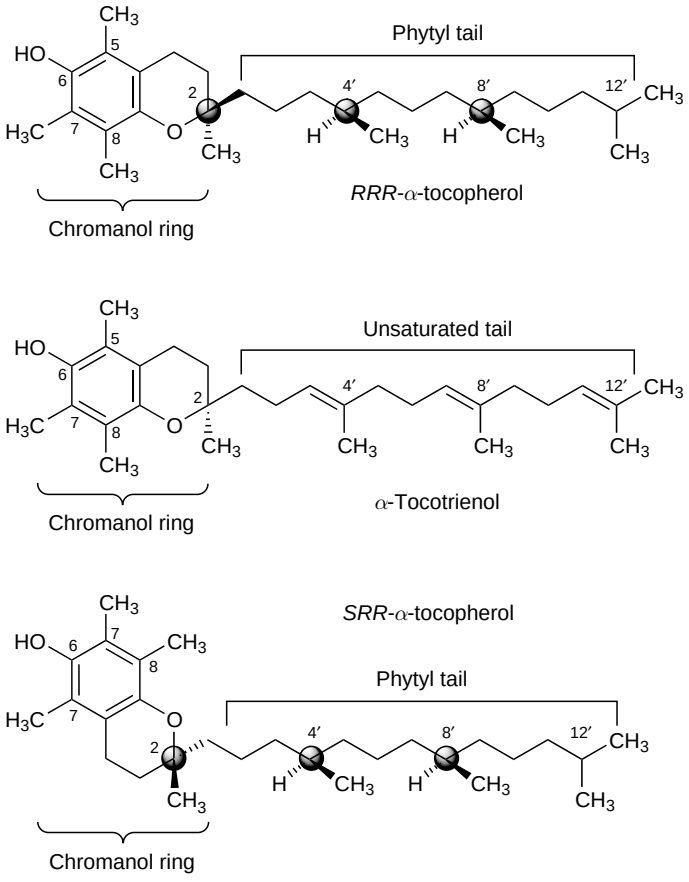

Figure 1 Structures of *RRR*-α-tocopherol, α-tocotrienol, and *SRR*-α-tocopherol.

α-Tocopherol equivalents

It is often assumed for the purpose of calculating vitamin E intakes from food in α-tocopherol equivalents (α-TEs) that γ-tocopherol can substitute for α-tocopherol with an efficiency of 10%. However, functionally γ-tocopherol is not equivalent to α-tocopherol and some caution should be used in applying α-TEs to estimates of α-tocopherol intakes when corn or soybean oils (hydrogenated vegetable oils) represent the major oils present in foods. These oils have high γ-tocopherol contents and if food tables reporting α-TEs are used to estimate dietary α-tocopherol, α-tocopherol intakes are overestimated. α-TEs are no longer recommended in the Food and Nutrition Board of the Institute of Medicine, National Academy of Sciences 2000 DRIs; only milligrams of α-tocopherol

Table 1 Estimated average requirements (EARs), recommended dietary allowances (RDAs), and average intakes (AIs) (mg day^{-1}) for α-tocopherol in adults and children

Lifestage	*EAR*	*RDA*	*AI*
0–6 months			4
7–12 months			6
1–3 years	5	6

and 2*R*-α-tocopherol (for synthetic vitamin E) should be included in estimates of vitamin E intakes.

Vitamin E Actions and Metabolism

Antioxidant Activity

Vitamin E is the most potent, lipid-soluble antioxidant in human plasma and tissues. Thus, vitamin E protects polyunsaturated fatty acids within membrane phospholipids and plasma lipoproteins. When a peroxyl radical forms in a membrane, it is 1000 times more likely to attack a vitamin E molecule than a polyunsaturated fatty acid (**Figure 2**). The hydroxyl group on the chromanol ring of vitamin E reacts with the peroxyl radical to form the corresponding lipid hydroperoxide and tocopheroxyl radical. Thus, vitamin E acts as a chain-breaking antioxidant, preventing further auto-oxidation of lipids.

The tocopheroxyl radical has a number of possible fates. It can react with another radical to form nonreactive products. Alternatively, it can be further oxidized to the tocopheryl quinone, a two-electron oxidation product. Another possibility is 'vitamin E recycling,' where the tocopheroxyl radical is restored to its unoxidized form by other antioxidants such as vitamin C, ubiquinol, or thiols, such as glutathione. This process will deplete these other antioxidants. For this reason, it is important to maintain a good intake of other dietary antioxidants.

Biologic Activity

Biologic activity is a term that has been used historically to indicate a disconnection between vitamin E antioxidant activities and *in vivo* activities. Observations in rodent experiments carried out in the 1930s formed the basis for determining the 'biologic activity' of vitamin E. Although the various vitamin E forms had somewhat similar structures and antioxidant activities, they differed in their abilities to prevent or reverse specific vitamin E deficiency symptoms (e.g., fetal resorption, muscular dystrophy, and encephalomalacia). α-Tocopherol with three methyl groups and a free hydroxyl group on the chromanol ring with the phytyl tail meeting the ring in the *R*-orientation (**Figure 1**) had the highest biological activity. This specific structural requirement for biological, but not chemical, activity is now known to be dependent upon the hepatic α-tocopherol transfer protein (α-TTP), as discussed below. α-TTP maintains plasma and, indirectly, tissue α-tocopherol concentrations.

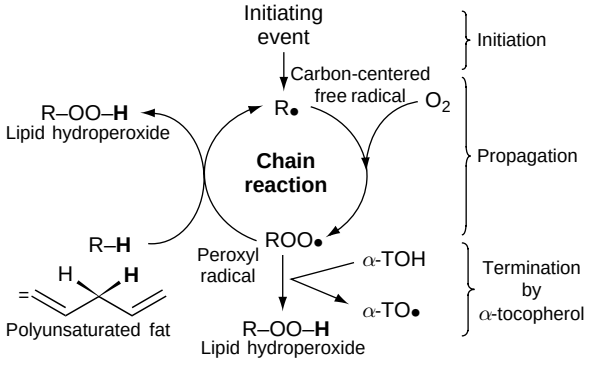

Figure 2 Vitamin E: chain-breaking antioxidant activity. Adapted from Burton GW and Traber MG (1990) Vitamin E: antioxidant activity, biokinetics, and bioavailability. *Annu Rev Nutr* **10**: 357–382.

Molecular Function

In addition to antioxidant activity, there are specific α-tocopherol-dependent functions that normalize cellular functions in a variety of cells. α-Tocopherol plays a critical role through its ability to inhibit the activity of protein kinase C, a central player in many signal transduction pathways. Specifically, it modulates pathways of platelet aggregation, endothelial cell nitric oxide production, monocyte/macrophage superoxide production, and smooth muscle cell proliferation. Regulation of adhesion molecule expression and inflammatory cell cytokine production by α-tocopherol has also been reported. However, most of the information in this area has been obtained from *in vitro* studies. More studies in humans are needed to relate α-tocopherol intakes and tissue concentrations to optimal tissue responses.

Vitamin E metabolism

α- and γ-tocopherols, as well as α-and γ-tocotrienols, are metabolized to α- and γ-CEHCs (2,5,7,8-tetramethyl- and 2,7,8-trimethyl-2-(2′ carboxyethyl)-6-hydroxychromans), respectively. About 1% of a dose of α-tocopherol or tocotrienol, or 5% of a dose of γ-tocopherol or tocotrienol is excreted in the urine as CEHCs. The importance of vitamin E metabolism in the regulation of vitamin E status is unknown.

Recommended Intake Levels

In 2000, the Food and Nutrition Board of the Institute of Medicine, National Academy of Sciences published the DRIs for vitamin C, vitamin E, selenium, and the carotenoids. Their recommendations for vitamin E appear in **Table 1**.

The requirements for vitamin E intakes are based primarily on long-term (5–7 years) depletion and repletion studies in humans. Serum α-tocopherol concentrations and corresponding hydrogen peroxide-induced erythrocyte hemolysis were determined

at various intervals. Serum concentrations necessary to prevent *in vitro* erythrocyte hemolysis in response known levels of vitamin E intake in subjects who had undergone experimentally induced vitamin E deficiency were used to determine estimated average requirements (EARs) for vitamin E. The recommended dietary allowances (RDAs) are levels that represent the daily α-tocopherol intakes required to ensure adequate nutrition in 95–97.5% of the population and are an overestimation of the level needed for most people in any given group.

Vitamin E Units

According to the US Pharmacopoeia (USP), 1 IU of vitamin E equals 1 mg *all rac* α-tocopheryl acetate, 0.67 mg *RRR*-α-tocopherol, or 0.74 mg *RRR*-α-tocopheryl acetate. These conversions were estimated on the relative 'biologic activities' of the various forms when tested in the rat assay for vitamin E deficiency, the fetal resorption assay. These USP IUs are currently used in labeling vitamin E supplements and food fortificants. It should be noted that the current RDA does not use vitamin E USP units but rather the recommendation for adults is set at 15 mg of *RRR*-α-tocopherol or 2*R*-α-tocopherols. Most foods contain *RRR*-α-tocopherol naturally, but foods that have been fortified with vitamin E contain the synthetic form, e.g., fortified breakfast cereals. If the amount of vitamin E on the label is given in international units, then this must be multiplied by the factors given in **Table 2** to obtain the amount of 2*R*-β-tocopherol.

Overdosage

In 2000 the Food and Nutrition Board of the Institute of Medicine, National Academy of Sciences recommended 1000 mg as an upper limit (UL) of all forms of α-tocopherol in supplements taken by adults 19 years and older, including pregnant and lactating women. ULs were set for children and adolescents by adjusting the adult limit on the basis of relative body weight. **Table 3** gives the α-tocopherol UL by age group. No UL was set for infants due to lack of adequate data. In 2000 the Food and Nutrition Board did recommend that food be the only source of vitamin E for infants. However, a UL of 21 mg day^{-1} was suggested for premature infants with birth weights of 1.5 kg, based on the adult UL.

Table 3 Upper limits (UL) for α-tocopherol intakes

Age (years)	*UL (mg day^{-1})*
1–3	200
4–8	300
9–13	600
14–18	800
>19	1000

Adapted from Food and Nutrition Board and Institute of Medicine (2000) *Dietary Reference Intakes for Vitamin C, Vitamin E, Selenium, and Carotenoids*. Washington, DC: National Academy Press.

Table 4 Upper limits (UL) reported in IU for α-tocopherol-containing supplements

	Number of IU that equal the UL
***all rac*-α-Tocopherol and esters**	
dl-α-Tocopheryl acetate	1100
dl-α-Tocopheryl succinate	1100
dl-α-Tocopherol	1100
***RRR*-α-Tocopherol and esters**	
d-α-Tocopheryl acetate	1500
d-α-Tocopheryl succinate	1500
d-α-Tocopherol	1500

Adapted from Food and Nutrition Board and Institute of Medicine (2000) *Dietary Reference Intakes for Vitamin C, Vitamin E, Selenium, and Carotenoids*. Washington, DC: National Academy Press.

The vitamin E UL was set for supplements because it is almost impossible to consume enough α-tocopherol-containing foods to achieve a daily 1000 mg intake for prolonged periods of time. The UL was defined for all forms of α-tocopherol, not just the 2*R* forms, because all of the forms in *all rac*-α-tocopherol are absorbed and delivered to the liver. The appropriate conversion factors are different from those shown in **Table 2**, and necessary to estimate the UL for supplements containing either *RRR*- or *all rac*-α-tocopherol supplements. The ULs given in IU are shown in **Table 4**. The UL for *RRR*-α-tocopherol is apparently higher because each capsule contains less α-tocopherol than those containing *all rac*-α-tocopherol.

Precautions and Adverse Reactions

High vitamin E intakes are associated with an increased tendency to bleed. It is not known if this is a result of decreased platelet aggregation caused by an inhibition of protein kinase C by α-tocopherol, some other platelet-related mechanism, or decreased clotting due to a vitamin K and E interaction causing abnormal blood clotting.

Individuals who are deficient in vitamin K or who are on anticoagulant therapy are at increased risk of uncontrolled bleeding. Patients on anticoagulant therapy should be monitored when taking vitamin E supplements to ensure adequate vitamin K intakes.

Adverse Effects of Drugs on Vitamin E Status

Drugs intended to promote weight loss by impairing fat absorption, such as Orlistat or sucrose polyester,

can also impair vitamin E and other fat-soluble vitamin absorption. Therefore, multivitamin supplementation is recommended with these drugs. Vitamin supplements should be taken with meals at times other than when these drugs are taken to allow adequate absorption of the fat-soluble vitamins.

Vitamin E Bioavailability

Absorption and Plasma Transport

Intestinal absorption of vitamin E is dependent upon normal processes of fat absorption. Specifically, both biliary and pancreatic secretions are necessary for solubilization of vitamin E in mixed micelles containing bile acids, fatty acids, and monoglycerides (**Figure 3**). α-Tocopheryl acetates (or other esters) from vitamin E supplements are hydrolyzed by pancreatic esterases to α-tocopherol prior to absorption. Following micellar uptake by enterocytes, vitamin E is incorporated into chylomicrons and secreted into the lymph. Once in the circulation, chylomicron triglycerides are hydrolyzed by lipoprotein lipase. During chylomicron catabolism in the circulation, vitamin E is nonspecifically transferred both to tissues and to other circulating lipoproteins.

It is not until the vitamin E-containing chylomicrons reach the liver that discrimination between the various dietary vitamin E forms occurs. The hepatic α-TTP preferentially facilitates secretion of α-tocopherol, specifically *2R*-α-tocopherols, and not other tocopherols or tocotrienols from the liver into the plasma in very low-density lipoproteins (VLDLs). In the circulation, VLDLs are catabolized to low-density lipoproteins (LDL are also known as the 'bad cholesterol' because high LDL levels are associated with increased risk of heart disease). During this lipolytic process, all of the circulating lipoproteins become enriched with α-tocopherol.

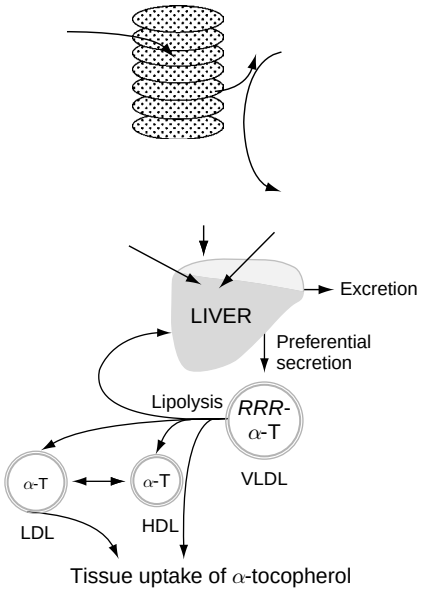

Figure 3 Intestinal vitamin E absorption and plasma lipoprotein transport. (Adapted from Traber MG (1998) Vitamin E. In: Shils ME, Olson JA, Shike M, and Ross AC (eds.) *Modern Nutrition in Health and Disease,* pp. 347–362. Baltimore: Williams & Wilkins.)

There is no evidence that vitamin E is transported in the plasma by a specific carrier protein, but rather it is nonspecifically transported in lipoproteins. An advantage of vitamin E transport in lipoproteins is that easily oxidizable lipids are protected by the simultaneous transport of this lipid-soluble antioxidant. Similarly, delivery of vitamin E to tissues is dependent upon lipid and lipoprotein metabolism. Thus, as peroxidizable lipids are taken up by tissue, the tissues simultaneously acquire a lipid-soluble antioxidant.

Plasma Concentrations, Kinetics, and Tissue Delivery

Plasma α-tocopherol concentrations in normal humans range from 11 to 37 $\mu mol\,l^{-1}$. When plasma lipids are taken into account the lower limits of normal are 1.6 µmol α-tocopherol/mmol lipid or 2.5 µmol α-tocopherol/mmol cholesterol. α-Tocopherol is transported in plasma lipoproteins, so if lipid concentrations are extraordinarily high or low, then correction for lipid levels are helpful to determine adequacy of vitamin E status. Additionally, α-tocopherol concentrations in erythrocytes, adipose tissue, or even peripheral nerves have been used to assess vitamin E status.

The apparent half-life of *RRR*-α-tocopherol in plasma of normal subjects is approximately 48 h, while that of *SRR*-α-tocopherol or γ-tocopherol is only 15 h.

Vitamin E is delivered to tissues by three mechanisms: transfer from triglyceride-rich lipoproteins during lipolysis; as a result of tissue lipoprotein uptake by various receptors that mediate lipoprotein uptake; and as a result of vitamin E exchange between lipoproteins or tissues. The regulation of tissue vitamin E is not well understood, but α-tocopherol is the predominant form in tissues as a result of its dominance in plasma.

Human Vitamin E Deficiency

Vitamin E deficiency was first described in children with fat malabsorption syndromes, principally abetalipoproteinemia, cystic fibrosis, and cholestatic liver disease. Subsequently, humans with severe vitamin E deficiency with no known defect in lipid or

lipoprotein metabolism were described to have a defect in the α-TTP gene.

Erythrocyte fragility, hemolysis, and anemia were described as vitamin E deficiency symptoms in various animals fed diets devoid of vitamin E. Additionally, studies in experimental animals have shown that a deficiency of both selenium (a required component of glutathione peroxidases) and vitamin E causes a more rapid and severe onset of debilitating deficiency symptoms. Hypothetically, a deficiency of both vitamins E and C should also cause more severe antioxidant deficiency symptoms, but most animals make their own vitamin C, so this interaction has not been unequivocally demonstrated in humans or animals.

In contrast to experimental vitamin E deficiency in rodents, in humans the major vitamin E deficiency symptom is a peripheral neuropathy characterized by the degeneration of the large caliber axons in the sensory neurons.

Vitamin E deficiency occurs only rarely in humans and almost never as a result of inadequate vitamin E intakes, therefore, interactions with other nutrients have not been well studied. There have been reports of vitamin E deficiency symptoms in persons with protein-calorie malnutrition. Vitamin E deficiency does occur as a result of genetic abnormalities in α-TTP and as a result of various fat malabsorption syndromes. Vitamin E supplementation halts the progression of the neurologic abnormalities caused by inadequate nerve tissue α-tocopherol and, in some cases, has reversed them.

Patients with these disorders require daily pharmacologic vitamin E doses for life to overcome the mechanisms leading to deficiency. Generally, patients with 'ataxia with vitamin E deficiency' are advised to consume 1000 mg *RRR*-α-tocopherol per day in divided doses, patients with abetalipoproteinemia 100 mg per kg body weight, and cystic fibrosis sufferers 400 mg day^{-1}. However, patients with fat malabsorption due to impaired biliary secretion generally do not absorb orally administered vitamin E. These patients are treated with special forms of vitamin E, such as α-tocopheryl polyethylene glycol succinate, that spontaneously form micelles, obviating the need for bile acids.

Chronic Disease Prevention

The frequency of human vitamin E deficiency is very rare. In individuals at risk, it is clear that vitamin E supplements should be recommended to prevent deficiency symptoms. What about vitamin E supplement use in normal individuals? Dietary changes such as decreasing fat intakes, substituting fat-free foods for fat-containing ones, and increased reliance on meals away from the home have resulted in decreased consumption of α-tocopherol-containing foods. Therefore, intakes of the vitamin E RDA of 15 mg α-tocopherol, may be difficult. Special attention to consuming nuts, seeds, and whole grains will improve α-tocopherol intakes; alternatively, multivitamin pills can be consumed.

Importantly, vitamin E's potential role in preventing or ameliorating chronic diseases associated with oxidative stress leads us to ask whether vitamin E supplements might be beneficial. For many vitamins, when 'excess' amounts are consumed, they are excreted and provide no added benefits. Antioxidant nutrients may, however, be different. Heart disease and stroke, cancer, chronic inflammation, impaired immune function, Alzheimer's disease – a case can be made for the role of oxygen free radicals in the etiology of all of these disorders, and even in aging itself. Do antioxidant nutrients counteract the effects of free radicals and thereby ameliorate these disorders? And, if so, do large antioxidant supplements have beneficial effects beyond 'required' amounts? The 2000 Food and Nutrition Board and Institute of Medicine DRI Report on Vitamin C, Vitamin E, Selenium, and Carotenoids stated that there was insufficient proof to warrant advocating supplementation with antioxidants. But, they also stated that the hypothesis that antioxidant supplements might have beneficial effects was promising. This remains a very controversial area in vitamin E research.

Physiology and Health Effects

P A Morrissey and M Kiely, University College Cork, Cork, Ireland

In 1922, Evans and Bishop discovered a fat-soluble dietary constituent that was essential for the prevention of fetal death and sterility in rats accidentally fed a diet containing rancid lard. This was originally called 'factor X' and 'antisterility factor' but was later named vitamin E. Subsequently, the multiple nature of the vitamin began to appear when two compounds with vitamin E activity were isolated and characterized from wheat germ oil. These compounds were designated α- and β-tocopherol, derived from the Greek 'tokos' for childbirth, 'phorein' meaning to bring forth, and 'ol' for the alcohol portion of the molecule. Later, two additional tocopherols, γ- and δ-tocopherol, as well as four tocotrienols were isolated from edible plant oils. After the initial discovery, more than 40 years passed before it was proved that vitamin E deficiency could cause disease in humans and was associated with antioxidant functions in cellular systems. It took another 25 years before the non-antioxidant properties of the vitamin were highlighted.

This article reviews the chemistry of the tocopherols; their dietary sources, absorption, transport, and storage; and their metabolic function. In addition, the potential role of dietary or supplemental tocopherol intake in the prevention of chronic disease and possible mechanisms for observed protective effects are discussed. Finally, a summary of the assessment of tocopherol status in humans, intake requirements, and an overview of the safety of high intakes is provided.

Chemistry

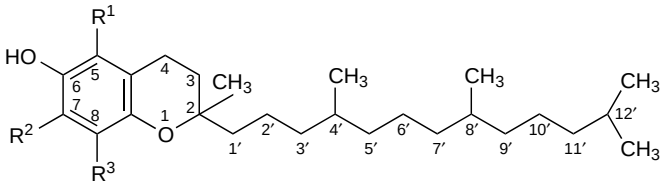
The chemistry of vitamin E is rather complex because there are eight structurally related forms—four tocopherols (α, β, γ, and δ) and four tocotrienols (α, β, γ, and δ)—that are synthesized from homogentisic acid and isopentenyl diphosphate in the plastid envelope of plants. The structures of α-, β-, γ-, and δ-tocopherols are shown in **Figure 1**. α-Tocopherol is methylated at C5, C7, and C8 on the chromanol ring, whereas the other homologs (β, γ, and δ) have different degrees of methylation (**Figure 1**). Tocopherols have a saturated phytyl side chain attached at C2 and have three chiral centers that are in the R configuration at positions C2, C4^1, and C8^1 in the naturally occurring forms, which are given the prefix 2R, 4^{1}R, and 8^{1}R (designated RRR). The members of the tocotrienols are unsaturated at C3^1, C7^1, and C11^1 in the isoprenoid side chain and possess one chiral center at C2 in addition to two sites of geometric isomerism at C3^1 and C7^1. Vitamin E biological activity is expressed as mg RRR-α-tocopherol equivalents (α-TE) whenever possible. The activity of RRR-α-tocopherol is 1. The activities of RRR-β-, RRR-γ-, and RRR-δ-tocopherol are 0.5, 0.1, and 0.03, respectively.

Dietary Sources

The composition and content of the different tocopherol components in plant tissue vary considerably, ranging from extremely low levels found in potato tubers to high levels found in oil seeds. α-Tocopherol is the predominant form in photosynthetic tissues and is mainly localized in plastids. The particular enrichment in the chloroplast membranes is probably related to the ability of tocopherols to quench or to scavenge reactive oxygen species and lipid peroxy radicals by physical or chemical means. In this way, the photosynthetic apparatus can be protected from oxygen toxicity and lipid peroxidation. In nonphotosynthetic tissues, γ-tocopherol frequently predominates and can be involved in the prevention of autoxidation of polyunsaturated fatty acids.

Most of the tocopherol content of wheat germ, sunflower, safflower, and canola and olive oils is in the form of α-tocopherol, and these oils contain approximately 1700, 500, 350, 200, and 120 mg α-TE kg^{-1}, respectively. Vegetable oils (e.g., corn, cottonseed, palm, soybean, and sesame) and nuts (e.g., Brazil nuts, pecans, and peanuts) are rich sources of γ-tocopherol. Corn and soybean oils contain 5–10 times as much γ-tocopherol as α-tocopherol-rich sources of γ-tocopherol, and each contains approximately 200 mg α-TE kg^{-1}. Because of the widespread use of these plant products, γ-tocopherol is considered to represent $\sim$70% of the vitamin E consumed in the typical US diet. The level of vitamin E in nuts ranges from 7 mg α-TE kg^{-1} in coconuts to 450 mg α-TE kg^{-1} in almonds. Cereals are moderate sources of vitamin E, providing between 6 (barley) and 23 mg α-TE kg^{-1} (rye). Fresh fruit and vegetables generally contain approximately 1–10 mg α-TE kg^{-1}. The concentration of vitamin E (α-tocopherol is the predominant form) in animal products is usually low, but these may be significant dietary sources because of their high consumption.

Mean dietary intakes of 6.3–13.0 mg α-TE per day have been reported in various European and US population studies. Data from the Third National Health and Nutrition Examination Survey



Compound	R^1	R^2	R^3
α-Tocopherol	CH_3	CH_3	CH_3
β-Tocopherol	CH_3	H	CH_3
γ-Tocopherol	H	CH_3	CH_3
δ-Tocopherol	H	H	CH_3

Figure 1 The four major forms of vitamin E (α-, β-, γ-, and δ-tocopherols) differ by the number and positions of methyl groups on the chromonol ring. In α-tocopherol, the most biologically active form, the chromonol ring is fully methylated. In β- and γ-tocopherols, the ring contains two methyl groups, whereas δ-tocopherol is methylated in one position. The corresponding tocotrienols have the same structural arrangement except for the presence of double bonds on the isoprenoid side chain of $C3^1$, $C7^1$, and $C11^1$.

(NHANES III) (1988–1994) in the United States indicate a median total intake (including supplements) of α-TE of 12.9 mg day^{-1} and a median intake from food only of 11.7 mg day^{-1} in men aged 31–50 years. In women in this age range, the median total intake (including supplements) of α-TE was 9.1 mg day^{-1} and the median intake from food only was 8.0 mg day^{-1}. In the United States, fats and oils used in spreads, etc. contribute 20.2% of the total vitamin E intake; vegetables, 15.1%; meat, poultry, and fish, 12.6%; desserts, 9.9%; breakfast cereals, 9.3%; fruit, 5.3%; bread and grain products, 5.3%; dairy products, 4.5%; and mixed main dishes, 4.0%.

The North/South Ireland Food Consumption Survey, published in 2001, reported that the median daily intake of vitamin E from all sources was 6.3 mg in men and 6.0 mg in women aged 18–64 years. The largest contributors of vitamin E to the diet were vegetables and vegetable dishes (18.9%) and potatoes and potato products (12.4%), most likely as a result of the oils used in composite dishes. Nutritional supplements contributed 5.5% of the vitamin E intake in men and 11.9% in women overall. In the subgroup that regularly consumed nutritional supplements (23% of total), vitamin E was the nutrient most frequently obtained in supplemental form in men (78%) and women (73%). In these people, supplements made a larger contribution to total vitamin E intakes than did food.

Absorption Metabolism and Excretion

Because of its hydrophobicity, vitamin E requires special transport mechanisms in the aqueous environment of plasma, body fluids, and cells. In humans, vitamin E is taken up in the proximal part of the intestine depending on the amount of food lipids, bile, and pancreatic esterases that are present. It is emulsified together with the fat-soluble components of food. Lipolysis and emulsification of the formed lipid droplets then lead to the spontaneous formation of mixed micelles, which are absorbed at the brush border membrane of the mucosa by passive diffusion. Both α- and γ-tocopherol and dietary fat are taken up without preference by the intestine and secreted in chylomicron particles together with triacylglycerol and cholesterol (**Figure 2**). The nearly identical incorporation of α- and γ-tocopherol in chylomicrons after supplementation with equal amounts of the two tocopherols indicates that their absorption is not selective (**Figure 2**). The chylomicrons are stored as secretory granula and eventually excreted by exocytosis to the lymphatic compartment, from which they reach the bloodstream via the *ductus thoracicus*. The exchange between the apolipoproteins of the chylomicrons (types AI, AII, and B_{48}) and high-density lipoprotein (HDL) (types C and E) triggers the intravascular degradation of the chylomicrons to remnants by the endothelial lipoprotein lipase (LPL) and is a prerequisite for the hepatic uptake of tocopherols (**Figure 2**). During LPL-mediated catabolism of chylomicron particles, some of the chylomicron-bound vitamin E appears to be transported and transferred to peripheral tissues, such as muscle, adipose, and brain (**Figure 2**). The formation of remnants favors the rapid uptake of the tocopherols via the hepatic receptors for apo-E and apo-B.

The chylomicron remnants are subsequently taken up by the liver, where α-tocopherol is preferentially

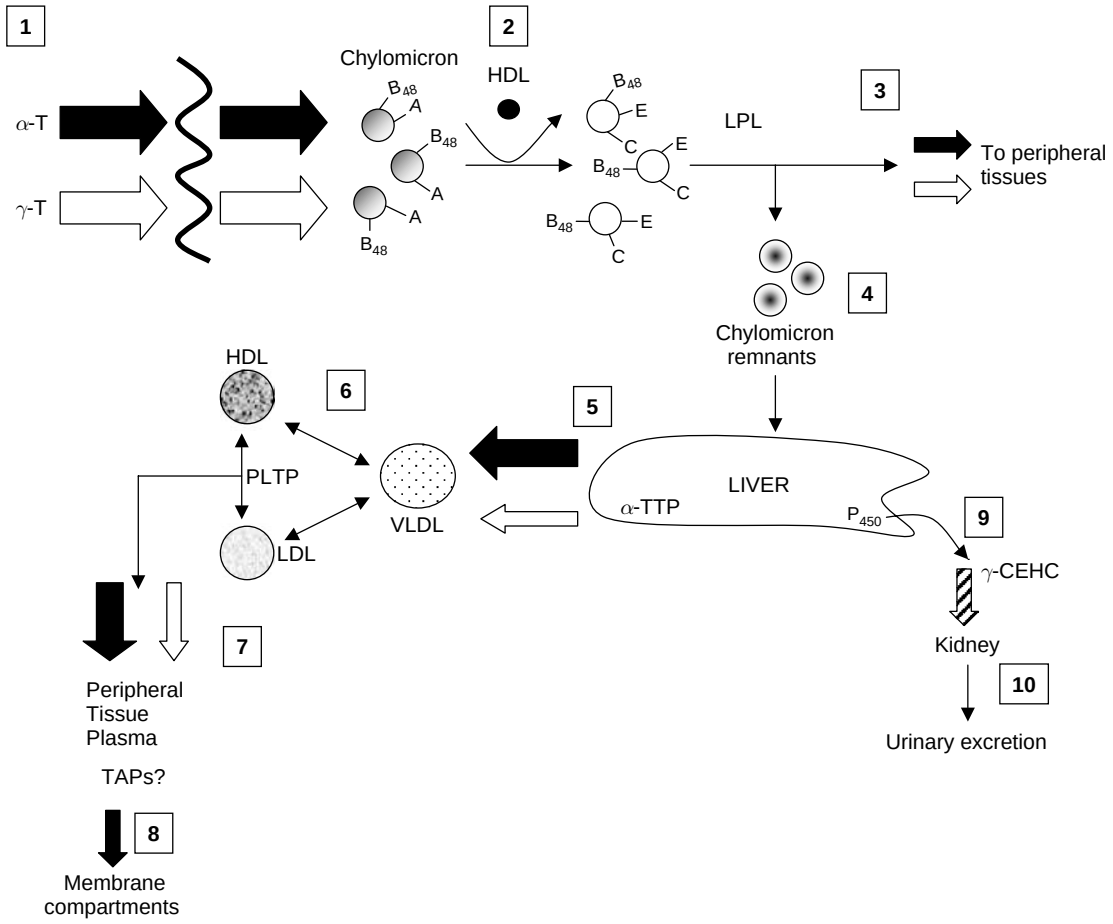


Figure 2 Absorption, transport, and metabolism of α-tocopherol (α-T) and γ-tocopherol (γ-T) in peripheral tissues. 1: Both α-T and γ-T are absorbed without preference by the intestine along with lipid and reassembled into chylomicrons. 2: Exchange between apolipoproteins of the chylomicrons (types AI, AII, and B_{48}) and high-density lipoprotein (HDL) (types C and E) occurs. 3: Chylomicrons are degraded to remnants by lipoprotein lipase (LPL) and some α-T and γ-T are transported to peripheral tissues. 4: The resulting chylomicron remnants are then taken up by the liver. 5: In the liver, most of the remaining α-T, but only a small fraction of γ-T, is reincorporated in nascent very low-density lipoproteins (VLDLs) by α-tocopherol transfer protein (α-TTP). 6: Plasma phospholipid transfer protein (PLTP) facilitates the exchange of tocopherol between HDL and LDL for delivery to tissues. 7: Plasma tocopherols are delivered to tissues by LDL and HDL. 8: Tocopherol-associated proteins (TAPs) probably facilitate intracellular tocopherol transfer between membrane compartments. 9: Substantial amounts of γ-T are degraded by a cytochrome P450-mediated reaction to 2,7,8-trimethyl-2-(β-carboxyethyl-6-hydroxychroman (γ-CEHC). 10: γ-CEHC is excreted into urine. Adapted from Azzi A and Stocker A (2000) Vitamin E: Non-antioxidant roles. *Progress in Lipid Research* **39**: 231–255; and from Jiang Q, Christen S, Shigenaga MK and Ames BN (2001) γ-Tocopherol, the major form of vitamin E in the US diet, deserves more attention. *American Journal of Clinical Nutrition* **74**: 714–722.

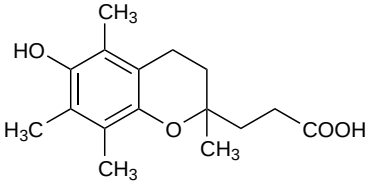
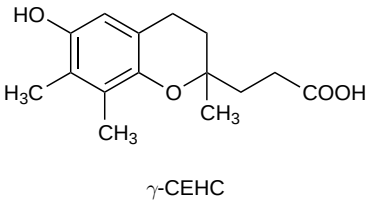
incorporated into nascent very low-density lipoprotein (VLDL) by a specific 32-kDa α-tocopherol transfer protein (α-TTP), which enables further distribution of α-tocopherol to peripheral cells (**Figure 2**). α-TTP is mainly expressed in the liver, in some parts of the brain, in the retina, in low amounts in fibroblasts, and in the placenta. α-TTP possesses stereospecificity as well as regiospecificity toward the most abundant isomer of vitamin E, (RRR)-α-tocopherol. The sorting process does not tolerate alteration at C2. As a consequence of the selective transfer mechanism, major parts of the natural homologs and nonnatural isomers of α-tocopherol are excluded from the plasma and secreted with the bile. Relative affinities of tocopherols for α-TTP are as follows: α-tocopherol, 100; β-tocopherol, 38; γ-tocopherol, 9; and δ-tocopherol, 2. A 75-kDa plasma phospholipid transfer protein (PLTP), which is known to catalyze the exchange of phospholipids and other amphipatic compounds between lipid structures, has been shown to facilitate the exchange of α-tocopherol from VLDL to HDL and LDL for further delivery to tissues (**Figure 2**).

A family of cellular tocopherol-associated proteins (TAPs) with the ability to bind and redistribute α-tocopherol has been identified. TAPs bind to α-tocopherol but not to other isomers of tocopherol. Present in all cells, TAPs may be specifically involved in intracellular α-tocopherol movement, for example, between membrane compartments and plasma membranes, or in optimizing the α-tocopherol content of membranes.

γ-Tocopherol appears to be mainly degraded to its hydrophilic 3′-carboxychromanol metabolite, 2,7,8-trimethyl-2-(β-carboxyethyl)-6-hydroxychroman (γ-CEHC) (**Figure 3**), and excreted in the urine. The mechanism of γ-tocopherol metabolism involves terminal cytochrome P450 (CYP)-mediated ω-hydroxylation of the tocopherol phytyl side chain, oxidation to the corresponding terminal carboxylic acid, and sequential removal of two- or three-carbon moieties by β-oxidation, ultimately yielding the hydrophilic 3′-carboxychromanol metabolite of the parent tocopherol that is excreted in the urine. Functional analysis of several recombinant human liver P450 enzymes revealed that tocopherol ω-hydroxylase activity was associated only with the cytochrome P450 isoform 4F2 (CYP4F2). Kinetic analysis of the tocopherol ω-hydroxylase activity in recombinant human CYP4F2 microsomal systems revealed similar K_m values (37 and 21 μM) but notably different V_{max} values (1.99 vs 0.16 nmol/nmol of P450/min) for γ- and α-tocopherol, respectively. The data suggest a role for the CYP-mediated ω-hydroxylase pathway in the preferential physiological retention of α-tocopherol and elimination of γ-tocopherol. In nonsupplemented individuals, a substantial proportion of the estimated daily intake of γ-tocopherol is excreted in human urine as its γ-CEHC metabolite, but a much smaller proportion of α-tocopherol is excreted as 2,5,7,8-tetramethyl-2-(β-carboxyethyl)-6-hydroxychroman (α-CEHC) (**Figure 3**). α-CEHC is excreted in large amounts only when the daily intake of α-tocopherol exceeds 150 mg or plasma concentrations of α-tocopherol are above a threshold of 30–40 μmol l^{-1}. Even then, urinary excretion of α-CEHC is lower than that of γ-CEHC.



α-CEHC



γ-CEHC

Figure 3 Chemical structures of 2,5,7,8-tetramethyl-2-(β-carboxyethyl)-6-hydroxychroman(α-CEHC) and 2,7,8-trimethyl-2-(β-carboxyethyl)-6-hydroxychroman (γ-CEHC).

It is likely that it is the capacity of α-TTP rather than the plasma α-tocopherol concentration that determines α-tocopherol degradation. Overall, hepatic catabolism of γ-tocopherol appears to be responsible for the relatively low preservation of γ-tocopherol in plasma and tissues, whereas α-TTP-mediated α-tocopherol transfer plays a key role in the preferential enrichment of α-tocopherol in most tissues. Supplementation with α-tocopherol depletes plasma and tissue γ-tocopherol levels. This is likely due to the preferential affinity of α-TTP for α-tocopherol. However, the depletion of γ-tocopherol may also occur because an increase in α-tocopherol may further reduce the incorporation of γ-tocopherol into VLDL, which leaves more γ-tocopherol to be degraded by CYP. On the other hand, γ-tocopherol supplementation may spare α-tocopherol from being degraded.

Plasma (RRR)-α-tocopherol incorporation is a saturable process. Plasma concentrations of α-tocopherol reach a threshold of 30–40 μmol l^{-1} despite supplementation with high levels (400 mg or greater) of (RRR)-α-tocopherol. Dose–response studies showed that the limitation in plasma α-tocopherol concentration appears to be a result of rapid replacement of circulating with newly absorbed α-tocopherol. Kinetic analysis has shown that the entire plasma pool of α-tocopherol is replaced daily. The highest concentrations of α-tocopherol in the body are in adipose tissues and adrenal glands. Adipose tissues are also a major store of the vitamin, followed by liver and skeletal muscle. The rate of uptake and turnover of α-tocopherol by different tissues varies greatly. Uptake is most rapid into lungs, liver, spleen, kidney, and red cells (in rats, $t_{1/2} < 15$ days) and slowest in brain, adipose tissues, and spinal cord ($t_{1/2} < 30$ days). Likewise, depletion of α-tocopherol from plasma and liver during times of dietary deficiency is rapid, whereas adipose tissue, brain, spinal cord, and neural tissues are much more difficult to deplete.

The major route for the elimination of tocopherol from the body is via the feces. Fecal tocopherol arises from incomplete absorption, secretion from mucosal cells, and biliary excretion. Excess

α-tocopherol as well as forms of vitamin E not preferentially used, such as synthetic racemic isomer mixtures, or γ-tocopherol are eliminated during the process of nascent VLDL secretion in the liver and are probably excreted into bile. In addition to the urinary excretion of γ-tocopherol as γ-CEHC, biliary excretion is an alternative route for elimination of excess γ-tocopherol. This is confirmed by the fact that the ratio of γ- to α-tocopherol in bile is sevenfold higher than in plasma.

Tocopherols as Antioxidants

Under normal physiological conditions, cellular systems are incessantly challenged by stressors arising from both internal and external sources. The most important potential stressors are reduced derivatives of oxygen, which are classified as reactive oxygen species (ROS), and include the superoxide anion ($O_2^{\cdot-}$), hydroxyl radical ($^{\cdot}OH$), and oxygen-centered radicals of organic compounds (peroxyl ($ROO^{\cdot}$) and alkoxyl ($RO^{\cdot}$)) together with other nonradical reactive compounds, such as hydrogen peroxide (H_2O_2). In addition, reactive nitrogen species such as nitric oxide ($NO^{\cdot}$), nitrogen dioxide ($NO_2^{\cdot}$), peroxynitrite ($ONOO^-$), and hypochlorous acid are involved.

Cellular systems have evolved a powerful and complex antioxidant defence system to limit inappropriate exposure to these stressors. α-Tocopherol is quantitatively the most important chain-breaking antioxidant in plasma and biological membranes. The antioxidant activities of chain-breaking antioxidants are determined primarily by how rapidly they scavenge peroxyl radicals, thereby preventing the propagation of free radical reactions. When the chromanol phenolic group of α-tocopherol (TOH) encounters a $ROO^{\cdot}$ it forms hydroperoxide (ROOH), and in the process a tocopheroxyl radical ($TO^{\cdot}$) is formed:

$$TOH + ROO^{\cdot} \xrightarrow{k_1} ROOH + TO^{\cdot}$$

The rate constant (k_1) for hydrogen abstraction from α-tocopherol is $2.35 \times 10^6\,M^{-1}\,s^{-1}$, which is higher than that for the other tocopherols and related phenols. Because the rate constant (k_2) for the chain propagation reaction between $ROO^{\cdot}$ and an unsaturated fatty acid (RH) ($ROO^{\cdot} + RH \rightarrow ROOH$) is much lower than k_1, at approximately $10^2\,M^{-1}\,s^{-1}$ α-tocopherol outcompetes the propagation reaction and scavenges the $ROO^{\cdot}$ $\sim 10^4$ times faster than RH reacts with $ROO^{\cdot}$. Thus, the kinetic properties of antioxidants, in particular α-tocopherol, require that only relatively small concentrations are required for them to be effective. The concentration of α-tocopherol in biological membranes is approximately 1 mol per 1000–2000 mol phospholipids (i.e., $\sim 1{:}10^3$). Ascorbic acid can reduce the tocopheroxyl radical ($TO^{\cdot}$) to its native state, and it has been concluded that part of the reason why low concentrations of α-tocopherol are such efficient antioxidants in biological systems is because of this capacity to be regenerated by intracellular reductants such as ascorbic acid.

The heteroxyclic chromanol ring of α-tocopherol has an optimised structure for resonance stabilization of the unpaired electron of the α-tocopheroxyl radical, and the electron-donating substituents (e.g., the three methyl groups) increase this effect. Because γ-tocopherol lacks one of the electron-donating methyl groups on the chromanol ring, it is somewhat less potent in donating electrons than α-tocopherol and is thus a slightly less powerful antioxidant. However, the unsubstituted C5 position on γ-tocopherol allows it to trap lipophilic electrophiles such as peroxynitrite, thereby protecting macromolecules from oxidation.

Vitamin E Deficiency

Vitamin E deficiency is seen rarely in humans. However, there may be a risk of vitamin E deficiency in premature infants because the placenta does not transfer α-tocopherol to the fetus in adequate amounts. When it occurs in older children and adults, it is usually a result of lipoprotein deficiencies or a lipid malabsorption syndrome. These include patients with abetalipoproteinemia or homozygous hypobetalipoproteinemia, those with cholestatic disease, and patients receiving total parenteral nutrition. There is also an extremely rare disorder in which primary vitamin E deficiency occurs in the absence of lipid malabsorption. This disorder is a rare autosomal recessive neurodegenerative disease caused by mutations in the gene for α-TTP. This disorder is known as ataxia with vitamin E deficiency (AVED). Patients with AVED have extraordinary low plasma vitamin E concentrations ($<5\,\mu g\,ml^{-1}$) and have an onset between 4 and 18 years, with progressive development of peripheral neuropathy, spinocerebellar ataxia, dysarthria, the absence of deep tendon reflexes, and vibratory and proprioceptive sensory loss. Patients with an α-TTP defect have enhanced urinary excretion of α-CEHC despite having much lower plasma α-tocopherol concentrations than healthy subjects. Therapeutic and prophylactic vitamin E supplementation (up to $2000\,mg\,day^{-1}$) prevents the onset of the disease before irreversible neurological damage develops.

Tocopherols and Low-Density Lipoprotein Modification

The hypothesis that oxidative stress plays an important role in the pathogenesis of atherosclerosis is generally accepted. Substantial *in vitro* evidence indicates that oxidized LDL is the component central to the initiation and/or progression of atherogenesis at the molecular and cellular level. The typical LDL particle is not only rich in cholesterol but also contains approximately 1300 molecules of RH, which are very sensitive to oxidation. Vitamin E, mainly α-tocopherol, is quantitatively the most important lipophilic antioxidant present in LDL particles. On average, each LDL particle is protected by ~6 mol α-tocopherol (range, 3–15 mol), 1 mol of γ-tocopherol, and small amounts of carotenoids.

All major cells of the artery wall, such as monocyte macrophages, endothelial cells, and smooth muscle cells, can modify LDL oxidatively *in vitro*. Monocytes have been shown to induce peroxidation of lipids such as those in LDL by the generation of reactive species, including superoxide anion, hydrogen peroxide, and hydroxyl radicals. Other oxidants have been implicated, including 15-lipoxygenase, myeloperoxidase-generated hypochlorous acid, and reactive nitrogen species such as peroxynitrite. *In vivo*, oxidized LDL particles are recognized by macrophage scavenger receptors and taken up by macrophages, forming lipid-laden foam cells in the fatty streak lesions. The free radical oxidation of LDL results in numerous structural changes that all depend on a common event—the peroxidation of polyunsaturated fatty acids in the LDL particle.

In vitro studies have indicated that increasing the vitamin E content of LDL particles increases their resistance to oxidation and decreases their uptake by macrophages. Vitamin E supplementation has also been reported to suppress macrophage uptake of oxidized LDL in human arterial lesions and decrease urinary F_2-isoprostane (a 'footprint' of free radical-mediated oxidation of arachidonic acid) concentrations. Reactive nitrogen species are also implicated in aortic oxidation of LDL and therefore potentially in atherosclerosis. Because of the nonsubstituted 5-position, γ-tocopherol reacts with peroxynitrite and other electrophilic mutagens generated during inflammation and forms a stable carbon-centered adduct, 5-nitro-γ-tocopherol. This mechanism of protecting LDL may be significant when γ-tocopherol constitutes a major portion of vitamin E in the diet. It is worth noting that the ability of γ-tocopherol to attenuate oxidative damage produced by these reactive species may prevent or delay the progression of other diseases as well as cardiovascular disease (CVD), in which inflammation plays a role, such as cancer, rheumatoid arthritis, inflammatory bowel disease, and neurodegenative disorders. In addition, γ-CEHC has natriuretic activity and functions in the kidney to control sodium excretion, and it regulates the body's extracellular fluid volume, an important determinant in hypertension and congestive heart failure.

Tocopherols and Other Metabolic Functions

Vitamin E, in addition to having a protective role in the oxidative modification of LDL, may affect or limit the progression of atherosclerosis and a number of other conditions in ways that are unrelated to its antioxidant activity. Some of these effects appear to stem from the ability of α-tocopherol, at physiological concentrations of vitamin E, to activate protein phosphatase 2A, which inhibits the activity of protein kinase C (PKC), a biological indicator of inflammation, by dephosphorylating the protein. PKC is an important element in the signal transduction cascade mediated by growth factors, such as platelet-derived growth factors, which are necessary for the progression and completion of the cell proliferation cycle.

The cellular effects of α-tocopherol-mediated inhibition of PKC depend on the cell type in question, but the cumulative effect is highly protective against the progression of atherosclerosis. PKC inhibition results in reduced smooth muscle cell proliferation, inhibition of platelet aggregation, and thus delayed intra-arterial thrombus formation. Endothelial cell function is preserved by the downregulation of adhesion molecule (ICAM-1 and VCAM-1) expression (possibly by downregulation of nuclear factor-κB) and hence prevention of monocyte and neutrophil adhesion, which is an important early event in the initiation of fatty streak formation and atherogenesis. In addition, PKC inhibition in monocytes reduces the production of reactive oxygen species by impairment of NADPH-oxidase assembly, which may help to reduce LDL oxidation.

The release of proinflammatory cytokines in monocytes, such as interleukin-1β and tumour necrosis factor-α, is impeded by α-tocopherol-mediated inhibition of the 5-lipoxygenase pathway, and production of eicosanoids, such as prostaglandin E_2 and thromboxane A_2, is impeded by γ-tocopherol-mediated inhibition of the cycloxygenase pathway. Lower circulating levels of inflammatory mediators, which are aggregatory and

vasoconstrictive, as well as inhibition of monocyte chemoattractant protein-1 (MCP-1) production, reduces the attraction of monocytes to inflammatory sites at the arterial wall and prevents the formation of foam cells. Furthermore, α-tocopherol increases production of prostacyclin, which has anti-aggregatory and vasodilatory properties, thereby reducing the risk of a coronary event. There is evidence that in a formed atherosclerotic plaque, vitamin E may have a stabilizing effect and prevent its rupture and subsequent clot formation. This may be an important contributor to the prevention of heart disease because plaque types that are most subject to rupture present the greatest threat.

Nitric oxide (NO) produced by NO synthase in the endothelium is important in the maintenance of vascular tone; it suppresses the expression of proinflammatory cytokines, adhesion molecules, and MCP-1. It also inhibits platelet adhesion, maintains the integrity of the arterial wall, and acts as an antioxidant. Vitamin E can reduce the inhibition of NO synthase by reactive oxygen species, thus maintaining NO production, either through its antioxidant activity or perhaps by suppressing PKC activity in smooth muscle.

Tocopherols and Cardiovascular Disease—Epidemiological Evidence

The effects of dietary vitamin E have been examined in several studies, many of which have reported a clear association between the reduction in the relative risk of CVD and high intake or supplement of vitamin E, although some have shown no such association. The Vitamin Substudy of the WHO/MONICA Project showed that in European populations whose classical risk factors for CVD were very similar, the 7-fold differences in CVD mortality could be explained at least to approximately 60% by differences in the plasma levels of vitamin E and up to 90% by the combination of vitamins E, A, and C. The Edinburgh Case Control Study and Basel Prospective Study consistently revealed an increased risk of ischemic heart disease and stroke for low plasma levels of vitamin E. However, other European population studies have not found an association between blood levels of vitamin E and end points of CVD. In the EURAMIC study, the adipose levels of vitamin E did not correlate with the relative risk of myocardial infarction.

A number of prospective studies have examined the association between vitamin E intake and risk of CHD. The Nurses' Health Study, conducted on 87 245 women, showed a 34% reduction in CHD in women who had consumed vitamin E supplements containing more than 67 mg α-TE daily for more than 2 years. However, there was no significant effect of vitamin E obtained from food sources. The Established Populations for Epidemiolodic Studies of the Elderly (EPESE) trials showed that the use of vitamin E supplements significantly decreased risks for all-cause-mortality and mortality from heart disease. Another prospective study, performed in Canada, reported a consistent inverse association between CVD and vitamin E supplement usage. The Health Professionals Study, conducted on 39 910 men aged 40–75 years, also showed that dietary intakes of vitamin E were not significantly correlated with reduced risk of CHD or death. A protective effect was seen in those who took 67–160 mg supplemental α-TE daily for more than 2 years. In contrast, the Iowa Women's Health Study reported that dietary vitamin E (mainly γ-tocopherol) was inversely associated with the risk of death from CVD. This association was particularly striking in the subgroup of women who did not consume vitamin supplements. There was little evidence that the intake of vitamin E from supplements (mainly α-tocopherol) was associated with a decreased risk of death from CVD. The reasons for the differences between dietary and supplemental vitamin E are not clear. However, some epidemiological studies point to the potential importance of γ-tocopherol in preventing heart disease. High dietary intake of nuts, an excellent source of γ-tocopherol, lowered serum cholesterol, improved plasma lipid profiles, and was inversely associated with the risk of death from heart disease.

The ability of α-tocopherol supplementation to prevent cardiovascular events in different populations was tested in four larger prospective clinical trials: The α-Tocopherol, β-Carotene Cancer Prevention (ATBC) study, the Cambridge Heart Antioxidant Study (CHAOS), the Gruppo Italiano per lo studio della Sopravvivenza nell'Infarto Miocardito (GISSI) trial, and the Heart Outcome Prevention Evaluation (HOPE) study. In addition, at least two smaller prospective clinical trials have been completed: the Secondary Prevention with Antioxidants of Cardiovascular Disease in Endstage Renal Disease (SPACE) study and the Antioxidant Supplementation in Atherosclerosis Prevention Study (ASAP).

In the ATBC study, the subjects who were supplemented with 50 mg *all rac*-α-tocopheryl acetate day^{-1} for 5–8 years had only a moderately lower incidence (4%) of angina pectoris than did the control subjects, and among male smokers,

cardiovascular mortality did not differ significantly between those who received supplementation and those who did not. However, subjects who received supplementation had a significantly higher incidence of haemorrhagic stroke than did the control subjects. Note that the ATBC study was not designed to investigate cardiovascular disease development. The results of the CHAOS trial, the first prospective trial with cardiovascular disease as an end point, were encouraging. The risks of nonfatal myocardial infarction declined 77% and total (fatal plus nonfatal) myocardial infarction declined 47% when patients with established coronary artery disease were treated with 268 or 536 mg α-TE daily for approximately 500 days. The GISSI study showed that feeding 211 mg α-TE day^{-1} for 3.5 years did not significantly reduce the rate of all-cause death, nonfatal myocardial infarction, or nonfatal stroke. However, in a later four-way reanalysis in which each individual variable was considered as an end point, there were significantly fewer (20%) cardiovascular deaths in the α-tocopherol group than in the control group. The HOPE study reported that vitamin E (400 IU (268 mg) day^{-1} RRR-α-tocopherol) treatment of CVD patients had no effect on reducing the primary end points, which included nonfatal myocardial infarction, stroke, and cardiovascular death. In the SPACE trial, haemodialysis patients with preexisting cardiovascular disease received 536 mg (RRR)-α-tocopherol or placebo day^{-1}. Patients who received vitamin E had a striking 54% reduction in cardiac events compared with control subjects.

In the ASAP study, men and women (all subjects had hypercholesterolemia at entry) were given vitamin E (91 mg twice daily), slow-release vitamin C (250 mg twice daily), a combination of both, or placebo for 3 years. The progression of atherosclerosis (the mean intima-media thickness of the common carotid artery measured) was significantly retarded only in the men who smoked and took both vitamins. It is important to note that, in general, women develop fewer cardiovascular events than do men. Thus, women may profit less from vitamin E treatment than men. In studies in which many women are enrolled, the low incidence of CVD may weaken the statistical power of the overall trial.

Tocopherols and Cancer—Epidemiological Evidence

Clinical and epidemiological data, together with evidence from experimental models, support a role for the involvement of free radicals throughout the cancer process. Attempts to prevent cancer using vitamin E are based on the rationale that oncogenesis results from free radicals attacking DNA. As an antioxidant, vitamin E may inhibit cancer formation by scavenging reactive oxygen or nitrogen species. Several studies of oral, pharyngeal, and cervical cancer found a relationship between vitamin E status and cancer risk. The evidence for stomach and pancreatic cancers has not been consistent, and no association with breast cancer has been found.

The Linxian, China, intervention trial provided evidence that nutritional supplementation may lower the risk of certain cancers. A modest but significant reduction in cancer mortality was observed in a general population trial in those receiving daily (for 5.25 years) a combination of β-carotene (15 mg), vitamin E (30 mg), and selenium (50 μg). The subjects who received this mixture had a 13% lower incidence of cancer and a 10% lower mortality from stomach and oesophageal cancer than did the subjects who did not receive the mixture. In the ATBC study, male smokers who took vitamin E supplements had a 34% lower incidence of prostate cancer and 41% lower mortality from prostate cancer than did those who did not take the supplements. In the United States, in a nested case–control study conducted to examine the association of α-tocopherol, γ-tocopherol, and selenium with the incidence of prostate cancer, a striking fivefold reduction in risk was observed for the men in the highest quintile of γ-tocopherol compared with those in the lowest. Overall, evidence for the protection from cancer by vitamin E is not compelling.

Tocopherols and Other Diseases—Epidemiological Evidence

Vitamin E appears to act as an immunosuppressant due to its ability to suppress both humoral and cellular immune responses. Tocopherol supplementation significantly enhances lymphocyte proliferation, interleukin-2 production, and delayed-type hypersensitivity skin response and decreases prostaglandin E_2 production by inhibiting cyclooxygenase activity. There appears to be compelling evidence that intervention with dietary antioxidants, such as vitamin E, may help maintain the well-preserved immune function of 'very healthy' elderly, restore the age-related decrease in immune function, and reduce the risk of several age-associated chronic diseases. Epidemiological evidence suggests an

association between the incidence of cataract and vitamin E status. In a prospective study, the sum of serum α- and γ-tocopherol, but neither tocopherol alone, was inversely associated with the incidence of age-related nuclear cataracts.

Among the most common neurologic diseases are neurodegenerative disorders such as Alzheimer's and Parkinson's disease, which may be caused by oxidative stress and mitochondrial dysfunction leading to progressive neural death. An increasing number of studies show that antioxidants (vitamin E and polyphenols) can block neuronal death *in vitro*. In a 2-year, double-blind, placebo-controlled, randomised trial of patients with moderately severe impairment from Alzheimer's disease, treatment with 1340 mg day^{-1} α-TE significantly slowed the progression of the disease. Clinical treatment of Alzheimer's patients with large doses of vitamin E (670 mg α-TE twice daily) is one of the key therapeutic guidelines of the American Academy of Neurology. In a multicentre, double-blind trial, vitamin E (1340 mg α-TE day^{-1}) was not beneficial in slowing functional decline or ameliorating the clinical features of Parkinson's disease. Administration of vitamin E significantly relieved symptoms in patients suffering from several types of acute or chronic inflammatory conditions, such as acute arthritis, rheumatoid arthritis, and osteoarthritis.

Vitamin E Status and Requirements

Interest in the role of vitamin E in disease prevention has encouraged the search for reliable indices of vitamin E status. Most studies in human subjects make use of static biomarkers of status, usually α-tocopherol concentrations in plasma, serum, erythrocytes, lymphocytes, platelets, lipoproteins, adipose tissues, buccal mucosal cells, and LDL, and the α-tocopherol:γ-tocopherol ratio in serum or plasma. Other markers of vitamin E status include susceptibility of erythrocyte or plasma LDL to oxidation, breath hydrocarbon exhalation, and the concentration of α-tocopherol quinone in cerebrospinal fluid. There is no consensus as to the threshold concentration of plasma or serum α-tocopherol at which a person can be defined as having inadequate tocopherol status, but values of $<$11.6, 11.6–16.2, and $>$16.2 μmol^{-1} are normally regarded as indicating a deficient, low, and acceptable vitamin E status, respectively. It is recommended that plasma or serum α-tocopherol concentrations be lipid-corrected (i.e., expressed relative to either the sum of cholesterol and triacylglycerol or cholesterol alone). For convenience, α-tocopherol:cholesterol is the simplest to obtain and probably the most useful, with values below 2.2 μmol α-tocopherol/mmol cholesterol indicating a risk or deficiency and an optimal value $>$5.2. It has been estimated that an average daily dietary intake of 15–30 mg α-tocopherol would be required to maintain this plasma level, an amount that could be obtained from dietary sources if a concerted effort were made to eat foods rich in vitamin E.

The US Institute of Medicine Food and Nutrition Board set an estimated average requirement (EAR) of 12 mg α-tocopherol for adults $>$19 years on the criterion of vitamin E intakes that were sufficient to prevent hydrogen peroxide-induced hemolysis in men. The same value was set for men and women on the basis that although body weight is smaller on average in women than men, fat mass as a percentage of body weight is higher on average in women. Because information is not available on the standard deviation of the requirement for vitamin E, the recommended dietary allowance (RDA) was established for men and women as the EAR (12 mg) plus twice the coefficient of variation (assumed to be 10%), rounded up, giving a value of 15 mg day^{-1}. In Europe, the Scientific Committee for Food did not set a population reference intake (PRI) for vitamin E on the basis that there is no evidence for deficiency from low intakes, and the frequency of distribution of intakes is skewed to the right, making it difficult to set a PRI that is not inappropriately high, especially for those with a low consumption of polyunsaturated fatty acid (PUFA), whose requirements are lower than those with a high consumption of PUFA.

It has been suggested that the optimum concentration of α-tocopherol in plasma for protection against cardiovascular disease and cancer is $>$30 μmol l^{-1}, given normal plasma lipid levels and in conjunction with a plasma vitamin C concentration $>$50 μmol l^{-1} and a β-carotene level $>$0.4 μmol l^{-1}. This has not been proven in large-scale human intervention trials, but even in the absence of conclusive evidence for a prophylactic effect of vitamin E on chronic disease prevention, some experts believe that a recommendation of a daily intake of 87–100 mg α-tocopherol is justifiable based on current evidence. Realistically, these levels can be achieved only by using nutritional supplements. The tolerable upper intake level for vitamin E is 1000 mg day^{-1}, based on studies showing hemorrhagic toxicity in rats, in the absence of human dose–response data.

VITAMIN K

C J Bates, MRC Human Nutrition Research, Cambridge, UK

The discovery of vitamin K as an essential nutrient arose in the late 1920s from Henrik Dam's studies of sterol metabolism. He observed that chicks fed a fat-free diet developed subcutaneous hemorrhages and anemia. A lipid extract of liver or of certain plant tissues was curative, and by 1935 he claimed discovery of a new vitamin in these extracts that he named 'vitamin K' from the German *Koagulation*. By the late 1930s, two chemically similar forms of the vitamin from different sources were recognized, namely phylloquinone or K_1 and menaquinone or K_2, which had been isolated from alfalfa and from putrefied fish meal, respectively (**Figure 1**). Phylloquinone, with its saturated phytyl side chain, is now understood to be the sole representative of vitamin K that occurs in plant tissues, especially in green leafy ones, where it acts as a component of the electron transport chain. The menaquinones, or MK-n, by contrast, comprise a broad family of representatives that have a variable length, unsaturated side chain, and are composed of one or more (sequential) isoprene units in place of the saturated phytyl side chain. These menaquinones can be produced by certain types of bacteria, both in the large bowel of animals and at other locations where they may contribute to human food sources of menaquinones. Germ-free rats become vitamin K deficient more readily than their conventional counterparts, and they can develop very low hepatic MK-4 levels. The specific menaquinone with the same side chain length as phylloquinone is called menatetranone, or MK-4, and this is produced commercially for human medication, especially in Japan. There is evidence that phylloquinone can be converted to MK-4 in animals and humans. Most bacterially synthesized menaquinones have longer side chains, typically 7–9 isoprene units and up to 13, which are indicated by 'n' in the MK-n shorthand notation. A synthetic homolog of phylloquinone, $K_{1(25)}$, is not found in nature and can therefore be used as an internal standard in the chromatographic separation and quantitation of vitamin K. Menadione, a water-soluble form of the vitamin that has a single methyl group in place of the side chain, has vitamin K activity (it can be converted to menatetranone *in vivo*) and is used in animal feeds, but it is not used in humans because of its toxicity at high doses.

Food Sources, Absorption, Distribution, and Turnover

Food sources of phylloquinone for man (**Table 1**) include green leafy vegetables as the major

[a]A dashed line means not detectable. Values obtained for MK-5 and MK-6 are omitted from this summary. The data demonstrate clearly (i) the huge difference in vitamin K contents between different foods and (ii) the preponderence of phylloquinone in some foods and of menaquinones (of several different chain lengths) in others.
[b]A Japanese food made from fermented soya bean curd.
Data from Schurgers LJ and Vermeer C (2000) Determination of phylloquinone and menaqunones in food. Haemostasis **30**: 298–307, **Table 2**.

quantitative source; however, its availability for absorption from these foods is thought to be relatively poor. Certain plant-derived oils, notably soya and canola oils, are also rich in the vitamin, which is probably much more readily available from such sources than it is from leaves. Menaquinones are typically obtained from foods, such as cheeses or Japanese 'natto' (fermented bean curd), in which bacterial fermentation has occurred. Smaller amounts of both phylloquinones and menaquinones are obtained from liver and other animal-derived foods.

Phylloquinone is highly lipophilic; however, at low concentrations it is transported by a saturable, energy-dependent transport system across the gut wall, mainly in the upper small intestine. Phylloquinone in foods consisting of plant tissues is much less readily bioavailable for absorption than the pure vitamin since it is tightly bound to the thylakoid membranes of the chloroplasts, and the absorption of vitamin K from plant foods is considerably improved by including additional fat in the meal. Its absorption also depends on the stimulation of bile salt and pancreatic lipase secretions. The long-chain menaquinones, which are even more lipophilic, are only passively absorbed and are much less bioavailable for absorption than phylloquinone. However, if given by injection (e.g., intracardially), they can be even more functionally active than phylloquinone. The relative bioavailability and bioactivity of the different forms and food sources of vitamin K need more research. Preliminary studies with

deuterium-labeled broccoli suggest that the bioavailability of endogenous vitamin K can be studied in humans by intrinsic stable isotope-labeling procedures.

Once absorbed, vitamin K is transported to the liver in the chylomicrons, where it becomes distributed among the triglyceride-rich chylomicron remnants (ca. 50%) and the low-density lipoprotein and high-density lipoprotein fractions of plasma (ca. 25% each). Plasma vitamin K concentrations, which are typically in the low nanomolar range in humans, are much lower than for the other fat-soluble vitamins (A, D, and E), and they are strongly correlated with the triglyceride content of the plasma. Indeed, some authorities prefer to express plasma vitamin K as a ratio to triglycerides instead of as a simple concentration. Differences between the apoE lipoprotein genetic variants affect plasma vitamin K, according to their different triglyceride clearance profiles. There is evidence for a major diurnal cycle of plasma vitamin K, with peak concentrations of both vitamin K and its associated triglycerides occurring in late evening and with lowest values in the morning. A kinetic study using radioactive vitamin K indicated that the turnover time of the exchangeable pool of the vitamin is quite short, approximately 1.5 days, and the first and second exponential decay curves had half-lives of 0.5–1 and 25–78 h, respectively. The exchangeable body pool size was only approximately 1 μg/kg body weight. The liver is an important repository of the vitamin for both plant-derived phylloquinone and the bacterially derived menaquinones. Depletion studies have indicated that the hepatic phylloquinone stores seem much more labile than the menaquinone stores, and that a functional deficiency accompanies the loss of the phylloquinone, which the remaining nondepleted menaquinones cannot prevent. Despite this, if menaquinones are given exogenously, they can be curative. Different tissues have different relative avidities for phylloquinone and menaquinones, and it has been suggested that they may have a different spectrum of functions from each other. Thus, in humans, phylloquinone is concentrated in liver, heart, and pancreas. The longer chain menaquinones, MK-6 to -11, are found mainly in liver with traces in heart and pancreas, but MK-4 is found especially in brain and kidney, where it exceeds phylloquinone concentrations. The tissue distribution in humans is similar to that in the rat.

The turnover of phylloquinone results in *ca.* 40–50% of the exchangeable body pool being transferred via the bile into the feces and 20% being excreted into the urine, the latter including the excretion of oxidized products that become conjugated as glucuronides.

Physiological Functions of Vitamin K: Interaction with Antagonists

Blood Coagulation Proteins

The principal physiological function that led to the discovery of vitamin K, and its confirmation as an essential vitamin for higher vertebrates, was its unique role in the blood clotting cascade. This cascade comprises a complex series of linked proenzyme-to-enzyme conversions, which leads eventually to a fibrin clot (**Figure 2**). Central to this process is the activation by calcium of gamma-carboxylated glutamyl (Gla) residues in some of the members of the cascade series: factors VII, IX, and X and factor II (prothrombin). In addition, there is an inhibitory level of control by proteins C, S, and possibly Z. All seven of these Gla proteins have Gla clusters that interact specifically with calcium so as to alter their polypeptide conformations and to permit their interaction with other members of the coagulation cascade (by exposing a phospholipid-binding domain) and hence leading either to activation or to inhibition of individual components. The Gla moieties of these and indeed all the vitamin K-dependent Gla proteins are formed by a post-translational carboxylation reaction catalyzed by the single enzyme, 'carboxylase,' at the

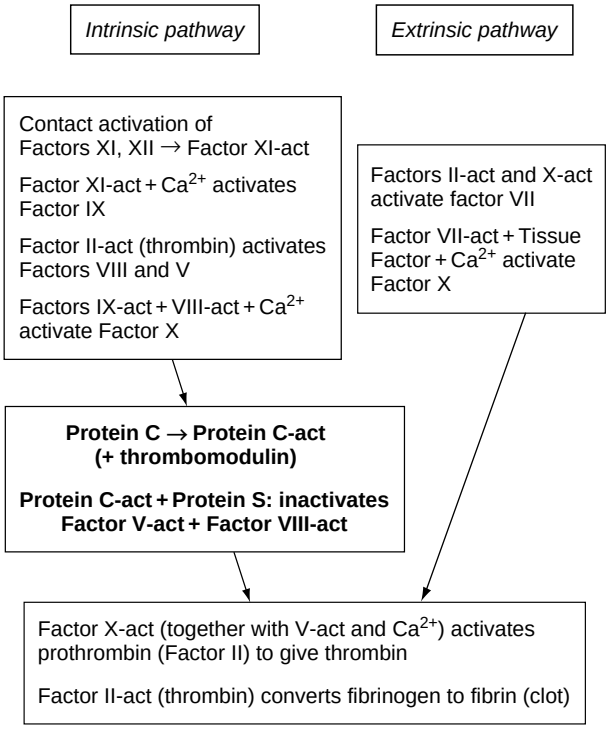

Figure 2 Vitamin K-dependent clotting factors. Factors II (prothrombin), VII, IX, and X and proteins C and S are all Gla proteins. The functions of proteins C and S, shown in bold, are inhibitory to the clotting cascade, whereas the other factors all form part of the cascade mechanism.

endoplasmic reticulum sites of Gla protein synthesis. In the case of the blood coagulation proteins, the sole site of synthesis is the liver. Each carboxylated protein has a C-terminal 'propeptide' sequence that binds the carboxylase enzyme, and directs a coordinated series of carboxylations of the recipient glutamyl residues, before the propeptide is removed and the fully carboxylated protein is then secreted into the extracellular space for transport into the plasma.

Vitamin K acts as the essential recycling cofactor (or cosubstrate) for all protein carboxylation, Gla-forming reactions (**Figure 3**). In its dihydro or quinol form, the vitamin reacts with molecular oxygen, thereby creating a highly reactive, high-energy carbanion at the Glu site for insertion of carbon dioxide, creating a new Gla residue. This vitamin K quinol oxidation step provides the essential energy for the endothermic carboxylation step. The other product of the reaction is the epoxide of vitamin K, comprising a three-membered carbon–oxygen ring. Since the oxidized vitamin needs to be recycled back to the quinol form before the next protein carboxylation cycle, a two-stage reduction process ensues, forming first vitamin K quinone and then the original quinol (**Figure 3**). Both of these reduction steps can be catalyzed by the enzyme vitamin K epoxide reductase, which is linked to a dithiol–disulfide reducing couple and which is highly sensitive to inhibition by the coumarin class of drugs, of which warfarin (**Figure 1**) is the best known and most commonly used member. The reduction of the intermediate vitamin K quinone to its quinol form can also be catalyzed by another, NAD(P)H-dependent, quinone reductase that is warfarin resistant, and for this reason the inhibition of carboxylation by warfarin can be reversed or antagonized by large doses of vitamin K provided exogenously in its normal quinone form. A severe deficiency of vitamin K, or treatment with coumarin drugs (for the control of excessive blood clotting tendency in humans), results in prolonged clotting times that can be detected by the standardized 'one stage prothrombin time' test, in which citrated or oxalated (i.e., calcium-complexed) blood is treated with tissue factor plus additional calcium so as to initiate the clotting process. However, a much more sensitive test for mild vitamin K deficiency is the PIVKA test (Proteins Induced by Vitamin K Absence or Antagonism), which is an immunological enzyme-linked immunosorbent assay (ELISA) test that specifically recognizes undercarboxylated blood clotting proteins and particularly des-gamma-carboxy prothrombin.

Proteins C and S, and possibly also Z, function differently from the other Gla-containing blood clotting factors that are an integral part of the fibrin-forming cascade. Protein C has a regulatory role, inactivating factors V and VIII, and in conjunction with protein S it also acts as a cofactor to enhance the rate of fibrinolysis of blood clots in locations where they are unwanted and potentially harmful. The exact function of protein Z remains unresolved, although interactions with thrombin and factor X have been reported. Clearly, there is a delicate balance of

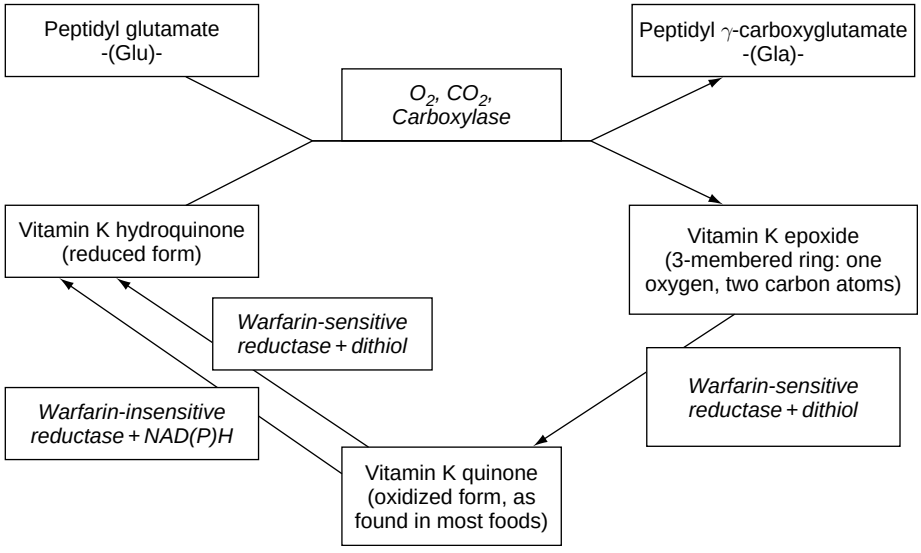

Figure 3 Vitamin K oxidation–reduction cycle during Gla formation. Oxidation of vitamin K hydroquinone (reduced vitamin) to vitamin K epoxide by molecular oxygen provides the energy needed to drive the carboxylation of peptidyl-Glu to peptidyl-Gla (i.e., gamma-carboxy glutamate). The vitamin K epoxide is then recycled by reduction with dithiols in two stages. The first stage requires a reductase enzyme that is coumarin drug (e.g., warfarin) inhibitable. The second stage can be catalyzed by either of two reductases, one of which is NAD(P)H dependent and is not warfarin inhibited.

pro- and anti-clot formation and removal activities among the vitamin K-dependent Gla proteins of the cascade, although the net effect of a deficiency of the vitamin or of its antagonism by drugs appears to be a reduction of the clotting tendency.

Bone Gla proteins

Protein S together with two other Gla proteins, osteocalcin (OC; or bone Gla protein) and matrix Gla protein (MGP), play a variety of only partly understood roles in bone and other mineralized tissues. Of these proteins, only OC is produced solely and specifically by mineralized tissue, whereas the other two (or at least their mRNA templates) are more widespread and occur also in soft tissues.

OC is synthesized specifically by osteoblasts and odontoblasts, and it accounts for ca. 15–20% of the noncollagen protein of the bone matrix. Approximately 20% is secreted into blood plasma, where it has no obvious function, but it has frequently been measured as an index of bone-forming (osteblastic) activity, and is present in increased amounts in plasma of people with certain bone diseases and of young infants. It is a small protein, MW 5700, with just three Gla residues. Unlike the blood coagulation Gla proteins, which in most people not severely vitamin K deficient and not vitamin K antagonist treated are almost completely carboxylated, circulating OC is at least 5–10% undercarboxylated in many population groups, as measured by assays that depend on the affinity of the undercarboxylated form for hydroxyapatite or a specific ELISA assay for the undercarboxylated form. Since vitamin K supplements can reduce its degree of undercarboxylation in many people, it has been proposed as a new and highly sensitive functional test of vitamin K status in man.

Despite the growing level of interest in its practical use as a status index, our understanding of the essential function of OC remains incomplete. Its affinity for calcium is less strong than that of the larger Gla proteins, but it binds avidly to hydroxyapatite and is chemotactic for osteoclasts and their progenitors. Moreover, it can enhance the differentiation of osteoclast progenitor cells in culture, which has been interpreted as implying a possible role in bone resorption. Transgenic mice that lack the gene for OC have increased bone mass, despite an increased number of osteoclasts. In humans, however, underhydroxylation of OC especially in postmenopausal women has been linked to low vitamin K intakes, reduced bone mineral density, and increased risk of fracture. Intervention with high-dose MK-4, mainly in Japan, has been reported to improve bone mineral density and decrease fracture risk. Although a single study in the United Kingdom suggested that a combination of vitamin K_1 and vitamin D supplements may benefit bone mineral density in postmenopausal women, considerably more research is needed in this area. The separate roles of OC and other vitamin K-dependent proteins also need to be clarified.

The second vitamin K-dependent Gla protein in bone, MGP, has a MW of 9600 and five Gla residues and is highly insoluble. Unlike OC, it is also found in cartilage, and, significantly, its mRNA occurs in several soft tissues including artery walls. Its synthesis is modulated by 1,25-dihydroxy vitamin D and by retinoic acid. Mice lacking the gene for MGP quickly developed calcified arteries and died of aortic rupture before 2 months of age. For this reason, MGP is believed to antagonize the pathological calcification of soft tissues and thus to protect them. The absence of MGP also led to inappropriate calcification of growth plate cartilage, reduced growth, osteopenia, and fracture in the MGP gene knockout mice. In humans, defects in the MGP gene are associated with Keutel's syndrome and chondroplasia punctata, in which cartilage calcification is abnormal. Similar abnormalities have been observed in infants whose mothers were treated with warfarin during the first trimester of pregnancy. In one study, low vitamin K intake was associated with atherosclerotic calcification of the aorta in postmenopausal women. Also, circulating MGP levels were found to be raised in severe atherosclerosis and in type 1 diabetes in humans. A specific immunoassay for MGP has been developed that should assist further research on this potentially important regulatory protein.

The third bone-associated Gla protein, protein S, is also involved with blood clotting. It is synthesized by osteoblast-like and osteblastoma cells in culture, and it has been detected in bone matrix. It is also synthesized by hepatocytes, megakaryocytes, and endothelial cells. Children with an inborn deficiency of it developed osteopenia and bone lesions; however, its precise functional role is unknown.

All three bone Gla proteins (and probably most other Gla proteins) have 'leader' or 'pre'-peptides when first formed on the endoplasmic reticulum (ER) that are required for translocation across the ER and are removed during this process. OC, protein S, and most other Gla proteins also have a pro-peptide sequence that is removed during secretion and that directs the action of the carboxylase enzyme before secretion. MGP differs from the other Gla proteins in that its carboxylase recognition sequence is not removed; instead, only a short (five-residue) carboxy-terminal sequence is removed from it. All known mammalian Gla proteins contain the characteristic amino acid sequence

Gla-X-X-X-Gla-X-Cys, where X represents an undefined amino acid. If vitamin K is in short supply or antagonized, certain Gla residues escape gamma-glutamyl formation more than others. Thus, in a study of OC, the Glu residue at position 17 was typically only 67% carboxylated, that at position 21 was 88% carboxylated, and that at position 24 was 93% carboxylated.

Surprisingly, in a meta-analysis of studies on warfarin-treated adult patients, no evidence of any increase in bone disorders was found.

Gas6 and Other Vitamin K-Requiring Gla Proteins

A Gla protein that is associated with the central nervous system, rather than with liver or bone, was discovered in 1993. In tissue culture models it had the properties of a growth arrest-specific (GAS) cell-signalling gene product. It acts as a ligand for a number of receptor protein kinases; it potentiates the growth of vascular smooth muscle cells, Schwann cells, and the neurons that synthesize gonadotropin-releasing hormones; and it can prevent apoptotic cell death. Knockout mice in which three Gas6 receptors are mutated had major neurological and spermatogenic abnormalities. There is interest in potential roles for Gas6 in Alzheimer's disease and Parkinson's disease. Clearly, these properties and emerging roles have helped to confirm the growing suspicion that vitamin K-dependent Gla proteins possess key functions beyond blood clotting and even bone remodelling. Gas6 has a MW of 75,000 with 11 or 12 Gla residues, and its structure is partly homologous with protein S.

Even less well characterized are several other Gla proteins from a variety of tissues. Kidney contains 'nephrocalcin,' with just two or three Gla residues, which may be involved in renal calcium transport (another important function that may be impaired by vitamin K deficiency in man). Atherocalcin, or plaque Gla protein, may be related or even identical to MGP. Proline-rich Gla proteins PRGP-1 and PRGP-2 are found predominantly in the spinal cord and thyroid gland, respectively, but their functions are unknown. Gla proteins occur in most vertebrates and also in molluscs, so their evolutionary appearance in the animal kingdom is probably quite ancient in origin.

Other, Probably Non-Gla Functions of Vitamin K

Vitamin K is thought to be involved in sphingolipid metabolism in certain bacteria by modulating serine palmitoyl transferase, and warfarin treatment decreased brain levels of sulfatides and galactocerebroside sulfotransferase activity in animals, which was reversible by vitamin K (either K_1 or MK-4). Therefore, it is now thought that vitamin K may be involved in sphingolipid metabolism, and this in turn has implications for its action as a second messenger as well as being a structural component. There are several functions of MK-4 that are shared by the isolated geranyl-geraniol side chain, which involve the induction of apoptosis of osteoclasts and of certain cancer cells in culture. Depriving certain tumours of vitamin K, both *in vitro* and *in vivo*, seemed to inhibit their growth and metastasis. Patients receiving warfarin for cardiovascular disease seem to have a reduced incidence of tumors, and warfarin may also suppress delayed-type hypersensitivity reactions.

Recent studies have suggested that MK-4, in particular, has a transcriptional regulatory function, for example, in osteosarcoma cell cultures, in which it binds to and activates the SXR steroid and xenobiotic receptor. This in turn increases mRNA levels for osteoblast markers: bone alkaline phosphatase, osteoprotogerin, osteopontin, and MGP. MK-4 and its isolated geranyl-geraniol side chain was also able to suppress the synthesis of prostaglandin E_2, which is a potent bone resorption catalyst. These observations have led to speculation (i) that some of the menaquinones may possess some functions that are not shared by phylloquinone, and (ii) that there may be implications for cell proliferation and for cancer risk from variations in the supply of vitamin K and in its speciation.

Population Groups at Risk of Vitamin K Deficiency

Because of the minimal extent of transfer of vitamin K across the placenta, the fetus and newborn infant have much lower circulating vitamin K than adults (typically 30-fold lower). In addition, human milk has a lower concentration of the vitamin than that of most other mammalian species. Although low vitamin K levels have not been found to affect the developing fetus in a functionally deleterious way, it is clear that the newborn, and especially the solely breast-fed infant, is at higher risk of functional deficiency than older infants and adults. In a minority of cases, this can lead to life-threatening or long-term damage associated with intracranial bleeding. Hemorrhagic disease of the newborn (HDN) is classified as early (first 24 h of life), classic (days 1–7), or late (2–12 weeks). Of these, the third category is most likely to involve dangerous intracranial bleeding. Risk factors for HDN include intestinal fat malabsorption and hepatic disease. In Western countries, since the 1950s, it has been routine practice to give prophylactic phylloquinone in a 1 or 2 mg dose at birth, and this has been found to considerably reduce the risk of HDN. An intramuscular depot dose was found to be

highly effective; however, a study in the United Kingdom in the 1990s suggested a possible link with childhood cancer. Despite little subsequent support for this contraindication, the adverse publicity led to a shift in practice toward oral dosing. An oral micellar preparation containing glycholate and lecithin has been developed that has improved absorption characteristics. Another approach toward the avoidance of late HDN is vitamin K supplementation of breastfeeding mothers since breast milk vitamin K levels can be increased substantially by dosage to the mother. Modern commercial formula feeds typically contain 50–125 μg phylloquinone/l.

Antibiotic-treated patients may be at increased risk of developing vitamin K deficiency. Some antibiotics may reduce the production of usable menaquinones by gut bacteria; others, such as cephalosporin, may exert vitamin K epoxide reductase inhibitory effects. Vitamins A and E in large doses may increase the risk of vitamin K deficiency and/or its sequelae in susceptible people. Thus, in one study, patients receiving anticoagulant drugs exhibited a further reduction of prothrombin levels if they were given 400 IU α-tocopherol per day for 4 weeks. The microsomal vitamin K-dependent carboxylase enzyme was found to be inhibited by α-tocopheryl quinone and, to a lesser extent, by α-tocopherol. It is also inhibited by other oxygen free radical antagonists. Control of blood clotting with warfarin-type drugs thus requires control of intakes of vitamins A and E as well as vitamin K so as to achieve consistent results.

As noted previously, some older people, especially postmenopausal women, seem to be at increased risk of developing marginal vitamin K deficiency, which manifests itself, for instance, by an increased percentage of undercarboxylated osteocalcin (ucOC) in the circulation. The sequelae of such marginal deficiency, and in particular its implications for bone health, are currently the subject of considerable research effort (**Table 2**). Several epidemiological cross-sectional studies have noted an association between higher vitamin K intakes and higher bone mineral density or lower fracture risk. One study reported that a subgroup of postmenopausal women who were 'fast losers' of calcium responded to vitamin K supplements by reduced calcium and hydroxyproline excretion. Although vitamins D and K have distinct functions in calcium absorption, and its distribution, deposition, and excretion, there is evidence that synergistic interactions can occur between them, and that both can affect the same cell-signalling pathways. Osteocalcin and MGP synthesis is stimulated by 1,25-dihydroxy vitamin D in cell culture.

MK-4 in large doses has been used for prophylaxis and treatment of osteoporosis, especially in Japan. A study in The Netherlands reported reduced bone loss after 2 years of treatment of postmenopausal women with amounts of phylloquinone that are achievable from dietary sources. More long-term intervention trials are needed.

Table 2 Studies (1985–2001) linking vitamin K intake, status, or effects of supplementation with bone health in humans

Nature of evidence	*No. of studies*
Serum vitamin K positively correlated with BMD	4
Serum vitamin K lower in people with hip or vertebral fractures	3
Vitamin K intake directly correlated with BMD	2
ucOC directly correlated with risk of hip fracture	5
ucOC inversely correlated with velocity of ultrasound (a measure of bone quality)	1
ucOC inversely correlated with BMD	2
Supplementation with phylloquinone increased carboxylation of osteocalcin	7
Supplementation with phylloquinone or menaquinone reduced calcium loss	3
Supplementation with phylloquinone increased markers of bone formation and reduced markers of bone resorption	1
Supplementation with phylloquinone (+vitamin D) increased BMD	1
Supplementation with menaquinone (+vitamin D) increased BMD	2
Supplementation with menaquinone alone increased BMD and/or decreased bone loss	6
Supplementation with menaquinone reduced fracture risk	2

BMD, bone mineral density; ucOC, undercarboxylated osteocalcin. Data from Weber P (2001) Vitamin K and bone health. *Nutrition* **17**: 880–887, and S. Karger AG, Basel.

Status, Requirements, and Recommended Intakes

Vitamin K status can be measured either by its concentration in plasma or by its efficacy in ensuring optimal carboxylase function, as indicated by specific carboxylated plasma proteins. Accurate assay of the very low concentrations of vitamin K that are present in plasma was a considerable analytical challenge, which was eventually solved by high-performance liquid chromatography (HPLC) followed by high-sensitivity coulometric or fluorometric detection. A popular method uses organic solvent extraction, a cartridge cleanup step, an HPLC separation followed by postcolumn reduction of the vitamin K quinone to the reduced quinol form by metallic zinc or other reductant, and finally fluorometric quantitation of the fluorescent quinol. A useful internal standard, not found in nature, is the homolog of phylloquinone, vitamin $K_{1(25)}$. With

modern detectors, analysis is possible with only 0.25 ml plasma. A published 'normal' range in the United States is 0.25–2.7 nmol/l, corresponding to approximate average daily intakes of 100 μg/day in men and 80 μg/day in women. As noted earlier, the phylloquinone content of plasma has a short half-life and is strongly correlated with plasma triglycerides. It is therefore not ideal as a long-term index of status. Alternatives include functional indices such as plasma prothrombin time (increased only by severe vitamin K deficiency), PIVKA, (which is more sensitive to marginal deficiency), and ucOC (which is the most sensitive functional indicator). These functional indices are not totally specific for vitamin K deficiency, although ucOC (for which monoclonal antibodies now exist) does appear to possess reasonably good specificity. Unfortunately, the different commercial kit assays measure different epitopes of OC, which makes harmonization difficult. Urinary total Gla is sensitive to vitamin K status, but it varies with age and has not yet proved to be very useful as a status indicator. Functional indices that are based on impaired carboxylase activity affecting other Gla proteins may be developed in the future.

Most estimates of the amount of phylloquinone needed to correct clotting changes suggest that adult human requirements are between 0.5 and 1 μg/kg/day. There are no reference nutrient intakes defined for vitamin K in the United Kingdom, although a 'safe intake' for adults was set in 1991 at 1 μg/kg/day and for infants 10 μg/day. In the United States, the Food and Nutrition Board of the National Academy of Sciences has defined an Adequate Intake (AI) of phylloquinone of 90 μg/day for adult women and 120 μg/day for adult men, with proportionately smaller values for children. For infants aged 0–6 months, the AI is only 2 μg/day, and it is 2.5 μg/day at 7–12 months, thus creating a larger proportional difference between infants and older age groups than for most micronutrients.

Both phylloquinone and the menaquinones appear to be nontoxic, even in multimilligram amounts. However, menadione, the water-soluble form of vitamin K, was found to cause hemolytic anemia, hyperbilirubinemia, and kernicturus in infants when >5 mg was given. Therefore, it is not currently used for human prophylaxis or treatment.

Since vitamin K is thought to have a wide range of functions in the body in addition to blood clotting, and some of these may have long-term health implications, research on requirements and optimal intakes, with multiple end points, is needed. Metabolic and health-related differences between the menaquinones and phylloquinone also need to be defined.

WEIGHT MANAGEMENT

Contents

Approaches

N Finer, Luton and Dunstable Hospital NHS Trust, Luton, UK

Weight loss and weight loss maintenance require a decrease in energy intake (diet), an increase in energy expenditure (exercise and physical activity), or both. Dietary management should encourage healthy eating, that is, an appropriately balanced intake of macro- and micronutrients. For most obese individuals this will entail not just a decrease in total energy intake, but specifically a decrease in fat intake, together with an increase in complex carbohydrates, fruit, and vegetables. Myriad diets have been popularized as a means to reducing energy intake, but few are recommended as meeting the overall nutritional needs of an obese individual, and many are so restrictive that they clearly could not be followed for more than a few weeks. Increasing exercise and physical activity has benefits beyond those that result from the relatively modest amounts of extra energy expended. These include a beneficial protection from excessive loss of lean body tissue during dieting, improved fitness and psychological health, and a greater likelihood of long-term weight maintenance. Diet and exercise are core components of behavioral treatments; such treatments, based on learning theories, also aim to help individuals become aware of the behaviors that have led to their weight gain, and to develop strategies to alter them. Weight loss can be achieved successfully with all strategies; behavioral therapies that include a strong focus on increasing exercise and activity seem to offer the best chances of long-term success.

The Concept of Desirable Weight

Body weight reflects the additive mass of the various tissues that make up the organism, and is a function of energy and nutrient balance over a prolonged period. Positive energy balance will result in weight gain (mainly from deposition of lipid in adipose tissue), while prolonged undernutrition will lead to weight loss. For most of human history, the dominant disorder of body weight has been thinness. Thinness, whether from malnutrition or disease, was associated with illness and was often a prelude to death; in societies where food supplies are scarce or seasonal, a high body weight may be seen as a desirable sign of health, and probably wealth. In contrast, in developed societies where levels of activity are low and food is plentiful, the growing prevalence of over-weight and obesity has been clearly linked to illness and premature mortality. The concept of a desirable weight at which health is optimal and the risk of disease minimal has not been easy to define, largely because of the effects of many other factors such as age, sex, social status, and smoking.

Dietary Management

Dietary management of obesity aims to reduce fat stores by changing eating habits to reduce energy intake below that required for weight maintenance. The term 'reducing diet' has been coined to describe such diets used to treat the obese. Since many obese individuals may eat a nutritionally inadequate (apart from energy) diet, it is important that advice on energy restriction is accompanied by the prescription of a 'healthy' diet that contains adequate protein, vitamins, calcium, trace elements, and a desirable ratio of complex carbohydrate to fat. Weight loss *per se* is of no medical benefit unless it is maintained, and this will require the obese individual to adhere to a permanent change in eating habits. Many think of a 'diet' as a temporary change in eating habits (often extreme or quirky), a view encouraged by many of the diet books that hold out the promise of easy and instant success. It is essential that the concept of a long-term change in dietary habits be accepted at the start of treatment.

The energy value of weight gained or lost is approximately 31 MJ kg^{-1} (7500 kcal kg^{-1}) since it is composed approximately of 3 parts fat to 1 part lean. Thus a daily energy deficit of 2.1 MJ (500 kcal) will produce a weight loss of about 2 kg per month. For the average man or woman this represents a 20–30% reduction in energy intake, although for the obese the percentage reduction will be smaller. Thus the severely obese, for example with a body mass index (BMI) of 35 or more, will need to follow an energy-restricted diet for months rather than weeks to reverse their obesity. As weight is lost, energy requirements fall, in part because of the reduced energetic mass of the person, and also because of adaptive changes in energy expenditure. For this reason, the rate of weight loss will eventually slow and reach a plateau for any fixed level of dietary energy restriction (**Figure 1**).

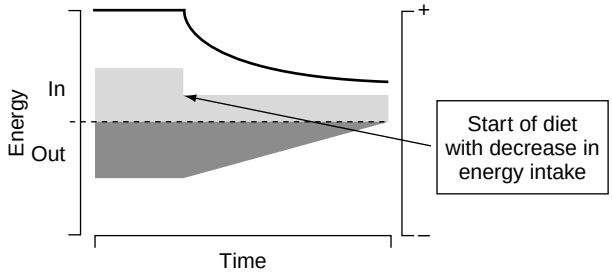

Figure 1 Fall in body weight (solid line) resulting from a fixed decrease in energy intake. Note that the rate of weight loss slows as the gap between energy expenditure (darker shading) and energy intake (lighter shading) narrows.

Myriad diets have been popularized and promoted directly to the public, reflecting every possible permutation of increasing or decreasing the major macronutrients. Fashion and commercialism have dictated many of them. **Table 1** shows the variety of diets that have been suggested, and used, for treating obesity. Many of these diets fail to focus on long-term dietary change, and the quirkiness of many makes it unlikely that they would be followed for long.

Current ideas on a reasonable reducing diet are that it should contain at least 100 g carbohydrate to prevent glycogen depletion and ketosis. High-carbohydrate diets are composed of complex carbohydrates and are thus of low energy density, which may aid management of hunger. Since high-carbohydrate diets are low in fat, they have the theoretical advantage of directly reducing the risk of cardiovascular disease. The energetic efficiency with which carbohydrate is converted and stored as fat is lower than that of dietary fat, providing a further advantage. Protein intake must be adequate to maintain lean body mass. Although there is an inevitable fall with weight loss, 0.8 g per kg per day + 1.75 g per 100 calorie deficit of protein (about 44 g daily for women and 56 g daily for men) should be consumed, and fat restricted to less than 30% of total energy. The diet should contain recommended daily intakes of vitamins, minerals, and electrolytes, if necessary by supplementation; 20–30 g daily of fiber should also be consumed.

Many diets prescribe an energy intake that is based on a generalized rather than an individualized assessment of energy needs. The common prescription of 4.2–5.0 MJ (1000–1200 kcal) daily may be problematic and inappropriate. Weight loss in men will be faster and greater compared to women of equal BMI, because of the relatively greater metabolic rate per kilogram of body weight of men. The very obese, whose daily energy requirements can be as high as 12.6 MJ (3000 kcal), may lose weight at an excessive rate and develop symptoms of ketosis, postural hypotension, or excessive hunger. Many obese patients fail to register or admit to the amount of food they consume, and claim that such a diet is more than their habitual intake.

One principle of energy prescription that has proved easy to administer and successful in outcome is to calculate energy requirements from standard formulas (**Table 2**), and prescribe a diet that provides a fixed energy deficit of 2.1 MJ (500 kcal). Compliance and weight loss were better with this approach than with a fixed 5 MJ (1200 kcal) diet.

A diametrically opposite approach is the use of very low-energy liquid diets. These were originally

Table 1 Types of diet used for treating obesity

Generic name for diet	*Typical dietetic modification*	*Popular example of diet*
Starvation diet	Less than 1.2 MJ (300 kcal) per day	Grapefruit and Black Coffee
Very low-energy (protein-sparing) diets[a]	About 2 MJ (500 kcal) per day with >50 g high-quality protein; usually liquid	Cambridge Diet Modifast
Low-energy diet[a]	5–7.5 MJ (1200–1800 kcal) per day often from menus, recipes	Weight Watchers TOPS
Fixed energy deficit diet[a]	Nutritionally balanced, individually tailored to produce fixed energy deficit (e.g., 2 MJ or 500 kcal per day) based on measured or predicted energy needs	Prescribed by dietitian
High-protein diet	Over 40% protein, thus low in carbohydrate and fat	Scarsdale Medical Diet
Low-protein diet		Beverly Hills Diet
High-fat diet	Restricted carbohydrate and protein	Drinking Man's Diet
Low-fat diet[a]	Restrict fat to <20% energy	Prescribed by dietitian Pritikin Diet
High-carbohydrate diet	Effectively low fat, may be high in fiber	F-Plan Diet
Low-carbohydrate diet	Limits carbohydrate to maximum <50 g daily	Yudkin Diet
Macronutrient choice[a]	Choice from lists of macronutrients to encourage intake of foods high in complex carbohydrates	No Counting Diet
Meal replacement	Liquid formula meals of about 1.7 MJ (400 kcal) to replace 1–2 meals daily	SlimFast
Fad diets	Varied; e.g., food combining diets that require macronutrients to be eaten separately and separated by time	Hay Diet

[a]Diets considered medically reasonable under defined circumstances.

Table 2 Formula for estimating resting metabolic rate (RMR) for men and women. The energy expenditure over 24 h can be estimated by multiplying by a factor related to activity levels (1.3, sedentary; 1.5, moderate activity; 1.8, physically very active)

Age (years)	*RMR*
Men	
18–30	0.063 × weight in kg + 2.896 MJ daily
31–60	0.048 × weight in kg + 3.653 MJ daily
>60	0.049 × weight in kg + 2.459 MJ daily
Women	
18–30	0.062 × weight in kg + 2.036 MJ daily
31–60	0.034 × weight in kg + 3.538 MJ daily
>60	0.038 × weight in kg + 2.755 MJ daily

developed in the 1960s to provide a nutritionally complete intake in terms of protein, vitamins, and micronutrients, but provide as little as 1.4 MJ (350 kcal) daily. The inclusion of sufficient high-quality protein was designed to prevent the excessive loss of lean body mass seen with starvation or other ketotic diets, hence the alternative term 'protein-sparing modified fast.' Appropriately selected, well-motivated patients are highly compliant with such diets, and their weight loss can be very rapid. Paradoxically, perhaps, patients seem to find it easier to mount levels of near-total restraint than more moderate restriction. It appears that withdrawing all solid or 'proper' food helps the patient to define himself or herself as 'not eating', in the same way that some quitting smokers find it easier to abstain completely from cigarettes rather than to cut down.

In the 1970s a commercial very low-energy diet formulation (the Last Chance Diet) was marketed, and was associated with a number of deaths from cardiac arrhythmia. This diet was deficient in essential amino acids and in minerals such as magnesium and potassium. It was withdrawn. In the 1980s newer, better formulated diets were commercially marketed. Concerns about their inappropriate use by already slim women, often with an eating disorder, forced governmental health agencies to issue guidelines on their use. In the US, a task force recommended that such diets contain at least 3.3 MJ (800 kcal), be supervised by experienced physicians, and be used only by those with a BMI more than 30, for less than 16 weeks. In the UK a report from the Committee on Medical Aspects of Food Policy suggested such diets should provide a minimum of 1.7 MJ (400 kcal) and 40 g protein daily for

women, and 2.1 MJ (500 kcal) and 50 g protein daily for men and tall women. They were recommended for use only by those with a BMI more than 25 and under medical supervision, for no longer than 4 weeks. The drawback of such diets is that unless they are combined with, or followed by, some other treatment (pharmacological or behavioral), weight regain, often soon and rapid, is almost universal.

More recently, low-energy liquid diets of around 3 MJ (750 kcal) daily have been popularized, often as part of an overall behavior modification program (see later), or in the form of sachets intended to be used as meal replacements. Both approaches have been shown to have potential for success in short-term studies lasting up to 1 year.

Exercise and Physical Activity

The term 'physical activity' refers to bodily movement produced by skeletal muscle that results in energy expenditure; it thus includes activities of daily living, as well as leisure activity from sport and exercise. The term 'exercise' refers to planned or structured bodily movements, usually undertaken in leisure time in order to improve fitness (e.g., aerobics), while 'sport' is physical activity usually in structured competitive situations (e.g., football). Physical activity at recommended levels (moderate intensity for 30 min for 5 days each week) is associated with many health benefits; these include lower all-cause mortality rates, fewer cardiovascular events such as myocardial infarction and stroke, and a lower incidence of metabolic disorders including non-insulin-dependent diabetes mellitus and osteoporosis. Levels of activity have been falling in Westernized societies largely because of a decrease in physical activity at work (from increasing mechanization) and increasingly sedentary leisure-time pursuits (such as television viewing). The Allied Dunbar National Fitness Survey of the UK showed that 70% of the population are insufficiently active, and a separate UK government survey showed that 1 in 3 adults could be classified as sedentary, i.e., taking less than half an hour of continuous moderate-intensity physical activity each week (**Figure 2**). Both cross-sectional data and prospective studies confirm an inverse relationship between physical activity and weight gain. The finding that in many countries such as the UK, average energy intake has fallen over the time that obesity has been increasing, emphasizes the importance of inactivity as a cause of obesity. These secular changes of inactivity are most marked in children who now spend much of their leisure time watching television or in other sedentary pursuits. Health authorities in many countries now

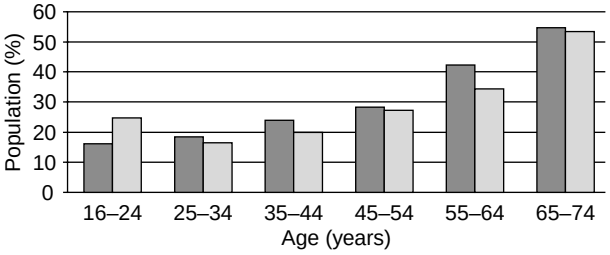

Figure 2 Percentage of adults in England by age and sex (1990–1991) with a sedentary life style; dark bars, men; light bars, women. Data from Fentem and Walker (1995) Setting targets for England: challenging, measurable and achievable. In: Killoran A (ed.) *Moving On: International Perspectives on Promoting Physical Activity*. London: Health Education Authority.

advocate an increase in physical activity as a means of preventing obesity and improving health and fitness. While there is agreement that such measures may be useful in preventing obesity, the role of exercise in treating obesity is less clear. Potential mechanisms linking exercise and activity with weight loss and weight loss maintenance are shown in **Figure 3**. Like dietary change, increasing time spent on exercise and activity can be seen as part of a generalized behavioral change, which can be self-reinforcing.

Exercise and activity raise energy expenditure over and above the resting metabolic rate. Under some circumstances, such as prolonged vigorous exercise in trained individuals, rates of energy expenditure remain elevated for some time after the cessation of exercise. Logically, therefore, exercise should be a useful way to treat obesity. However, the amounts of exercise-induced energy expenditure are small in comparison with potential changes in energy intake.

The energy cost of activity and exercise can be expressed as a multiple of resting metabolic rate, termed a MET; the term 'physical activity level' (PAL) represents the total daily energy expenditure divided by the resting energy expenditure; it typically averages 1.5. The energy costs of walking are about 2.0 MET – for a 70 kg individual this is about 0.5 MJ h^{-1} (120 kcal h^{-1}) – while gentle running costs about 8 MET or 2 MJ h^{-1} (480 kcal h^{-1}). A moderately fit individual would only be able to maintain a level of exercise of 7 MET for about 30 min, representing an additional energy expenditure of about 1.5 MJ (360 kcal) resulting, if energy intake were maintained, in a weight loss of about 0.3 kg per week.

Energy expenditure remains above baseline for some time after exercise has stopped; this is termed 'post-exercise energy expenditure.' The effect is small and only produced by very high levels of activity, capable of achievement only by elite

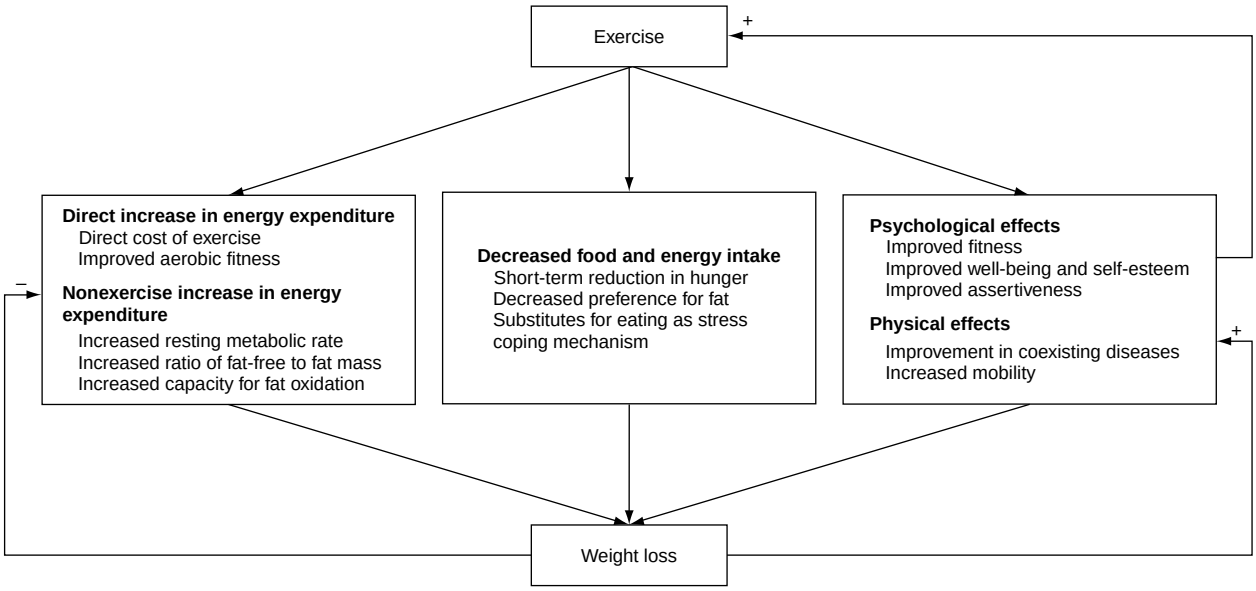

Figure 3 Mechanisms linking exercise with weight loss and weight loss maintenance.

athletes. The mechanism for this effect is unknown. Moderate intensity exercise programs, of the sort prescribed to the obese, are unlikely to raise energy expenditure by more than about 0.2 MJ (50 kcal) per exercise session.

Regular exercise does, however, elevate long-term energy expenditure by its effect on altering body composition. Resting metabolic rate is proportional to the fat-free mass. Exercise increases muscle development and bone mass, so directly raising metabolic rate. The purpose of weight loss is to reduce fat mass, with as little loss of fat-free mass (FFM) as possible. The loss of fat to meet the extra energy requirements of regular exercise will decrease the ratio of fat to FFM and thus indirectly favor an increase in resting metabolic rate for any given body weight. These effects are modest, and mainly only seen from the sort of high-intensity excercise achieved by athletes. Even endurance-level training over periods of up to 12 weeks increases nonexercising daily energy expenditure by less than 0.8 MJ (190 kcal).

The effects of exercise are thus quantitatively small. The relatively small potential for exercise to reduce body weight is borne out by the results of trials of exercise in obesity treatment, which suggest that exercise programs achieve weight losses of less than 0.1 kg per week, and that total weight loss averages about 3 kg. In one meta-analysis of five controlled trials of exercise without dietary restriction, mean weight loss in 95 men was 2.6 kg over 30 weeks, compared with a gain of 0.4 kg in the control group.

Programes that combine dietary and exercise interventions can be more successful, but it is often difficult to separate the effects of one from the other. In order to explore the effect of exercise on the composition of weight loss during dieting, Garrow analyzed data from 21 randomized, controlled studies. All trials that combined exercise and diet and included information about weight and FFM loss were included (**Figure 4**). A small reduction in the percentage of FFM lost is observed if exercise is included with the dietetic intervention. Thus, for example, in a woman losing 15 kg, exercise would reduce her FFM loss from 3.6 kg (24%) to 3.0 kg (20%). Similar but quantitatively greater benefits are seen in men: for a 15 kg weight loss, exercise reduced FFM loss from 3.6 kg (24%) to 2.5 kg (17%).

Activity and exercise are strong predictors for successful weight loss maintenance. A number of studies have shown that obese women who have lost weight and continue to undertake regular exercise are 3–4 times more likely to maintain their weight loss over a follow-up period of 2–3 years. The amount of exercise also correlates with the degree of success. In one study of about a hundred obese men and women who had lost about 27 kg, those with high levels of exercise were maintaining an average of 18 kg loss at 3 years, compared with 9 kg in the moderate exercise group and no weight loss in the nonexercisers. The importance of exercise and weight loss maintenance is demonstrated by a 2-year study of obese subjects treated by either diet, exercise, or a combination of the two. Weight loss in the diet group at 1 year was 6.8 kg, in the exercise group 2.9 kg, and 8.9 kg in the combination treatment group. However, after 2 years

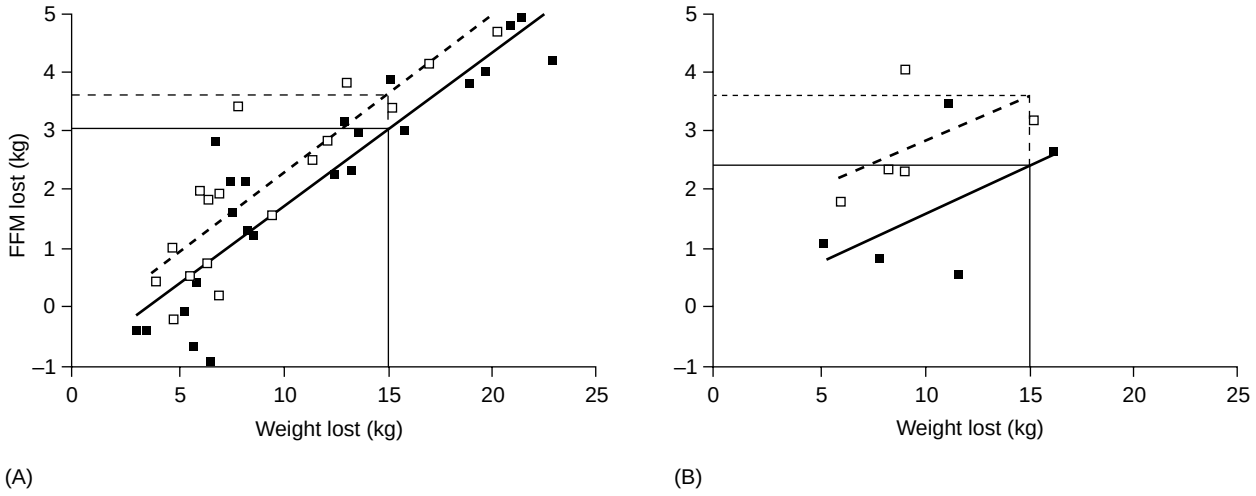

Figure 4 Relationship of total weight loss to fat-free mass loss in women (A) and men (B) undertaking a diet with exercise (solid squares, solid line) or without exercise (open squares, broken line). Data from 21 randomized controlled studies, collated by Garrow JS, Summerbell CD (1995) Meta-analysis: effect of exercise, with or without dieting, on the body composition of overweight subjects. *Eur J Clin Nutr* **49**: 1–10.

the groups that had included exercise were maintaining losses of 2.2–2.7 kg while those on diet alone had only managed to maintain a 0.9 kg loss. Similar findings have been seen in dieters from commercial slimming groups.

Behavior Modification

Behavioral modification is seen as the cornerstone of any treatment program that seeks to empower and enable obese individuals to make voluntary changes in life style. Any therapy relies to a greater or lesser extent on such a principle. For example, treating hypertension should be an apparently straight-forward clinical management issue, but patient non-compliance with medication is common. The skilled clinician will often include the principles of behavior therapy in consultations to help the patient understand and put into practice the new 'life style' of taking their drugs regularly. The approach in obesity is firmly based on theories of learning, and relies on the concept that behaviors associated with weight gain and weight maintenance are to a significant extent learned and subject to modification. Such a behavioral theory is not undermined by the knowledge that genetic and environmental factors are also important in determining the predisposition to obesity. A prerequisite for successful behavior change is that the individual must be 'ready' and motivated to change. It is common practice to assess this aspect of 'readiness' prior to enrolling patients in behavioral programs, and a number of standardized and validated questionnaires are available. Because behavioral programs are intensive of therapist time, patients are often treated in groups, often with manuals, which allow for individual study. These groups are usually 'closed;' that is, a small group of patients start the program simultaneously and go through it together. This contrasts with many commercial diet groups, in which patients are free to join or leave at any time. More recently computeraided interventions have been developed, but as yet results are not promising.

The components of a typical behavior modification programme are shown in **Table 3**. For each area, patients need to learn the underlying concepts, recognize the importance to their own situation, and practise strategies to change their behavior. The results of a large number of programs have been published, either as audit outcome or as comparative trials. Programs vary in duration from 12 weeks to 52 weeks (there has been a trend since the 1970s to lengthen treatment time). Drop-out rates are clearly biased by selection procedures, but are typically 10–20%. Weight loss during treatment is typically 10–15% of initial weight, at a rate of about 0.5 kg per week. In order to strengthen the impact of the intervention on weight loss, many programs have included a period of time on very low-energy or liquid-based diets. This approach of a complete withdrawal for a time from established (abnormal) eating habits can be usefully integrated into a model of behavior change, and is well and positively tolerated by obese patients. Although data suggest that the greater weight loss induced by very low-energy diets has little effect on the long-term results in terms of weight loss maintenance, these diets do represent a practical and pragmatic initial approach to treating patients in a group, especially when many individuals within such a group may resist

Table 3 The components of a typical behavior modification program

Domain	*Intervention strategy*	*Example*
Self-monitoring	Food intake diaries	Food diaries
	Exercise and activity	Activity logs
	Weight change	Regular weighing and recording on weight charts
Nutrition	Nutrition knowledge	Energy, macronutrients, understanding food labeling
	Healthy eating	Low fat, high complex carbohydrate, adequate fruit and vegetable intake
Exercise and activity	Increasing daily energy-using activities	Using stairs not escalators
	Decreasing sedentariness	Decrease television viewing
	Formal exercise	Group workouts at sports centers
Goal setting	Realistic rates of weight loss	Aim for 0.5–1.0 kg weekly
	Realistic target weight	10% weight loss as initial goal
	Weight maintenance	
Problem solving	Identifying conflicts with aims	Holidays, parties, restaurant meals
	Interpersonal conflicts	The unhelpful relative or friend
	Stimulus control and negative feelings	Hunger on returning home from work
Cognitive change	Modifying thoughts about and responses to food cues	Good and bad foods; food as a reward; coping with 'highly desirable' foods
	Self-esteem and assertiveness training	Recognizing and exerting choice
	Preventing relapse	Acceptance of occasional small weight gains

the idea that they are able to lose weight on conventional reduced-energy diets.

Research is now directed towards finding ways of improving the results of such programs in terms of long-term weight loss maintenance. An increased focus on weight-maintaining behavior rather than weight loss, a stronger emphasis on increasing activity and exercise, and better relapse strategies are being evaluated. Targeting the needs of specific subgroups, for example those with binge eating disorders or dysfunctional family circumstances, is another way in which behavioral therapy may be improved.

Weight Maintenance

H A Raynor and R R Wing, Brown University, Providence, RI, USA

Most of the developed world is in the midst of an obesity epidemic. In the United States, more than 60% of adults are overweight and obese. The negative impact of obesity on health outcomes and health care costs has heightened awareness of the importance of achieving successful weight loss maintenance. This article reviews information obtained from observational and experimental studies on successful weight loss maintenance. First, the definition

and prevalence of successful weight loss maintenance are presented, and why weight loss maintenance may be difficult is discussed. Next, factors identified in research examining weight loss maintenance, obtained from the National Weight Control Registry (NWCR) in the United States and from randomized controlled trials examining long-term weight loss and weight loss maintenance, are described. Finally, general recommendations for achieving successful weight loss maintenance are provided.

Definition of Successful Weight Loss Maintenance

There is no universally accepted definition of successful weight loss maintenance. We recommend the following definition: an intentional weight loss of $\geq$10% of initial body weight that is maintained for >1 year. Several points in this definition should be noted. First, the definition requires that the weight loss be intentional; this is important since several studies suggest that unintentional weight loss occurs frequently and may likely have different causes and consequences than intentional weight loss. Second, criteria for both magnitude and duration of the weight loss are set. The criterion of 10% weight loss is recommended since weight losses of this magnitude have been shown to have positive health consequence. The 1-year duration is selected in keeping with the US Institute of Medicine definition. However, examining both 1-year and 5-year maintenance of weight loss is suggested.

Data on Prevalence of Long-Term Maintenance of Weight Loss

Most information about long-term maintenance of weight loss comes from obesity treatment studies. In such studies, overweight individuals who receive a lifestyle intervention achieve a weight loss of approximately 7–10 kg at 6 months. Typically, the maximum weight loss occurs at 6 months, followed by weight maintenance for the next 6 months and then gradual weight regain. This pattern of weight change is illustrated in the Diabetes Prevention Program (DPP). DPP is a multicenter clinical trial of the effects of lifestyle intervention, metformin, and placebo on the development of diabetes in more than 3000 individuals with impaired glucose tolerance. **Figure 1** shows that participants in lifestyle intervention achieved an average weight loss of 7 kg (7% of initial body weight) at 6 months, maintained this weight loss through 12 months, and then gradually regained weight.

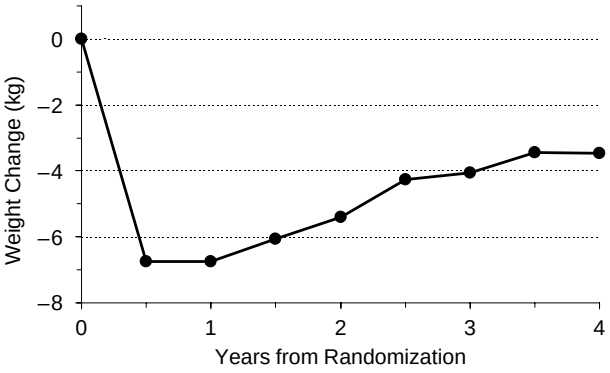

Figure 1 Average weight loss achieved in the lifestyle intervention of the Diabetes Prevention Program.

Few lifestyle treatment programs provide follow-up beyond 1 or 2 years. One study reported that at 5-year follow-up 13% of participants remained >5 kg below their baseline weight. Likewise, 22% of participants were >5 kg below baseline weight at 5 years in another lifestyle intervention.

These studies may underestimate the prevalence of successful long-term weight loss because they are based on a single episode of weight loss and likely involve a selected sample who find weight loss most problematic. For example, a random digit dialing telephone survey of 500 adults in the United States found that 228 of these adults reported being overweight (body mass index >27) at their heaviest weight. Sixty-nine of the 228 individuals were currently at least 10% below their highest body weight and had maintained at least a weight loss of $\geq$10% for at least 1 year (mean weight loss was 19.1 kg, maintained for 7 years). When successful weight losers were further restricted to those who reported intentional weight loss of >10% maintained for >1 year, 47 (20.6%) of the 228 overweight participants met this criterion. Thus, 20% of overweight individuals appear to meet the criteria specified for "success."

Why is Weight Loss Maintenance Difficult?

Long-term weight loss maintenance may be difficult due to a combination of physiological, environmental, and psychological factors. Proposed physiological factors contributing to weight regain include reduced resting metabolic rate and insulin and leptin resistance. However, investigations examining metabolic factors in individuals who have lost weight have not been able to consistently document changes in physiological characteristics that would explain the tendency for weight regain to occur. Environmental

factors may affect energy balance by promoting increased intake and/or reduced energy expenditure, causing weight regain to occur. The strong impact that environmental cues have on energy intake and expenditure have recently been acknowledged, as Americans are now described to be living in an "obesogenic environment." This environment provides greater exposure to a variety of highly palatable, energy-dense foods and expanding portion sizes that potentially increase intake. Additionally, the environment is filled with products of convenience and efficiency that promote decreased energy expenditure. The psychological self-control needed to override these environmental cues may be difficult for most people to sustain over long periods. Finally, during obesity treatment, weight loss can provide reinforcement for adherence to eating and activity prescriptions that promote weight loss. During weight loss maintenance, weight loss no longer occurs; therefore, there is less reinforcement of healthy eating and activity behaviors, causing motivation for sustaining these behaviors to decrease.

Research on Successful Weight Loss Maintenance

Although many individuals have difficulty sustaining weight loss, some are able to maintain a substantial amount of weight loss over a long period of time. To increase the prevalence of successful weight loss maintenance, two types of research investigating weight loss maintenance have been conducted: observational and experimental. In observational research, successful weight loss maintainers are identified and information about how they maintain their weight loss is collected. With experimental research, variables that are believed to affect weight status are manipulated and weight change over time is measured.

The National Weight Control Registry

The largest observational study of successful weight losers is the NWCR in the United States. The NWCR is a registry of individuals who have lost at least 13.6 kg and kept it off at least 1 year. On average, these participants have lost more than 27.3 kg and kept it off more than 6 years. Information that registry members have provided has aided in learning about the weight loss maintenance process.

Registry participants are recruited through newspaper and magazine articles and thus are a self-selected population. The registry members are primarily female (80%) and Caucasian (97%). Many have a strong genetic predisposition to obesity, with 73% having one or both parents with obesity and 46% having been overweight as a child.

Participants in the registry are asked to indicate how they lost their weight in this successful effort. Approximately half say they lost the weight entirely on their own, whereas the other half reported receiving some type of assistance from a physician, dietician, or commercial program. The combination of diet plus exercise was used by 89%, with the most common dietary strategy being restricting intake of certain types of foods.

Although there is marked heterogeneity in the approaches used for weight loss, there appear to be some common themes for weight loss maintenance. The first common element is consumption of a low-calorie, low-fat diet. Registry participants are consuming an average of 1381 kcal/day, with 24% of calories from fat, 19% from protein, and 56% from carbohydrates. Very few (less than 1%) report consuming a low-carbohydrate diet (less than 24% of calories from carbohydrates).

Registry members report eating an average of 4.87 meals or snacks per day. More than three-fourths of the sample report eating breakfast every day of the week, whereas less than 5% report never eating breakfast. Consuming breakfast may be an important behavioral characteristic of successful weight losers.

These long-term changes in diet in registry members are accompanied by long-term changes in physical activity. Women in the registry report 2545 kcal/week of physical activity and men report 3293 kcals/week. This is equivalent to 1 h per day of brisk activity. Approximately half of registry members engage in walking plus another form of physical activity, including cycling, weight lifting, aerobics, running, or stair climbing. Only 9% of registry members maintain weight loss without physical activity.

The final characteristic of registry members is that they weigh themselves regularly. More than 44% weigh themselves daily and 31% weigh themselves at least once a week. Frequent monitoring of weight may allow these individuals to quickly catch small weight gains and institute corrective actions. See **Table 1** for a summary of the strategies that registry

Table 1 Strategies used by successful weight loss maintainers in the National Weight Control Registry

Area	*Strategy*
Diet	Consuming a low-calorie, low-fat diet
	Consuming breakfast regularly
Physical activity	Engaging in 1 h of moderate–intense physical activity per day
Behavioral tools	Self-monitoring of weight

members have reported as being helpful for successful weight loss maintenance.

Experimental Studies Examining Weight Loss Maintenance

Our understanding of weight loss maintenance comes not only from the study of successful weight losers but also from randomized clinical trials evaluating specific treatment components. These trials are stronger scientifically because participants are randomly assigned to treatment conditions and all aspects of the intervention are kept constant except the factor under investigation. However, these studies are limited by their short duration (typically 1 or 2 years) and their relatively small sample size (usually 100–200 participants).

In experimental studies of weight loss maintenance, the primary focus is usually on overall weight loss (from baseline to the end of the study), usually defined as long-term weight loss, rather than on maintenance of weight loss from the end of the initial treatment (typically 6 months) to study end. Overall weight loss is selected as the variable of interest because it is most strongly associated with health impact. In addition, focusing on weight change from end of treatment to follow-up would make those who lost small amounts of weight but maintained that weight loss in full appear to be more successful than those who lost large amounts of weight and regained some.

Experimental research has focused on three main ways to increase long-term weight loss (**Figure 2**). The first is to increase the rate of initial weight loss so that a greater amount of weight loss occurs during the first 6 months of treatment. A second focus is to improve maintenance of weight loss achieved after the first 6 months of treatment. Finally, combining both of these approaches is considered the ideal approach.

Several strategies have been tested in experimental studies of weight loss maintenance, including focusing on energy balance, in which changes in diet and/or physical activity are used to create larger energy deficits that produce greater weight loss, or focusing on intensifying behavioral components of interventions so that skills necessary for sustaining weight loss can be maintained over a longer period. These strategies have been implemented during the initial weight loss treatment phase and the weight loss maintenance phase.

Energy Balance

In order to produce weight loss, it is necessary to modify energy balance by eating less and/or exercising more. A substantial body of research suggests that the combination of diet plus exercise is most effective for long-term maintenance of weight loss.

Diet

Within the context of diet, weight loss researchers have focused primarily on the level of caloric restriction and the degree of structure in the diet. Typically, behavioral weight loss programs recommend a low-calorie, low-fat diet. Participants are instructed to eat 1000–1500 kcals/day (low-calorie diet), depending on their initial body weight, and to reduce dietary fat to 20–25% of calories. There are no specific foods that are required or prohibited, but consumption of complex carbohydrates and guidelines based on the Food Guide Pyramid are stressed. Participants are instructed to self-monitor the calories and fat grams in all foods they consume. Self-monitoring is recommended daily for the first 6 months, and 1 week per month thereafter. Adherence to self-monitoring has been shown to be one of the best predictors of maintenance of weight loss.

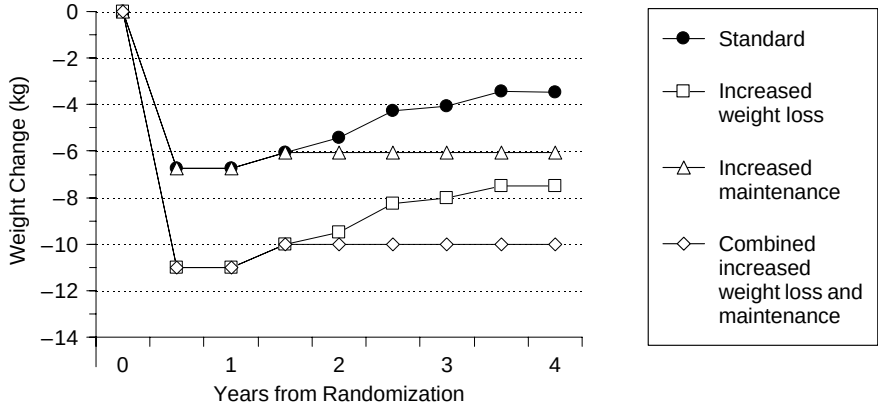

Figure 2 Ways to increase average long-term weight loss maintenance achieved in experimental research.

Very low-calorie diets Very low-calorie diets (VLCDs) are dietary regimens that provide approximately 400–600 kcal per day usually as a liquid formula. VLCDs have been shown to produce excellent initial weight losses (−20 kg at 12 weeks); this effect is due in part to the degree of caloric restriction and in part to decreased dietary variety and the use of portion-controlled foods in these regimens. Given the large initial weight loss produced by VLCDs, it was hoped that combining these diets with behavioral approaches would maximize long-term weight loss. Although VLCDs improve initial weight loss, they do not appear to produce better long-term weight loss than low calorie diets (LCDs). Difficulty with weight maintenance in programs with a VLCD appears to occur during the transition from the VLCD to a diet composed of conventional foods.

Since VLCDs have been very effective at decreasing intake, the effect of intermittent use of VLCDs (initiating weight loss with a VLCD, transitioning to conventional foods, and then returning to a VLCD) on long-term weight loss has also been investigated, but results have been less than promising. During a 50-week behavioral obesity intervention, in which a VLCD was prescribed for weeks 1 through 12 and 24 through 36, weight loss at week 50 was not significantly different between an intermittent VLCD and a LCD.

VLCDs with caloric levels between 400 and 800 kcals/day have been compared to examine if greater caloric restriction produces better weight loss. One study compared two outpatient groups with different caloric prescriptions, 420 and 800 kcals/day, and found that weight loss was not significantly different between the groups. This suggests that VLCDs may produce greater initial weight loss not only by restricting calories but also by increasing the structure of the diet.

Structured low-calorie diets Several studies have investigated different ways to increase the structure of LCDs. Structure in the diet can be strengthened by decreasing variety and/or food choices and by controlling portion sizes consumed. A study examined whether providing food to participants, which controls portion size and decreases food choice, improved long-term weight loss during a standard behavioral intervention using an LCD. Participants were provided all of the food they should eat for five breakfasts and dinners each week for 18 months. Participants receiving the food provisions had greater weight loss at 6 months (−10.1 vs. −7.7 kg), 12 months (−9.1 vs. −4.5 kg), and 18 months (−6.4 vs. −4.1 kg) than those participants receiving a standard intervention, even though both groups had identical calorie goals (1000–1500 kcals/day). However, even with the greater dietary structure, participants still regained weight during the maintenance phase.

Structure in the diet, by decreasing food choices, can also be increased by providing structured meal plans and detailed grocery lists. One investigation that provided meal plans and grocery lists along with a standard intervention showed greater weight loss than the standard intervention alone. The weight losses achieved with the meal plans were similar to those achieved with food provisions.

Using portion-controlled foods available in the marketplace, such as frozen entrees and meal replacement products such as Slim-FastR, also increases dietary structure. When an LCD composed of conventional foods was compared to an LCD using two Slim-FastR meal replacements, two Slim-FastR snack bars, and a healthy dinner, the diet using the Slim-FastR portion-controlled foods produced better weight loss at 3 months (−7.1 vs. −1.3 kg). For the next 24 months, both groups were instructed to consume one Slim-FastR meal replacement and snack bar per day. At 27 months, the Slim-FastR group still had better weight loss (−10.4 vs. −7.7 kg), and the greater weight loss was maintained at 4 years (−9.5 vs. −4.1 kg) in those participants available for follow-up.

Food provisions have also been used during a maintenance intervention as a rescue strategy. However, used in this manner, food provisions were not helpful in improving weight loss maintenance compared to a maintenance program without food provisions.

Consequently, increasing dietary structure by decreasing variety and food choices and/or using portion-controlled foods appears to improve long-term weight loss. These changes in the diet may increase adherence to an LCD, thereby producing greater weight loss, especially during the first 6 months of obesity treatment.

Physical Activity

Correlational studies suggest that physical activity is the single best predictor of long-term maintained weight loss. Physical activity is important because it increases energy expenditure, but it may also reduce hunger and improve mood. Physical activity is usually prescribed at a level of 1000 kcals/week or 150 minutes of moderate–intense activity per week; however, long-term weight loss has been found to be greater in participants who are active 200 minutes or more per week compared to those who are active 150 minutes or less per week during weight loss

interventions. Similarly, the NWCR data discussed earlier show that successful weight loss maintainers are very active, reporting more than 2500 kcals/week of activity. This suggests that an exercise prescription of at least 200 minutes per week may be needed to improve long-term weight loss. One study compared the effect of a standard activity recommendation (1000 kcals/week) versus a higher physical activity prescription (2500 kcals/week, equivalent to walking 75 minutes 5 days per week) in a standard behavioral weight loss intervention. The group with the higher physical activity prescription had greater long-term weight loss at 12 months (−8.5 vs. −6.1 kg) and 18 months (−6.7 vs. −4.1 kg). However, even with the higher exercise prescriptions, participants still regained weight during the maintenance phase.

Strategies for improving maintenance of physical activity One of the most challenging problems with physical activity in weight control programs is adherence to activity prescriptions. One way to increase activity adherence is to prescribe activity in short bouts (40 minutes/day in four 10-minute bouts) rather than in long bouts (40 minutes/day in one bout). Accumulating activity during the day may make it easier to achieve physical activity goals. Although short bouts of exercise improved initial adoption of exercise, they did not appear to increase physical activity adherence or weight loss at 12 and 18 months. Participants have also been provided with personal trainers, supervised walks, home exercise equipment, and financial incentives to improve physical activity adherence. Although personal trainers and financial incentives did increase attendance at exercise sessions, neither improved total exercise achieved or weight loss at 18 months. Providing participants with home exercise equipment has been shown to improve both adherence to physical activity and weight loss. Participants given home exercise equipment and encouraged to exercise in multiple short bouts had greater long-term weight loss (18 months) than those prescribed short bouts without equipment (−7.4 vs. −3.7 kg). The results of this study suggest that home exercise equipment and other approaches that make exercise more convenient may facilitate long-term adherence and consequently weight loss maintenance.

Another approach evaluated for increasing long-term physical activity adherence is focusing specifically on physical activity during a weight maintenance program. A 6-month exercise-focused maintenance program, which included supervised group walking sessions, individual and group incentives for exercise completion, and relapse prevention training aimed at maintaining physical activity, was compared to a weight-focused maintenance program, which focused on group problem solving of weight-related problems. No differences were found between the groups in terms of exercise participation and energy expenditure at the end of the maintenance program or at 6-month follow-up. The weight-focused group had better maintenance of weight losses over 6-month follow-up (3.1 vs. 5.2 kg). These results and findings from other studies suggest that placing too much emphasis on activity may detract from the dietary component of weight loss interventions and consequently decrease long-term weight loss success.

Taken together, it appears that physical activity at higher prescriptions, $\geq$200 minutes per week, aids long-term weight loss. However, adherence to this amount of activity may be difficult, and providing home exercise equipment with a physical activity prescription of multiple short bouts may be a promising approach.

Intensifying the Behavioral Component

Whereas the research described previously focused on ways to enhance negative energy balance through modifications in diet and physical activity, other investigations have examined ways to intensify behavioral components in weight loss or weight loss maintenance interventions. These strategies include extending professional contact, increasing social support, enhancing motivation using incentives, providing skills training, and combining some of these strategies into multicomponent maintenance programs.

Extending professional contact As noted previously, the maximum weight loss in a behavioral weight loss intervention is typically attained at 6 months, which also represents the end of the weekly phase of therapy and the start of the less intense maintenance phase. Weight regain is commonly assumed to be due to a failure to continue practicing effective behavioral techniques when treatment transitions. One way to sustain behavioral strategies is to lengthen treatment or to continue to provide some form of professional contact during the maintenance phase.

Lengthening the initial phase of treatment has been shown to increase initial weight loss. For example, when behavioral treatments of identical content, differing only in length of treatment (20 vs. 40 weeks), are compared, the two programs produce similar weight losses at 20 weeks (−9.5 kg), but the extended treatment produces greater weight

loss at 40 weeks (−13.6 vs. −6.4 kg). Based on this, several investigators tried to develop year-long programs with weekly meetings throughout. Weight losses at the end of the year were 10–14 kg, but attendance became quite poor toward the end of the program and the cost-effectiveness of such long-term weekly programs was questioned. Thus, investigators have considered how best to provide contact after the end of the 6-month weekly program.

One of the first methods employed to extend professional contact during the maintenance phase was the use of booster sessions. Booster sessions take place on a fairly infrequent basis after treatment, with an increasing interval of time between sessions to fade professional contact (e.g., meeting at months 1, 3, 6, and 12). Booster contacts have yielded inconsistent results. This finding and the fact that better maintenance of weight loss occurs when participants continue to be seen biweekly suggest that patients need a fairly high level of contact during maintenance. Studies using biweekly maintenance programs have found better weight loss maintenance at 6-month (120% (continued weight loss) vs. 83% (weight regain)) and 18-month (87 vs. 33%) follow-ups compared to a control intervention receiving no maintenance component. The specific content of the maintenance sessions appears less critical than the frequency of ongoing contact, the regular weighing of patients, and the emphasis on continued self-monitoring. Although face-to-face contact appears most effective, it may also be possible to provide extended contact by phone, mail, or e-mail.

Social support Another approach to provide long-term support is to involve friends and family of participants in the treatment program. Spouses have been included in treatment, but the effects have been mixed. A meta-analysis of the spouse support literature showed a small positive effect through 2 or 3 months of follow-up. One study examined the effectiveness of natural social support (participants were recruited with three other friends and family members who were all losing weight in the same program) and experimentally created social support (through the use of intragroup activities and intergroup competitions) during a standard behavioral weight loss intervention. Sixty-six percent of participants recruited with a friend and given the social support intervention retained their weight loss in full from month 4 to month 10 compared to 24% of individuals recruited alone and given the standard behavioral intervention without any social support intervention.

Peer support can also be developed among group members in the same weight loss intervention. Support from other members of the group may explain the finding that group treatment tends to be more successful than individual therapy. One investigation conducted a 7-month weight loss maintenance program involving peer support following a behavioral obesity treatment. Participants formed peer self-help groups, which met biweekly and used group problem-solving skills to handle difficulties with weight loss. The peer support group maintained a greater weight loss at 1-year follow-up than the control group that received no maintenance program (−6.5 vs. −3.1 kg). These studies suggest that social support is helpful in long-term weight loss and weight loss maintenance.

Incentives for weight loss and weight loss maintenance Behavioral interventions used in obesity treatments focus on changing antecedents and consequences of behaviors that influence energy balance. Behaviors that produce negative energy balance, and consequential weight loss, can be reinforced, thereby increasing the likelihood that these behaviors will continue. The effects of contracting for healthy behaviors and weight loss have been inconsistent. Contracting with participants to attend supervised exercise sessions doubled the number of walks attended but had no effect on overall activity level or weight loss. Likewise, providing financial incentives (a substantial cash payment was given each week to participants when the weekly weight loss goal was met) during a standard behavioral weight loss program had no effect on long-term weight loss. Procedures in which patients deposit money at the start of the program and then earn portions back each week for meeting specific weight loss goals or self-reported caloric intake goals appear more effective. In one study showing positive results, the financial deposits were returned based on the average weight loss of the whole group.

Skills training Another approach to improve maintenance of weight loss is to provide participants with training in specific skills. These specific skills can provide participants with the ability to cope with high-risk situations that increase the likelihood of a relapse of problematic eating and activity behaviors.

Two types of skill-based maintenance programs, provided after the completion of a standard behavioral weight loss intervention, have been investigated. One approach focuses on relapse prevention, in which participants are taught a

variety of methods to anticipate and cope with the problem of relapse in weight loss maintenance. In the second approach, participants are taught to use the steps of problem-solving to manage difficulties during weight loss maintenance. After 1 year of a maintenance program, participants in the problem-solving intervention had better weight loss than those who had received no maintenance program following treatment (−10.8 vs. −4.1 kg). There was no difference in weight loss between participants in the relapse prevention program and those participants who received no maintenance program (−5.9 vs. −4.1 kg). These results suggest that strengthening problem-solving skills during weight maintenance improves weight loss maintenance.

Multicomponent programs Since long-term weight loss maintenance is believed to be difficult for many reasons, an approach that combines several different strategies used after initial weight loss treatment may produce better weight loss maintenance. These multicomponent maintenance programs have used different combinations of extending professional contact, increasing peer support, providing incentives, and increasing physical activity. All programs using a multicomponent maintenance program show better weight loss maintenance at 18-month follow-up compared to no maintenance program, but the multicomponent programs do not produce greater weight loss maintenance than simple programs that just extend professional contact.

Conclusion

Successful weight loss maintenance can be challenging. However, information obtained from the NWCR, a registry of long-term successful weight loss maintainers, and from experimental studies that have examined different approaches to improve weight loss maintenance indicates that there are several strategies that may assist with long-term weight loss maintenance. These strategies are described in **Table 2**. Most notably, it is vital to recognize that for successful weight loss maintenance, individuals must continue to consume less calories and to engage in a greater level of physical activity than they did prior to weight loss; otherwise, they will return to a state of positive energy balance, in which weight (re)gain occurs.

Information from the NWCR suggests that to sustain weight loss, a low-calorie, low-fat diet is needed. Experimental studies show that at least during the weight loss phase, a structured low-calorie diet improves long-term weight loss. The structure of the diet can be increased by using food provisions, structured meal plans, and/or meal replacements. In addition, maintaining structure in the diet may help sustain a lower calorie diet, thus helping with weight maintenance.

Being physically active, for at least 200 minutes per week, also seems to aid in successful weight loss maintenance. Both experimental studies and self-reported activity information from registry participants support this recommendation. Ways to assist with achieving this level of activity include having

Table 2 Helpful strategies for successful weight loss maintenance

Area	*Strategy*
Diet	Consume a low-calorie (~1500 calories per day) diet
	Consume a low-fat (<30% calories from fat) diet
	To assist with consuming a low-calorie diet, increase structure in the diet using
	Food provision
	Meal plans
	Meal replacements
Physical activity	Be active at a moderate–intense level for at least 200 minutes per week
	To assist with achieving at least 200 minutes of activity per week,
	Have exercise equipment available at home
	Allow activity to accumulate during the day (in at least 10-minute bouts)
Self-monitoring	Record body weight at least once per week and not more than once per day
Professional contact	Extend professional contact beyond initial treatment
	Should occur on at least a biweekly basis
	Can occur in person or by phone, possibly Internet
Social support	Include support from other individuals also working toward weight loss or weight loss maintenance
	Can be from family, friends, or other members of treatment group
Skills training	Include problem-solving focused on weight loss maintenance during maintenance programs

exercise equipment available at home and accumulating activity in short (at least 10 minutes) bouts during the day.

In formalized behavioral programs, other strategies that may improve weight loss maintenance include extending professional contact beyond the initial 6 months of weekly treatments. To be most helpful, this contact should occur on a biweekly basis. Extending contact using technologies such as the Internet is being investigated and shows promise. Including peer support during both the weight loss and the weight maintenance phases of treatment can also improve long-term weight loss. In addition, during the maintenance phase, the focus of the intervention should be problem-solving difficulties related to maintaining weight loss. To date, studies suggest that effective long-term treatment of obesity may require several different strategies, implemented over an extended period of time. Although these tactics improve long-term weight loss, many patients still regain weight after the initial 6-month treatment. Consequently, further research on improving successful weight loss maintenance is needed.

Weight Cycling

L Lissner, Sahlgrenska Academy at Göteborg University, Göteborg, Sweden

> Is it better to have lost and regained than never to have lost at all?
>
> —Weight cycling refrain loosely adapted from Alfred Lord Tennyson

Weight Cycling—A Health Risk?

The term 'weight cycling' is used in the fields of nutrition and obesity research to refer to losses and subsequent regains of body weight typically occurring in association with weight loss dieting. Interest in this phenomenon was initially based on the observation that conventional weight loss programs are often unsuccessful in the long term. Dieting recidivism thus sets the stage for weight cycling, popularly referred to as yo-yo dieting, whereby dieters undergo multiple cycles of weight loss and regain in pursuit of their ideal body weights.

There seems to be little disagreement that weight cycling is one of the most difficult therapeutic aspects in the management of obesity. The majority of obese subjects seeking treatment have previously experienced cycles of weight loss and regain. Examples of weight cycling in two case studies are shown in **Figure 1**. These examples illustrate several phenomena that are important when considering weight cycling in humans: Weight losses and subsequent regains frequently occur in conjunction with intentional weight loss dieting; however, weight changes vary in magnitude and important fluctuations may be missed if weight measurements are taken at infrequent time intervals. Moreover, these two cases

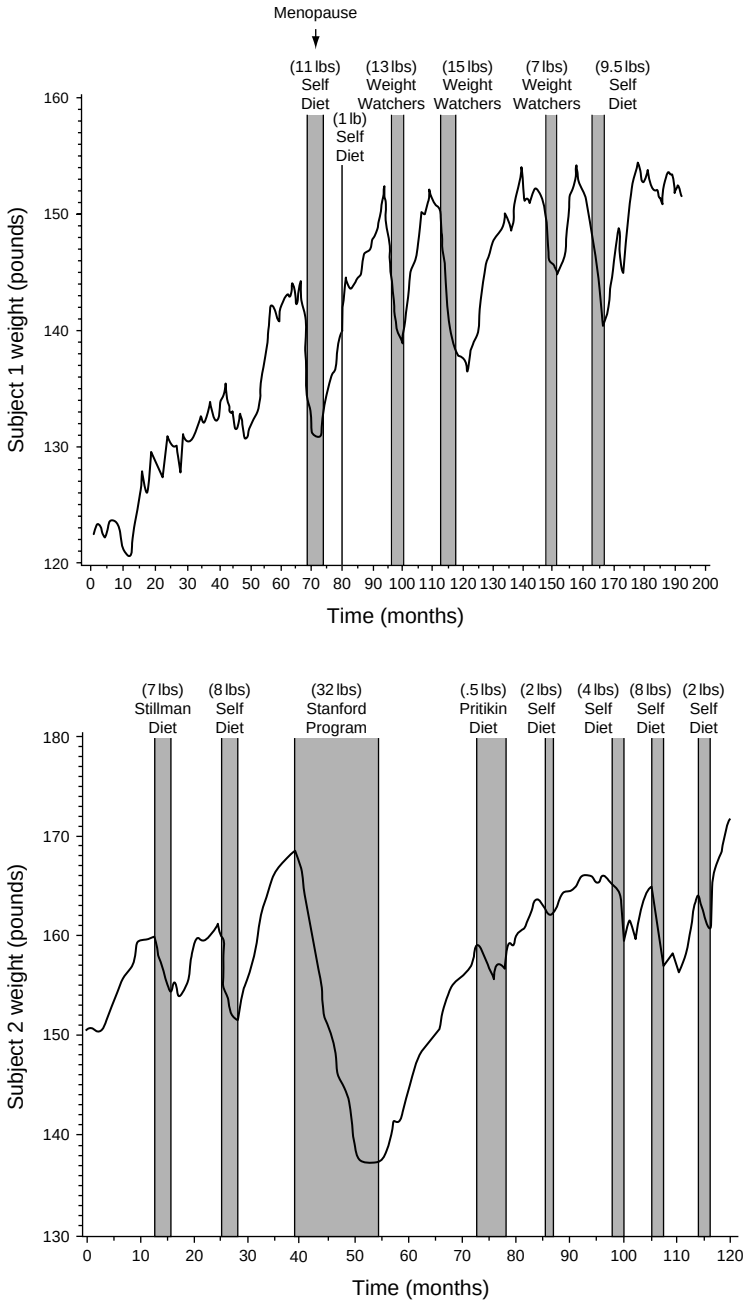

Figure 1 Monthly body weights (average of daily weights) of two female subjects, self-monitored over time. Reproduced with permission from Black DR, Pack DJ, and Hovell MF (1991) A time-series analysis of longitudinal weight changes in two adult women. *International Journal of Obesity* **15**: 623–633.

illustrate the common observation that intentional weight losses are frequently followed by regains in excess of the original body weight, and that true weight stability may be difficult to achieve.

Dieting to control body weight is not confined to overweight individuals but has been widely reported even among men and women who have never been overweight. As described by Jeffery in 1984, 72.5 and 43.7% of surveyed women and men, respectively, had dieted to lose weight; even among women who had never been overweight, the majority reported having been on weight loss diets. Although it is traditionally assumed that adherence to weight reduction diets is beneficial to health, the high rates of dieting and weight loss recidivism, among the nonobese as well as the obese, have naturally created concern regarding potential negative health consequences. However, weight cycling can be intentional or unintentional, and the most recent generation of research on weight cycling has

focused on intentional weight loss as the risk factor of relevance to the weight cycling debate.

In this article, some of the main points of this debate are highlighted. The first epidemiological studies suggesting health implications of weight cycling were reviewed in 1992, at which time the majority of available observational evidence indicated adverse consequences. Subsequently, this topic became a source of considerable controversy, and a number of investigators continued to examine this issue, focusing on possible effects of weight cycling on metabolism, chronic disease, and mental health. This article also provides an overview of knowledge in this area, together with some methodological controversies surrounding existing research on weight cycling.

The Metabolic Hypothesis

Given the fact that most people who lose weight are unable to sustain their losses, a metabolic hypothesis was formulated. It was proposed that if weight loss dieting caused permanent decreases in metabolic rate, the weight would be easily regained and every subsequent weight loss attempt would be more difficult. In the 1990s, the National Task Force on the Prevention and Treatment of Obesity in the United States reviewed the evidence and reported an overall lack of support for the hypothesis that weight cycling promoted obesity, increased body fat, or had permanent effects on metabolism. This report also concluded that the majority of available data in animals did not independently link weight cycling to any parameter of energy balance (food intake, body composition, or energy expenditure). This conclusion was supported by studies in humans, using a variety of designs, that failed to document irreversible effects of weight loss on metabolic rate, body composition, or adipose tissue distribution after regain. Also of interest in this context is the observation that, despite their regains in lost weight, weight cyclers tend to gain less (not more) weight over time than their weight-stable peers.

Weight Cycling and Mortality

Although most studies have not borne out the original idea that weight cycling alters metabolic rate, the possibility that weight fluctuation predicts chronic disease and death has been more difficult to discount. A number of prospective epidemiological studies have shown that an individual's variations in body weight over time, a proxy for weight cycling, can be used as statistical predictors for subsequent mortality and disease end points. Positive associations have been reported between body weight fluctuation and all-cause mortality in several but not all such studies.

These findings are often expressed in terms of relative risk estimates, which represent the mortality rates in a weight-fluctuating group compared to the rates in a weight-stable group. The relative risk estimates for all-cause mortality have been reported to be as high as 2, indicating a double excess mortality risk in the weight fluctuators. Some investigators have reported that significant associations are restricted to certain types of individual (i.e., nonobese or nonsmoking subgroups). It has been reported that the excess risk of mortality in weight-unstable men may be to a large extent explained by preexisting disease. Moreover, an analysis of data from the Multiple Risk Factors Intervention Trial concluded that any adverse effects of weight fluctuation were occurring in relatively normal weight subjects.

As an example, results are shown from a reanalysis of a longitudinal population study of Swedish women started in 1968 when subjects were 38–60 years old. Women were weighed on three occasions during a 12-year observation period, based on which four subcategories of weight change could be created: stable, weight gain, weight loss, and weight cycle. Specifically, these groups were defined as (i) women whose weights remained stable within ± 3 kg; those who (ii) gained or (iii) lost at least 3 kg between the first and last observation; and (iv) those who had lost and then regained at least 3 kg, or gained then lost 3 kg, without an overall change of more than 3 kg from the first to final observation. When these groups were followed for an additional 20 years, it was found that the weight loss group and weight cycling group both had approximately double the risk of mortality compared to the weight stable women (**Figure 2**). It may be argued that the weight losses and subsequent gains may not be voluntary but rather reflect preexisting diseases. However, after exclusion of women with prevalent or incident cancer, diabetes, or cardiovascular disease during the entire period of weight observation, the excess mortality in the fluctuating group was not attenuated, suggesting that morbidity from these conditions was not the underlying cause of the fluctuations or reason for the association. These findings and similar observations in a number of other populations have not been adequately explained by biologically plausible mechanisms.

Weight Cycling and Cardiovascular Disease

Most investigators have considered it more informative to focus on the association between weight

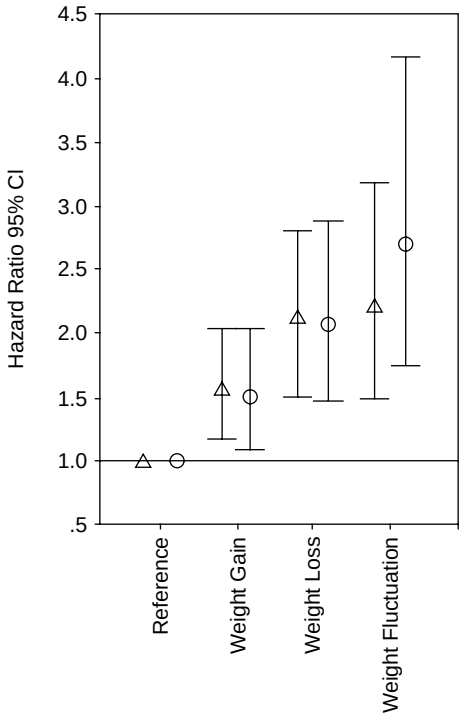

Figure 2 Relative risks with 95% confidence interval for 20-year all-cause mortality in relation to previous 12-year weight changes in the Prospective Population Study of Women in Göteborg. Triangular symbols refer to risks of total mortality, adjusted for age and final body mass index in 800 women. Circular symbols display results after excluding 99 prevalent cases of coronary heart disease, diabetes, or cancer during 12 years of weight observation.

fluctuation and specific diseases and causes of death and have frequently observed positive associations between weight fluctuation and cardiovascular disease end points. However, the results have not always been in agreement; data from the Framingham study showed excess cardiovascular disease among male and female weight fluctuators, whereas in men from the Baltimore Longitudinal Study on Aging there was no association between weight fluctuation and coronary heart disease. Two additional studies in male populations are illustrated in **Figure 3**. Both show a pattern of elevated risk of mortality from cardiovascular or coronary heart disease among weight cycling men and consistently lowest risk associated with stable body weight, based on which it has been concluded that stable weight over time is associated with best health.

It has been hypothesized that some of the observed associations between weight fluctuation and cardiovascular disease may be explained by changes in cardiovascular risk factors occurring during weight gain that are not fully reversible with weight loss. This possibility has been explored using longitudinal data on body weight and risk factors that are concurrently measured on multiple occasions. A systematic review of these studies by the National Task Force on the Prevention and Treatment of Obesity revealed no consistent associations between weight fluctuation and concomitant increases in traditional cardiovascular disease risk factors, such as blood pressure and serum cholesterol.

Hypertension has also been examined as an end point in a number of studies with somewhat mixed results. Based on data from the Nurse's Health Study II, it has been reported that intentional weight cycling is not associated with significant excess risk of development of hypertension. In contrast, a retrospective study indicated that a positive history of weight cycling among obese women as well as the

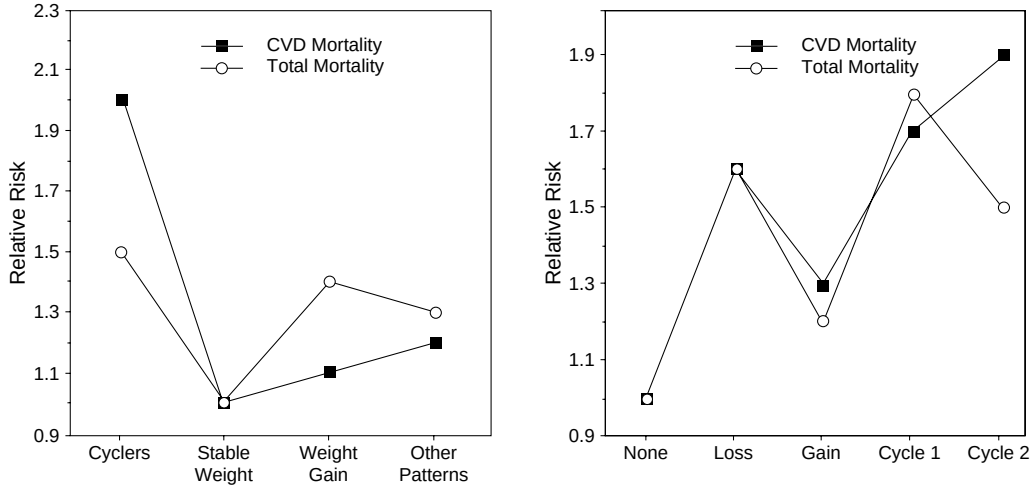

Figure 3 Total and cardiovascular disease (CVD) mortality in male subjects with different weight change patterns. (Left) Data from the Chicago Western Electric Study (Hamm *et al.*, 1989); (right) data from MRFIT (Blair *et al.*, 1991). Cycle 1 refers to cycle ending with weight loss, while cycle 2 ends with a weight gain. Reproduced with permission from Jeffrey RW (1996) Does weight cycling present a health risk? *American Journal of Clinical Nutrition* **63**(supplement): 452S–455S.

sum of weight regained increased the likelihood of being hypertensive. Interestingly, a possible beneficial effect of one weight cycle has been reported: In this blood pressure reduction trial, weight returned to baseline levels after 3 years, whereas blood pressure remained well below control levels. Control subjects in this study experienced a net weight gain, and one interpretation of this study is that a weight cycle did not predispose further hypertension but, rather, seemed to deter further weight gains at control levels, as also observed in the Nurses Health Study II.

Other Health Outcomes: Bone Status, Cancer, and Diabetes

Although a number of the original weight cycling studies also tested associations between weight cycling and cancer, cancer end points have typically not followed the same patterns as cardiovascular disease. It has also been observed that temporary weight cycling (weight loss followed by weight gain) is not associated with increased risk of postmenopausal breast cancer.

It has been proposed that weight cycling may affect bone density and fracture risk, but the evidence here is also mixed. For instance, one study observed that men and women with most weight variability had an increased incidence of hip fracture, whereas another observed no apparent relation between weight cycling and bone density.

Finally, a number of studies have examined associations between weight cycling and diabetes and have yielded little evidence of a relation. According to findings from the Nurses Health Study, no association was found between weight fluctuation and diabetes incidence. In another study, glucose tolerance and weight fluctuations were directly monitored in obese patients, and no deterioration was observed to be directly associated with weight cycling. Interestingly, the Diabetes Prevention Program Research Group found that the diabetes reduction achieved over 4 years with a lifestyle intervention was not diminished with the gradual regaining of more than half of the weight lost. This observation is an indication that a period of weight reduction may exert a net benefit for diabetes, even if weight is subsequently regained.

Psychological Consequences

It has often been assumed that the experience of dieting followed by involuntary regain of the weight lost must take a psychological toll, independent of any medical consequences of weight fluctuation. The possible psychological effects of weight cycling among obese people were the topic of a literature review that reported that weight cycling was not associated with depression or other psychopathology or depressogenic cognitive styles. It was observed, however, that weight cycling was associated with decreased perceptions of health and well-being, decreased eating self-efficacy, and weak increases in binge eating severity. Subsequently, it was concluded that an individual's perception of being a weight cycler may be more related to psychological problems than the actual number of pounds lost and regained over time. In 2000, the National Task Force on the Prevention and Treatment of Obesity concluded that concerns that dieting induces eating disorders or other psychological dysfunction in overweight and obese adults are generally not supported by empirical studies. This is in contrast to the wide belief that dieting is a necessary precursor for subsequent development of eating disorders.

Methodological Issues

Although a number of studies have shown that increased weight fluctuation is associated with subsequent occurrence of adverse health outcomes, a number of methodological problems make interpretation of these findings difficult. For example, weight gain, weight loss, and weight cycling are often considered separately, but it is almost impossible to determine their degree of overlap in observational studies. An individual who is observed to be systematically gaining weight at two points in time may experience a number of unmeasured fluctuations in the interim. The statistical complexities in defining weight cycling were reviewed in 1994 by the National Task Force on the Prevention and Treatment of Obesity.

A frequent critical observation surrounding this type of research is that different studies may be measuring quite different kinds of weight change—voluntary and involuntary. Involuntary changes may reflect serious underlying illness, depression, and other nondieting phenomena. However, intentional dieting may also occur by a variety of dietary methods, some of which are more detrimental to health than others. When focusing exclusively on voluntary losses, it has been suggested that preexisting medical conditions may profoundly influence associations with subsequent mortality risk. The issue of volition may shed light on the problem, but the specific impact of previous and current illness on epidemiological associations between weight cycling and longevity is still not fully understood. Other covarying factors besides intentionality of weight change and underlying illness may be producing artifactual associations in observational studies. These include

aging, smoking and other lifestyle choices, degree and regional pattern of adiposity, and psychological factors. In epidemiological analyses, various types of statistical corrections can be made for potential confounding factors of this type, although adjustment may be incomplete. Finally, biological plausibility is always an issue to consider when reviewing any epidemiological evidence and has been a particular concern when considering the observations of excess risk in association with weight fluctuations.

Conclusion

As summarized in **Table 1**, many but not all epidemiological studies indicate that men and women undergoing body weight fluctuations are at higher risk of mortality and/or cardiovascular disease than individuals experiencing less fluctuation, but the lack of biologically plausible mechanisms to explain these associations has limited the conclusions that can be drawn. Moreover, the evidence for effects on psychological and other health end points is inconclusive. Uncontrolled confounding from disease states resulting in a loss–gain or gain–loss pattern must be considered a plausible explanation for some of these findings, underscoring the difficulty of using observational data to study weight cycling. Moreover, some studies are emerging suggesting that even limited periods of weight reduction may be beneficial in the long term. Experimental data and intervention studies are required for confirmation of the weight cycling hypothesis. The published observational studies of subjects whose weight changes are known to be caused by dieting have been important contributions to the critical discussion of the weight cycling phenomenon, but additional studies are needed in which weight fluctuations are assessed in a more controlled manner.

Regarding the hypothesis that dieting exacerbates the problem of obesity and weight gain, most studies have failed to demonstrate that weight fluctuation per se depresses metabolic rate. Available research on the effects of weight cycling on both metabolism and disease thus provides little basis to discourage overweight patients from losing weight. Nevertheless, one of the conclusions of the 1994 report from the National Task Force on the Prevention and Treatment of Obesity was that individuals who are not obese and who have no risk factors for obesity-related illness should not undertake weight loss efforts. The only uncontroversial message of the weight cycling research is that overweight individuals need to be counselled in skills to maintain weight loss, and that relapse prevention should be a more central focus of weight loss programs.

In conclusion, although this research has drawn attention to the necessity of developing improved behavioral and nutritional strategies for sustaining weight reductions and thus preventing weight cycling, the evidence relating weight cycling to adverse health outcomes must be considered equivocal. Regarding the hypothesis that weight cycling exacerbates weight problems, a 1995 opinion survey of obesity researchers concluded that weight cycling was not considered a very important cause of obesity, and little convincing evidence has emerged in recent years to change that conclusion. With regard to the question in the 'weight cycling refrain' at the beginning of the article regarding possible consequences of weight cycling, the current knowledge suggests that it is probably not worse to have lost and regained than never to have lost at all. However, there remain some curious and persistent results in the experimental as well as epidemiological literature suggesting that we do not completely understand the phenomenon.

Table 1 Summary of hypothesized weight cycling effects and selected sources of evidence

Hypothesized adverse health consequences of weight cycling	*Comments (with suggested reading)*
Psychological consequences	Not supported by evidence (reviewed by National Task Force (2000))
Metabolic rate and body composition	Not supported by evidence (reviewed by National Task Force (1994))
All-cause mortality	Supported by most prospective studies, not by others (reviewed in Lissner and Brownell (1992) and by National Task Force (1994))
Cardiovascular disease	Supported by most prospective studies, not others (reviewed in Lissner and Brownell (1992) and National Task Force (1994))
Diabetes	Not supported by epidemiological studies (Field *et al.*, 2004); mixed evidence from clinical setting (Guagnano *et al.*, 2000)
Cancer	Not supported by epidemiological studies (Lissner *et al.*, 1991; Trentham-Dietz *et al.*, 2000)
Bone health	Evidence mixed and limited (Meyer *et al.*, 1998; Gallagher *et al.*, 2002)

WHOLE GRAINS

R Lang, University of Teeside, Middlesbrough, UK
S A Jebb, MRC Human Nutrition Research, Cambridge, UK

Introduction

There is growing interest in the benefits of traditional dietary patterns with an emphasis on unrefined, plant-based foods. Whole-grain foods are rich in dietary fiber, antioxidants, and a range of other nutrients that may offer health benefits. This chapter will review the epidemiological analyses showing a reduced risk of premature death and decreases in the incidence of cardiovascular disease (CVD), type 2 diabetes, and cancer. However since whole-grain consumption is frequently linked to other positive dietary and life style behaviors (including increased consumption of fruit and vegetables and increased physical activity) more randomized controlled intervention studies are required to support these association studies. Moreover, further research is required to confirm putative mechanistic hypotheses, which include the positive effects of dietary fiber on lipid metabolism, improved glucose homeostasis as a consequence of a reduced glycemic response, or the

antioxidant properties of these foods, which may have beneficial effects on vascular reactivity and inflammation.

What are Whole Grains?

Cereal grains are the seeds of the plant and they house the embryo and the necessary food reserves required for germination. Forming the dietary staples in many countries, the major grains in the human diet are wheat, rice, and corn (maize). Consumption of oats, millet, barley, sorghum, and rye are more limited.

The basic structure of the grain (regardless of plant type) is shown in **Figure 1**. There are essentially three layers, the endosperm, bran, and germ layers, each of which have a unique role within germination, but which also contain essential nutrients and phytochemicals important within the human diet and linked to health benefits.

The Bran Layer

The bran layer is the outer thick-walled structure of the grain. It is rich in B vitamins and phytonutrients such as flavonoids and indoles plus a small amount of protein. It also contains antioxidant compounds including phytoestrogens such as lignans and isoflavones. These hormonally active compounds, similar to estrogen, may influence sex hormone metabolism and may impact on hormone-related disease. The bran also contains factors that may decrease bioavailability of nutrients such as phytic acid, tannins, and enzyme inhibitors. It is also where the bulk of insoluble fiber is found. The insoluble fiber contained within the bran layer has long been recognized to play an important role in intestinal health, by optimizing bowel transit time and increasing fecal weight. But some of the health benefits associated with a high-fiber diet may come from other components, and not just from the fiber itself. For example, the oligosaccharides found within the starchy endosperm layer behave in a similar manner to soluble nonstarch polysaccharides (NSP) and may therefore be useful in controlling blood lipid profiles and blood glucose. In addition, oligosaccharides are natural prebiotics, which encourage the proliferation of healthy microflora within the gut. Colonization of specific bacteria within the colon, such as bifidobacteria, has been implicated in benefits to the immune system, cholesterol lowering, and reducing the risk of colon cancer through the fermentation of these carbohydrates into short-chain fatty acids.

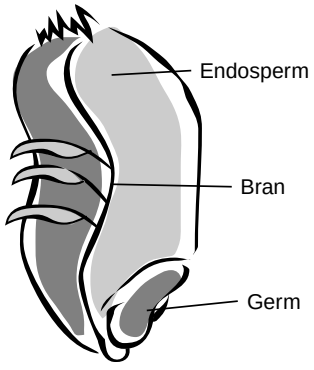

Figure 1 A grain of wheat. (Reproduced with kind permission from the British Nutrition Foundation: http://www.nutrition.org.uk)

The Germ Layer

This is the plant embryo and it contains a concentrated source of minerals such as iron and zinc plus vitamin E. These and other antioxidants provide defense systems against reactive oxygen species not only for the plant, but also for those who consume the grain. Indeed, the pH conditions of the stomach have been shown to cause a dramatic increase in the activity of these antioxidants. Whole grains contain a greater concentration of antioxidants than many fruits and vegetables.

The Endosperm

This makes up about 80% of the grain and is the starchy component comprising mainly carbohydrates including resistant starch and oligosaccharides such as fructans, inulin, and oligofructose. These behave in a similar manner to soluble NSP within the gut. The endosperm also contains B vitamins, in particular riboflavin and pantothenic acid, and some protein.

Definition of Whole Grain

Whole grains are defined as those that are used in their entirety in the food production process, so that all three layers are present within the product. This distinguishes them from refined grains. Regardless of how much of the grain is used, the milling process determines particle size and hence has an impact on handling within the body. Many whole and refined grains are processed in some way to enhance flavor, texture, color, and shelf life. As long as the whole of the grain is used in the process, the food is described as whole grain. However, there is some debate as to whether the disruption of the intact grain modulates the health impact. Certainly, it tends to increase the glycemic index of the food, which may have

implications for the risk of metabolic disease, especially type 2 diabetes.

The vast majority of grains consumed within Western countries are refined, and the outer germ and bran layers are removed to leave only the starchy endosperm. The refining process may reduce some nutrients such as zinc, selenium, and vitamin E by as much as 90%. In some cases vitamins and minerals are reintroduced through fortification and restoration, but the bioavailability and relative health effects of these nutrients when consumed in their natural state compared to artificial methods of fortification is not known.

At present there is no uniform definition of a whole-grain food, but for the purposes of health claims the proportion of whole-grain cereal used within a food product is critical. In 1999 the Food and Drug Administration in the US approved a health claim for use on packing to help consumers choose foods that contained a significant amount of the whole grain. Products must contain at least 51% whole grain by weight, i.e., must be the largest component of the product, to be entitled to carry the health claim. This allows a clear distinction between the refined and partially or nonrefined products available to the consumer. For example, a product made of 100% whole wheat could be labeled as whole grain, but a multigrain loaf containing 75% white flour and 25% wholemeal flour could not. In the UK, the Joint Health Claims Initiative has adopted a similar definition.

Consumption of Whole Grains

Recent studies have shown low levels of consumption of whole-grain foods in the general population of the most affluent countries. In the US data was collected from over 9000 US citizens aged 20 years or over who participated in the 1994–96 USDA's continuing survey of food intakes. Using an interview technique and serving sizes defined by the Food Guide Pyramid, food consumption over 2 nonconsecutive days was examined. It was found that 29% of the sample were nonconsumers of whole grains and the average number of daily servings was less than 1 per day. The proportion of the sample reaching the recommended 3 servings per day was 8%.

Intakes are similarly low in the UK. Using data from two nationally representative surveys whole-grain consumption was assessed: the Diet and Nutritional Survey of British Adults 1986–87 included over 2000 adults aged between 16 and 64 years, and the National Diet and Nutrition Survey of people aged 65 years and over included over 1000 free-living adults (from a total of over 2000 participants which included free-living and institutionalized individuals) during 1994–95. Dietary data was collected using a 7-day diary recording weighed food in 1986–87, and a 4-day weighed food diary in 1994–95. Whole-grain foods were identified as those having at least 51% whole-grain ingredients by weight and a serving was defined as each occasion the food appeared within the recording period. Both surveys showed that approximately 30% of individuals did not consume any whole-grain foods during the survey period (29% in 1986–87 and 33.5% in 1994–95), and over 97% of adults did not meet the US recommendation of 3 servings per day. Median consumption was less than 1 serving per day.

In comparison to the US and the UK, whole-grain foods are consumed in greater quantities in Scandinavian countries. In Finland, rye bread has always been a staple and consequently whole-grain intakes have always been high. In Norway, food disappearance data suggest that consumption of whole-grain foods is four times that seen in the US, but is lower than that seen in Finland. In the Scandinavian studies, however, estimation of consumption of whole grain was not based on number of servings but utilized measures such as a bread score based on number of slices of bread consumed multiplied by the proportion of whole-grain flour; 24-h recall techniques of whole-grain foods consumed; and simply the number of slices of bread consumed. These differing techniques make it difficult to directly compare findings in Scandinavia with the UK and US.

However, within populations the consumption of whole grains is influenced by a number of social and demographic factors. Most surveys have found an increase in whole grain consumption with age. For example, in the UK, there was a median of 1 serving per week in the 16–24-year-olds rising to 3 servings per week in the 35–64-year-olds (1986–87 survey).

Consumption in the survey of people aged 65 years and over showed higher intakes of 5 servings per week (1994–95 survey) but it is not clear whether this reflects a secular trend or a continuing effect of age. In general, men consume more whole-grain foods than women. This may reflect a greater food intake overall, rather than a specific preference for whole-grain varieties. In the US, white adults consume more whole-grain foods than black Americans, and Mexican Americans consume the least whole grains.

In the US and UK, income and level of education are also positively associated with whole-grain consumption, but in Finland, the highest intakes of rye bread are observed in the lower socioeconomic groups. In the US and UK, whole-grain

consumers are less likely to smoke, tend to be regular exercisers and consume more fruits and vegetables. These findings suggest an association of whole-grain consumption with other positive life style traits.

Whole Grains and Health

Epidemiological evidence suggests an inverse relationship between the consumption of whole-grain foods and the relative risk of a number of chronic diseases. Studies have found that habitual consumption of whole-grain foods is associated with reductions in premature mortality, risk of coronary heart disease, ischemic stroke, and type 2 diabetes.

All Cause Mortality

Three large prospective epidemiological studies have considered the relationship between whole-grain consumption and all cause mortality (**Table 1**). Using a variety of measures to assess whole-grain consumption, all three studies concluded that the more whole-grain foods were consumed, the lower the risk of death from a number of chronic diseases. Women in the Iowa Women's Study were followed over a 9-year period. The population was divided into quintiles of whole grain intake using a food frequency questionnaire (FFQ). Intakes varied considerably from 1.5 servings per week in the lowest quintile and 22.5 servings per week in the highest, yet an inverse association between whole-grain intake and the risk of death was observed across quintiles, with a 40% reduction in total mortality ($P < 0.0001$) in those consuming at least one serving of whole-grain foods per day. Even when adjusted for confounders such as age, energy intake, hypertension, heart disease, diabetes, cancer, body mass index (BMI), waist–hip ratio (WHR), physical activity, alcohol intake, smoking, positive dietary habits such as fruit and vegetable consumption, fat intake, and red meat and fish consumption, the significant inverse relationship remained ($P = 0.005$). In contrast, refined grain intake was associated with increased mortality for those in the quintile of highest refined grain intake compared to those in the quintile of lowest intake (**Figure 2**).

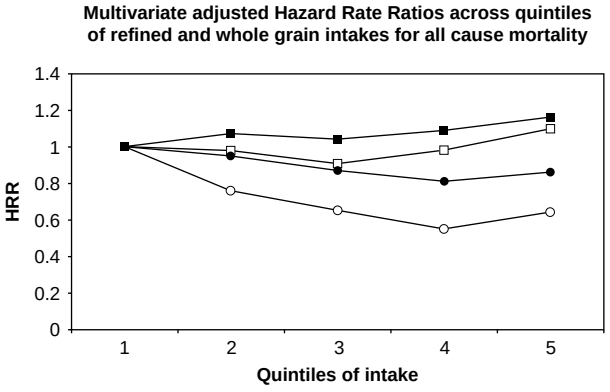

Figure 2 ○ (WG) and □ (refined) adjusted HRR for age and total energy intake. ● (WG) and □ (refined) adjusted for age, energy intake, marital status, education, high blood pressure, diabetes, heart disease, cancer, BMI, WHR, physical activity, smoking, alcohol intake, use of vitamin supplements, HRT, total fat, saturated fat, intake of fruits and vegetables, intake of meat and intake of fish and seafood.

Similarly in over 47 000 men and women in Norway aged 35–56 years studied over 9 years, hazard rate ratios (HRR) for total mortality were inverse and graded across whole-grain bread score categories in men and women between the highest and lowest bread score after adjustment for a range of dietary and lifestyle factors. The bread score was calculated using number of slices consumed per day and the proportion of whole-grain flour used. The analysis found that both components of the whole grain scoring system contributed to these inverse trends (% deaths between highest and lowest

Physician's Health Study	Breakfast cereal FFQ (WG classified as 25% w/w)	HRR ↓ with ↑ consumption	Liu *et al.* (2003) Is intake of breakfast cereals related to total and cause-specific mortality in men? *American Journal of Clinical Nutrition* **77**: 594–599.

scores categories: 7% versus 10% for men and 2.7% versus 4.6% for women).

In the Physicians' Health Study, breakfast cereal consumption was used as an indicator of whole-grain intake in over 86 000 US male physicians aged 40–84 years studied over 5.5 years. Breakfast cereal consumption was assessed using a semiquantitative FFQ where men had to report the amount, frequency, brand, and type of cereal consumed over the previous year. Whole-grain cereals were classified as those with >25% whole grain or bran by weight; all others were considered to be refined grains. Whole-grain breakfast cereal consumption was inversely associated with total mortality independent of a range of dietary and lifestyle considerations.

The use of bread and cereal intakes as a measure of total whole-grain consumption is of some concern, as the extent to which they correlate with overall whole-grain consumption is uncertain. Indeed, such studies also fail to distinguish whether it is in fact something within the whole-grain package that is of benefit, or something else entirely.

Cardiovascular Disease

Cardiovascular diseases are responsible for over a third of all deaths and are the biggest contributor to the global burden of disease. There are a number of studies to suggest that individuals who consume a diet rich in whole-grain foods have a lower incidence of heart disease, although the mechanism is still unclear (see **Table 2**).

Increases in the consumption of whole grains have been shown to decrease CHD deaths and the risk of stroke and heart disease in some, but not all, epidemiological analyses. In the study of postmenopausal Iowan women there was a reduction in relative risk (RR) of ischemic heart disease of about a third in those consuming at least 1 serving of whole-grain foods per day. This relationship was attributable to differences in the consumption of dark breads and whole-grain breakfast cereals while less common whole-grain foods such as popcorn, brown rice, and oatmeal showed no relationship with CVD. A significant inverse relationship between increasing whole-grain intake and risk was also observed for CHD and total CVD, but not stroke alone (**Figure 3**).

Similar results were obtained in the Nurses' Health Study of 75 000 women aged 38–63 years who were free from existing diabetes, angina, myocardial infarction, stroke, or other CVDs at baseline. Here, a significant inverse relationship was observed between CHD and whole-grain consumption even after multivariate adjustment for known confounders such as age, smoking, BMI, alcohol, and other dietary and lifestyle factors. For each additional serving of whole-grain food per day, the authors found a relative risk of 0.91 (95% confidence interval (CI) 0.85, 0.97) for CHD risk.

In this study there was also a significant inverse relationship between whole-grain intake and risk of ischemic stroke. After adjustment for smoking and other known CVD risk factors, the relationship was

Table 2 Summary of the evidence relating a reduced risk of CVD to increased whole-grain consumption

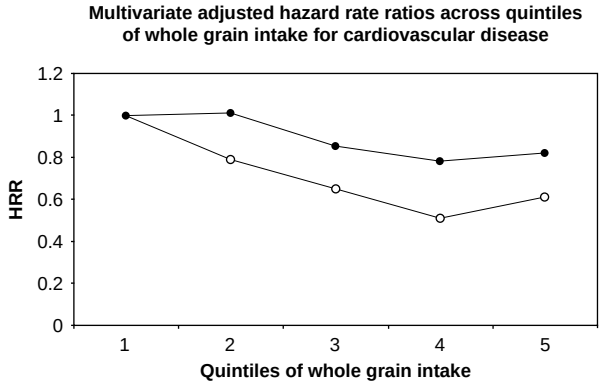

Figure 3 ○ adjusted HRR for age and total energy intake. ● adjusted for age, energy intake, marital status, education, high blood pressure, diabetes, heart disease, cancer, BMI, WHR, physical activity, smoking, alcohol intake, use of vitamin supplements, HRT, total fat, saturated fat, intake of fruits and vegetables, intake of meat and intake of fish and seafood.

attenuated but remained significant. However, after further adjustment for assorted dietary variables (folate, vitamin E, fiber, magnesium, and potassium), the effect was no longer significant. Unlike previous studies, the authors defined the different categories of stroke and found that although risk of hemorrhagic stroke or incident fatal strokes did not appear to be influenced by whole-grain consumption, total stroke risk was inversely related to consumption of whole-grain foods.

It is notable that in many studies subjects with the highest intake of whole-grain foods also had the healthiest lifestyles and the relationship with whole-grain foods is attenuated after adjustment for other diet and lifestyle variables. The exact mechanisms of protection are unclear. Diets rich in whole-grain foods tend to reduce serum LDL-cholesterol and TAG levels whilst increasing HDL-cholesterol concentrations and blood pressure is lower. This may be due in part to the dietary fiber, but the effect usually persists after adjustment for fiber intake. Whole grains also contain a number of specific components that may have heart health benefits, including antioxidants (vitamin E and selenium), B vitamins, flavonoids, and indoles. These may reduce oxidative stress and homocysteine levels, and the isoflavone content of these grains may positively influence vascular reactivity and the inflammatory state.

Type 2 Diabetes

The prevalence of type 2 diabetes has reached epidemic proportions with over 150 million cases diagnosed worldwide; this number is expected to double by 2025. The concurrent rise in obesity has been directly linked to insulin resistance and compensatory hyperinsulinemia and eventual type 2 diabetes, with over 80% of diagnosed type 2 diabetes being the result of excess body fat. Public health recommendations to reduce fat intake, especially saturated fat, have led to a rise in the proportion of carbohydrates (particularly refined carbohydrates) in the diet with consequences for postprandial glucose and insulin metabolism. The source of carbohydrate is also important. Whole-grain foods commonly have a low glycemic index because whole-grain foods with an intact bran and germ layer have a much smaller impact on blood glucose than refined carbohydrate foods because of their larger particle size, slowing the rate of enzymic attack. The level of soluble fiber within whole grains has also been identified as a possible protector and the higher amylose content is also thought to be beneficial. Slower rates of digestion are observed when foods have more compact granules, contain high levels of viscous soluble fiber, and have a higher amylose to amylopectin ratio.

The relationship between whole grains and diabetes has been studied in five large cohorts as highlighted in **Table 3**. All of the studies have found an inverse relationship between consumption of whole grains or cereal fiber and disease reduction despite slight variations in methodology.

As a proxy measure of whole-grain consumption, the relationship between the intake of total and specific sources of dietary fiber, dietary glycemic index, and glycemic load in the Nurses' Health Study and the Health Professional's Study was examined. Among the 65 173 women who participated during 1986–1992, women in the highest quintile of cereal fiber intake had a 28% lower risk of diabetes than those in the lowest quintile of intake (RR 0.72; 95% CI 0.58, 0.90; $P = 0.001$), a significant reduction that was not observed with fruit or vegetable fiber intakes. In men there was an inverse relationship between cereal fiber intake and risk of type 2 diabetes: a reduction in risk of 30% following adjustment for confounders. Again, no significant relationship of fruit or vegetable fiber to diabetes risk was observed.

The fiber content of whole grains has been suggested as a possible explanation for the inverse relationship between total and whole-grain intakes and risk of type 2 diabetes observed in a 10-year follow-up of Finnish men ($n = 2286$) and women ($n = 2030$). When the highest and lowest quartiles of whole-grain consumption were compared there was an over 30% reduction in risk following adjustment for age, sex, geographic area, and energy intake. Cereal fiber, but not that from fruits and vegetables, was inversely related to risk of type 2 diabetes even after adjustment for a number of

Insulin sensitivity	11 hyperinsulinemic overweight patients	Reduction in fasting insulin following diet rich in whole grains	Pereira *et al.* (2002) Effect of whole grains on insulin sensitivity in overweight hyperinsulinaemic adults. *American Journal of Clinical Nutrition* **75**: 848–855.

confounders. Adjustment for cereal fiber considerably weakened the association between whole-grain consumption and risk of type 2 diabetes, suggesting that this may be a significant component of the whole-grain package.

The effect of whole-grain consumption specifically, rather than fiber intakes, on incidence of type 2 diabetes was examined in the Health Professional's Follow-up Study. Over a 12-year follow-up period, intakes of whole and refined grains were analyzed using a validated semiquantitative FFQ. Despite no baseline history of diabetes or CVD, 1197 cases of incident type 2 diabetes were identified in this male cohort. Following adjustment for dietary and life style confounders including age, smoking, physical activity, and fruit and vegetable intake, there was a reduced risk of type 2 diabetes of almost 40% in those with the highest quintile compared with the lowest quintile of whole-grain intakes. The results were attenuated after adjustment for BMI, although the relationship remained significant. In those with a BMI $>30\,kg\,m^{-2}$ the association between whole grain and type 2 diabetes was weak, whereas in those men with a BMI $<30\,kg\,m^{-2}$ a 50% risk reduction was observed in those who consumed the most whole grains. However, after adjusting for components of the whole-grain package such as cereal fiber, magnesium, and glycemic load, the statistical significance was lost (**Figure 4**).

These findings in men were similar to those observed by Liu *et al.* (2000) when they looked specifically at whole and refined grain intakes in the women participating in the Nurses' Health

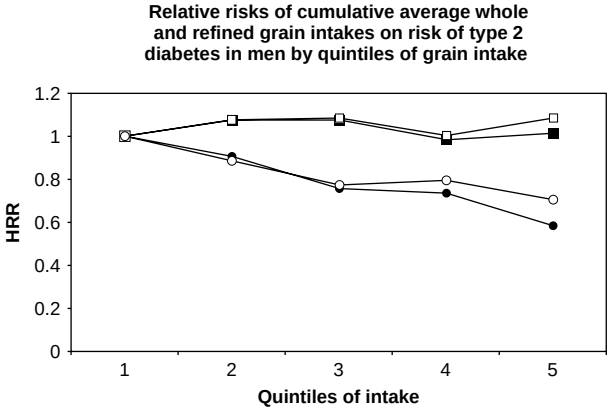

Figure 4 ○ adjusted for age, period, physical activity, energy intake, missing FFQ data, smoking, family history of diabetes, alcohol intake, fruit intake and vegetable intake. ● additionally adjusted for BMI $<30kg/m^2$ and $>30kg/m^2$.

Study. During the 10-year follow-up, 1879 cases of incident type 2 diabetes were confirmed. Although the women with the highest intake of whole grain had other beneficial dietary and lifestyle factors, whole-grain intake was inversely related to risk. There was a significant inverse association between the highest and lowest quintiles of whole-grain intake after adjustment for age and energy intake. Although attenuated after adjustment for BMI and other lifestyle factors, the relationship remained significant. Again BMI appeared to be the strongest confounding factor. Women in the lowest quintile of intake ratio (those with low whole grain or large refined grain intakes) had a 57% greater risk of type 2 diabetes than women in the highest quintile.

In a cross-sectional assessment of 2941 subjects in the Framingham Offspring Study the effect of whole-grain intake on metabolic risk factors for type 2 diabetes and CVD was examined. Dietary intake was assessed using a semiquantitative FFQ in the participants who were free from diabetes or high cholesterol. Breakfast cereal type was used to quantify whole-grain intakes based on a whole-grain content of over 25%. Other foods identified as whole grain were dark breads, popcorn, and oatmeal. Whole-grain intakes were similar between men and women (mean 8.3 and 8.8 servings per week, respectively) but refined grain intakes were much higher (22.0 and 18.5 servings per week, respectively). Similar to other studies, those in the highest quintile of whole-grain intakes (20.5 servings per week) had lower BMI, were less likely to smoke or drink, and dietary habits were better. Following adjustment for a host of confounding factors, whole-grain consumption in the highest quintile was associated with a significant reduction in fasting insulin in comparison to those in the lowest quintile of intake. Even after further adjustment for BMI and dietary factors such as vegetable and fat intakes, this relationship remained significant, but was no longer significant after further adjustment for magnesium, and insoluble and soluble fibers. The association between whole grain and fasting insulin was most striking in those with a BMI $>30\,\mathrm{kg\,m^{-2}}$ with the highest fasting insulin levels being observed in those with the highest BMI and the lowest intake of whole-grain foods.

Prospective epidemiological studies are generally stronger than cross-sectional associations. In the CARDIA study by Pereira and coworkers, a significant inverse relationship was observed between whole-grain foods and fasting insulin levels among over 3500 black and white young Americans aged 18–30 years. A dietary history was collected at baseline and 7 years later, while insulin measurements were collected at 10 years follow-up. After adjustment for a number of dietary and lifestyle factors an inverse and graded response was observed between whole-grain intake at 7 years and the insulin measurements collected at 10 years follow-up, although the relationship was not significant in black women.

There is only one small intervention study that examines the impact of increasing wholegrain consumption. In this study, it was found that after 6 weeks there was a 10% reduction in fasting insulin compared to results observed following the refined grain diet ($141 \pm 3.9\,\mathrm{pmol\,l^{-1}}$ versus $156 \pm 3.9\,\mathrm{pmol\,l^{-1}}$; $P < 0.01$). This relationship remained even after adjustment for body weight changes (nonsignificant change of $-0.7\,\mathrm{kg}$ on whole-grain diet) and physical activity.

As for other diseases the mechanism of the effect of wholegrain on insulin sensitivity is not entirely clear and may in part be mediated through effects on body weight. Cereal fiber and possibly certain micronutrients such as magnesium may also be important since the wholegrain effect is attenuated after adjustment for these variables.

Cancer

Dietary factors are thought to account for about 35% of all cancers but the role of any specific dietary factor or dietary regime has only been established for certain types of cancer. Only a few studies have looked at the links between wholegrain intake and cancer. In the Iowa Women's Study there was a 30% reduction in cancer deaths when comparing those with the highest quintile of whole-grain intake to those in the lowest quintile, after adjustment for age and energy intake. However, once other dietary and lifestyle factors were included within the multivariate analysis this relationship was attenuated and lost its statistical significance. Similar findings were observed in the Norwegian County Study with a 28% reduction in cancer deaths from the highest to lowest quintile of wholegrain when adjusted for age and energy intake. However, the effect was no longer significant after further adjustment for other dietary and lifestyle factors.

A number of studies have used case–control designs to investigate the relationship between whole-grain consumption and cancer incidence, although these suffer from the inherent flaws of such study designs, especially those involving recall of past dietary habits. In an analysis of 40 case–control studies, 90% of the studies included had an odds ratio (OR) <1, of which 55% reached statistical significance in favor of a benefit of wholegrain. The pooled OR for high versus low intakes of whole-grain foods was 0.66 (95% CI

0.60, 0.72). Most data pertain to the link with cancers of the digestive tract. The majority of pooled-odds ratios for specific cancers were between 0.5 and 0.8, except for breast and prostate cancers, which were 0.86 and 0.90, respectively. The differing types of dietary data collection impacted on the findings. Where only whole-grain frequency was recorded the pooled OR was 0.82 in those who ate whole grains infrequently and 0.59 among habitual consumers ($P < 0.0001$ for trend). Similar results were found in those studies reporting intake by tertiles (OR 0.81 and 0.62 for the second and third tertiles, respectively; $P = 0.0001$) and those reporting actual quantities of intake found a downward trend in ORs as the dose increases, although the trend is not strong ($P = 0.18$) suggesting that the dose-response relationship between whole grain and cancer types may only be modest.

The whole-grain package contains a number of components that have been identified as having beneficial effects on cancer risk, including antioxidants and flavonoids, isoflavones, fermentable carbohydrates, and resistant starch. Although many studies have been conducted looking at the effect of individual components that can be found within the whole-grain package on cancer risk, few studies have looked specifically at whole grains *per se*. Although a relationship has been observed between whole-grain consumption and cancer deaths, studies of cancer incidence and whole-grain consumption are not significant after adjustment for potential confounders. This is a good example of how consumption of whole-grain foods appears to be a marker of dietary habits associated with a reduction in risk, and they are not necessarily specifically important in their own right.

Dietary Recommendations

The epidemiological data suggest that health benefits can be obtained at relatively low levels of whole-grain consumption, typically 1–3 servings per day. In most studies, there was no clear dose–response relationship and a suggestion of a threshold effect as benefits were seen at the third quintile of whole-grain intakes with no further reduction in risk as intakes increased. However, assessment of intakes in different countries show that this threshold level of intake is not being achieved.

International dietary Guidelines recommend increased grain consumption. At present, the USA is the only nation to specify exact quantities of whole grain foods, and it is only within the last few years that whole grains have been considered seperately from total grain foods.

The recommendations for grains have evolved over time to reflect changes in research and to simplify and clarify consumer messages. The latest American Dietary Guidelines (2005) now state a recommendation of 3 or more ounce-equivalent portions of whole-grain foods daily, with a further recommendation that at least half of grain consumption should be whole-grain.

This recommendation of three servings per day was also specifically incorporated in the Department of Health and Health Services nutrition objectives for 2010 (US Department of Health and Human Services, 2000).

In the UK, the Food Standards Agency explicitly encourages consumers to select whole-grain varieties in their healthy eating advice, although no exact quantities are given. Many other European countries also tend to place emphasis on only cereals and fiber, without necessarily specifically highlighting whole grains.

Using data compiled from focus groups and consumer interviews in the US, a number of reasons as to why consumption of whole-grain foods may be low have been indentified. Consumers report difficulties in identifying whole-grain foods and express limited knowledge about the preparation and cooking of whole-grain foods. Adolescents in particular reported that whole-grain foods were bland and have a dry taste. While breakfast cereals appear to be well received in this age group, whole-grain breads were described as dry and bitter. Furthermore, whole-grain varieties of bread, pasta, and rice tend to be more expensive and this may deter those in low income and vulnerable groups.

In a UK intervention study to increase whole-grain consumption, 25–40-year-olds were encouraged to increase whole-grain food consumption over a period of 2 weeks by gradually increasing servings from 1 to 5 servings per day. Volunteers were given positive health messages about eating more whole-grain foods, were helped in identifying such food products, and were also given advice on how to incorporate them easily into their existing diet. In post study focus groups, participants were positive about the changes made and were happy to continue consuming whole-grain foods but at lower levels than that prescribed during the study period. Similar to findings in the US, breakfast was found to be a good meal to change habit and breakfast cereals and bread type was deemed the easiest way of incorporating whole-grain foods.

Consumer research suggests that few people are aware of the health benefits of whole-grain foods. Although other food groups, such as fruits and vegetables, have been identified as possessing health benefits, the association between whole-grain foods and

a reduced risk of a number of chronic diseases is not recognized among the general population or indeed health professionals. Recent health claims in the US and UK may help to address this knowledge gap. In addition, consumer initiatives such as the 'Whole Grain for Health' campaign in the UK, and 'Go Grains' in Australia provide ongoing education relating to the benefits of including whole-grain products within the diet.

WORLD HEALTH ORGANIZATION

J Akré, World Health Organization, Geneva, Switzerland

The World Health Organization (WHO) is the intergovernmental organization within the United Nations (UN) system that acts as the directing and coordinating authority on international health work. It performs its functions through three principal bodies—the World Health Assembly, the Executive Board, and the Secretariat. The objective of WHO, which has 191 member states, is the attainment by all peoples of the highest possible level of health. While its headquarters is located in Geneva, Switzerland, the organization is decentralized in six regions, each with its own regional committee and regional office. WHO's regular budget—US$842 654 000 for the biennium 1998–1999—is augmented by voluntary contributions, which are roughly equivalent to regular budget levels. WHO works closely with and through others, including other agencies of the UN system, nongovernmental organizations, and collaborating centres around the world in numerous disciplines. In restructuring its programs in the mid-1990s in the face of resource constraints, WHO decided to place emphasis on meeting the most pressing health needs. In seeking to prevent and overcome malnutrition, WHO promotes the tailoring of approaches to fit circumstances. While the rapidly increasing threat of noncommunicable diseases accounts for at least 40% of all deaths in developing countries and 75% in industrialized countries, many millions still cannot meet basic needs for energy and protein, are deficient in essential micronutrients, or are severely malnourished. Thus, coordinated action is called for on both fronts. Consistent with the unique normative, scientific, and advisory role that WHO has played for the last half century, the organization strives to support all its member states in developing food and nutrition policies that will make healthy choices the easy choices for their populations.

Birth of the World Health Organization

For many thousands of years, people have exchanged remedies and diseases without really thinking of ways to work together to promote health that could go beyond purely parochial concerns. Early attempts at international cooperation in health were limited to small groups of countries, which discussed a few obviously contagious diseases such as cholera and smallpox, and strategies such as quarantine to keep them at bay. Although 11 international sanitary conferences were held in Europe between 1851 and 1903, it was not until 1907 that a worldwide international institution—the Office International d'Hygiène Publique—was founded to prepare and administer international sanitary conventions and to provide national health administrations with an opportunity for regular contacts and discussion.

The terrible epidemics which raged through Europe at the end of World War I, coupled with the mass movement of liberated prisoners of war, constituted a menace to Europe of such magnitude as to require coordinated international effort. The League of Red Cross Societies, created in 1919, attempted the task but quickly realized that intergovernmental action was essential to cope with a problem of such magnitude. As the charter of the Office International d'Hygiène Publique did not give enough power for action in individual countries, provision for necessary measures had to be made by the League of Nations, then in the process of creation.

The Geneva-based League, during its short and unhappy history between the two world wars, had been the first to invoke international health cooperation to deal with many kinds of health problems. In the same period, the Pan American Sanitary Organization, originally established in 1902, continued to work in its own geographical sphere. (In 1958 it became the Pan American Health Organization (PAHO), which serves as WHO regional office for the Americas (see below).)

In 1945, the UN Conference on International Organization, meeting in San Francisco, unanimously approved a proposal by Brazil and China to establish an autonomous international health organization within the UN system. The following year, an international conference held in New York set up an interim commission and approved the *Constitution of the World Health Organization*. This came into force on 7 April 1948, when the 26th government, out of a total of 61 signatories, formally ratified it in its national parliament. Since then, 7 April is celebrated every year as World Health Day, when attention around the globe is focused on a theme of major international public health importance. Today, the health agency based in Geneva, Switzerland, is owned and operated by the governments of 191 countries, representing almost the entire population of the world, as reflected in its emblem (**Figure 1**).

Figure 1 WHO emblem.

The Task Entrusted to WHO

WHO is defined by its constitution as the directing and coordinating authority on international health work. Its aim is 'the attainment by all peoples of the highest possible level of health,' which is 'one of the fundamental rights of every human being.' The constitution lists specifically a number of responsibilities. These include the following:

- to stimulate the eradication of epidemic, endemic, and other diseases;
- to promote improved nutrition, housing, sanitation, working conditions, and other aspects of environmental hygiene;
- to propose international conventions and agreements in health matters;
- to promote and conduct research in the field of health;
- to develop international standards for food, biological, and pharmaceutical products;
- to assist in developing an informed public opinion among all peoples on matters of health.

The agreed policy of WHO is a determined and structured effort by all countries to bring health within the reach of everyone. 'Health' is defined by WHO's constitution as a 'state of complete physical, mental, and social well-being and not merely the absence of disease and infirmity.' It is seen as a shared responsibility, calling for a high degree of self-reliance from the individual, the family, the community, and, of course, the nation as a whole. Because the determinants of health are so broad, the efforts of the health sector must be supported and augmented by those of many other related sectors, including agriculture, water and sanitation, finance, industry, planning, communication, and education.

WHO provided the first truly global framework for setting international standards to promote and protect health. In keeping with postwar faith in the power of technology, WHO initially operated as a technical organization, fuelled by advances in bio-medical research and the belief that new medical discoveries would bring spectacular improvements in health. One of its first tasks was to develop mechanisms, still in effect today, for identifying urgent research needs and then linking the world's leading specialists and research institutes in a concerted attack on the problem. Tangible results came in the form of new diagnostic tests, therapeutic drugs, and vaccines. WHO also standardised the classification of diseases, terminology, nomenclature, reporting systems, research protocols, and quality and safety specifications for foods, drinking water, and pharmaceutical products. Consumers the world over benefit from these standards, which are continually revised in the light of new knowledge.

As research advances produced the means for conquering one disease after another, WHO shifted its emphasis to problems of logistics. Research took on social and ethical dimensions as the organization sought ways to extend the benefits of modern medicine to the world's populations. The early promise that sophisticated technology would bring spectacular improvements in health paled, however, against the reality of the millions of people who had no access to basic medical services. Given its constitutionally defined universal mandate and humanitarian mission, WHO began advocating changes that would eventually revolutionize the way public health was perceived. In a world that remained diseaseridden and suffering despite unprecedented technical advances, it became a matter of equity and social justice to make health progress available to all people through new approaches, new strategies, and better management of resources.

High technology as an end in itself was replaced by the concept of appropriate technology, affordable and culturally acceptable to the people who would use it. To come to terms with the soaring costs of medical care in affluent countries as well as the lack of funds in developing countries, WHO placed preventive—as opposed to curative—medicine in the forefront. The concept of primary health care, with its emphasis on individual responsibility for health and its conviction that the best help is self-help, began to take shape.

The age of technical paternalism came to a formal close in 1979 when the member states of WHO unanimously adopted the goal of 'Health for All by the Year 2000,' founded on the principles of primary health care

that had been elaborated in 1978 during the International Conference on Primary Health Care at Alma-Ata (Kazakstan). Commitment to this time-limited goal guided much of the organization's work over the next decade, though the promotion of research, particularly on disease prevention and control, continues in full force as part of WHO's global plan to push the world forward through the protection and promotion of health (see below).

Structure

WHO is a specialized agency of the UN, as provided for in the *Charter of the United Nations*. A goal-oriented organization with policies, program, and budget defined through well-developed mechanisms, WHO consists of three constituent bodies:

- The *World Health Assembly*, which is the highest decision-making body, is held in May each year and is attended by delegations from WHO's 191 member states and two associate members. Its main tasks are to decide on major policy matters and to approve the biennial program budget.
- The *Executive Board* consists of 32 persons, acting in their personal capacity, highly qualified in the field of health and designated for a 3-year term by as many member states, which are chosen by the Health Assembly on the basis of equitable geographical distribution. The board, which normally meets twice a year, gives effect to the decisions and policies of the Assembly, while advising it and preparing its agenda.
- The *Secretariat* serves to carry out the decisions of the World Health Assembly and the Executive Board; it is the entire staff of WHO headed by the director-general, who is appointed as its chief technical and administrative officer for a 5-year term by the World Health Assembly on the nomination of the Executive Board.

In general, all technical activities that are of universal applicability—such as biological and epidemiological standardization, the overall assessment of the efficacy of methods and materials, and promoting the control of disease—are the responsibility of the headquarters in Geneva (**Figure 2**). WHO's highly decentralized structure enables it to respond directly to the needs of its membership, upon request, through its six regions, each consisting of a regional committee and a regional office. The regional offices, with their own directors, are responsible for formulating policies of a regional character and for monitoring regional activities. In many countries there is a resident WHO representative who is the main intermediary for support of WHO and who participates with the government in

Figure 2 The headquarters of WHO in Geneva, Switzerland. Photograph by T. Farkas.

planning and managing national health programs. The location of the six regional offices and the member states covered are shown in **Figure 3**.

Some 40% of WHO's 4300 staff members, including PAHO, work in countries all over the world, either in field programs or as WHO representatives; 30% are in the six regional offices and 30% at headquarters in Geneva.

WHO's normative, i.e., standard-setting, functions also include preparation and updating of the *International Classification of Diseases*, assignment of generic names for pharmaceuticals, and, since 1957, evaluating the safety for human consumption of selected food additives and contaminants in food and establishing acceptable daily intakes for these substances through the Joint FAO (Food and Agriculture Organization)/WHO Expert Committee on Food Additives.

The committee's reports, as well as those of a similar FAO/WHO group responsible for evaluating the safety of pesticide residues, are used in the formulation of national food legislation intended to protect consumers from hazardous additives or contaminants and by the Codex Alimentarius Commission—another joint FAO/WHO body—in establishing international food standards. (Food legislation is one of the many topics regularly covered by one of WHO's half-dozen specialized international periodicals, the quarterly *International Digest of Health Legislation*.) Codex originated at a time—the early 1960s—when international efforts were being made to increase world trade by reducing tariff barriers, as well as nontariff barriers resulting from differing food regulations. Consistent with a dynamic system that is still changing to deal with ever-changing circumstances, the international community has decided to use health-related Codex standards, guidelines, and recommendations as a reference in implementing relevant aspects of the trade agreements administered by the World Trade Organization (WTO) since 1995.

While the member making the largest contribution to the WHO regular budget is assessed at a maximum 25%, members making the smallest each pay 0.01%. Apart from its regular budget—US$842 654 000 for the biennium 1998–1999—WHO receives voluntary contributions from both governmental and nongovernmental sources. In recent years the total amount of these contributions has been roughly equivalent to regular budget levels. They include contributions for fostering research in tropical diseases and human reproduction, improving community water supply, expanding immunization, preventing and controlling diarrheal diseases, leprosy, malaria, and yaws, and preparing a credible emergency health response to disasters and natural catastrophes.

Working with Others

From its beginning, WHO set out to work not through its small staff alone but with and through others. Many thousands of individual researchers

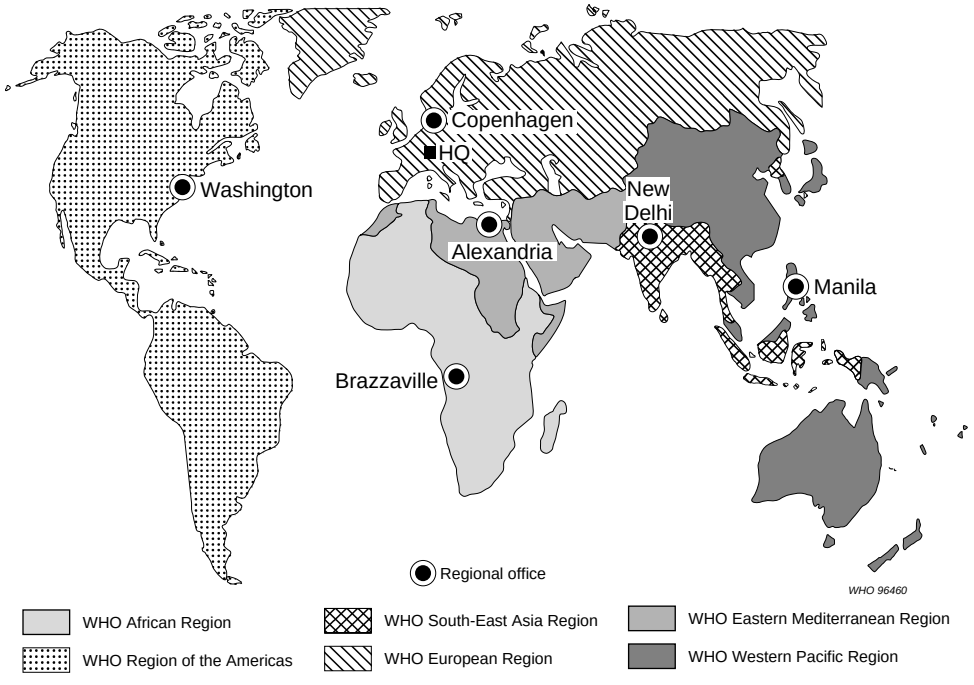

Figure 3 WHO regional offices and the areas they serve.

and scientists, including Nobel laureates, have put their talents at the disposal of WHO—and their number continues to grow. The same is true of WHO collaborating centers, which have grown steadily in number and breadth of disciplines. Rather than duplicate efforts, WHO entrusts critical technical functions to established laboratories and research institutes.

From the outset, WHO was also mandated to work with other agencies within the newly created UN family of organizations. Food and nutrition work, for example, quite naturally came to involve the FAO, as did work against animal diseases and, as mentioned above, in the area of food additives, food standards, pesticide residues, and contaminants. Later, WHO joined forces with the International Labor Organization (ILO) and the United Nations Environment Program (UNEP) in establishing the International Program on Chemical Safety. Recognition of the increasing seriousness of the global burden of malnutrition led WHO and FAO to convene jointly, in Rome in December 1992, the International Conference on Nutrition, which was attended by over 1000 representatives of 159 member states and the European Union. The resulting World Declaration and Plan of Action for Nutrition pledged to eliminate or substantially reduce the major forms of malnutrition and their contributing factors before the end of the decade. The declaration's nine goals for the year 2000 and the strategy and actions of the Plan of Action serve as the platform for WHO's support to countries, especially those most in need, in five priority areas:

- assessment, prevention, and management of protein–energy malnutrition;
- overcoming micronutrient malnutrition (chiefly iodine deficiency disorders, and vitamin A and iron deficiencies);
- improvements in infant and young child feeding (breast feeding and complementary feeding);
- nutrition emergencies, particularly training in preparedness and management;
- prevention of diet-related noncommunicable diseases (including obesity, cardiovascular diseases, and some cancers) and food-related communicable diseases (including diarrhea and parasites).

The views of the United Nations Educational, Scientific and Cultural Organization (UNESCO) are regularly sought, for example, on questions relating to bioethics and the health of schoolchildren. Occupational health is likewise a shared activity with the ILO, while drug dependence and abuse call for collaboration with the United Nations International Drug Control Program. After nearly a decade of providing direct financial support and technical guidance for AIDS (acquired immunodeficiency syndrome) activities in more than 150 developing countries, in January 1996 WHO became one of the cosponsors, together with the United Nations Children's Fund (UNICEF), the United Nations Development Program (UNDP), the United Nations Population Fund (UNFPA), UNESCO, and the World Bank, of the Joint United Nations Program on HIV/AIDS (UNAIDS). Building on the relationship already established with the General Agreement on Tariffs and Trade (GATT), WHO works with the GATT's successor, the WTO, in connection with health-related Codex standards, guidelines, and recommendations.

One of WHO's closest partners has been UNICEF, with which, for example, the early yaws and malaria campaigns were carried out. More recently, joint activities include support to countries in preventing and controlling micronutrient malnutrition and improving infant and young child feeding practices by promoting breast feeding and appropriate complementary feeding practices with emphasis on using locally available foods. To guide their concerted efforts in all fields, since 1948 the two agencies regularly confer on matters of joint health policy.

Collaboration was also initiated with professional, charitable, and other nongovernmental organizations (NGOs) pursuing aims consonant with those of WHO. By the end of the first decade, WHO had established official relations with no fewer than 40 such bodies, ranging from the International Council of Nurses to the International Commission on Radiation Units and Measurements, and from the World Federation for Mental Health to the International Union of Nutritional Sciences. Work of vital importance for WHO's technical programmes of support for its membership has been made possible through the enthusiasm and resources of these and other valuable organizations, which have in turn benefited from the moral support and the technical information provided by WHO.

Collaboration continues unabated; examples include joint work on cancer pain relief with the International Association for the Study of Pain; efforts to ensure safe blood and blood products undertaken by WHO's Blood Safety unit together with the blood programs of the International Federation of Red Cross and Red Crescent Societies, the International Society of Blood Transfusion, and the World Federation of Hemophilia; support for polio eradication provided through Rotary International; reinforcement of technical support to member states for the prevention and control of iodine deficiency disorders with the help of the

International Council for Control of Iodine Deficiency Disorders; and implementation of the Joint WHO/UNICEF Baby-Friendly Hospital Initiative—which strives to ensure the world over a health care environment for new-borns where breast-feeding is the norm—with the help of La Leche League International and the International Lactation Consultant Association. The success of these joint ventures is most strikingly illustrated by the ever-lengthening list of NGOs admitted into official relations with WHO, which now numbers more than 190.

Gearing Up for the Twenty-First Century

Using pragmatic tools in pursuit of its visionary goal, WHO strives to respond to its constitutional mandate through its evolving program of activities. These are based on the needs and priorities of activities determined by member states themselves through the organization's governing bodies, the World Health Assembly and the Executive Board. Changes in program emphasis occur in response to altered political, social, economic, and environmental realities.

For example, respecting the new issues and priorities of the times for WHO includes meeting the challenge implicit in redirecting the human and financial resources that, logically, should be released by the breakup of old Cold War alliances; forging new partnerships to mobilize social, political, and therefore financial support for health development and international health cooperation; and opening itself up still further to all sectors of society, including NGOs and the private sector. It means grappling with the multiple consequences for health of accelerating social and demographic changes, including population growth and encroachment on forest areas and other ecological zones, aging population structure, migration—including the mass movement of disaster-affected populations—and urbanization. It calls for dealing creatively with the impact of the indebtedness, incurred over time, that has led many countries to reduce public spending in health services, which are often regarded as being only an expenditure rather than an investment in human potential. Ironically, this last challenge comes at the very moment when WHO itself is operating within severe financial constraints. After working with a zero-growth budget policy since 1984–1985, WHO's 1996–1997 budget suffered a drastic reduction estimated at 14% in real terms, while the number of staff worldwide dropped from just under 5400 in 1990 to 4300 in 1998. In contrast, the extraordinary changes in the political landscape during the same period saw the number of WHO member states increase from 166 to 191.

WHO must face up to threats to human health that respect no national boundaries, such as uncontrolled dumping of toxic wastes and pollution of land, water, and air, and prodigious consumption and mismanagement of natural resources. The solution of these problems hinges, to a large extent, on the degree to which WHO is able to harness the interdependence of nations and peoples as a positive force for conciliating between competing present and future needs.

In the face of changing demands, WHO is doing its utmost to preserve its inclusive approach to health and to emphasize the continuity between prevention, care, rehabilitation, and health promotion for all people through the different stages of their lives. In restructuring its programs and activities in the light of resource constraints, WHO is placing emphasis on meeting the most pressing health needs based on the following priorities:

- those which present a health emergency;
- those which affect the poorest countries and the most vulnerable groups;
- those which produce the heaviest burden of death, suffering, and disability;
- those which represent a major impediment to social and economic development.

In 1995 the Executive Board and the World Health Assembly, as part of an overall global reform process, identified the need to review the basic primary health care principles of Alma-Ata, recommit member states to those principles, and renew aspects of the strategy to achieve *Health for All* in the light of changing global circumstances. Since 1978 many countries not present at Alma-Ata had attained statehood; a generation of health workers had graduated; and several key determinants of health—social, political, economic, demographic, and epidemiological—had profoundly affected the health profile of populations and the level of inequalities between various subgroups. Moreover, the opportunity for improving health through multisectoral approaches, application of appropriate technology, and greater emphasis on participatory approaches all require that countries, regions, and the international community look afresh at how international health policy for this century can truly improve the long-term health status of the world's poorest countries and communities.

Food, Nutrition, and World Health—Meeting the Global Challenge

Freedom from hunger and malnutrition, essential to the enjoyment of the highest attainable standard of

health, is among the fundamental rights of every human being. What is more, there can be no sound social and economic development without adequate food and nutrition. This is not the same as saying that people in rich countries necessarily have a better chance of being properly nourished than do people in poor countries. There is much more to achieving healthy nutritional status than can be conveyed by such simplistic labels as 'developed' and 'developing' where countries—and most of all people—are concerned.

Even if there is some truth in the axiom 'we are what we eat,' it is clear that nutritional status—a characteristic common to all that can be measured and monitored—depends on considerably more than diet. For individuals, it is best understood as the result of the complex interaction between health at any given moment, the food that is eaten, and the surrounding physical, social, and economic environment. Nutritional status not only reflects the quantity of available food but also its quality, including safety, while showing to what extent the body can transform food into nutrients that will protect and promote health and permit people to function to the best advantage. Because the environment and its impact vary so greatly from individual to individual, there can be no 'standard' answer to the problem of malnutrition. Moreover, no single strategy to combat it will produce the same results in every case. The approach to preventing and overcoming malnutrition thus has to be tailored to fit the circumstances.

Nutrition and the Sweep of History

Looking back in history, one can see that a major shift is taking place in the impact on humanity of the main factors—poor diet and ill health—that have traditionally accounted for most malnutrition. Over the centuries the human species survived hand-to-mouth on whatever it could manage to hunt, gather, harvest, or hoard. The diet which fuelled most of human evolution was low in fat and very low in sugar but high in fiber and other complex carbohydrates.

In the overall context of human development, it is only recently that people in high-income countries could stop worrying about the threat of occasional hunger and increasingly indulge in preferred foods owing to radical improvements in methods of food production, processing, storage, and distribution. Only in recent decades, as people benefited from greater control of infectious disease and better access to safe food, have research findings confirmed the well-founded suspicion that dietary preferences may influence the onset of several major chronic diseases, including coronary heart disease, stroke, various cancers, diabetes mellitus, gastrointestinal disorders, and various bone and joint diseases. Although many dietary factors have been investigated, those most frequently linked to such diseases figure prominently in a pattern of eating typified by the high consumption of energy-dense foods of animal origin and of foods processed or prepared with added fat, sugar, and salt.

As a result, grade 2 overweight, which warrants close attention, is relatively common in industrialized and many developing countries—up to 20% of Europeans and of Whites in the US 60 years of age are affected. The figure increases to 40% for women in eastern European and Mediterranean countries and Black women in the USA. Even higher prevalences are observed among American Indians, Hispanic Americans, and Pacific islanders. While the prevalence of grade 2 overweight is much lower in some African and Asian countries—the range is about 3% to 17%—in South America and the Caribbean it is close to that in many European countries, about 25%. WHO estimates that major noncommunicable diseases (NCDs) are responsible for at least 40% of all deaths in developing countries and 75% in industrialized countries, where cardiovascular diseases are the first cause of mortality and cancer is the third. By the year 2020, NCDs will account for about three-quarters of all deaths in the developing world.

Meanwhile, over 800 million people still cannot meet basic needs for energy and protein, more than 2000 million people are deficient in essential micronutrients, and an estimated 174 million children under 5 years of age in developing countries are malnourished, as indicated by low weight for age, while 230 million are stunted. Malnutrition results in poor physical and cognitive development as well as lower resistance to illness. Nearly half of the estimated 11 million deaths occurring annually among children under 5—or about 49% of young child mortality in developing countries—are associated with malnutrition.

Simultaneous Action on Two Overlapping Fronts

For these reasons, to promote healthy nutrition for all people it is necessary to take simultaneous action on two distinct, if overlapping, fronts. On the one hand, many less-favored nations remain handicapped by a formidable array of development constraints, including rapidly

increasing population, unproductive agriculture, environmental degradation, limited health service coverage, and war and civil strife. Among the most visible—and tragic—consequences are the many millions of wasted and stunted children who do not have enough protein and energy in their diets, who suffer from cretinism and other permanent brain damage because their diets and those of their parents are deficient in iodine, or who go blind or even die for lack of vitamin A. It is in just such environments that diarrheal diseases resulting from contaminated food and water, frequently compounded by seasonal or chronic food shortages, take their heaviest toll in terms of malnutrition, ill health, and premature death.

On the other hand, there has been a significant drop in recent years in the prevalence of infectious disease, while food availability and the quality of diets have improved for populations the world over. The result in many countries has been a sharp reduction in infant and child mortality and longer adult life expectancy. These and related factors have paved the way for a dramatic expansion of a different type of nutrition crisis: Diet-related chronic disorders are now flourishing in environments where, not so long ago, infectious diseases were the greatest menace to health. Too often, one type of malnutrition is being exchanged, or—worse still—being superimposed upon another, with no net gain for human health in the process.

Labels such as 'rich' or 'poor' and 'developed' or 'developing,' by themselves, provide little insight into what causes malnutrition and how it can be overcome. The fact is, wherever people reside, it is the *way they live, what they eat*, and *how they interact with their environment* that determine their nutritional status. Healthy nutritional status is by no means the monopoly of rich countries, any more than malnutrition is somehow the prerogative of poor ones. Whatever the cultural influences at work in a given milieu, all governments are challenged to develop food and nutrition policies that will make healthy choices the easy choices for their populations. Consistent with the unique normative, scientific, and advisory role that WHO has played for the last half century, the organization strives to support all its 191 member states in doing just this.

Introduction

Zinc is only moderately abundant in nature, ranking 23rd of the elements. Of the trace elements in the body, it is second only to iron, but, in contrast to iron, it has a single redox state. Together with its size and charge characteristics, this has led to its widespread use in proteins of the body. The number of zinc proteins is unknown but growing, and they include numerous enzymes and many more nuclear proteins that regulate gene expression. Further sets of proteins are responsible for zinc homeostasis. The binding sites and functions of zinc within some of these proteins are well understood, but for others these are less clear. In particular, the links between the biochemical roles of zinc within proteins and its physiological functions are often obscure. The range of physiological functions of zinc is broad and can be observed in all tissues of the body. In general, zinc is required for DNA synthesis, cell division and growth, for protein synthesis and macronutrient metabolism, and for the development and appropriate function of most body systems. The lack of an appropriate assessment tool makes it difficult to estimate the prevalence of zinc deficiency, but undiagnosed marginal zinc deficiency may be a concern.

The History of Zinc as a Nutrient

The essentiality of zinc for bacterial growth has been known for almost 150 years. Later, it was shown to be required by plants and then, in 1934, by rats. In the succeeding years, the essentiality of zinc was demonstrated for other species. The fact that zinc is used widely by plants and animals and is therefore reasonably widespread in the food supply led to the position that human zinc deficiency was unlikely. It was not until the early 1960s that Prasad and others in Iran described a syndrome of dwarfism and lack of sexual development in teenage boys and young adults. The young Iranian men consumed a diet based on unleavened bread with very little animal protein and also ate large amounts of clay (geophagia). They were anemic and responded to treatment with ferrous sulfate coupled with a more balanced diet including animal protein. The other symptoms also resolved, but it seemed unlikely that lack of iron itself was responsible. Prasad then moved to Egypt, where he encountered a similar syndrome. His Egyptian patients were not geophagic, but they ate mostly bread and beans and were infested with *Schistosoma* and hookworm. Zinc deficiency was documented in these individuals, and treatment with zinc was more effective at increasing growth rates than either iron supplementation or a diet including animal protein. Thus, dietary zinc deficiency was

demonstrated, presumably due to impaired absorption because of the high fiber and phytate contents of the diet. While severe zinc deficiency is not a frequent problem in developed countries, the prevalence of milder symptoms is unknown. In the USA, mild symptoms of zinc deficiency have occasionally been reported (see below under Human Zinc Deficiency).

Chemistry of Zinc

The conjunction of the chemical properties of zinc underlies its biological significance. It is a relatively small ion (with an atomic number of 30) and carries a positive charge of two. It attracts electrons as a strong Lewis acid, and this property can be important in its catalytic functions. It has relatively flexible coordination geometry and, while binding its ligands with high affinity, exhibits rapid rates of exchange, which can facilitate chemical reactions and biological processes. All this is coupled with its single redox state, in contrast to the multiple redox states of iron and copper, which eliminates the danger of oxidative damage. While other trace elements may share some of these properties, none share them all. This is what makes zinc so valuable for protein structure and function.

Zinc in Foods

Zinc is associated with proteins in the body and is found associated with proteins in food. Thus, protein-rich foods tend to be good sources (**Table 1**). However, there is great variability, from egg whites, which have almost no zinc, to oysters, at $750\,mg\,kg^{-1}$. The physiological function of these high concentrations in oysters is unknown, though the zinc is concentrated in cells thought to serve a phagocytic/host defense function. In addition, the bioavailability of zinc may be quite variable, owing to other food components eaten at the same time. Grains and legumes may be relatively rich sources, but bioavailability is limited owing to their phytate content. On the other hand, animal proteins appear to enhance zinc absorption.

Table 1 Dietary sources of zinc

Food	*Zinc content ($mg\,kg^{-1}$ raw weight)*
Oysters	750
Beef, lean	59
Pork	26
Chicken breast	8
Chicken leg	18
Salmon	4
Egg, whole	11
Egg white	0.3
Milk, whole	4
Cheese, cheddar	31
Wheat, whole flour	29
Wheat, white flour	7
Rice, brown	20
Rice, polished	12
Kidney beans	27
Lentils	36
Potatoes	3
Broccoli	4
Apples	0.4

Control of Zinc Homeostasis

The size and charge characteristics of zinc mandate the use of carriers to traverse biological membranes. Two families of transporters have been described and partially characterized. The ZIP family (ZRT (zinc-regulated transporter)- and IRT (iron-regulated transporter)-related proteins, named after homologous transport proteins in yeast and plants) appears to move zinc into the cytoplasm of the cell, either from outside the cell or from subcellular compartments. The second group of transporters, the CDF (cation diffusion factor) family, is responsible for zinc egress from the cytoplasm. This latter family includes ZnT-1, which has been localized to plasma membranes and functions as a cellular efflux protein, and ZnT-2, which transports zinc into storage vesicles under conditions of high cellular zinc. Collectively, the ZIP and CDF proteins are likely to underlie the homeostatic control of zinc distribution around the body.

Zinc Absorption

The absorption, distribution, and excretion of zinc are shown in **Figure 1**. Overall, about 20–40% of consumed zinc is absorbed, depending on the bioavailability within the particular food source. Zinc is absorbed by both saturable and non-saturable processes, with the greatest rates of absorption occurring in the jejunum. Absorption is adjusted to meet needs, being proportionately increased in deficiency states and reduced when intake is high. Zinc status is reflected by the intestinal concentration of the zinc-binding protein metallothionein (MT). MT may trap zinc within the epithelial cells, causing it to be lost in feces as the cells are sloughed off. This may be part of the explanation of how zinc absorption is adjusted to meet needs. Acrodermatitis enteropathica is an autosomal recessive condition of zinc malabsorption, which can lead to severe deficiency. The gene alteration that leads to this condition has recently been identified in *ZIP4*, which encodes one of the zinc transporters. This protein has been localized to the apical membrane of intestinal epithelial cells and, given the severity of the symptoms associated with its inactivation,

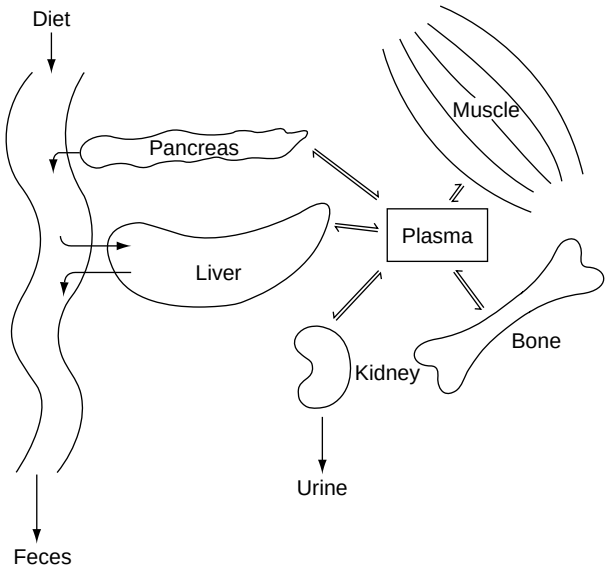

Figure 1 Whole-body zinc homeostasis. Zinc in the intestine comes from the diet and from endogenous secretions. A portion is absorbed, but much is lost in the feces, which are the major route of excretion. Absorbed zinc passes through the liver and then to the general circulation. Zinc is distributed throughout the body, with muscle and bone constituting the largest pools. A minor but controlled amount of zinc is lost in the urine.

appears to be necessary for normal zinc absorption. The zinc efflux protein ZnT-1 is found at the basolateral membrane and probably promotes the passage of zinc out of the intestine. Acrodermatitis enteropathica can be treated with large doses of zinc, supporting the existence of paracellular transport at high intake levels. A large amount of zinc is secreted into the gut from the pancreas and intestine (**Figure 1**). Malabsorption syndromes can lead to a failure to reabsorb these endogenous secretions and, hence, to rapid loss of body zinc.

Transport and Distribution

The zinc pool in plasma is relatively small, representing only about 0.1% of total body zinc. It circulates bound to albumin and α-2-macroglobulin, and about 3% is complexed with amino-acids. About fivefold greater amounts of zinc are found in whole blood, with erythrocytes accounting for about 75% of the total. However, about 85% of erythrocyte zinc is complexed within carbonic anhydrase and therefore does not exchange easily. The egress of zinc from the circulation across endothelial cells and into tissues of the body is not well understood. Uptake in association with albumin has been suggested, but members of the ZIP family of transporters are likely to play a role here. The tissue distribution of zinc is relatively uniform. All cells require the mineral, and no cell stores it. The concentration of zinc in the adult human is about $0.5\,\mu mol\,g^{-1}$, giving a total body content of about 2 g. More than half is found in skeletal muscle, and about 30% is found in bone. The bone pool appears to be more labile than the muscle pool and has been used as an index of zinc status in experimental animals. The liver represents another labile pool. It receives dietary zinc from the portal circulation and contains about 5% of body zinc.

Excretion

Zinc is lost from the body primarily through the feces (**Figure 1**). Feces contain unabsorbed dietary zinc, zinc contained within intestinal epithelial cells that have been sloughed off, and endogenous zinc secretions into the gut from the pancreas, the gall bladder, and the cells lining the gastrointestinal tract. The endogenous secretions and the extent to which they are reabsorbed can be controlled and constitute an important homeostatic mechanism for regulating zinc status. Zinc losses in urine are relatively minor but do respond to extremes of intake to help maintain homeostasis. Shed skin cells, sweat, hair, menstrual blood, and semen are additional routes of loss.

Zinc Biochemistry

Zinc homeostasis and action involve an intimate association of the mineral with proteins. These proteins include membrane transporters responsible for the absorption of zinc in the gut and its passage into and out of cells and subcellular organelles, transport and delivery proteins (both in the circulation and within cells), sensing proteins that will adjust homeostasis and function according to zinc availability, and a large range of proteins to which zinc is ultimately delivered. Two major classes of these latter proteins are the enzymes and transcription factors. In addition to its association with proteins, zinc within cells is also found associated with membrane lipids and both DNA and RNA. The functions of these pools of zinc are not clear.

Homeostasis

The interaction of zinc with its transporters has not been well characterized, though transmembrane domains have been identified that are thought to be responsible for the transport function. Free concentrations of zinc within the cell appear to be extremely low and may not constitute a sufficient pool for the supply of zinc to its protein ligands. This suggests the existence of delivery proteins, and this role has been suggested for MT, which has been shown to transfer zinc to apoenzymes *in vitro*. MT

was originally discovered as a cytoplasmic heavy-metal-binding protein, which was thought to prevent metal toxicity within cells. Additional more significant roles were suggested by the realization that there are multiple MT genes, which have been conserved through evolution. It is a small protein that is unusually rich in cysteine and can bind seven atoms of zinc. MT may influence the subcellular distribution and availability of zinc, since its own distribution varies. For example, the nuclear content of MT varies with the cell cycle. MT expression is regulated not only by heavy metals but also by a range of other signals including glucocorticoids, interleukins, and cyclic adenosine monophosphate. In addition, its zinc-binding activity is influenced by the cellular redox state. For example, an increase in the glutathione disulfide–glutathione ratio results in the release of zinc from MT and thus an increase in its availability for other proteins. However, deletion of individual MT genes in mice has not resulted in major pathologies, questioning the significance of these proteins.

Investigation of the mechanism whereby zinc regulates the expression of MT led to the discovery of the single protein known to act as a zinc sensor within mammalian cells, MTF-1 (metal response element (MRE)-binding transcription factor-1). MTF-1 binds to MREs in the promoter region of MT and other genes and regulates their expression. The ability of MTF-1 to localize to the nucleus and bind to its target genes depends on its zinc content. Thus, an increase in cellular zinc levels results in greater MTF-1 activity and, consequently, increased expression of its target genes. In addition to MT, which will bind more zinc, these include ZnT-1, which will transport zinc out of the cell. These mechanisms underlying cellular zinc homeostasis are illustrated in **Figure 2**.

Zinc Enzymes

The three-dimensional structures of more than 200 zinc-containing enzymes have now been characterized, and many more enzymes have been identified. All six International Union of Biochemistry classes are represented. Zinc enzymes can be divided into three groups according to the role played by zinc within the protein. In the catalytic group (e.g., carbonic anhydrase), zinc is a direct participant in the catalytic function of the enzyme. The zinc atom is coordinated by three amino-acids from the enzyme and a molecule of water at the active site. In enzymes with structural zinc sites (e.g., protein kinase C), the metal binds four amino-acids within the protein and ensures appropriate folding for bioactivity. Enzymes in which zinc serves a co-catalytic function (e.g., superoxide dismutase) contain two or three zinc atoms, two

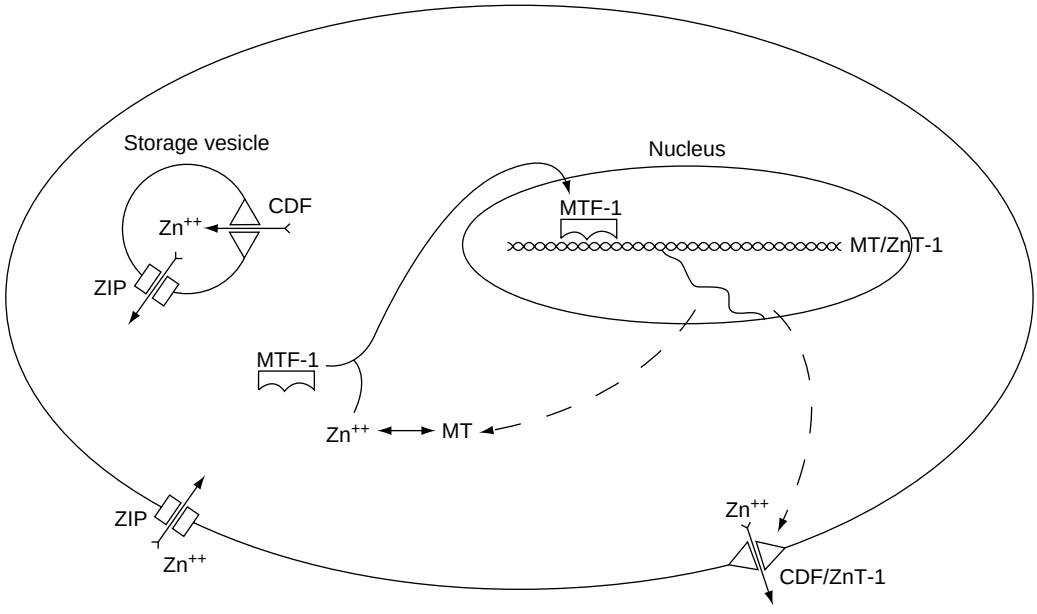

Figure 2 Cellular zinc homeostasis. Zinc is delivered to the cytoplasm from either the extracellular space or vesicles within the cell by members of the ZIP family of transporters. A rise in cellular zinc results in activation and nuclear translocation of MTF-1. In the nucleus, MTF-1 regulates the transcription of a set of target genes, including MT and ZnT-1. MT will bind zinc, and ZnT-1 will transport zinc out across the plasma membrane. MT may govern the delivery of zinc to other proteins within the cell. Other members of the CDF family transport zinc into vesicles.

Table 2 Examples of mammalian zinc-dependent enzymes

Enzyme	*Function*
RNA polymerase	Transcription and synthesis of mRNA
Carboxypeptidase A	Protein digestion in the intestine
Protein kinase C	Signal transduction
Carbonic anhydrase	Respiration, buffering, and hydration of carbon dioxide
Cytochrome *c* oxidase	Respiration and electron transport chain
Alcohol dehydrogenase	Ethanol metabolism
Superoxide dismutase	Inactivation of free radicals
Nitric oxide synthase	Signalling and vasodilation
Angiotensin converting enzyme	Blood-pressure regulation and activation of angiotensinogen

of which are coordinated by a shared amino-acid residue. Coordination sites are widely spaced on the protein, and the zinc may be used for both structural and catalytic functions. In addition to these three groups, zinc has also been found to serve a bridging function between two separate polypeptides to stabilize a biologically active larger complex (e.g., nitric oxide synthase). A selection of zinc enzymes is included in **Table 2**, which helps to illustrate the wide variety of metabolic functions requiring zinc.

Zinc Transcription Factors

There are many zinc enzymes, but there appear to be even more transcription factors that use zinc. These sites have all been identified in the last 20 years and have been less thoroughly investigated than the zinc enzymes. Variable numbers of zinc atoms are each coordinated by four cysteine/histidine residues to stabilize a DNA binding structure. A search of the human genome has revealed over 1000 genes (about 3% of those identified) containing these characteristic zinc finger domains. An important class of zinc finger transcription factors is the steroid/thyroid receptor superfamily, which is responsible for mediating the biological response to a wide range of hormonal and metabolic signals, including retinoic acid and vitamin D. These factors all have nine conserved cysteine residues in the DNA binding region, eight of which are coordinated by two atoms of zinc. Loss of zinc from these sites would interrupt biological function, but it is not clear that this ever happens in a physiological context. Recently, the new array technologies have been used to assess the genome-wide response to changing zinc availability in different tissues, including intestine, liver, and cells of the immune system. The gene products that have been identified as zinc sensitive by these approaches amount to about 5% of the expressed genes within a tissue. They do not necessarily encode zinc proteins themselves but rather proteins whose transcription is altered by zinc. MTF-1 is likely to mediate some but not all of these changes, and other transcription factors whose activity is dependent on zinc may soon be found.

Zinc Physiology

The enormous range of biochemical roles for zinc predicts a large number of physiological functions. The physiological roles of zinc may be further extended to include secondary effects mediated by altered food intake and effects on the functions of other nutrients. While the physiological roles for zinc are well described, it is important to note that the connections between the biochemistry and physiology of zinc remain unclear. Thus, in zinc deficiency the specific zinc-sensitive biochemical step leading to altered physiology is usually unknown. This disconnection will become apparent as the physiological roles of zinc are considered. The broad distribution of zinc through the body at the organ, cellular, and even protein levels suggests that the functions of most systems are dependent upon zinc. Its physiological roles become manifest in cases of deficiency, and that framework will be used to discuss the principal functions here.

Growth

The requirement of zinc for the growth of numerous organisms, ranging from bacteria to humans, is well established. Growth failure is a relatively early consequence of zinc deficiency in experimental animals. Given the lack of a zinc store, in the absence of a sufficient dietary supply zinc will be immediately unavailable for new tissue. Numerous processes seem to contribute to the growth failure. Experiments in animals have shown that zinc deficiency leads to a drop in food intake, though the use of control animals pair-fed an identical amount of a zinc-sufficient diet demonstrates a clear role for a lack of zinc beyond its effects on feeding behavior. The endocrine system is involved with multiple effects of zinc deficiency on the somatotrophic axis, notably a reduction in circulating concentrations of insulin-like growth factor 1 (IGF-1). Again, this appears to be only part of the story since force-feeding a zinc-deficient diet and administering exogenous IGF-1 both fail to correct the growth failure caused by zinc deficiency. Growth of cultured cells is

dependent on media zinc. DNA synthesis is interrupted. Production of thymidine kinase mRNA is diminished by the removal of zinc, but again this appears to be only a partial explanation. The IGF-1 signalling pathway within cells also seems to be affected. Zinc is also required for wound healing, presumably owing to related processes.

Immune Function

The immune system appears to be particularly sensitive to zinc deficiency, in comparison with the rest of the body. Lymphopenia and thymic atrophy are observed, and both cell-mediated and antibody-mediated responses are reduced. As with growth, multiple mechanisms appear to be at play. In addition to its generalized effects on DNA synthesis, zinc deficiency appears to induce apoptosis, resulting in a loss of B-cell and T-cell precursors within the bone marrow. Thymulin is a zinc-dependent enzyme that stimulates the development of T cells within the thymus. The production of cytokines by mononuclear cells is also reduced by zinc deficiency. It appears likely that these effects can be of clinical significance. Infections occur more frequently in individuals with acrodermatitis enteropathica, and reduced immune function is accompanied by zinc deficiency in several other conditions, including sickle-cell anemia and various gastrointestinal disorders. In the USA, zinc lozenges have become popular as a treatment for the common cold. Results from controlled trials of this treatment have been variable, but a shortening of cold duration may occur. It would appear reasonable to suppose that treatment effectiveness would depend on initial zinc status, with greater success being seen in individuals with marginal undetected zinc deficiency.

Reproduction

The original description of zinc deficiency in humans included lack of pubertal development. Spermatogenesis is a zinc-dependent process. Seminal fluid is particularly rich in zinc, and the sperm appear to accumulate zinc from this source prior to ejaculation. Zinc is also crucial for normal fetal development, and deficiency leads to abnormalities in humans and animals. Maternal zinc deficiency has been linked with pregnancy-associated morbidity, including pre-term delivery.

Nervous System

The brain is one of the sites that has been shown to be particularly sensitive to zinc deficiency during fetal development, with neural-tube defects and other disorders being found. While this work was performed in animals, a similar relationship appears likely in humans. Zinc is distributed throughout the brain, but greater concentrations are found within the hippocampus. Here, a brain-specific transporter, ZnT-3, concentrates zinc in vesicles within glutamatergic neurones. It is co-secreted with the neurotransmitter and appears to serve as a modulator of neurotransmission. Very high concentrations of zinc ($>100\,\mu M$) are found within the synaptic cleft during this process. In addition, brain injury resulting from ischemia or trauma causes the release of massive amounts of zinc, which is thought to be responsible for the resultant cell death.

Antioxidant Defense System

Although zinc is not itself an antioxidant, there are several ways in which it participates in the antioxidant defense system of the body, with important implications for health. It can bind to thiol groups in proteins, making them less susceptible to oxidation. By displacing redox-reactive metals such as iron and copper from both proteins and lipids it can reduce the metal-induced formation of hydroxyl radicals and thus protect the macromolecules. Its role in inducing MT has already been mentioned, and this protein scavenges hydroxyl radicals. Increased oxidative stress results in the release of zinc from MT, presumably making it more available for other proteins. Copper/zinc superoxide dismutase is an important zinc-containing antioxidant enzyme whose activity is impaired in the deficient state. In general, animal studies have revealed an association between zinc deficiency and increased oxidative stress. The likelihood of increased oxidative stress under conditions of zinc deficiency suggests a potential anticarcinogenic role for this mineral. This connection is further supported by the finding that the tumor suppressor gene p53, which is frequently mutated in human cancers, is a zinc-containing transcription factor whose expression is also dependent on zinc.

Macronutrient Metabolism

Many of the enzymes of intermediary metabolism contain zinc, and deficiency affects all macronutrients. Protein synthesis and DNA and RNA synthesis require zinc. Insulin is secreted from the pancreas and circulates in association with zinc. This secretion is diminished under conditions of zinc deficiency, leading to impaired glucose metabolism. Lipid metabolism is also affected, with zinc deficiency being associated with reductions in circulating high-density lipoproteins.

Human Zinc Deficiency

In addition to dietary inadequacy, there are several routes that lead to zinc deficiency. Acrodermatitis enteropathica, the genetic disorder of zinc malabsorption, has already been mentioned. Other, more generalized, malabsorption syndromes (e.g., coeliac disease) can also lead to zinc deficiency. Deficiency has also resulted from inappropriate intravenous feeding and the use of chelation therapy. Children are likely to be particularly at risk of zinc deficiency, because of its involvement in growth.

Mild

Given the difficulty of assessing marginal impairments in zinc status, the effects of deficiency can often be verified only by a response to treatment. Growth provides a good example of this. Children in Denver, Colorado, who were of low height for their age increased their growth rates in response to zinc supplementation, whereas zinc had no effect in children of normal height. In addition to improved growth, improvements in immune function, taste and smell acuity, and reproductive function have been noted with zinc supplementation.

Severe

Severe human zinc deficiency has been well characterized by the original descriptions in the Middle East and in patients with acrodermatitis enteropathica. The symptoms of mild deficiency are continued and exaggerated. Thus, stunting can be extreme and is accompanied by delayed sexual maturation and impotence. Characteristic skin lesions are found, originating around the mouth and nose but becoming widespread as deficiency develops. Diarrhea is also present. Deficits in taste and smell are accompanied by anorexia and other behavioral changes, including increased irritability and impaired cognitive function. Eye pathologies similar to those seen in vitamin A deficiency are observed.

Zinc Toxicity

Toxicity of zinc from food sources has not been reported and seems unlikely since absorption is homeostatically regulated. Acute gastrointestinal symptoms and headaches have been reported after ingestion of amounts about 10–20-fold higher than the recommended intakes. Chronic ingestion of these large amounts has been shown to impair immune response and lipoprotein metabolism. However, the key danger of excessive zinc intake is reduced copper status. This is probably due to a zinc-induced blockage of copper absorption and in fact is clinically useful in individuals with Wilson's disease, a condition of copper toxicity. In the USA, an upper limit of $40\,mg\,day^{-1}$ has been set for adults, because of the threat to copper status. The popularity of zinc lozenges for treatment of the common cold could lead to this intake being exceeded. Thus, the use of these treatments should be of limited duration.

Assessment

The prevalence of marginal zinc deficiency in human populations is unknown because of the lack of a good means of assessing zinc status. Measurement of plasma zinc is straightforward, but it does not serve as a reliable indicator of zinc status. Plasma zinc is a quantitatively minor pool that can be easily influenced by minor shifts in tissue zinc. Plasma concentrations do not fall with decreasing dietary intake, except at very low intakes. Plasma zinc can also be affected by factors unrelated to zinc status (e.g., time of day, stress, and infection). Cellular components of blood can be assayed, but erythrocyte concentrations of zinc are maintained in deficient states and variable results have been found with leucocytes. Hair zinc concentrations may reflect available zinc but will also depend on the rate of hair growth.

Several different zinc-dependent enzymes have been investigated as potential markers of zinc status, but none have proved reliable. MT in blood cells has been suggested as a useful indicator of zinc status, assayed at either the protein or the mRNA level. MT expression is likely to be regulated by factors other than zinc and therefore may lack the specificity required of a good indicator. The gene-array approaches that have recently been used to determine the global effects of zinc deficiency within a tissue would appear to offer hope for the identification of an appropriate functional marker of zinc status.

Recommended Intakes

In the absence of a reliable index of zinc status, both the US Food and Nutrition Board and the Food and Agriculture Organization (FAO)/World Health Organization (WHO) Expert Committee used the factorial approach to estimate human zinc requirements. As shown in **Table 3**, the FAO/WHO give three sets of recommendations, depending on the zinc bioavailability of the diet. The US Food and Nutrition Board figures fall between those given for moderate- and low-availability diets. Both groups also set upper limits for intake, based largely on the risk of impairing copper status. These values

Table 3 Recommended intakes of zinc

Age group		*US–Canadian recommended dietary allowance*	*FAO/WHO reference nutrient intake Bioavailability*		
			High	*Moderate*	*Low*
Children (1–3 years old)		3	2.4	4.1	8.3
Adolescents (14–18 years old)	Female	9	4.3	7.2	14.4
	Male	11	5.1	8.6	17.1
Adults (>19 years old)	Female	8	3.0	4.9	9.8
	Male	11	4.2	7.0	14.0
Pregnant women	Third trimester	11	6.0	10.0	20.0
Lactating women	0–3 months	12	5.8	9.5	19.0

are similar (40 mg for the US Food and Nutrition Board, 45 mg for FAO/WHO, for adults).

Deficiency in Developing Countries, Intervention Studies

C Hotz, National Institute of Public Health, Morelos, Mexico

Introduction

Knowledge of the occurrence of zinc deficiency and its importance to human health has increased greatly in recent years. Available evidence indicates that zinc deficiency is an important contributing factor to impaired growth and development, morbidity, and mortality among children in underprivileged settings. Presently, there are few estimates of the prevalence of zinc deficiency in developing countries based on dietary intake or biochemical indices. However, national level estimates of the adequacy of zinc in the food supply and the prevalence of childhood growth stunting can be used to inform on the relative risk of zinc deficiency among countries. National programs to improve zinc status through either supplementation or food fortification are just being initiated.

Recognition of Zinc Deficiency in Developing Countries

The recognition of zinc deficiency as an important contributor to the high rates of morbidity, mortality, and delayed growth and development among

children is relatively recent in contrast to the earlier recognition of the importance and widespread occurrence of deficiencies of iodine, vitamin A, and iron. Coordinated efforts to address vitamin A deficiency in less developed countries were formally initiated by the establishment of the International Vitamin A Consultative Group (IVACG) in 1975. In the mid-1980s, similar groups were founded for the control of iodine deficiency disorders (International Council for the Control of Iodine Deficiency Disorders; ICC/IDD) and iron deficiency (International Nutritional Anemias Consultative Group; INACG). It was not until the year 2000 that a similar group emerged, the International Zinc Nutrition Consultative Group (IZiNCG), to promote the control of zinc deficiency in more vulnerable populations.

The detection of zinc deficiency in populations and the recognition of its association with health outcomes have been somewhat more challenging for zinc than for other nutrients, contributing to the delay in efforts to control it. The ability to diagnose zinc deficiency in individuals using biochemical measures is somewhat limited. For example, the concentration of zinc in serum or plasma may not diminish until the depletion of zinc is more advanced, making it less useful for diagnosing mild to moderate zinc deficiency states in individuals. Other possible biochemical indicators of zinc status have not been consistently demonstrated to reflect change in zinc status. These limitations may have subsequently dampened enthusiasm for evaluating zinc status at the population level. Furthermore, the health conditions that are clearly associated with zinc deficiency (e.g., childhood growth stunting, common childhood infections, and mortality; described in further detail below) are general in nature and have multiple causes. This is in contrast to the strong iconic association of iodine deficiency with goiter and cretinism, vitamin A deficiency with eye disorders and blindness, and iron deficiency with easily diagnosable anemia. The nonspecific nature of health outcomes associated with zinc deficiency is in concordance with the role of zinc in a wide variety of biological functions, covering all human physiological systems. Thus, the very nature of zinc metabolism and the ubiquity of zinc in biological functions at the molecular, cellular, and physiological levels has likely contributed to the difficulties and delays in recognizing the important contribution of zinc deficiency to impaired health and development. A brief history of the knowledge of zinc deficiency in developing countries is presented in **Table 1**.

Table 1 History of knowledge of zinc deficiency in developing countries

Year	*Event or publication*
1963	Relationship between zinc deficiency and hypogonadal dwarfism noted in Egypt
1972	The role of zinc deficiency in hypogonadal dwarfism described in Iran
1974	Zinc demonstrated to increase linear growth, weight, and bone age in Iranian pubertal boys
1982	Supplemental zinc demonstrated to increase linear growth in Chinese preschool children
1993	Supplemental zinc during pregnancy demonstrated to increase birth weight and gestational age of infants in India
1996	Supplemental zinc demonstrated to decrease the prevalence of diarrhea and pneumonia among malnourished children in Vietnam
1999	Pooled analysis of randomized, controlled, zinc supplementation trials indicates a significant positive effect of zinc on reducing the incidence of diarrhea and pneumonia
2000	Establishment of the International Zinc Nutrition Consultative Group (IZiNCG)
2001	Mortality reduced by zinc supplementation among low-birth-weight infants in India
	Zinc supplementation recommended as adjunctive therapy for childhood diarrhea
2002	Meta-analysis of randomized, controlled zinc supplementation trials indicates a modest but significant overall improvement in growth

Causes of Zinc Deficiency in Developing Countries

Although the etiology of zinc deficiency in developing countries has not been thoroughly studied, the main contributing factor is believed to be inadequate intake of zinc in bioavailable (i.e., available for absorption across the intestine) forms.

Inadequate Dietary Intake of Zinc

In general, the risk of inadequate intake of dietary zinc within a population may be associated with the nature of the food supply, and its content and relative bioavailability of zinc. Animal source foods, in particular shellfish, small whole fish, beef, and organ meats such as liver and kidney, are rich sources of zinc. Furthermore, the zinc contained in animal source foods is more highly bioavailable than from plant source foods; the presence of certain amino acids (e.g., histidine, methioinine), or perhaps other unidentified factors, may facilitate the intestinal absorption of zinc from animal flesh foods. Plant source foods, such as most fruits and vegetables including green leaves, and starchy roots and tubers, have relatively low zinc content. While whole grains and legumes have moderate to high

zinc content, these foods also contain large quantities of phytate (phytic acid or myo-inositol hexaphosphate), the most potent identified dietary inhibitor of zinc absorption. The zinc and phytate content, and the phytate:zinc molar ratio of some foods are shown in **Table 2**.

Plants synthesize phytate, which occurs in highest concentration in seeds and to a lesser extent in vegetative plant parts. Phytate forms chelates with zinc and other minerals; as this compound is largely undigested and is not absorbed, it carries the chelated portion of dietary zinc out of the intestine, thus reducing the amount of zinc available for absorption. The phytate:zinc molar ratio of the diet can be used to estimate the bioavailability of zinc. Populations with a heavy dietary reliance on unrefined cereals or legumes, complemented with only small amounts of zinc-rich animal source foods, will have lower intakes of bioavailable zinc. Although milling cereal grains removes large amounts of phytate, it also removes large amounts of zinc. Thus, among populations with a heavy dietary reliance on refined cereals (e.g., rice) or starchy roots and tubers (e.g., potatoes, cassava) with small amounts of zinc-rich animal foods, the total intake of dietary zinc will be low. In either case, low food intakes due to food insecurity will exacerbate the risk of not meeting daily physiological requirements for absorbed zinc.

Table 2 The content of zinc and phytate, and the phytate:zinc molar ratio in uncooked foods

Food	*Zinc (mg/100 g)*	*Phytate (mg/100 g)*	*Phytate:zinc molar ratio*
Cereals			
Corn	1.8	800	44
Pasta	0.7	282	40
Rice (milled)	1.1	352	32

Orange	0.1	0	–
Mango	0.0	20	–
Animal source foods			
Beef	3.0	0	–
Chicken	1.3	0	–
Eggs	1.1	0	–
Fish	0.5	0	–
Milk	0.4	0	–
Pork	1.9	0	–

Other Causes of Zinc Deficiency

There are a few other commonly occurring conditions in developing country settings that may contribute to zinc deficiency. Diarrhea may not only lead to a reduced absorption of dietary zinc during the episode due to increased intestinal transit time, but may also cause an increase in the loss of body zinc. Under normal physiological conditions, zinc is secreted into the intestine in large quantities together with digestive juices but is largely reabsorbed again; diarrhea may interfere with the reabsorption of this zinc. Given the important role of the intestine in regulating dietary zinc absorption, and the secretion and reabsorption of body zinc during digestion, conditions that affect the health or integrity of the intestine, such as tropical enteropathy, could interfere with the adequate maintenance of zinc balance. The contribution of these conditions to zinc deficiency in developing countries requires investigation.

Prevalence of Zinc Deficiency in Developing Countries: Available Evidence

Relatively little information on population zinc status has been collected at the national or subnational level in developing countries. Thus, only very limited estimates of the prevalence of zinc deficiency are available that are based on the proportion of the population with low concentrations of serum zinc or inadequate dietary zinc intakes. Estimates of the magnitude of risk of zinc deficiency in a population have therefore been derived from more indirect indicators, such as the:

- adequacy of zinc in the national food supply;
- national prevalence of childhood growth stunting; and
- occurrence of a positive response of health conditions to supplemental zinc as determined by randomized, controlled zinc supplementation trials.

Adequacy of Zinc in the National Food Supply

As described above, the nature of the food supply will provide some information on the likelihood of risk of

Table 3 Adequacy of dietary zinc in the food supply in major developing country regions, as compared to North America

	Population (millions)	*Zinc (mg/caput/day)*	*Phytate:zinc molar ratio*	*Zinc from animal source foods (%)*	*Estimated population at risk of inadequate zinc intake (%)*
North America	305	12.5	11	61	10
China	1256	12.4	16	37	14
Latin America and Caribbean	498	10.3	20	42	25

inadequate dietary zinc within a population. Information compiled by the United Nation's Food and Agriculture Organization has been used to estimate the potential risk of inadequate zinc in the food supply for a large number of countries. This estimate uses country level data on the per capita amounts of 95 different food commodities available for human consumption, and estimates of the zinc content and phytate:zinc molar ratio of these foods, to calculate the per capita amount of bioavailable zinc in the food supply. The per capita amount of bioavailable zinc is compared to the physiological requirement for absorbed zinc weighted for the demographic distribution of the population. The theoretical proportion of the population at risk of inadequate dietary zinc is used to estimate the relative risk of zinc deficiency at the national level. For example, countries with 25% or more of the population at risk of inadequate dietary zinc are considered to be at elevated risk. This information is limited in that it represents the national average situation and cannot identify subnational populations that may be at elevated risk. In the absence of more direct measures of zinc status, such estimates will justify the need to conduct population surveys that measure risk of zinc deficiency more directly.

Estimates of the proportion of the population at risk of inadequate dietary zinc based on food supply data have been calculated for 176 countries; a summary of the tabulations by developing country region is given in **Table 3**, and compared to those from North America. Overall, these estimates suggest that about 20% of the world's population is at risk of inadequate dietary zinc intake.

National Prevalence of Childhood Growth Stunting

Zinc deficiency is a common limiting factor to adequate child growth in developing country settings. A meta-analysis of 25 studies using a randomized, placebo-controlled design, which measured change in linear growth of children following zinc supplementation for at least 2 months, indicated that supplemental zinc had an overall, positive effect on linear growth. This meta-analysis also demonstrated that a low group mean index of child height-for-age (i.e., 1.58 SD below the reference median for height-for-age) predicts an improvement in linear growth in response to supplemental zinc. Therefore, a high prevalence of childhood growth stunting in a population represents an elevated risk of zinc deficiency. The World Health Organization suggests that when the prevalence of children with height-for-age of 2 SD below the reference median is 20% or higher, childhood growth stunting should be considered a problem of public health concern; this prevalence may likewise be indicative of an elevated risk of zinc deficiency. The World Health Organization maintains a global database on the prevalence of low height-for-age at the national and subnational level for a large number of countries.

Occurrence of a Positive Response of Health Conditions to Supplemental Zinc

Suggestive evidence for the widespread occurrence of zinc deficiency in developing regions is derived from the large number of countries from a wide geographical range where positive health changes were observed in response to supplemental zinc. The health conditions that have been positively affected by supplemental zinc, as demonstrated through randomized, controlled, community-based zinc supplementation trials and the locations of these studies are described in detail in the following section.

Consequences of Zinc Deficiency in Developing Countries: Evidence Derived from Zinc Supplementation Trials

In the context of developing country settings, present knowledge on the health consequences of zinc

deficiency has been almost entirely derived from community-based trials of zinc supplementation among populations at possible risk of zinc deficiency. In these trials, individuals in the study population are randomly allocated to receive either a zinc supplement, usually in the form of tablets or syrups, or the same supplement format without zinc (i.e., placebo). The condition under study is then monitored for a given period (typically for 2 months to one year), and the occurrence of or change in the condition is compared between the zinc-supplemented group and the corresponding control group. Given that several other nutritional and environmental factors can influence the health conditions hypothesized to occur with zinc deficiency, such studies have been essential in demonstrating unequivocally the causal role of zinc deficiency in these conditions among human populations. The following section provides an overview of the population groups at elevated risk of zinc deficiency, and the health consequences associated with zinc deficiency, as concluded from these studies.

Groups at Elevated Risk of Zinc Deficiency

In accordance with age and physiological status, some population groups have increased daily physiological requirements for absorbed zinc. The incorporation of zinc in new tissues being synthesized such as occurs during growth and pregnancy or the secretion of zinc in breast milk during lactation require that relatively larger amounts of zinc are absorbed daily. These increased needs for zinc increase the challenge of acquiring sufficient amounts of absorbable zinc from the food supply. Those groups with higher zinc requirements and who are thus at elevated risk of zinc deficiency include:

- infants (particularly those born prematurely);
- young children;
- children recovering from severe malnutrition;
- adolescents; and
- pregnant and lactating women.

At least some evidence exists for the occurrence of zinc deficiency among each of these groups in developing country settings. The elderly may also be at elevated risk of zinc deficiency, due to a decline in adequacy of zinc intakes and possibly a reduction in the absorption of dietary zinc. However, evidence for zinc deficiency among the elderly has thus far only been derived from industrialized countries; elderly populations have not been the subject of study of zinc deficiency in developing countries.

Growth and Development of Children

Many children in developing country settings experience poor growth, in comparison to relatively healthy children from more developed countries. The prevalence of low height-for-age and weight-for-age indices among children under 5 years of age are used as indicators of poor living conditions, to which poor diet, poor environmental and social conditions, and higher exposure to infectious diseases contribute. Similar conditions can result in impaired neurobehavioral development and cognitive function, putting children in developing countries at further disadvantage. Evidence exists for a specific role of zinc in both of these aspects of child development. **Table 4** provides a summary of countries in which improved growth or development in response to supplemental zinc has been clearly demonstrated.

Growth Zinc plays an important role in child growth. Several mechanisms may be involved, including the role of zinc in the transcription and translation of genetic material and, perhaps more importantly, the regulatory role of zinc in the primary endocrine system, which controls growth (i.e., the growth hormone-somatomedin axis). Specifically, zinc status is associated with the concentration of circulating insulin-like growth factor-1, the principal growth factor that controls early childhood growth. Among populations where growth retardation occurs, both height and weight gain have improved following supplemental zinc. Stimulation of linear growth appears to be the primary response, while the increase in body weight likely reflects the synthesis of lean tissue such as bone, cartilage, and muscle associated with linear growth. This is evident because, in general, weight does not increase independently of increased height in response to supplemental zinc.

The magnitude of improvement in linear growth in response to supplemental zinc is, not surprisingly, greater among children experiencing growth retardation (or 'stunting'; >2 SD below the median height-for-age of international reference data). Zinc deficiency has been demonstrated to be an important limiting factor to growth of children across a wide range of geographical settings in developing regions (**Table 4**). It should be noted that not all studies have demonstrated a significant, positive effect of zinc on growth. Possible explanations for this include: the prevalence or severity of growth stunting in the study communities was low; zinc status was adequate; or deficiencies of other growth-limiting nutrients coexisted thus preventing a positive effect of zinc on growth. The latter

Table 4 Countries from developing regions with documented evidence of improved growth or development in response to supplemental zinc

Region	*Country*	*Population group*	*Development outcome improved*
Eastern Mediterranean	Iran	Pubertal boys	Height, weight, bone age
Latin America and Caribbean	Belize	Preschool children	Height
	Brazil	Low-birth-weight infants	Weight
	Chile	Low-birth-weight infants	Length
		Severely malnourished infants	Length gain
		Preschool children (boys only)	Height
		Preadolescent and adolescent children (boys only)	Height
	Guatemala	Infants (growth stunted)	Length, lean body mass, physical activity
		Preadolescent children	Mid upper arm circumference
	Jamaica	Severely malnourished infants and preschool children	Lean tissue synthesis
South and Southeast Asia	Bangladesh	Infants (low serum zinc concentration)	Weight
		Severely malnourished infants and preschool children	Weight gain
	China	Infants	Length, weight
		Preschool children	Height, weight
		Preadolescent children	Heel-to-knee height[a]
			Neuropsychological performance
	India	Preschool children	Physical activity level
	Japan	Preadolescent children	Height
	Vietnam	Preschool children (growth stunted)	Height, weight
Sub-Saharan Africa	Ethiopia	Infants (growth-stunted)	Length
	Uganda	Preschool and school-aged children	Mid upper arm circumference

[a]An improvement with supplemental zinc was observed only when administered simultaneously with other micronutrients.

situation may also explain the observation in some studies of a transient effect of zinc on growth.

Low-birth-weight infants (<2.5 kg) may have additional needs for zinc, presumably to facilitate their rapid postnatal catch-up growth. Some benefits of supplemental zinc to growth have been observed among low-birth-weight infants in the first 6 months of life.

Severely malnourished infants and children have exhibited improved rates of weight gain, height gain, or synthesis of lean tissue when supplemental zinc has been included in their usual rehabilitation treatment regimen. In these recovering children, zinc has been shown to augment the deposition of lean tissue by increasing protein synthesis.

Cognitive function and behavior There are a few possible mechanisms by which zinc may be speculated to affect neurobehavioral function; these include neurotransmission in the synapses or development of the central nervous system via the synthesis of genetic material, proteins, and cell replication. Adequate zinc status appears to be important for certain aspects of neurobehavioral development among infants and children, although these associations are not conclusive. Higher levels of activity, specifically more frequent engagement in walking or playing as opposed to sitting or watching, have been observed among infants in developing country settings in response to supplemental zinc. Nonetheless, other studies have failed to demonstrate an effect of zinc on motor scores as assessed by Bayley Scales or Griffiths' Developmental Assessment and, in one case, a negative effect on the mental development index was observed.

Evidence for improved cognitive function among school-aged children has been derived from studies of urban and rural children in China. In the rural population of children, the positive effect of zinc on cognitive function was dependent on the provision of other supplemental micronutrients, while in the urban group, supplemental zinc had a positive effect that was independent of the provision of other micronutrients. It is possible that some of the inconsistencies in the studies of neurobehavioral development occur due to concurrent deficiencies of other nutrients that also play a role in cognition (e.g., iodine, iron).

Infectious Diseases Among Children

Zinc has many roles in the immune system, contributing both to specific and nonspecific immune functions. Indeed, there is ample information indicating that zinc deficiency makes an important

Table 5 Countries from developing regions with documented evidence of a reduced prevalence of infectious disease in response to supplemental zinc for prevention

Region	*Country*	*Population studied*	*Health condition*
Latin America and Caribbean	Mexico	Preschool children	Diarrhea
	Guatemala	Infants	Diarrhea
	Peru	Preschool children	Diarrhea
South and Southeast Asia	India	Infants and preschool children	Diarrhea
	India	Infants and preschool children (recovered from acute diarrhea)	Pneumonia
		Infants (term, small-for-gestational-age)	Mortality
	Vietnam	Infants and preschool children (growth stunted and underweight)	Diarrhea Pneumonia
Sub-Saharan Africa	Burkina Faso	Infants and preschool children	Diarrhea
	Ethiopia	Infants	Diarrhea
Western Pacific	Papua New Guinea	Infants and preschool children	Malaria

contribution to some of the most common childhood infections that occur in developing countries, as summarized in **Table 5**.

Diarrhea Zinc has an important role in both the prevention and treatment of diarrhea, which may be mediated both through functions in immune competence and maintenance of the integrity of the intestine. Studies in various settings indicate that provision of supplemental zinc on a nearly daily basis reduces the incidence of childhood diarrhea by nearly 20%, and reduces the prevalence of diarrhea by about 25%. The magnitude of this decrease is similar to that expected from programs to improve water quality and sanitation. There is no strong evidence to suggest that greater benefits of zinc in diarrhea prevention would occur among children who are growth stunted. Rather, all children living under poor conditions with exposure to diarrheal pathogens may potentially benefit from improved zinc intakes.

Zinc also has therapeutic benefits for recovery from diarrheal infections. Overall, supplemental zinc provided to children during recovery from either acute or persistent diarrhea leads to a reduction in the duration and severity of the episode. It has been recommended that zinc be used in the management of acute diarrhea, in conjunction with oral rehydration therapy. The current recommendation is to provide 10–20 mg of zinc once daily for 10–14 days.

Lower respiratory tract infections Zinc deficiency appears to be associated with an increased incidence of pneumonia. Evidence thus far indicates that supplemental zinc reduces the incidence of pneumonia in children by about 40%.

Malaria Only a few studies to date have considered the possible importance of zinc in protection against malaria. Nonetheless, while it is unlikely that improved zinc status could prevent infection with malarial parasites, it does appear that zinc may reduce the severity of the infection or the symptoms of morbidity associated with the infection. Evidence for this is suggested by a reduction in the number of visits to health facilities due to malaria, but not in the number of cases of malaria as determined during daily surveillance at the child's home, when children in malaria endemic areas were provided with supplemental zinc.

Mortality Given the contribution of zinc deficiency to three of the most common causes of death among children in developing countries (i.e., diarrhea, pneumonia, and malaria) it can be expected that zinc deficiency also contributes substantially to childhood mortality among these populations. Although still limited, available information does suggest that supplemental zinc leads to sizeable reductions in mortality among vulnerable groups of children. In Bangladesh, evaluation of a program that provided supplemental zinc for 14 days as treatment for diarrhea demonstrated a 68% reduction in mortality among infants and preschool children. Mortality was also reduced by two-thirds following supplemental zinc among low-birth-weight infants in India. A nearly 60% reduction in child mortality was observed among children in Burkina Faso, although this was not statistically significant. Further large-scale studies are required to better quantify the impact of zinc on child mortality.

Pregnancy: Maternal, Fetal and Infant Health

Few firm conclusions can be made as to the consequences of zinc deficiency during pregnancy on

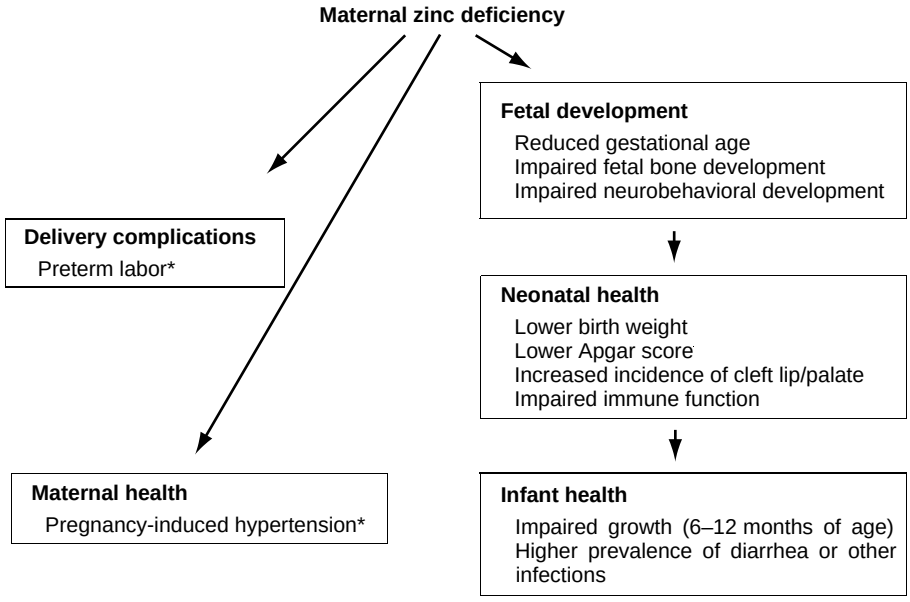

Figure 1 Several consequences of maternal zinc deficiency during pregnancy on maternal health, fetal development, and infant health have been observed in developing and more industrialized countries. These consequences have been confirmed by randomized, placebo-controlled trials of maternal zinc supplementation. Not all of the consequences have been observed in all studies, and the reasons for inconsistent results among studies are not well understood. *Determined from studies in industrialized countries only.

maternal, fetal, and infant health. Results from zinc supplementation trials have been inconsistent and therefore difficult to interpret. This may be partly attributed to inadequate study design or failure to consider the zinc status of the women studied. Most earlier studies focused on the evaluation of gestational age and birth weight as primary outcomes. However, zinc deficiency may also manifest itself in more specific qualities of health and development of the fetus and infant, as summarized in **Figure 1**. While there is some evidence from industrialized countries that zinc deficiency contributes to complications during pregnancy, delivery, and postpartum, these outcomes have not been adequately studied in developing countries.

Control of Zinc Deficiency in Developing Countries

Efforts to control zinc deficiency in national programs are only just being initiated. The following information describes the current state of development of zinc nutrition programs, and some direction for the future.

Zinc-Containing Pharmacological Supplements

As exemplified by the results of controlled trials, zinc supplementation is an efficacious (i.e., effective under controlled study conditions) strategy to prevent zinc deficiency. However, the effectiveness of this strategy under realistic conditions will depend on the success of in-country programs to distribute zinc supplements to vulnerable populations and on their use by the intended recipients. At present, few such zinc supplementation programs are in place. It may be more feasible to add zinc to iron supplements, use of which is widely advocated for the prevention of iron deficiency anemia in young children and women of childbearing age. However, some evidence indicates that when these two minerals are combined, their ability to improve either zinc or iron status diminishes. The competitive interaction between iron and zinc at the level of intestinal absorption or post-absorption may explain this observation. Research is required to determine optimal supplementation schemes for the prevention of iron and zinc deficiencies simultaneously.

Given the recent recommendation for the use of zinc in the management of acute diarrhea and the resultant reduction of childhood mortality observed in one study to date, it is expected that diarrheal treatment programs including supplemental zinc will ensue.

Enrichment (Fortification) of Foods with Zinc

A few countries from developing regions have implemented a policy for the fortification of staple foods with zinc. Mexico established a program whereby wheat and corn (maize) flour producers could

voluntarily add zinc to their products (20 mg/kg flour). Indonesia has also implemented a national program for the fortification of wheat flour, which includes addition of zinc. The fortification of condiments, such as fish sauce or seasoning powders in Asia, may serve as an additional vehicle for zinc fortification in the future. Several countries are adding zinc (and other micronutrients) to foods that are distributed in programs targeted to specific, vulnerable population groups. For example, in Chile and Argentina milk powder for use by young children is fortified with zinc, while in Mexico a milk powder-based supplement with added zinc is directed towards young children as well as pregnant and lactating women. As yet, there is an absence of information on the effectiveness of these programs to improve population zinc status.

Modification of Foods and Diets

Several strategies apart from the use of pharmacological supplements and food fortification have been suggested for the improvement of dietary zinc intake in developing country settings. Cereal crops, such as wheat, corn, and rice, are being bred to contain higher concentrations of zinc in the grain portion. Cereals that have a reduced content of phytate have also been produced but still require further testing of their agricultural viability and effect on improving zinc status when used in the context of a usual diet. Promotion of the production and use of zinc-rich foods through community level education and provision of starter materials could also be used. The efficacy of most of these alternative strategies to improve population zinc status has not yet been tested.
